5. Add 50 µl of sodium metabisulfite (5 mg/ml in 50 mM sodium phosphate [pH 7.5]).
6. Apply the solution to a 5-ml column of Sephadex G-25 (equilibrated in 50 mM sodium phosphate [pH 7.5]) (please see Appendix 8).
7. Collect 0.5-ml fractions until all of the radioactivity has eluted (~3 ml).
8. Pool the radioactive material.

   Usually, >95% of the radiolabel is incorporated, and the specific activity of the radiolabeled antibody exceeds 10^8 cpm/mg. Do not store radiolabeled antibody for prolonged periods before use.

Antibodies

Primary antibody

For advice on choosing primary and secondary antibodies, please see the information panel on **USING ANTIBODIES IN IMMUNOLOGICAL SCREENING** at the end of this chapter. For further information on antibodies, please see the information panels in Appendix 9.

Media

LB or SOB agar plates

Include the appropriate antibiotic for the expression system or vector used to construct the cDNA library. Each 90-mm Petri dish should contain 30–35 ml of agar medium, whereas each 150-mm plate should contain ~50 ml. The plates must be dry; otherwise, the top agarose will peel off when the nitrocellulose filter is removed. Usually, 2-day-old plates that have been dried for an additional 1–2 hours at 37°C with their lids slightly open work well.

LB or SOB agar plates containing 1 mM IPTG

Plates containing IPTG are required if the expression vector carries the lac promoter. For additional details on IPTG-induced expression of proteins, please see the discussion on Expression Vectors Containing an IPTG-inducible Promoter in the introduction to Chapter 15.

Special Equipment

Air incubators preset at 30°C and 42°C

These are required if the expression vector carries the bacteriophage λ p_R promoter (e.g., pEX series); otherwise the incubators are set at 37°C.

Forceps, blunt-ended

Needle (18-gauge) and syringe filled with waterproof black ink (India Ink)

Nitrocellulose filters

Filters suitable for binding protein and immunoblotting include nitrocellulose filters free of Triton X-100 (Millipore HATF or equivalent) and supported nitrocellulose derivatives such as Hybond-C extra (Amersham Pharmacia Biotech). Nylon membranes and charged nylon membranes should not be used for immunological screening because of their poor retention of proteins and high backgrounds.

Number the filters with a soft-lead pencil or ballpoint pen, wet them with water, and sandwich them between dry Whatman 3MM papers. Wrap the stack of filters in aluminum foil, and sterilize them by autoclaving at 10 psi (0.70 kg/cm^2) on liquid cycle.

Plastic box and Glass Petri dish

Whatman 3MM papers, in a stack

Prepare one Whatman 3MM paper for each filter plus a few spares. Wrap the stack of papers in aluminum foil, and sterilize them by autoclaving at 10 psi (0.70 kg/cm^2) on liquid cycle.

Vectors and Bacterial Strains

Plasmid expression library

Construct a cDNA library in an appropriate expression vector as described in Chapter 11 or purchase the library from a commercial supplier.

Additional Reagents

Step 19 of this protocol requires the reagents listed in Protocol 1.

METHOD

Preparation of Master Plates and Filters

1. Use sterile blunt-ended forceps (e.g., Millipore forceps) to place a sterile nitrocellulose filter, numbered side down, on an LB (or SOB) plate. Remove the filter from the plate, invert it, and replace it, numbered side up.
2. Apply the bacteria in a small volume of liquid (<0.5 ml containing up to 20,000 bacteria for a 138-mm filter, <0.2 ml containing up to 10,000 bacteria for an 82-mm filter). Spread the liquid over the surface of the filter with a sterile bent glass rod. Leave a border 2–3 mm wide at the edge of the filter free of bacteria. Store the plates at room temperature until all of the liquid has been absorbed.
3. Invert the plates and incubate them until very small (0.1-mm diameter) colonies appear (8–10 hours).

   Grow colonies containing expression vectors carrying the *lac* promoter at 37°C. Grow colonies containing expression vectors carrying the bacteriophage λ p_R promoter at 30°C to prevent the expression of fusion proteins.

Preparation of Replica Filters

4. Wet a numbered, sterile nitrocellulose filter by touching it, numbered side up, to the surface of a fresh agar plate containing the appropriate antibiotic. Leave the filter in contact with the surface of the agar. The numbers on the set of replica filters should correspond to those on the master filters.
5. Use sterile blunt-ended forceps to remove the master filter gently from one of the agar plates (Step 3) and place it, colony side up, on the stack of sterile Whatman 3MM papers.

6. Carefully place the second, correspondingly numbered, wetted filter numbered side down on top of the master filter, being careful not to move the filters once contact has been made. Place a circle of 3MM paper on top of the filter sandwich. Place the bottom of an empty Petri dish on top of the 3MM paper and exert hand pressure on the sandwich.

7. Use an 18-gauge needle to make a characteristic set of registration holes in the filters while they are sandwiched together. Gently peel the filters apart. Transfer the replica filter to the plate used for wetting (Step 4). Transfer the master filter, colony side up, to a fresh agar plate containing the appropriate antibiotic.

   If required, several replicas can be made from a single master filter. However, if the master filter is to be used to make more than two replicas, reincubate it for a few hours to allow the colonies to regenerate. Generally, it is best to make only two replicas from a single master to avoid problems caused by smearing of the colonies.

8. Repeat Steps 4–7 until all the master filters have been replicated.

9. Induce the expression of a gene cloned into an expression vector carrying the *lac* promoter as described below.

   a. Incubate the plates (masters and replicas) at 37°C until colonies 1–2 mm in diameter have appeared. Colonies on the master plates generally reach the desired size more rapidly.

   b. Allow the master plates to cool to room temperature on the laboratory bench, wrap them in plastic film, and store them at 4°C until the results of the immunological screens are available.

   c. Transfer the replica filters numbered side up to fresh agar plates, prewarmed to 37°C, containing IPTG at a concentration of 1 mM. Incubate the IPTG-containing plates for a further 2–4 hours.

   d. To induce synthesis in expression vectors that carry the bacteriophage λ p_R promoter (e.g., the pEX vectors; please see Appendix 3), transfer the filters to a series of prewarmed agar plates and incubate them for 2–4 hours at 42°C.

Processing Filters for Immunological Screening of Colonies

10. Use blunt-ended forceps to remove the nitrocellulose filters from the plates and place them on damp paper towels *in a chemical fume hood.* Cover the filters with an inverted plastic box. Place an open glass Petri dish containing chloroform under the box with the filters. Expose the bacterial colonies on the filters to chloroform vapor for 15 minutes.

11. Transfer small groups of filters to Petri dishes containing lysis buffer (6 ml per 82-mm filter, 12 ml per 138-mm filter). When all of the filters have been submerged, stack the Petri dishes on a rotary platform and agitate the lysis buffer by gentle rotation of the platform. Lysis of the bacterial colonies takes 12–16 hours at room temperature.

12. Transfer the filters to Petri dishes or glass trays containing TNT buffer. Incubate the filters for 30 minutes at room temperature.

13. Repeat Step 12 using fresh TNT buffer.

14. Transfer the filters, one by one, to a glass tray containing TNT buffer. Use Kimwipes to remove the residue of the colonies from the surfaces of the filters.

Detection of Clones Expressing Fusion Protein

▲ **IMPORTANT** Do not allow the filters to dry out during any of the subsequent steps. Antibodies bound nonspecifically and reversibly to wet filters become permanently attached if the filters dry out. It is also essential that the filters do not stick to one another when they are immersed in the various buffers and antibody solutions. This problem can be minimized by dividing the filters into small batches (e.g., five filters per batch) and using a separate large Petri dish for each batch. The Petri dishes can be stacked on top of one another on a slowly rotating platform shaker.

15. When all of the filters have been rinsed, transfer them one at a time to a fresh batch of TNT buffer. After transfer, agitate the buffer and filters gently for a further 30 minutes at room temperature.

    If necessary, the filters may be removed from the buffer at this stage, wrapped in Saran Wrap, and stored for up to 24 hours at 4°C.

16. Use blunt-ended forceps to transfer the filters individually to glass trays or Petri dishes containing blocking buffer (7.5 ml for each 82-mm filter, 15 ml for each 138-mm filter). When all of the filters have been submerged, agitate the buffer slowly on a rotary platform for 30 minutes at room temperature.

17. Use blunt-ended forceps to transfer the filters to fresh glass trays or Petri dishes containing the primary antibody diluted in blocking buffer (7.5 ml for each 82-mm filter, 15 ml for each 138-mm filter). Use the greatest dilution of antibody that gives acceptable background yet still allows detection of 50–100 pg of denatured antigen. When all of the filters have been submerged, agitate the solution gently on a rotary platform for 2–4 hours at room temperature.

    The antibody solution can be stored at 4°C and reused several times. Sodium azide should be added to a final concentration of 0.05% (w/v) to inhibit the growth of microorganisms.

18. Wash the filters for 10 minutes in each of the buffers below in the order given. Transfer the filters individually from one buffer to the next. Use 7.5 ml of each buffer for each 82-mm filter and 15 ml for each 138-mm filter.

    TNT buffer containing 0.1% bovine serum albumin
    TNT buffer containing 0.1% bovine serum albumin and 0.1% Nonidet P-40
    TNT buffer containing 0.1% bovine serum albumin

19. Detect the antigen-antibody complexes with the chosen radiochemical, chromogenic, or chemiluminescent reagent.

RADIOCHEMICAL SCREENING

Use ~1 μCi of ^{125}I-labeled protein A or immunoglobulin per filter. Radiolabeled protein A is available from commercial sources (specific activity 2–100 μCi/μg). Radioiodinated second antibody is available commercially, or it can be prepared as described in the panel on **RADIOIODINATION OF IgG** above in Materials.

a. Dilute radiolabeled ligands in blocking buffer (7.5 ml for each 82-mm filter, 15 ml for each 138-mm filter).

b. Incubate the filters for 1 hour at room temperature, and then wash them several times in TNT buffer before establishing autoradiographs as described in Appendix 9.

Continue at Step 20.

CHROMOGENIC SCREENING

Antibodies coupled to horseradish peroxidase (HRP) or alkaline phosphatase (AP) that react with species-specific determinants on primary antibodies are available from commercial sources and should be used at the recommended dilution in accordance with the manufacturer's instructions. Typically, 5 µl of conjugated antiserum is used for each 82-mm filter in 7.5 ml of blocking buffer (without sodium azide). For further details on HRP, please see the information panels in Appendix 9.

Antigen-Antibody-Antibody-AP Complexes Located Using BCIP and NBT

Materials for Chromogenic Screening with AP-conjugated Antibodies

Alkaline phosphatase-conjugated anti-immunoglobulin antibodies
AP buffer
100 mM Tris-Cl (pH 9.5)
100 mM NaCl
5 mM $MgCl_2$
5-Bromo-4-chloro-3-indolyl phosphate (BCIP)
Dimethylformamide **<!>**
Nitro blue tetrazolium (NBT)

a. Gently agitate the filters for 1.5–2 hours at room temperature in the solution of AP-conjugated antibody.

b. Wash the filters as described in Step 18.

c. Prepare stock solutions of BCIP (50 mg/ml in 100% dimethylformamide) and NBT (50 mg/ml in 70% dimethylformamide). These solutions are stable when stored in the dark.

d. Prepare the BCIP/NBT developing solution just before use as follows:

i. Add 33 µl of the NBT solution to 5 ml of AP buffer and mix well.

ii. Add 16.5 µl of the stock solution of BCIP. Mix again. Protect the solution from strong light and use it within 1 hour.

e. Blot the washed filters on paper towels.

f. Incubate the filters (Step d) in the BCIP/NBT developing solution (7.5 ml for each 82-mm filter, 15 ml for each 138-mm filter) for several hours at room temperature.

g. Rinse the filters briefly in two changes of H_2O. An intense purple color will develop at the site of antigen-antibody complexes.

Continue at Step 20.

Antigen-Antibody-Antibody-HRP Complexes Located Using 4-Chloro-1-Naphthol

Materials for Chromogenic Screening with HRP-conjugated Antibodies

4-Chloro-1-naphthol
H_2O_2 (30%) **<!>**
HRP-conjugated anti-immunoglobulin antibodies
Methanol **<!>**
NaCl (5 M)
Tris-Cl (1 M, pH 7.5)
Tris-Cl (10 mM, pH 7.5) containing 150 mM NaCl

a. Gently agitate the filters for 1.5–2 hours at room temperature in the solution of HRP-conjugated antibody.

b. Wash the filters as described in Step 18.

c. To prepare developing solution, dissolve 60 mg of 4-chloro-1-naphthol in 20 ml of ice-cold methanol. Just before use, mix the solution with 100 ml of 10 mM Tris-Cl (pH 7.5), 150 mM NaCl containing 60 µl of 30% H_2O_2.

d. Blot the washed filters on paper towels and wash them briefly in 10 mM Tris-Cl (pH 7.5) containing 150 mM NaCl.

e. Incubate the filters for 15–20 minutes at room temperature in the 4-chloro-1-naphthol developing solution (10 ml for each 82-mm filter, 25 ml for each 138-mm filter).

f. Wash the filters in two changes of H_2O. An intense purple color will develop at the site of antigen-antibody complexes.

Biotinylated species-specific antibodies and avidin-conjugated HRP are available from commercial sources. They should be diluted according to individual manufacturer's instructions and used for immunological screening as described above for HRP-conjugated antibodies.

Continue at Step 20.

CHEMILUMINESCENT SCREENING

Chemiluminescence is the most sensitive method for detecting immunopositive colonies. The secondary antibody is typically conjugated to either AP or HRP. Use of AP-conjugated antibodies requires substrates such as 1,2-dioxetane phosphates that emit light at a maximum wavelength of 466 nm upon dephosphorylation. HRP-conjugated antibodies oxidize the substrate luminol, which in the presence of hydrogen peroxide and phenol, emits an intense light emission with a maximum at 428 nm. With either system, the light emission can be captured by autoradiography. Chemiluminescent detection is quick, produces a permanent record of the screened filter (an X-ray film or phosphoimage), and is sensitive (1–10 pg of antigen in a colony can be detected). Two potential drawbacks are the high costs of reagents and the need to identify positives on the original agar plate by comparison to an autoradiograph. A typical protocol follows.

Materials for Chemiluminescent Screening

AP- or HRP-conjugated anti-immunoglobulin antibodies
Chemiluminescent substrates (commercially available from, e.g., Tropix)
Saran Wrap

a. Gently agitate the filters for 1.5–2 hours at room temperature in the solution of AP- or HRP-conjugated antibody.

b. Wash the filters as described in Step 18.

c. Prepare the chemiluminescent substrates according to the manufacturer's instructions.

d. Incubate the washed filters in the chemiluminescent substrates for 1–5 minutes (again, consult the manufacturer's recommendations for optimal exposure times).

e. Drain the excess solution from the filters, and immediately wrap the filters in Saran Wrap. Do not allow the filters to dry out.

f. Establish an autoradiogram (please see Appendix 9). Typically, the initial exposure is for 1 minute. This interval provides enough information to establish the proper exposure time.

Continue at Step 20.

20. Identify the locations of positive colonies or, if made, compare the duplicate filters, searching for coincident signals. For screens involving radiolabeled or chemiluminescent probes, compare the resulting autoradiograms with the agar plates on a light box. For screens involving chromogenic reagents that leave a visible positive residue on the filter, carry out the following steps.
    a. Lay a sheet of Saran Wrap or Mylar film over the filters.
    b. On the surface of the Saran Wrap, mark the locations of the holes in the filters and the locations of antigen-positive clones with different colored waterproof markers. Label the Saran Wrap to identify the plates from which the filters were derived.
    c. Place the sheet of Saran Wrap on a light box, and align the plates containing the original bacterial colonies on top of it.
    d. Identify the areas containing the positive colonies, and transfer a segment of each putative colony to 1 ml of LB medium containing the appropriate antibiotic. Incubate the cultures for 12–16 hours at the appropriate temperature.
    e. Keep the sheet of Saran Wrap, which provides a permanent record of the locations of the positive colonies. The colored spots on the original filters fade quite rapidly.
21. Repeat the process of plating and screening until a homogeneous population of immunopositive colonies is obtained.
22. Validate the clones isolated by immunological screening using one of the methods discussed in the panel on **VALIDATION OF CLONES ISOLATED BY IMMUNOLOGICAL SCREENING** at the end of Protocol 1.

Protocol 3

Removal of Cross-reactive Antibodies from Antiserum: Pseudoscreening

SEVERAL METHODS CAN BE USED TO REMOVE ANTIBODIES that react with bacterial- and phage-encoded proteins from polyclonal sera:

- ***Incubating the antiserum with nitrocellulose filters*** to which nonrecombinant bacteriophage plaques have been transferred (this protocol).
- ***Incubating the antiserum with a lysate*** of *E. coli* host cells prior to screening (Protocol 4).
- ***Chromatography of the antiserum*** on a resin to which *E. coli* proteins have been covalently attached (Protocol 5).

It is not easy to predict which of these methods will yield the optimum antiserum for immunoscreening purposes; thus, more than one method may be required to free an antiserum of cross-reacting antibodies. For example, the adsorption method described in this protocol works only for preparations of antiserum that contain relatively low titers of anti-*E. coli* antibodies. If the treated antiserum continues to give an unacceptably high level of reaction with host components, it should be further purified by chromatography on a column that contains immobilized *E. coli* components (Protocol 5).

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Blocking buffer

10 mM Tris-Cl (pH 8.0)
150 mM NaCl
0.05% (v/v) Tween-20
blocking agent (1% w/v gelatin, 3% w/v bovine serum albumin, or 5% w/v nonfat dried milk)

Opinion of the relative virtues of these agents varies from laboratory to laboratory. We recommend that the investigator carry out preliminary experiments to determine which of them works best with the chosen primary and secondary antibodies. Blocking buffer can be stored at 4°C and reused several times. Sodium azide **<!>** should be added to a final concentration of 0.05% (w/v) to inhibit the growth of microorganisms.

Antibodies

Antibody preparation that is to be used for screening

Media

LB agar plates

Each 90-mm Petri dish should contain 30–35 ml of agar medium. Each 150-mm plate should contain ~50 ml of agar medium. The plates must be dry; otherwise, the top agarose will peel off when the nitrocellulose filter is removed. Usually, 2-day-old plates that have been dried for an additional 1–2 hours at 37°C with the lids slightly open work well.

LB top agarose

Melt the top agarose just before use by microwaving for a short period of time and then cooling to 47°C. Dispense the molten top agar as 3-ml aliquots (for 90-mm plates) or 7.5-ml aliquots (for 150-mm plates) in sterile tubes. Place the aliquots in a 47°C heating block or water bath to prevent the top agar from gelling.

Special Equipment

Nitrocellulose filters

Filters suitable for binding protein and immunoblotting include nitrocellulose filters free of Triton X-100 (Millipore HATF or equivalent), and supported nitrocellulose derivatives such as Hybond-C extra (Amersham Pharmacia Biotech). Nylon membranes and charged nylon membranes should not be used for immunological screening because of their poor retention of proteins and high backgrounds.

Additional Reagents

Step 1 of this protocol requires the reagents listed in Chapter 2, Protocol 1.
Step 2 of this protocol requires the reagents listed in Protocol 1 of this chapter.

Vectors and Bacterial Strains

Bacteriophage λ vector

Use the expression vector and bacterial strain that was used to produce the cDNA library of interest.

METHOD

1. On ten LB agar plates, plate out nonrecombinant bacteriophage λ so as to obtain semiconfluent lysis of the bacterial lawn (please see Chapter 2, Protocol 1).

2. Prepare imprints of the lysed lawns on nitrocellulose filters as described in Steps 5–12 of Protocol 1, but omitting the treatment with IPTG.

   It is not necessary to key the filters as described in Protocol 1, Step 8.

3. Dilute the preparation of antibody that is to be used for screening 1:10 with blocking buffer.

4. Incubate the filters for 6 hours with the diluted antibody. The treated antibody may be stored at 4°C in the presence of 0.05% (w/v) sodium azide until used for immunological screening.

   This method can be adapted easily to remove anti-*E. coli* antibodies by pseudoscreening of bacterial colonies. On nitrocellulose filters, establish bacterial colonies that carry the empty expression vector (please see Protocol 2). Then follow the cell lysis and filter washing procedures described in Protocol 2, Steps 10–16. Finally, treat the antiserum as described in Steps 3 and 4 above.

ALTERNATIVE PROTOCOL: ADSORBING ANTIBODIES WITH LYSATES OF BACTERIOPHAGE-INFECTED CELLS

This method to adsorb antibodies that react with bacteriophage-encoded proteins involves incubating five strips of nitrocellulose (3 x 10 cm) in a lysate of bacteriophage-infected cells. The lysate is provided as a component of several commercially available kits that contain materials required for immunoscreening of plaques (e.g., please see Stratagene's picoBlue Immunoscreening Kit or Novagen's Phagefinder Immunoscreening Kit).

Method

1. Incubate five (3 x 10 cm) strips of nitrocellulose in a lysate of bacteriophage-infected cells.
2. Remove the strips from the lysate and incubate them for 1 hour at room temperature in blocking buffer.
3. Dilute 1–2 ml of the antibody preparation 1:10 in blocking buffer and incubate with one of the filters for 20 minutes at room temperature.
4. Remove the strip of nitrocellulose and replace with a fresh strip.
5. Repeat this process until all five strips have been used. The adsorbed antibody may be stored at 4°C in the presence of 0.05% (w/v) sodium azide until used for immunological screening.

Protocol 4

Removal of Cross-reactive Antibodies from Antiserum: Incubation with *E. coli* Lysate

THIS PROTOCOL DESCRIBES A METHOD FOR REMOVING FROM POLYCLONAL antisera antibodies that react with bacterial-encoded proteins by incubating the antisera with a bacterial lysate. This method of adsorption only works for preparations of antisera that contain relatively low titers of anti-*E. coli* antibodies. If the treated antiserum continues to give an unacceptably high level of reaction with host components, it should be further purified by chromatography on a column that contains immobilized *E. coli* components (Protocol 5).

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Blocking buffer

10 mM Tris-Cl (pH 8.0)
150 mM NaCl
0.05% (v/v) Tween-20
blocking agent (1% w/v gelatin, 3% w/v bovine serum albumin, or 5% w/v nonfat dried milk)

Opinion of the relative virtues of these agents varies from laboratory to laboratory. We recommend that the investigator carry out preliminary experiments to determine which of them works best with the chosen primary and secondary antibodies. Blocking buffer can be stored at 4°C and reused several times. Sodium azide **<!>** should be added to a final concentration of 0.05% (w/v) to inhibit the growth of microorganisms.

Cell resuspension buffer

50 mM Tris-Cl (pH 8.0)
10 mM EDTA (pH 8.0)

Filter-sterilize and store the buffer at 4°C in 50-ml aliquots.

Antibodies

Antibody preparation that is to be used for screening

Media

LB medium

Centrifuges and Rotors

Sorvall GSA rotor or equivalent

Special Equipment

Probe sonicator appropriate for sonication of bacterial cells

Vectors and Bacterial Strains

E. coli *strain Y1090*hsdR

This strain can be obtained from Stratagene, Life Technologies, or the ATCC (www.atcc.org).

METHOD

1. Grow a 100-ml culture of *E. coli* strain Y1090*hsdR* to saturation in LB medium.
2. Harvest the cells by centrifugation at 5000*g* (5500 rpm in a Sorvall GSA rotor) for 10 minutes at 4°C.
3. Resuspend the cells in 3 ml of cell resuspension buffer. Freeze and thaw the suspension several times, and then sonicate it at full power for six periods of 20 seconds, each at 0°C.
4. Centrifuge the extract at maximum speed for 10 minutes at 4°C in a microfuge. Transfer the supernatant to a fresh tube. Store the lysate at –20°C.
5. Just before using the lysate, dilute the preparation of antibody that is to be used for screening 1:10 with blocking buffer.
6. Add 0.5 ml of lysate for every milliliter of antibody preparation to be processed. Incubate the mixture for 4 hours at room temperature on a slowly rotating wheel. The treated antibody may be stored at 4°C in the presence of 0.05% (w/v) sodium azide until used for immunological screening.

Protocol 5

Removal of Cross-reactive Antibodies from Antiserum: Affinity Chromatography

THIS PROTOCOL, ADAPTED FROM DE WET ET AL. (1984), DESCRIBES A METHOD for removing antibodies that react with bacterial-encoded proteins by passing a crude preparation of immunoglobulins through an affinity matrix bound to bacterial proteins. This procedure can also be used with extracts of cultured cells or tissues to remove cross-reacting antibodies. It is of course crucial that the antigen of interest not be present in the extract attached to the column.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Cell lysis buffer

0.1 M sodium borate (pH 8.0)
1 M NaCl

Sterilize the cell lysis buffer using a 0.45-μm filter, and store at room temperature. Approximately 100 ml of cell lysis buffer is required per 1 liter of bacterial culture.

NaOH (1 N) **<!>**

Tris-buffered saline (TBS) and TBS containing 0.2% (w/v) sodium azide **<!>**

Triton X-100

Enzymes and Buffers

Lysozyme

Use a molecular biology grade of lysozyme. Add solid lysozyme to assist lysis of bacterial cells.

Pancreatic DNase I

Add solid DNase I to the bacterial cell lysate to digest chromosomal DNA.

Antibodies

Antibody preparation that is to be used for screening

This protocol works best when using an IgG fraction, prepared by chromatography of the antiserum on protein A–Sepharose. For a method of protein A–Sepharose chromatography, please see Harlow and Lane (1999).

Media

Growth medium

One liter of growth medium appropriate for the *E. coli* strain of choice is required.

Centrifuges and Rotors

Sorvall GSA rotor or equivalent

Sorvall SS-34 rotor or equivalent

Special Equipment

Chromatography column

A 5-ml plastic syringe plugged with glass wool or a Bio-Rad Poly-Prep column is suitable.

Cyanogen-bromide-activated Sepharose 4B (Amersham Pharmacia Biotech) or Affi-Gel 10 (Bio-Rad)

Vectors and Bacterial Strains

E. coli *strain used as host for preparation of expression library*

METHOD

1. Grow a 1-liter culture of the appropriate strain of *E. coli* (e.g., Y1090*hsdR*, XL1-Blue, or DH1) to stationary phase.
2. Recover the bacteria by centrifugation at 4000*g* (5000 rpm in a Sorvall GSA rotor) for 20 minutes at 4°C.
3. Pour off the medium, and stand the centrifuge tubes in an inverted position to allow the last traces of medium to drain away.
4. Resuspend the pellet in 100 ml of cell lysis buffer.
5. Add 200 mg of lysozyme, and incubate the bacterial suspension for 20 minutes at room temperature.
6. Add 1 mg of pancreatic DNase I and 200 µl of Triton X-100.
7. Incubate the bacterial suspension for 1 hour at 4°C, or until the turbidity clears and the viscosity decreases.
8. Centrifuge the bacterial lysate at 8000*g* (8200 rpm in a Sorvall SS-34 rotor) for 20 minutes at 4°C. Carefully decant the supernatant into a fresh flask.
9. Adjust the pH of the supernatant to 9.0 with 1 M NaOH.
10. Determine the concentration of protein in the lysate using the Lowry, Bradford, or other method of measurement.

11. Chill the extract to 0°C, and then bind the bacterial proteins to cyanogen-bromide-activated Sepharose 4B or to Affi-Gel 10 according to the manufacturer's instructions.
12. Before use, equilibrate the Sepharose 4B or Affi-Gel 10 resin containing conjugated *E. coli* proteins in TBS containing 0.2% (w/v) sodium azide.
13. Use 1 ml of settled volume of resin coupled to *E. coli* antigen for each milligram of IgG protein to be purified by affinity chromatography. Mix the IgG and the coupled resin and incubate for 12–18 hours at room temperature on a rotating wheel device.
14. Load the slurry into a chromatography column. Recover the antibody by washing the column with TBS. Collect fractions (0.2 column volume each) until the OD_{280} drops to zero. Pool the fractions containing antibody, and store the pool at –20°C until it is used for immunological screening.

Protocol 6

Identifying DNA-binding Proteins in Bacteriophage λ Expression Libraries

COMPLEMENTARY DNA LIBRARIES CONSTRUCTED IN BACTERIOPHAGE EXPRESSION VECTORS can be screened with synthetic oligonucleotides to identify clones corresponding to specific DNA-binding proteins (Singh et al. 1988; Vinson et al. 1988). The methods are very similar to those used for immunological screening of expression libraries, except that the nitrocellulose filters carrying immobilized proteins are screened with ^{32}P-labeled double-stranded DNA rather than with antibodies. Initially, screening was carried out with radiolabeled double-stranded DNA carrying a single binding site (Singh et al. 1988). However, under these circumstances, the signal from a positive clone was often weak and easily washed from the filter. The equilibrium association binding constants of sequence-specific DNA-binding proteins range from 10^8 to 10^{12} M^{-1}. Assuming that a protein has an equilibrium association binding constant of 10^{10} M^{-1} and an association rate constant of 10^7 $M^{-1}\cdot s^{-1}$, the dissociation rate constant of the resulting DNA-protein complex will be 10^{-3} $M^{-1}\cdot s^{-1}$, and its half-life will be ~10 minutes (Singh et al. 1988; Singh 1993). Thus, only one eighth of the complexes will survive a 30-minute wash. Consequently, screening of expression libraries with double-stranded oligonucleotide probes is unlikely to be successful if the equilibrium association binding constant of the DNA-binding protein is $<10^9$ M^{-1}. The problem can be alleviated by using a concatenated probe that contains multiple binding sites (Clerc et al. 1988; Staudt et al. 1988; Vinson et al. 1988). In side-by-side comparisons, a much stronger signal was generated with probes containing multiple binding sites, presumably because the probe is tethered at more than one site to the DNA-binding protein produced in the bacteriophage plaque. With concatenated probes that have been radiolabeled to a specific activity in excess of 10^8 cpm/μg, it is possible to detect as little as 1 pg of a β-galactosidase fusion protein that contains a DNA-binding site (Singh 1993).

Plaques generated by recombinant λgt11 bacteriophages typically contain 50–100 pg of fusion protein. However, only a small proportion of the protein produced by the bacteriophage-infected cells would normally be folded into a conformation suitable for binding to its DNA ligand. This situation can sometimes be improved by exposing the fusion protein briefly to denaturing agents (Vinson et al. 1988). Nitrocellulose filters carrying the fusion proteins synthesized by recombinant bacteriophages are soaked in 6 M guanidine HCl. During this process, insoluble aggregates of fusion proteins are solubilized and denatured proteins are made accessible to solvent. The denaturant is then gradually removed, potentially allowing an increased proportion of the fusion protein to refold into a conformationally active form. However, it is important to note

that exposure to denaturant is not always beneficial, apparently because some proteins are not readily renatured after treatment with guanidine HCl. A safe course of action is to first screen a set of filters containing protein imprints that have been exposed to guanidine HCl. If no clones of interest are identified, the screening should be repeated, this time using a set of protein imprints that have not been treated with guanidine HCl. In some cases, it is possible to use Southwestern blotting to find out whether the DNA-binding protein of interest will survive denaturation and renaturation. In this technique, nuclear extracts containing the protein of interest are fractionated by SDS-polyacrylamide gel electrophoresis, transferred to nitrocellulose membranes, and probed with a catenated oligonucleotide probe, before and after being exposed to a cycle of denaturation and renaturation with guanidine HCl. A positive result, in which a single polypeptide is shown to bind the relevant probe, provides encouragement to screening an expression library (Müller et al. 1988). Aliquots of the nuclear extracts, treated and untreated with guanidine HCl, can be assayed for specific DNA-binding activity in methylation protection experiments, by DNase I footprinting, or in electrophoretic mobility shift assays (please see Chapter 17).

Potentially positive plaques that react strongly with double-stranded oligonucleotide probes are picked, replated at appropriate dilutions, and retested for their ability to react with both specific and nonfunctional concatenated oligonucleotide probes. If possible, the nonfunctional probes should be generated from oligonucleotides containing base substitutions known to prevent interaction between the target protein and its binding site. The aim of the second round of screening is to identify clones encoding proteins that react with the wild-type oligonucleotide but not the mutant version of the DNA-binding site. Clones with these properties are used to generate lysogenic strains of bacteria that may be induced to synthesize large amounts of protein for use in biochemical assays. Ultimately, the functionality of the protein must be demonstrated in expression experiments in which a plasmid carrying the full-length cloned cDNA is introduced into target cells together with a plasmid containing multiple copies of the recognition sequence upstream of a basal promoter and the coding sequence of a reporter protein. The ability of the protein encoded by the cDNA to activate or repress transcription from the promoter can then be assayed by analysis of RNA extracted from the transfected cells.

Concatenated probes are usually prepared by transferring ^{32}P residues to the 5′-hydroxyl termini of two complementary synthetic oligonucleotides, annealing the phosphorylated and radiolabeled DNAs, and ligating the annealed DNAs to form concatemers. Alternatively, the double-stranded concatemers may be radiolabeled by using reverse transcriptase or the Klenow fragment to catalyze template-directed addition of [α-^{32}P]dNTPs to recessed 3′ termini. Replica filters are prepared from a bacteriophage λ expression library. The radiolabeled concatemers are then used to probe the filters for plaques harboring the proteins of interest. The following protocol was provided by Steve McKnight (University of Texas Southwestern Medical Center, Dallas).

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

ATP (100 mM)

Make two ATP solutions, 10 mM and 50 mM, respectively, by dilution of the 100 mM stock into 25 mM Tris-Cl (pH 8.0).

10x Binding buffer
250 mM HEPES (pH 7.9)
30 mM $MgCl_2$
40 mM KCl

1x Binding buffer containing 1 mM dithiothreitol
This solution is used to dilute full-strength denaturation solution to generate the series of washes in the protocol. Please see Steps 11–13 to calculate the volume of solution required.

1x Binding buffer containing 1 mM dithiothreitol and 0.25% nonfat dry milk
Approximately 75 ml of 1x binding buffer is needed per 82-mm filter screened or 180 ml per 138-mm filter. Do not scrimp on the amounts of this buffer used in the washing procedure.

1x Binding buffer containing 5% (w/v) nonfat dry milk
About 10 ml of this blocking solution is needed per 82-mm filter screened or 25 ml per 138-mm filter.

1x Binding buffer containing 0.25% (w/v) nonfat dry milk
About 10 ml of this blocking solution is needed per 82-mm filter screened or 25 ml per 138-mm filter.

Denaturation solution (freshly made)
Dilute 10x binding buffer (see above) with 5 volumes of distilled H_2O. The resulting solution (2x binding buffer) is then added to the appropriate amount of solid guanidine HCl **<!>** to make a 6 M solution. When the guanidine HCl has completely dissolved, adjust the concentration of the binding buffer to 1x with distilled H_2O and add dithiothreitol to a final concentration of 1 mM. About 15 ml of full-strength (6 M) denaturation solution is needed for each 82-mm filter to be screened, or 25 ml for each 138-mm filter.

Dithiothreitol (1 M)

EDTA (0.5 M)

Ethanol

10x Kinase/ligase buffer
500 mM Tris-Cl (pH 7.6)
100 mM $MgCl_2$

Phenol:chloroform (1:1, v/v) **<!>**

Screening buffer
1x binding buffer
0.25% (w/v) nonfat dry milk
1 mM dithiothreitol
10 µg/ml denatured salmon or herring sperm DNA
About 10 ml of screening buffer is needed for each 82-mm filter or 25 ml for each 138-mm filter. For preparation of denatured salmon or herring sperm DNA, please see Chapter 6, Protocol 10.

SDS (20% w/v)

Sodium acetate (3 M, pH 5.2)

TE (pH 8.0)

Enzymes and Buffers

Bacteriophage T4 DNA ligase

Bacteriophage T4 polynucleotide kinase

Nucleic Acids and Oligonucleotides

Synthetic oligonucleotides
Single-stranded oligonucleotides of complementary sequence, 20–25 nucleotides in length, should be purified by gel electrophoresis and Sep-Pak chromatography as described in Chapter 10, Protocol 1 and dissolved in TE (pH 7.6) at a concentration of 0.2 mg/ml. When reannealed, the central region of the oligonucleotides should form a double-stranded monomeric version of the site that has been established by gel retention or Southwestern blotting to be optimum for binding of the target protein. At least one complementary pair of "mutant" oligonucleotides is also required in the second round of screening. When annealed, the central region of the "mutant" oligonucleotide duplex should form a defective version of the optimum binding site that is unable to bind the target protein. Sequential screening with a positive probe (the optimum double-stranded binding sequence) and a negative probe (the closely related but mutated double-stranded sequence) eliminates most false positives.

Both pairs of oligonucleotides should be designed with protruding, cohensive termini that can be ligated to one another.

Radioactive Compounds

[α-^{32}P]ATP (10 mCi/ml, 5000 Ci/mmole) <!>

Gels

Nondenaturing polyacrylamide gel <!>
Please see Step 7.

Special Equipment

Adhesive labels marked with radioactive ink or chemiluminescent markers <!>
Reusable alternatives to radioactive ink are chemiluminescent markers available from Stratagene (Glogos). The markers can be used many times and should be exposed to fluorescent light just before each new round of autoradiography.

Baking dishes (12 x 8 inches)
Crystallizing dish
Forceps, blunt-ended
Needle (18-gauge) and syringe filled with waterproof black ink (India Ink)
Nitrocellulose filters
Sephadex G-75 spun column, equilibrated in TE (pH 7.6)
Water baths preset to 16°C, 65°C, and 85°C
Whatman 3MM blotting paper

Additional Reagents

Steps 8 and 10 of this protocol require the reagents listed in Protocol 1 of this chapter.

METHOD

Preparation of Radiolabeled Concatenated Probes

1. Set up two separate phosphorylation reactions, each containing one of the synthetic oligonucleotides to be annealed:

oligonucleotide	200 ng
10x kinase/ligase buffer	2.5 µl
100 mM dithiothreitol	2.5 µl
[γ-^{32}P]ATP	100 µCi
H_2O	to 23 µl
bacteriophage T4 polynucleotide kinase (8–10 units/µl)	2 µl

   Incubate the reactions for 1 hour at 37°C.

2. Mix the two phosphorylation reactions together. Anneal the oligonucleotides by incubating the mixture in the following sequence, which is most conveniently carried out in a thermal cycler:

   2 minutes at 85°C
   15 minutes at 65°C
   15 minutes at 37°C
   15 minutes at 22°C
   15 minutes at 4°C

3. Add 4 µl of bacteriophage T4 DNA ligase (1 Weiss unit/µl) and 1 µl of 50 mM ATP. Incubate the mixture for 12 hours at 16°C.
4. Add 0.5 M EDTA (pH 8.0) to a final concentration of 5 mM.
5. Separate the labeled oligonucleotides from unused [γ-^{32}P]ATP, single-stranded oligonucleotides, and unligated double-stranded oligonucleotides by spun-column chromatography through a Sephadex G-75 column (please see Appendix 8).
6. Estimate the specific activity of the final probe.

   The specific activity should be ≥2 x 10^6 cpm/pmole.

   It is also possible to achieve the specific activity required in this protocol by filling the recessed 3′ ends of unlabeled concatenated oligonucleotides. After the ligation, set up the end-filling reaction as described in Protocol 7 of Chapter 10. Wherever possible, use two [α-^{32}P]dNTPs in each reaction to increase the specific activity of the radiolabeled products. At the end of the reaction, separate the labeled oligonucleotides from the unused [α-^{32}P]dNTPs by spun-column chromatography (please see Appendix 8).
7. Analyze the size of the radiolabeled DNA by nondenaturing polyacrylamide gel electrophoresis and autoradiography (please see Appendix 9). If all has gone well in the above annealing and radiolabeling experiment, the concatenated DNA should form a ladder of polymers of the original duplex oligonucleotide.

Preparation of Filters

8. Prepare agar plates containing plaques of the bacteriophage λ expression library and numbered nitrocellulose filters exactly as described in Protocol 1, Steps 1–8.

   Wherever possible, use an unamplified expression library. If the protein of interest is toxic to bacteria or suppresses growth of the recombinant bacteriophage, the clone may be underrepresented in amplified libraries.
9. Use blunt-ended forceps (e.g., Millipore forceps) to remove the numbered nitrocellulose filters from the lawn of plaques and place them on Whatman 3MM paper with the side exposed to the plaques facing upward. Allow the filters to dry for 15 minutes at room temperature.
10. Lay a second (numbered) filter impregnated with IPTG on each agar plate (please see Step 4 of Protocol 1). Use an 18-gauge needle to make holes in each filter in the same locations as the holes used to key the first filter to the lawn. Incubate the plates for 2 additional hours at 37°C and then remove the filters. Allow them to dry at room temperature as described in the preceding step.

    ▲ **IMPORTANT** Carry out all subsequent steps at 4°C. The first set of filters is probed directly without denaturation with guanidine HCl (i.e., omitting Steps 11–13), whereas the second set is processed as described in Steps 11–14.
11. Place the second set of numbered filters in a 12 x 8-inch baking dish containing denaturation solution at 4°C. Agitate the filters gently on a platform shaker for 5 minutes at 4°C. Decant the denaturation solution, and replace it with fresh solution. Agitate the filters for an additional 5 minutes at 4°C.
12. Decant the second batch of denaturation solution into a graduated cylinder. Dilute the solution with an equal volume of 1x binding buffer containing dithiothreitol. Pour this solution into a clean glass dish, and transfer the filters to the solution one at a time, making sure that each filter becomes thoroughly exposed to the diluted denaturation solution containing dithiothreitol.

13. Repeat the process described in Step 12 four more times, diluting the denaturation solution by a factor of 2 each time. The concentrations of guanidine HCl in the solutions are therefore 3 M (Step 11), 1.5 M, 0.75 M, 0.375 M, 0.187 M, and 0.094 M. Finally, wash the filters twice in 1x binding buffer containing dithiothreitol.

14. Place both sets of numbered filters (i.e., denatured and nondenatured) in 1x binding buffer containing 5% nonfat dried milk. Agitate the filters gently for 30 minutes at 4°C.

15. Rinse the filters in 1x binding buffer containing 0.25% nonfat dried milk.

Probing of Immobilized Proteins with Radiolabeled DNA

16. In a crystallizing dish, add the ^{32}P-labeled concatenated DNA probe from Step 5 to screening buffer to make a hybridization solution (~10 ml for each 82-mm filter or ~25 ml for each 138-mm filter).

    Optimal results are usually obtained when the final concentration of radiolabeled probe (specific activity 2×10^8 to 5×10^8 cpm/μg) in the screening reaction is ~25 ng/ml. However, concentrations as low as 2.5 ng/ml can be used if the amount of probe is limiting.

    In the original description of this method (Singh et al. 1988), poly(dI:dC) was used as a nonspecific competitor. However, lower backgrounds are generally achieved when sonicated, denatured salmon sperm or calf thymus DNA is used. It is possible that the presence of some DNA binding–fusion proteins will be masked by any DNA, synthetic or complex, that is used as a competitor. Sensitivity to various blocking reagents such as salmon sperm DNA, poly(dI:dC), poly(A), and others should be established in gel retardation assays or Southwestern blotting (please see Chapter 17) before cDNA screening.

17. Transfer the filters to the radiolabeled probe solution in the crystallizing dish. Incubate the filters with gentle agitation on a rotating platform for 2–12 hours at 4°C.

    The ionic composition of the binding/screening buffer used here is suitable for many DNA-protein interactions. However, in some cases, it may be necessary to adjust the concentrations of salt and magnesium ions to conform to the optimal conditions for binding established in gel retardation assays or other methods. An alternative to the binding buffer recommended here is a buffer containing 25 mM HEPES (pH 7.9)/25 mM NaCl/5 mM $MgCl_2$/0.5 mM DTT (Singh 1993).

18. Wash the filters for 5 minutes at 4°C in a large volume (25 ml for each 82-mm filter, 60 ml for each 138-mm filter) of binding buffer containing 1 mM dithiothreitol and 0.25% nonfat dried milk.

19. Repeat Step 18 twice more.

20. Decant the final wash buffer. Arrange the damp filters on a sheet of Saran Wrap. Cover the filters with another sheet of Saran Wrap. Apply adhesive labels marked with radioactive ink or chemiluminescent markers to several asymmetric locations on the Saran Wrap.

    Cover the radioactive labels with Scotch Tape to prevent contamination with the radioactive ink of the film holder or intensifying screen.

21. Establish an autoradiograph as described in Appendix 9.

22. Pick positive plaques, and rescreen them with specific and nonspecific probes as discussed in the introduction to this protocol.

    Filters may be reprobed for other DNA-binding protein cDNAs by repeating the denaturation/renaturation cycle (Steps 11–13), which effectively removes the probe from the filters.

Protocol 7

Preparation of Lysates Containing Fusion Proteins Encoded by Bacteriophage λ Lysogens: Lysis of Bacterial Colonies

THE ISOLATION OF RECOMBINANT BACTERIOPHAGES ENCODING FUSION PROTEINS that bind to an antibody, a double-stranded oligonucleotide, or other type of ligand is just the first step in the cloning of cDNAs that code for an enzyme, structural protein, or transcription factor of interest. Additional experiments are required to ensure that the desired protein has been identified. The next steps in the expression cloning process are production of the fusion protein and testing of the expressed protein for unique properties such as DNA binding, enzymatic activity, or immunochemical specificity. Fusion proteins can be produced following the formation of bacteriophage λ lysogens (this protocol) or after lytic infection of an *E. coli* host (Protocols 8 and 9). In the former method, a bacteriophage lysogen is constructed from the recombinant bacteriophage λ expressing the fusion protein of interest. The resulting colonies are induced to synthesize the fusion protein, which is isolated from the lysogen, and then subjected to further functional and biochemical analyses. This method has three advantages over the lytic infection of a bacterial host:

- λgt11 genomes inherited as part of the host-cell chromosome may be more genetically stable than genomes propagated by lytic infection.
- The repression of synthesis of potentially toxic fusion proteins may be more complete in cells containing only one integrated copy of the recombinant genome rather than in lytically infected cells that rapidly accumulate many hundreds of copies of the fusion gene.
- The amount of fusion protein produced in a lysogenic colony is at least 10 times greater than in a bacteriophage λ plaque (Mutzel et al. 1990).

Lysogens do, however, have two drawbacks. The formation and induction of lysogens requires several days to complete, and, for unknown reasons, a small minority of bacteriophage λ recombinants are unable to form stable lysogens (Huynh et al. 1985).

Bacteriophage λ vectors λgt11, λgt18-23, λZAP, and λZipLox carry a mutation (*cIts857*) that renders the repressor encoded by the viral *cI* gene thermosensitive. At 42°C, where the *cIts857* repressor is only partially functional (Lieb 1979), these vectors (and recombinants derived from them) form plaques on strains of *E. coli* (such as Y1090*hsdR*) that carry the amber suppressor *supF*. At temperatures where the repressor is active (32°C), these bacteriophage strains can also form lysogens (Young and Davis 1983b). Such lysogens can be stably maintained as prophage only when lysogenic cultures are carried out at 32°C. Lytic development of bacteriophage begins immediately after the temperature is raised (Sussman and Jacob 1962).

After a recombinant λgt11 that synthesizes a fusion protein of interest has been identified, lysogens are established from which preparative amounts of the recombinant protein can be

obtained. Because the foreign cDNA sequence is fused to the carboxyl terminus of β-galactosidase, the standard method involves production of lysogens in *E. coli* strain Y1089 and induction of the *lacZ* fusion protein by IPTG (Mierendorf et al. 1987). Alternatively, fusion proteins can be prepared from liquid (Runge 1992) or plate cultures (Huang and Jong 1994) of strain Y1090 that have been lytically infected with high multiplicities of the recombinant bacteriophage. In the following protocol, modified from Snyder et al. (1987), Singh et al. (1989), and Singh (1993), lysogens of individual recombinant bacteriophages are generated at 32°C and then exposed briefly to high temperature (44°C), which inactivates the thermolabile repressor and induces a round of lytic bacteriophage infection (for more details, please see the introduction to Chapter 2). Synthesis of the fusion protein encoded by the recombinant bacteriophage is induced by treating the cells with IPTG.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

IPTG (1 M)

Approximately 40 µl of 1 M IPTG is required per lysogen induced.

Lysogen extraction buffer

50 mM Tris-Cl (pH 7.5)
1 mM EDTA (pH 8.0)
5 mM dithiothreitol
50 µg/ml phenylmethylsulfonyl fluoride (PMSF) **<!>**

Add PMSF to the lysogen extraction buffer just before it is used in Steps 13 and 18. Approximately 100 ml of lysogen extraction buffer is needed per 20 lysogens induced.

NaCl (5 M)

Store the solution of NaCl at 4°C.

Enzymes and Buffers

Lysozyme (10 mg/ml)

Dissolve solid lysozyme (molecular biology grade) at a concentration of 10 mg/ml in 10 mM Tris-Cl (pH 8.0). This solution should be freshly prepared for use in Step 15.

Media

LB agar plates containing 50 µg/ml ampicillin
LB medium
LB medium containing 50 µg/ml ampicillin
LB medium containing 10 mM $MgCl_2$
LB medium containing 10 mM $MgCl_2$, 0.2% (w/v) maltose, and 50 µg/ml ampicillin

Special Equipment

Air incubators preset to 32°C and 42°C
Liquid nitrogen **<!>**
Millipore filter(s)

Circular 138-mm filters (Millipore type VS, 0.025-µm pore size filters) are used to dialyze the lysates. As many as 20 lysates can be dialyzed per filter.

Shaking water bath preset to 44°C

A static H_2O bath set at 44°C will usually suffice if a shaking water bath is not available.

Toothpicks or Inoculating loops

Additional Reagents

Step 1 of this protocol requires the reagents listed in Chapter 2, Protocol 3.

Vectors and Bacterial Strains

Bacteriophage λgt11, λgt18-23, λZAP, and λZipLox recombinant

This protocol has been optimized for a bacteriophage λgt11 recombinant that expresses a recombinant fusion protein (identified by methods outlined in Protocol 1 or 6 or by hybridization and DNA sequence analysis). Recombinants constructed in many other bacteriophage λ expression vectors can be used to establish lysogens essentially as described here.

E. coli strains Y1090hsdR and Y1089

These strains, which are available from the ATCC (www.atcc.org), are maintained on LB agar plates containing 50 µg/ml ampicillin. The Y1090 and Y1089 strains carry mutations in the *lon* gene, which encodes an ATP-dependent protease. Fusion proteins expressed in these strains are often more stable than those expressed in strains lacking this mutation. Y1089 carries the *hflA* mutation, which dramatically increases the frequency of lysogenization by bacteriophage λ. In addition, Y1089 lacks a suppressor tRNA gene; thus, the amber mutation in the *S* gene (lysis gene) of λgt11 is not suppressed in this strain, allowing large amounts of bacteriophage-λ-encoded gene products (including LacZ fusion proteins) to accumulate to high levels within an induced cell. For additional information on *E. coli* strains Y1090 and Y1089, please see the information panel on **PLASMID AND BACTERIOPHAGE λ EXPRESSION VECTORS.**

METHOD

1. Make a plate stock of each of the recombinant bacteriophage(s) of interest using the methods described in Chapter 2, Protocols 2–3. The titer of the stocks, measured on *E. coli* strain Y1090*hsdR*, should be $>10^{10}$ pfu/ml.
2. Grow a 2-ml culture of *E. coli* strain Y1089 to saturation in LB medium containing 10 mM $MgCl_2$, 0.2% maltose, and ampicillin (50 µg/ml).
3. Dilute 50 µl of the saturated culture with 2 ml of LB medium containing 10 mM $MgCl_2$. Transfer four 100-µl aliquots of the diluted culture to fresh culture tubes.
4. To each of three of the tubes, add 1×10^7, 5×10^7, and 2×10^8 plaque-forming units of the bacteriophage stock. The fourth tube should receive no bacteriophage. Incubate all four tubes for 20 minutes at 37°C to allow virus attachment.
5. Dilute 10 µl of each of the four cultures with 10 ml of LB medium. Immediately plate aliquots (100 µl) of each of the four diluted cultures onto LB agar plates containing 50 µg/ml ampicillin. Incubate the plates for 18–24 hours at 32°C.

   A lawn of cells should appear on the plates inoculated with the uninfected culture of *E. coli* Y1089. Infected cultures should give rise to 50–500 colonies, depending on the density of the original saturated culture and on the exact multiplicity of bacteriophage infection.
6. Use sterile toothpicks or inoculating loops to transfer a series of individual colonies onto two LB plates that contain 50 µg/ml ampicillin. Incubate one plate at 32°C and the other plate at 42°C for 12–16 hours. Clones that give rise to colonies at 32°C but not at 42°C are lysogenic for recombinant bacteriophage λgt11. Usually, 10–70% of the colonies tested are lysogens.
7. Inoculate 2 ml of LB medium containing 50 µg/ml ampicillin with individual bacteriophage λgt11 lysogens. Grow the cultures for 12–16 hours at 32°C with vigorous agitation (300 cycles/minute in a rotary shaker).
8. Add 50 µl of each culture to 4 ml of prewarmed (32°C) LB medium containing 50 µg/ml ampicillin. Continue incubation at 32°C with vigorous agitation.

9. Grow the cultures until the OD_{600} = 0.45 (~3 hours of incubation).

   ▲ **IMPORTANT** The OD_{600} of the cultures should not exceed 0.5 (~2 x 10^8 bacteria/ml) before induction of the lysogens.

10. Transfer the cultures to a shaking water bath equilibrated to 44°C. Incubate the cultures for 15 minutes at 44°C.

    The maximal efficiency of induction is obtained by rapidly raising the temperature from 32°C to 44°C. It is therefore preferable to transfer the cultures to a water bath set at 44°C rather than to a hot-air incubator. Shake the cultures vigorously from time to time during incubation at 44°C, if using a static water bath.

    Heating to these temperatures only partially inactivates the *cIts*857 repressor, which can also renature when the culture is cooled to 37°C (Mandal and Lieb 1976). However, the concentration of repressor is too low to prevent synthesis of Cro protein, which binds to OR3 and prevents further synthesis of the repressor. After heating, the culture becomes irretrievably committed to a cycle of lytic bacteriophage growth.

11. Add IPTG to each culture to a final concentration of 10 mM, and then incubate the cultures for 1 hour at 37°C with vigorous agitation.

12. Transfer 1.5-ml aliquots of each of the induced lysogenic cultures to two microfuge tubes. Immediately centrifuge the tubes at maximum speed for 30 seconds at 4°C in a microfuge.

13. Remove the medium by aspiration, and then rapidly resuspend the bacterial pellets by vortexing in 100 µl of lysogen extraction buffer.

14. Close the caps of the tubes, and place the tubes in liquid nitrogen.

15. After 2 minutes, recover the tubes from the liquid nitrogen. Hold the tubes in one hand to warm them until the lysates just thaw, and then immediately add to each tube 20 µl of 10 mg/ml lysozyme. Store the tubes for 15 minutes in an ice bath.

16. Add 250 µl of 5 M NaCl to each tube. Mix the contents by flicking the side of each tube with a finger. Incubate the tubes for 30 minutes at 4°C on a rotating wheel.

17. Centrifuge the tubes at maximum speed for 30 minutes at 4°C in a microfuge.

18. Float a Millipore filter (Type VS, 0.025-µm pore size) on the surface of a Petri dish (150 mm) filled with lysogen extraction buffer at 4°C.

    This step is best carried out in a corner of a cold room away from drafts. Take care that no lysogen extraction buffer spills over onto the upper surface of the filter.

19. Transfer the supernatants from the centrifuge tubes to the upper surface of the filter. Up to 20 different samples can be applied to the same filter.

20. After 1–2 hours at 4°C, transfer the dialyzed samples to fresh microfuge tubes, which can be stored at –70°C until needed.

21. Analyze the cell lysates directly for the presence of DNA-binding proteins, for example, in methylation protection experiments, by DNase I footprinting, or in gel electrophoresis DNA-binding assays (electrophoretic mobility-shift assays) (please see Chapter 17).

    Fusion proteins can be purified using commercially available affinity chromatography kits (e.g., ProtoSorb LacZ immunoaffinity absorbent, Promega) or as described in Chapter 15.

    Crude lysates or purified fusion protein can be assayed for the presence of an enzyme activity associated with the foreign protein or for immunochemical cross-reactivity by immunoblotting.

    Purified fusion proteins can be used to raise antibodies against the foreign protein, which in turn can be used to confirm the identity of a suspected cDNA-encoded protein (by tissue surveys or analysis of partially purified fractions), to inhibit an enzyme activity, or to purify the native foreign protein by affinity chromatography.

Protocol 8

Preparation of Lysates Containing Fusion Proteins Encoded by Bacteriophage λ: Lytic Infections on Agar Plates

FUSION PROTEINS ENCODED BY BACTERIOPHAGE λ RECOMBINANTS are generally prepared from lysogenic colonies of *E. coli* strain 1089. However, the production of lysogens from large numbers of individual plaques can be tiresome and may not be successful in every case (Huynh et al. 1985). As an alternative, a lytic bacteriophage infection can be established either in soft agarose (this protocol) or in liquid culture (Protocol 9). Following induced expression, the fusion protein can be recovered from the infected bacterial cells.

In general, these protocols are more versatile, require less IPTG, and yield more fusion protein than induced bacterial lysogens. However, they require a greater amount of recombinant bacteriophage than is needed to establish lysogens. In addition, greater accumulation of the fusion protein in the host cells may, in rare cases, disrupt lytic expression systems. This protocol was adapted from Huang et al. (1989) and Huang and Jong (1994).

MATERIALS

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Control overlay solution (6 ml required for each recombinant plaque analyzed)

10 mM $MgSO_4$

0.5x LB medium

For an LB medium recipe, please see Appendix 2. After autoclaving the 0.5x medium, supplement it with 1 M $MgSO_4$ to bring its final concentration to 10 mM. For each 150-mm agar plate, 6 ml of IPTG overlay solution is required.

IPTG overlay solution (12 ml required for each recombinant plaque analyzed)

0.5x LB medium

5 mM IPTG

10 mM $MgSO_4$

For an LB medium recipe, please see Appendix 2. After autoclaving the 0.5x medium, supplement it with 1 M IPTG (2.38 g of IPTG in a final volume of 10 ml of sterile H_2O) and 1 M $MgSO_4$ (24.6 g of $MgSO \cdot 7H_2O$ in a final volume of 100 ml of sterile H_2O) to bring their final concentrations to 5 and 10 mM, respectively. For each 150-mm agar plate, 12 ml of IPTG overlay solution is required.

$MgSO_4 \cdot 7H_2O$ (1 M)

SM

Media

LB agar plates (150 mm)
Freshly poured plates that have been equilibrated to room temperature give the best results.

LB medium containing 50 µg/ml ampicillin

LB top agarose containing 10 mM $MgSO_4$ and 50 µg/ml ampicillin

Centrifuges and Rotors

Sorvall SS-34 rotor or equivalent

Special Equipment

Air incubator preset to 4°C

Vectors and Bacterial Strains

Bacteriophage λgt11 recombinant
Prepare a stock of recombinant bacteriophage λ of known titer by soaking an individual plaque in ~100 µl of SM for at least 2 hours at room temperature or by preparing a plate lysate (please see Chapter 2, Protocol 3).

E. coli *strain Y1090*hsdR
This strain is available from the ATCC (www.atcc.org) and is maintained on LB agar plates containing 50 µg/ml ampicillin. The strain carries a mutation in the *lon* gene, which encodes an ATP-dependent protease. Fusion proteins expressed in this strain are often more stable than those expressed in strains lacking this mutation.

METHOD

1. Inoculate 50 ml of LB medium containing 50 µg/ml ampicillin with a single colony of *E. coli* Y1090*hsdR*. Grow the culture overnight at 37°C with moderate agitation (250 cycles/minute in a rotary shaker).
2. Transfer the culture to a centrifuge tube, and centrifuge the cells at 4000*g* (5800 rpm in a Sorvall SS-34 rotor) for 10 minutes at room temperature.
3. Discard the supernatant, and resuspend the cell pellet in 20 ml of 10 mM $MgSO_4$. Measure the OD_{600} of a 1/100 dilution of the resuspended cells and prepare a plating stock by diluting the resuspended cells to a final concentration of 2.0 OD_{600}/ml with 10 mM $MgSO_4$.
4. Transfer three 0.2-ml aliquots of the plating stock of *E. coli* Y1090*hsdR* to fresh tubes. To two of the tubes, add 2×10^5 to 5×10^6 pfu of the recombinant bacteriophage λgt11 stock. The third tube serves as an uninfected control. Incubate the tubes for 20 minutes at 37°C to allow the virus to attach to the cells.
5. Add 7.5 ml of molten LB top agarose containing 10 mM $MgSO_4$ and 50 µg/ml ampicillin to one of the tubes. Mix the contents, and immediately pour the top agarose onto a 150-mm LB agar plate.
6. Repeat Step 5 with each of the remaining tubes.
7. Incubate the agar plates for 4 hours at 42°C.
8. Remove the plates from the incubator. Add 6 ml of control overlay solution to one of the infected plates. Add 12 ml of IPTG overlay solution to the two remaining plates.
9. Return the plates to the 42°C incubator for 3–5 hours.

10. Remove the plates from the incubator and transfer the overlay solutions into individual sterile tubes.

The fusion protein is released from infected cells at the point of lysis and diffuses into the overlay solution. Most of the bacterial debris remains in the agarose and does not contaminate the overlay solution.

As much as 200 µg of fusion protein can be produced per 150-mm plate. According to Huang and Jong (1994), the induction process can be repeated as many as five times on each plate, although maximum expression is obtained in the first two inductions. Repeat inductions are carried out by removing the protein-infused overlay solution, allowing the plate to recover for 1 hour at 37°C, followed by addition of fresh overlay solution.

In a variation of this protocol (Lillibridge and Philipp 1993), the recombinant phage expressing the desired fusion protein is used to form a large "maxiplaque" on a lawn of *E. coli*. The plaque and underlying agar are cored from the plate, dounced in a homogenizer, and resuspended in 2× SDS-loading buffer for polyacrylamide gel electrophoresis and immunoblotting. Starting with a plaque, their procedure requires ~6.5 hours to reach the stage of gel electrophoresis.

11. Detect the fusion protein in the overlay solution by immunoblotting or by DNA-binding assays if the original phage was isolated as described in Protocol 6.

No immunological reactivity or DNA-binding activity should be detected in the overlay solution derived from the uninfected culture or in the overlay solution from which IPTG was omitted.

For assays involving the detection of enzyme activity, overlay solutions can be dialyzed against an appropriate buffer before analysis.

12. Purify the β-galactosidase fusion protein from the overlay solution by affinity chromatography using commercially available kits (e.g., Promega ProtoSorb), or as described in Chapter 15, Protocol 1. Dialyze the overlay solution before purification of the protein to remove IPTG.

Protocol 9

Preparation of Lysates Containing Fusion Proteins Encoded by Bacteriophage λ: Lytic Infections in Liquid Medium

THIS RAPID METHOD IS USED TO SCREEN BACTERIOPHAGE λGT11 RECOMBINANTS for the production of immunodetectable fusion proteins. However, with some effort (i.e., optimization of the multiplicity of infection ratio, inactivation of the bacteriophage λ*c*I gene at 42°C, and harvesting just before lysis), the method can be used to produce preparative amounts of a fusion protein (Runge 1992).

For an assessment of the merits of expressing protein fusions in lytic versus lysogenic cultures, and in liquid versus solid medium, please see the introductions to Protocols 7 and 8.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Cell lysis buffer (100 µl required for each plaque analyzed)
- 50 mM Tris-Cl (pH 6.8)
- 100 mM dithiothreitol
- 2% (w/v) SDS
- 0.1% (w/v) bromophenol blue
- 10% (v/v) glycerol

IPTG (1 M) (70 µl required for each plaque analyzed)

$MgSO_4 \cdot 7H_2O$ (1 M)

Phenylmethysulfonyl fluoride (PMSF) (100 mM) **<!>**

SM

Discard each aliquot after use to minimize contamination.

Gels

SDS-polyacrylamide gel **<!>**

Please see Step 12.

Media

LB medium containing 50 µg/ml ampicillin

Centrifuges and Rotors

Sorvall SS-34 rotor or equivalent

Special Equipment

Boiling-water bath
Liquid nitrogen <!>

Vectors and Bacterial Strains

Bacteriophage λgt11 recombinant

Prepare stocks of bacteriophage λ recombinants by soaking individual plaques in ~1 ml of SM for at least 2 hours at room temperature or by preparing a plate lysate (please see Chapter 2, Protocol 3).

E. coli *strain Y1090*hsdR

This strain is available from the ATCC (www.atcc.org). For information on *E. coli* strain Y1090, please see the information panel on **PLASMID AND BACTERIOPHAGE λ EXPRESSION VECTORS**.

METHOD

1. Inoculate 50 ml of LB medium containing 50 µg/ml ampicillin with a single colony of *E. coli* Y1090*hsdR*. Grow the culture overnight at 37°C with moderate agitation (250 cycles/minute in a rotary shaker).
2. Transfer the culture to a centrifuge tube, and centrifuge the cells at 4000*g* (5800 rpm in a Sorvall SS-34 rotor) for 10 minutes at room temperature.
3. Discard the supernatant, and resuspend the cell pellet in 25 ml of 10 mM $MgSO_4$. Store the bacterial suspension on ice until required.
4. In sterile 15-ml tubes, mix 8 ml of LB containing 50 µg/ml ampicillin, 400 µl of bacterial suspension, and 100 µl of phage lysate.

   Because the fusion protein is isolated from the infected cells themselves rather than from the lysate (as in Protocol 8), it is important to obtain a productive infection with the λgt11 phage of interest while avoiding premature lysis of the culture. For this reason, low multiplicities of infection (~1 pfu per 16,000 cells) are used in the procedure.
5. Place the tubes in a 37°C shaking water bath for 2 hours.
6. Transfer a 1-ml aliquot of each culture of infected cells to a sterile microfuge tube. Store the tightly capped tubes in liquid nitrogen. Add 70 µl of 1 M IPTG to the remainder of the infected cultures and continue the incubation at 37°C.
7. At hourly intervals thereafter, withdraw 1-ml aliquots of each culture of infected cells to microfuge tubes. Store the tightly capped tubes in liquid nitrogen. Collect aliquots in this fashion for a period of 4 hours.
8. Incubate the remainder of the infected cultures for a further 12 hours at 37°C. Remove a final 1-ml sample from each culture. Place the tightly capped tubes in liquid nitrogen for 30 minutes.

9. Thaw all the samples and collect the infected bacteria by centrifugation at maximum speed for 1 minute at room temperature in a microfuge. Decant and discard the bacterial medium.
10. Add 100 µl of cell lysis buffer to each tube and rapidly resuspend the cell pellets by vigorous vortexing.
11. Place the samples in a boiling-water bath for 3 minutes. Transfer the samples to room temperature, add 1 µl of 100 mM PMSF, and mix the contents of the tubes by vortexing.
12. Analyze the samples directly by SDS-polyacrylamide gel electrophoresis and immunoblotting. Just before electrophoresis, spin the samples at maximum speed for 1 minute in a microfuge. Load a 25-µl aliquot of the supernatant from this spin onto the SDS-polyacrylamide gel.

    Alternatively, the samples may be stored at –70°C before analysis.

    The amount of the fusion protein of interest should increase progressively in the samples of cultures treated with IPTG for 1–4 hours. Thereafter, the amount of protein may increase, remain the same, or decrease depending on whether the infected cells lyse and release protein into the medium.

PLASMID AND BACTERIOPHAGE λ EXPRESSION VECTORS

Expression libraries can be constructed in plasmid or bacteriophage λ vectors that carry a strong, regulated prokaryotic promoter and a ribosome-binding site. A few vectors are available that express only the sequences of the foreign protein (please see Chapter 15 and Table A3-1 in Appendix 3). More commonly, however, the foreign DNA sequences are cloned into a restriction site that lies within the coding sequences of a prokaryotic or eukaryotic gene (or fragment of a gene) located immediately downstream from the prokaryotic promoter/ribosome-binding site. In many vectors, this gene is *E. coli lacZ*, which encodes β-galactosidase. If the foreign sequences are inserted in the correct orientation and reading frame, a fusion protein is produced that consists of β-galactosidase sequences linked to polypeptide sequences encoded by the cloned DNA. The fusion protein, which is synthesized upon induction of the *lac* promoter with isopropyl-β-thiogalactoside, may retain or lose β-galactosidase activity or the ability to take part in α-complementation (please see Chapter 1), depending on the nature of the foreign sequences and the site at which they are inserted. Insertion of foreign sequences into β-galactosidase, or into other proteins such as maltose-binding protein, thioredoxin, or the glutathione-*S*-transferase of *Schistosoma japonicum*, often enhances the stability of the fusion protein in the host bacterium (Kupper et al. 1981; Stanley 1983; di Guan et al. 1988; Smith and Johnson 1988; LaVallie et al. 1993).

Expression libraries constructed in bacteriophage λ and plasmid vectors differ from one another in one major respect. Libraries constructed in bacteriophage λ vectors are plated on a bacterial lawn, which is progressively lysed during the next few hours as a natural consequence of bacteriophage growth. The resulting debris is transferred to nitrocellulose filters and screened for the presence of immunoreactive material. By contrast, plasmid libraries are maintained as transformed bacterial colonies that must be lysed in situ on nitrocellulose filters before intracellular fusion proteins can be screened with antibodies or other ligands. Expression libraries constructed in plasmids therefore suffer from a significant disadvantage: the labor involved in generating the replicas of the library that are used for immunological screening. Usually, master copies of plasmid libraries are grown on nitrocellulose filters, and several replicas are then generated by transferring the colonies in situ to fresh nitrocellulose filters (please see Protocol 2). This is a laborious process that can be repeated only a few times before the colonies on the master filter become smeared beyond recognition. Colonies growing on the replica filters are lysed and screened with a labeled ligand specific for the gene product of interest. Clones that react with the labeled ligand are recovered from the master filter and analyzed further. Although these procedures are easy to accomplish when only a few clones are to be screened, they are logistically demanding when large libraries consisting of 10^6 or more colonies are to be screened. For most purposes, therefore, bacteriophage expression vectors are the vehicles of choice for immunological screening of large libraries.

The vast majority of cDNA expression libraries are constructed in bacteriophage λgt11, its close relatives λgt18-23, λZAP (or the λZAP Express or λZAPII derivatives), λZipLox, or λORF8. These bacteriophages carry one of two modified *E. coli lacZ* genes. λgt11 and λORF8 contain a complete copy of the *lacZ* gene with a cloning site located 53 bp upstream of the translational termination codon. cDNAs inserted in the correct orientation and reading frame are expressed to yield fusion proteins whose amino termini consist of β-galactosidase sequences and whose carboxyl termini consist of foreign sequences. Vectors such as λZipLox and λZAP contain a fragment of the *lacZ* gene spanning the promoter-operator and the amino-terminal encoding region (Ullmann et al. 1967). cDNAs inserted into the polylinker are expressed as a fusion protein consisting of the amino-terminal 6 amino acids of β-galactosidase followed by carboxy-terminal foreign sequences. With both types of vectors, some of the foreign sequences display antigenic epitopes that can be detected using specific antibodies.

Bacteriophage λ vectors used for the construction of expression libraries usually (λORF8 is an exception) have a mutant copy of the λ repressor gene (*cIts857*), which encodes a temperature-sensitive repressor protein, and they carry an amber mutation in the *S* (lysis) gene. At temperatures that inactivate the repressor (42°C), these bacteriophage form plaques on strains of *E. coli* (such as Y1090*hsdR*) that carry an amber suppressor *(supF)*. Strain Y1090*hsdR* displays additional properties that are useful in immunological screening: It carries a plasmid (pMC9) that encodes the *lac* repressor, and it is deficient in the product of the *lon*

gene, an ATP-dependent endoprotease (for review, please see Gottesman and Maurizi 1992). The absence of a functional *lon* protease extends the half-life of many β-galactosidase fusion proteins. A related strain of *E. coli*, Y1089, in addition to the *lon* mutation, also carries a mutation in *hflA*, which dramatically increases the frequency of lysogenization by bacteriophage λ. In addition, because Y1089 lacks a suppressor tRNA gene, the amber mutation in the *S* gene (lysis gene) of λgt11 is not suppressed, allowing large amounts of bacteriophage λ-encoded gene products (including *lacZ* fusion proteins) to accumulate to high levels within an induced cell. For further details of the properties of λgt11, λgt18-23, λZAP, λZipLox, and λORF8, please see the introduction to Chapter 11 and Appendix 3.

Libraries of bacteriophage λ established as lysogens in *E. coli* host strain Y1090 offer potential advantages for screening of expression libraries: λ genomes inherited as part of the host-cell chromosome may be more stable genetically than genomes propagated by lytic infection, and the repression of synthesis of potentially toxic fusion proteins may be more complete in cells containing only one integrated copy of the recombinant genome than in lytically infected cells that rapidly accumulate many hundreds of copies of the fusion gene. Expression of fusion protein in a lysogenic colony can be as much as 20 times higher than the 0.25 fmole of target protein typically expressed in a bacteriophage plaque (Lacombe et al. 1987). Despite these apparent advantages, most libraries constructed in λgt11 are no longer propagated as lysogens nor screened after induction because some recombinants are unable to form stable lysogens (Huynh et al. 1985). The increased amounts of fusion protein synthesized in induced lysogens are rarely of practical advantage since imprints of conventional bacteriophage λ plaques contain ample quantities of material for detection by antisera of high specificity and reasonable titer. Screening of lysogens may, however, offer some advantages when using proteins such as calmodulin as probes or when using small ligands (e.g., cAMP) with a low affinity for the target protein. The high concentration of target protein in an induced lysogenic colony may significantly shift the binding equilibrium in favor of complex formation between a ligand and its target and hence raise the intensity of the signal to the point where it becomes detectable (Mutzel et al. 1990; Mutzel 1994).

Although lysogens are no longer used for screening entire bacteriophage λ libraries with immunological probes or double-stranded oligonucleotide probes, they are routinely used to analyze the properties of fusion proteins encoded by individual bacteriophage recombinants. The bacteriophages recovered from an individual plaque are used to establish lysogenic derivatives of *E. coli* strain Y1090*hsdR* or Y1089*hflA*, which can be induced to synthesize fusion proteins in quantities sufficient for biochemical analysis (please see Protocol 7).

Genomic DNA and cDNA Expression Libraries

Two types of expression libraries can be constructed in plasmid and bacteriophage λ expression vectors: cDNA and genomic DNA libraries. For prokaryotic organisms, whose genomes contain few introns, there is little to be gained by constructing cDNA libraries in these vectors. Instead, randomly sheared genomic DNA can be used to create a library (for details, please see Chapter 11) in which all coding sequences are proportionally represented (e.g., please see Young et al. 1985). The optimal average length of the sheared fragments of DNA used to construct libraries of this kind depends on the size of the gene of interest: The smaller the gene, the smaller the genomic DNA fragments. Ideally, the size of the fragments should be approximately one-half the predicted size of the gene. This size range reduces the chance that the coding sequences of the gene of interest will be preceded by upstream termination sequences.

A similar strategy can be used with eukaryotic organisms such as yeasts, whose genomes are comparatively small and consist predominantly of coding sequences. The probability (P) of creating a recombinant containing the sequences of the gene of interest in the correct reading frame and orientation for expression is:

$$P = \frac{\text{size of the coding region of the gene of interest (in kb)}}{\text{size of genome (in kb)} \times 6}$$

The factor of 6 takes into account the fact that a given DNA fragment can be inserted into the vector in two possible orientations and that only one of the three potential reading frames is correct for expression. The

proportion of clones expressing the particular fusion protein is then 1:1/*P*. For example, in a genomic DNA expression library, the proportion of recombinants capable of expressing a fusion protein encoded by a gene whose coding region is 1.5 kb in length is predicted to be:

Organism	Genome size (kb)	Proportion
E. coli	4.0×10^3	$1{:}1.6 \times 10^4$
Yeast	1.4×10^4	$1{:}5.6 \times 10^4$
Drosophila	1.8×10^5	$1{:}7.2 \times 10^5$

In theory, these frequencies will be attained only if the cloned genomic DNA fragments are considerably smaller (<50%) than the size of the coding sequence of interest. In practice, however, the frequency of positive clones is somewhat higher than expected. Although the reasons for this outcome are not understood, a possible clue comes from the observation that a high proportion of clones isolated from genomic DNA expression libraries by immunological screening do not synthesize fusion proteins (Goto and Wang 1984; Ozkaynak et al. 1984; Snyder et al. 1986). Because expression of these cloned genes is dependent on transcription from the *lacZ* promoter, it seems likely that the clones carry out-of-frame insertions and that translation of the foreign sequences is initiated at an internal methionine codon. More rarely, the foreign sequences may carry signals that can direct transcription and translation in *E. coli*.

As the size of eukaryotic genomes increases, the fraction that is occupied by coding sequences shrinks dramatically, and the average length of individual exons decreases to ~200 bp (Go 1983). The idea of screening genomic DNA expression libraries then becomes much less attractive. In the case of the mammalian genome (3×10^9 bp), reconstruction experiments suggest that it would be necessary to screen a library of at least 10^7 clones (average size 200–300 bp) to detect a recombinant expressing a particular epitope (Rüther et al. 1982). Even then, only epitopes encoded by DNA sequences contained within a single exon would be detected. The use of cDNA libraries solves these problems by consolidating the coding sequences of individual genes into single clones and eliminating the nonproductive screening of clones that consist of intron and repetitive sequences.

Mammalian cDNA libraries used for immunological screening usually have a complexity of at least 10^6 independent recombinants. In libraries constructed by nondirectional cloning, only one recombinant in six will carry an insert in the correct orientation and frame for expression. However, in libraries established by directional cloning, the proportion of useful clones rises to one in three. Most directionally cloned libraries are constructed by random priming of cDNA synthesis rather than by oligo(dT) priming. Random-primed libraries contain a higher proportion of sequences that lie toward the 5′ region of the mRNA and therefore would be expected to express epitopes that map to the amino-terminal sequences of the protein, whereas expression libraries generated by oligo(dT) priming are likely to be enriched for epitopes located in the carboxy-terminal regions of the target protein. To maximize the chance of detecting a clone by immunological probes, many investigators screen a composite library containing a representative mixture of cDNA clones generated by each method of priming.

USING ANTIBODIES IN IMMUNOLOGICAL SCREENING

Choosing the Antibody

Ideally, an antibody used for screening of expression libraries should be polyclonal, absolutely specific for conformation-independent epitopes that are displayed on both native and denatured forms of the protein, of high titer, and of the IgG class. This combination of properties is rarely found in a single antiserum, and it is often necessary to screen expression libraries with preparations of antibodies that are far from ideal. To determine whether the available batches of antisera are suitable as probes, serial dilutions of several independent antisera should be tested for the following properties:

- ***Reactivity with the protein of interest on a western blot.*** Denatured proteins transferred from an SDS-polyacrylamide gel are likely to display many of the same epitopes as the cognate fusion protein synthesized in bacteria. The foreign polypeptide sequences of most fusion proteins are unlikely to fold into completely native structures and, after transfer to a nitrocellulose filter, may undergo further denaturation. Antisera that fail to detect the protein of interest on a western blot are probably specific for epitopes displayed only on the native protein and therefore may be unsuitable as probes for expression libraries.
- ***Specific immunoprecipitation of a polypeptide of the predicted size from in vitro translation reactions primed with the same mRNA used to construct the expression library.*** An antiserum reacting strongly in this test must be directed primarily against epitopes that are displayed on unmodified, and probably unfolded, proteins. Clearly, antisera that recognize oligosaccharides or other modifying groups found on eukaryotic proteins are of no value for screening prokaryotic expression libraries.
- ***Production of weak or undetectable signals when reacted with bacteria expressing the sequences of the vector alone.*** Antisera should be tested by screening two nitrocellulose filters, one containing imprints of nonrecombinant plaques or colonies formed by the vector alone and the other containing imprints of a small fraction (e.g., 1–5000 plaques or colonies) of the expression library that is to be screened. A series of dilutions containing known amounts of the native and denatured (boiled) antigen (20 pg to 100 ng) of interest are spotted onto a separate filter. The three filters are then cut into sections, which are screened with different dilutions of antiserum. The aim is to find a dilution that displays a high level of specific reactivity with the antigen but does not react nonspecifically with prokaryotic proteins. Typically, the range of dilutions used in this test is 1:200–1:5000 for polyclonal antisera, IgG fractions, ascitic fluids, and affinity-purified antisera and 1:10–1:100 for supernatant fluids from cloned hybridomas grown in vitro. Ideally, the antibody should be capable of detecting as little as 50–100 pg of antigen in an area the size of a small bacterial colony. The amount of antigen present in colonies and plaques expressing fusion proteins varies widely depending on the toxicity of the fusion protein, its rate of degradation, and its physical state. However, an antiserum capable of detecting as little as 50–100 pg of denatured antigen should allow all but the most labile of fusion proteins to be recognized.

Both polyclonal antisera and monoclonal antibodies can meet the above criteria, and both have been used successfully to identify recombinants that express cloned sequences of interest. Each has different advantages. Polyclonal antisera are usually able to react with several different epitopes, which may be encoded by different regions of the gene of interest. Recombinants carrying fragments of this gene may therefore be detected by polyclonal antisera. By contrast, monoclonal antibodies, which by definition are able to react with only one epitope, may detect only a particular subset of the recombinants that express sequences of the gene of interest. However, monoclonal antibodies generally show much lower levels of background reactivity with *E. coli* components than do polyclonal antisera. The best reagents for immunological screening are therefore pools of monoclonal antibodies directed against different epitopes on the protein of interest or high-titer polyclonal antisera that do not react with host components. Before screening an expression library, it is essential to carry out a series of western blots or to optimize the conditions for binding the antibody to its target protein. The goal is to ascertain the following:

- A dilution of the antibody that generates a strong signal with the target protein and a low level of background against other proteins present in the bacterial lysate.
- The optimal time and temperature of incubation.
- Washing conditions that will discriminate between antibody molecules bound to their target protein and antibodies bound nonspecifically to, for example, the nitrocellulose membrane.

If, as is sometimes the case, the antiserum reacts strongly with components of lysates of bacteriophage-infected cells, it must be purified before being used to screen an expression library. For further information, please see Purification of Antisera below.

Purification of Antisera

When the antisera to be used for screening react with only one protein of the expected molecular weight on a western blot, further antigen-specific purification is not necessary. However, if the antibodies that react with the antigen of interest are of the IgG class, they may be easily purified and concentrated by affinity chromatography on protein A–Sepharose columns (Goudswaard et al. 1978). Preparations of IgG used for immunological screening usually give lower backgrounds than whole sera.

Antisera that react with several different proteins usually have been raised against impure antigen and are therefore likely to react with recombinant clones other than those specifying the protein of interest. In this case, the antibody should be purified by affinity chromatography on columns of the immobilized antigen. Note that affinity purification must be carried out with an independent preparation of antigen free of the contaminants, which may be difficult to obtain. In this case, there are two options. First, the library may be screened with the available polyclonal antisera; immunoreactive clones must then be analyzed by a test that can distinguish unambiguously between false and true positives. Alternatively, impure preparations of antigen may be used to generate clonal lines of hybridomas that secrete monoclonal antibodies specific for the protein of interest.

Components in polyclonal antisera or preparations of IgG that react with antigens produced by *E. coli* may be removed by immunoabsorption, for example, by incubating the diluted antiserum with nitrocellulose filters coated with lysed bacterial colonies or the debris of nonrecombinant plaques (pseudoscreening; please see Protocol 3 of this chapter). This process can be repeated several times, until all of the anti-*E. coli* antibodies have been removed. Alternatively, the diluted antiserum can be mixed with an extract of *E. coli* made by freezing-thawing and sonication (please see Protocol 4 of this chapter). The absorbed diluted antiserum can then be used to probe expression libraries without further treatment. The most effective procedure is to expose undiluted antiserum or purified IgG to lysates of *E. coli* that have been immobilized on cyanogen-bromide-activated Sepharose 4B as described by de Wet et al. (1984) (please see Protocol 5 of this chapter).

Several manufacturers of kits used for immunological screening provide lysates of bacterial cultures infected with bacteriophage λ vectors. These lysates can be used to check by western blotting whether an antibody directed against the target protein also reacts with components specified by the bacteriophage vector and/or its host.

Molecular Cloning

A LABORATORY MANUAL

THIRD EDITION

Chapter 15

Expression of Cloned Genes in *Escherichia coli*

BECAUSE OF THE VAST FUND OF KNOWLEDGE ABOUT ITS GENETICS, biochemistry, and molecular biology, *Escherichia coli* is the system of first choice for expression of many heterologous proteins: Genetic manipulations are straightfoward, cultures of *E. coli* are easily and inexpensively grown, and many foreign proteins are well-tolerated and may be expressed at high levels. During the past 20 years, several hundred recombinant proteins have been expressed in *E. coli* using one or another of the vector systems described in this chapter. However, *E. coli* is not always the host of choice. For example, proteins whose full biological activity requires posttranslational modification (e.g., glycosylation or cleavage at specific sites) may best be expressed in a eukaryotic host. It is therefore important before embarking on an expression project to assess the final goal and to determine which host-vector system may be most appropriate. These systems are reviewed in the information panel on **EXPRESSION OF CLONED GENES** at the end of this chapter.

CHOOSING AN EXPRESSION SYSTEM

Factors that influence the choice of a system for expression of a particular protein in *E. coli* are listed below.

- ***The size of the protein.*** Small cytosolic proteins and polypeptides (<100 residues in length) are best expressed in *E. coli* as fusion proteins composed of carrier sequences linked by a standard peptide bond to the target protein (please see section on Fusion Proteins, p. 15.4). The carrier often stabilizes the protein of interest against intracellular degradation and provides a ligand-binding site that can be used for affinity purification. The target protein may frequently be recovered in an active form by including a proteolytic cleavage site at an appropriate location in the fusion protein.

  Cytosolic proteins >100 residues in length are the most problematic proteins to express in either system. In *E. coli*, these proteins are often unstable or form insoluble inclusion bodies. In mammalian cells, problems can arise in distinguishing the foreign protein from its endogenous homolog.

- ***The amount of protein needed.*** If only small quantities of the target protein are required — for example, when screening a series of site-directed mutants for enzymatic activity — there is little point in trying to optimize production. Most of the standard expression plasmids can be used successfully if the enzyme can be assayed in crude extracts of *E. coli*. However, if purification of an active protein is necessary and/or if the protein is required in large quantities, it is usually necessary to explore several different host-vector systems and purification schemes before finding one that is workable on a large scale.

- ***Whether active protein is required.*** If the purpose of expressing the target protein is simply to obtain material for raising antibodies, there is no point in trying to obtain active protein. Instead, expression systems can be used that facilitate purification of the target protein, irrespective of its state of biological activity or denaturation. Here, the formation of inclusion bodies is a great advantage for isolating insoluble protein, as are tags that can be used during affinity purification of the target protein.

  If the target protein is to be used in biochemical or cell biological studies, then maintaining or restoring protein function is important and ease of purification matters less. In some cases, direct expression vectors may be used to produce soluble, active proteins. In most cases, however, the expressed protein will be insoluble and must be purified from inclusion bodies, solubilized, and refolded into an active form.

When the expressed protein is to be used in structural studies, it is best to express the target as a soluble protein. It may be necessary to test expression in several different strains of *E. coli* to establish conditions that minimize misfolding in vivo, and to take great care to minimize denaturation in vitro to maintain the proper configuration of the protein (please see the panel on **ADDITIONAL PROTOCOL: REFOLDING SOLUBILIZED PROTEINS RECOVERED FROM INCLUSION BODIES** in Protocol 8).

CHOOSING A PROMOTER AND VECTOR SYSTEM

The following categories of expression vectors, based on the type of promoter, are described in detail in the first series of protocols in this chapter (please also see the information panel on ***E. COLI* EXPRESSION SYSTEMS**).

Expression Vectors Containing an IPTG-inducible Promoter (Protocol 1)

Several different vectors based on the *lac* operon are used for high-level expression of foreign proteins in *E. coli*, including:

- ***The* trp-lac *(tac) promoter.*** *tac* is a hybrid *trp-lac* promoter containing the –35 region of the *trp* promoter fused to the –10 region of the *lac*UV5 promoter; it is regulated by the *lac* repressor and is independent of cAMP regulation mediated by the *crp* gene product (Amann et al. 1983; de Boer et al. 1983). A useful *tac* promoter expression plasmid (pKK223-3 [Brosius and Holy 1984]) is available from Pharmacia.

- ***The* trp-lac *(trc) promoter.*** *trc* is another version of the *lac* repressor-regulated hybrid *trp-lac* promoter containing the –35 region of the *trp* promoter fused to the –10 region of the *lac*UV5 promoter (Amann and Brosius 1985). The only difference between the *trc* and *tac* promoters is the distance separating the –35 and –10 regions of the promoter. In the *trc* promoter, these two elements are separated by a consensus distance (17 bp), whereas in the *tac* promoter, they are separated by 16 bp. This difference has little or no effect on the expression levels of foreign proteins (Amann and Brosius 1985). The expression plasmid p*Trc* 99A, available from Pharmacia, carries the *trc* promoter.

- ***The* lac *promoter.*** Any general-purpose vector (pUC, pTZ, pSK, pBluescript, pGEM, etc.) designed for blue/white screening for clones containing inserts of foreign DNA can be used to express a foreign protein, usually as a fusion protein with amino acids encoded by the amino terminus of the *lacZ* gene and/or the polylinker sequence (for further details, please see the information panel on **LACZ FUSIONS**). Although the *lac* promoter is not as strong as the *tac* or *trc* promoters, the high copy number of most general-purpose vectors allows expression of foreign proteins at respectable levels. Maximum induction of the *lac* promoter requires the action of the cAMP activator protein (CAP, the *crp* gene product), which is most active when cells are grown in medium lacking glucose. Media that contain glucose as a carbon source should not be used to express genes cloned into these vectors.

Expression Vectors Containing the Bacteriophage T7 Promoter (Protocol 2)

The pET series of vectors, originally developed by Studier et al. (1990) and since expanded, allow regulated expression of foreign genes by bacteriophage T7 RNA polymerase. These vectors typically carry the colicin E1 (colE1) replicon of pBR322 and confer resistance to ampicillin or kanamycin. Their multiple cloning sites allow an inserted coding sequence to be placed under

control of the "natural" promoter for T7 RNA polymerase (the ϕ10 promoter), or under the control of the so-called "T7*lac*" promoter, a derivative of the natural promoter that has the *lac* operator (*lacO*) placed so that binding of the *lac* repressor blocks transcription initiation.

Expression Vectors Containing the Bacteriophage λ p_L Promoter (Protocol 3)

In vectors of this class, the bacteriophage λ p_L promoter is regulated by a temperature-sensitive repressor, *cIts857*, which represses p_L-driven transcription at low temperatures but not at elevated temperatures. p_L vectors are particularly useful if the expressed gene product is toxic to *E. coli*. Several p_L vectors are commercially available including the pHUB series (Bernard and Helinski 1979), pPLc series (Remaut et al. 1981), pKC30 (Rao 1984), pAS1 (Rosenberg et al. 1983), pRM1/pRM9 (Mieschendahl et al. 1986), and pTrxFus (LaVallie et al. 1993). *E. coli* strains (e.g., M5219) harboring the *cIts857* mutation must be used as hosts for expression vectors carrying the bacteriophage λ p_L promoter.

FUSION PROTEINS

Gene fusions are created by joining together two or more open reading frames in a desired order. Expression of fused reading frames generates hybrid proteins in which the protein of interest is attached to the amino terminus or the carboxyl terminus of a carrier protein (Itakura et al. 1977; Goeddel et al. 1979; for review, please see Uhlén and Moks 1990; LaVallie and McCoy 1995). Fusion proteins have a vast array of potential uses.

- ***Attaching target proteins to a domain*** of known enzymatic function and/or antigenic composition may provide a convenient method to "tag" and isolate the target protein sequences.
- ***Joining the target protein to topogenic signals*** may allow the fusion protein to be directed to specific cellular compartments.
- ***Adding "carrier" sequences*** may protect the target protein from proteolysis in prokaryotic hosts.
- ***Adding carrier sequences*** may improve the solubility of the target protein and may prevent the formation of insoluble inclusion bodies (please see the following section on Dealing with Insoluble Proteins).

Table 15-1 contains a summary of vectors widely used for creation and expression of fusion proteins.

Purification of Fusion Proteins

By fusing the polypeptide of interest to a carrier that has high affinity for a specific ligand, almost any fusion protein can be purified by affinity chromatography, often in a single step. More than 20 different fusion systems have been designed for, or adapted to, affinity purification. The primary features of a vector used for constructing a fusion protein are shown in Figure 15-1. Many of these fusion vectors are based on LacZ, but other carrier proteins that have been used successfully include *malE*, glutathione-*S*-transferase, and staphylococcal protein A. Recently, identification tags derived from well-characterized ligand-binding proteins have been partially supplanted by artificial tags that have no counterpart in the natural world. The best known of these are (1) a polyhistidine sequence that binds to columns carrying Zn^{2+} or Ni^{2+} (Smith et al. 1988) and (2) FLAG, a designer heptapeptide that is both hydrophilic and immunoreactive. The five carboxy-

terminal amino acids of FLAG constitute a recognition site for the protease enterokinase, which can be used to remove the peptide from the target protein (Dykes et al. 1988; Hopp et al. 1988). Table 15-2 lists a number of fusion systems, each of which has been used successfully in several laboratories for affinity purification of different fusion proteins.

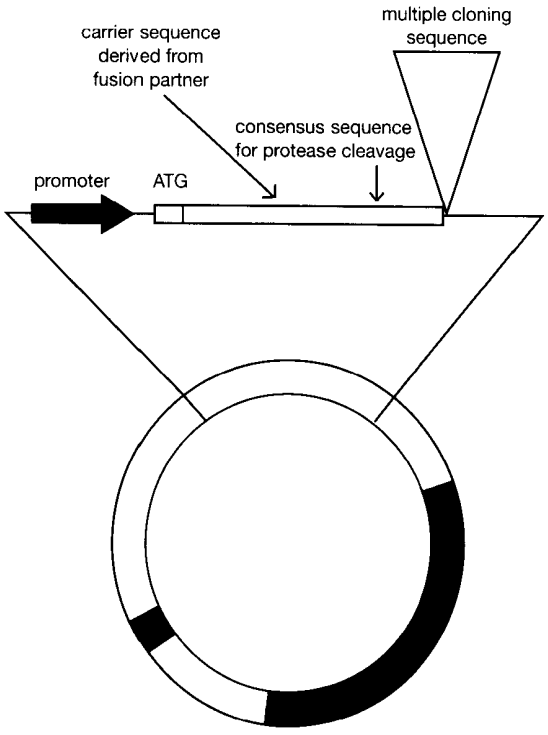

FIGURE 15-1 Schematic of a Generic Fusion Vector

Poly(histidine)	immobilized Zn^{2+} or Ni^{2+}	acid gradient (pH 6.0 to pH 4.0) imidazole (up to 0.5 M)	Smith et al. (1988)
FLAG	antibody specific for FLAG	EDTA at neutral pH or glycine buffer at pH 3.0	Hopp et al. (1988)
Poly(arginine)	S-Sepharose	gradient of NaCl	Brewer and Sassenfeld (1985)
Poly(cysteine)	thiopropyl-Sepharose	mercaptoethanol or dithiothreitol	Persson et al. (1988)
Poly(phenylalanine)	phenyl-Superose	ethylene glycol	Persson et al. (1988)

[a]TPEG and APTG are acronyms for the same compound: *p*-aminophenyl-β-D-thio-galactoside, which was first used for purification of β-galactosidase by Steers et al. (1971).

Fusion proteins produced in *E. coli* are often excellent immunogens that can be used to raise antisera against the target sequences. However, in many cases, the penalty for attaching a ligand-binding domain to the target sequences is loss of biological activity.

Cleavage of Fusion Proteins

To obtain the polypeptide of interest in a native and biologically active form, it must be cleaved from the remainder of the fusion protein. Although both chemical and enzymatic methods have been developed to cleave peptide bonds at the joint between the sequences of the target protein and the carrier protein, efficient removal of the tag or carrier protein remains a major problem. Chemical methods are specific to a particular amino acid or small group of amino acids. For example, cyanogen bromide cleaves only at methionine residues, whereas formic acid cleaves only at proline residues that are preceded by aspartic acid residues (please see Table 15-3). If these potential sites are present in the joint region of the fusion protein and are absent from the target sequences, chemical cleavage can be used to release intact target sequences from fusion proteins.

Cyanogen bromide, for example, has been used in the production of somatostatin (Itakura et al. 1977) and in the processing of β-galactosidase-insulin A chain fusion and β-galactosidase-insulin B chain fusion (Goeddel et al. 1979). In addition, the polylinker sequences of many expression plasmids contain a *Bam*HI site, 5′-NGGATCCN-3′. If this sequence of two codons (GAT and CCN), which encode the dipeptide AspPro, is in-frame with the fusion protein, then formic acid can be used to cleave the polypeptide (Table 15-3). In practice, however, chemical

cleavage is of limited use since most target proteins contain one or more potential cleavage sites. In addition, chemical cleavage is rarely as specific as it should be and is generally carried out under harsh reaction conditions that tend to denature the target protein. In most cases, therefore, the target protein is obtained in poor yield and in an inactive state.

Target proteins can sometimes be separated from the carrier sequences by enzymatic cleavage. This requires planning because the fusion protein must be designed so that it contains a specific proteolytic cleavage site at the joint between the target sequences and the carrier protein. This problem has been greatly ameliorated by the development of commercially available vectors containing a polycloning site downstream from the sequences coding for the carrier protein and a proteolytic cleavage site. For example, in the pMAL2 family of vectors, the coding sequence of interest is fused in-frame to the 3′ end of a synthetic sequence encoding the four-amino-acid recognition site for Factor Xa (Ile-Asp/Glu-Gly-Arg) (Nagai and Thøgerson 1984; Nambiar et al. 1987). Upstream of this sequence is a segment of DNA encoding the *E. coli* MalE protein. Factor Xa cleaves the peptide bond that is carboxy-terminal to the arginine residue in the recognition site (see Figure 15-2).

By carefully choosing the restriction sites that will be used to insert the target sequences into the vector, it is possible to arrange that few, if any, foreign amino acids remain attached to the amino terminus of the target protein after cleavage. Similar strategies can be used with many of the other enzymatic cleavage systems listed in Table 15-3.

Although this method of purifying the sequences of the protein of interest from the fusion protein looks great on paper, it works cleanly only ~50% of the time. With many enzymes, the efficiency of the proteolytic cleavage reaction is poor unless the fusion protein has been denatured with 6 M guanidine hydrochloride or 8 M urea or after a "spacer" has been inserted on one or both sides of the cleavage site. In other cases, because the specificity of the protease is not absolute or because the enzyme used for cleavage is contaminated by other proteases, the protein of interest is cleaved internally at sites that are related to the recognition site (Nagai and Thøgerson 1984, 1987; Dykes et al. 1988; Lauritzen et al. 1991). Problems of this type can sometimes, but not always, be solved by changing proteases or by using vectors (e.g., those coding for glutathione reductase or thioredoxin fusions) that typically express fusion proteins in a soluble form rather than in an inclusion body.

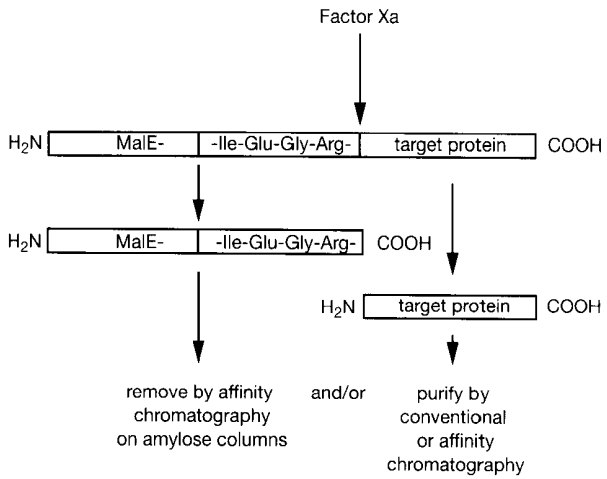

FIGURE 15-2 Cleavage of Fusion Proteins by Factor Xa

Factor Xa cleaves the peptide bond that is carboxy-terminal to the arginine residue in the recognition site.

Because few direct comparisons of the efficiency of cleavage of specific proteins by different proteases have been published, it is impossible to recommend one system over another with confidence. However, in one comparative study, the TEV (tobacco etch virus) protease was far more efficient at cleaving glutathione-*S*-transferase- and maltose-binding protein fusions than Factor Xa. TEV protease also has advantages over other proteases: Cleavage at cryptic sites occurs rarely if at all; the enzyme is fully active in the presence of common inhibitors of proteases and works at low temperatures (4–30°C) (Polayes et al. 1994). Finally, the TEV protease is itself available (from Life Technologies) as a fusion protein carrying a polyhistidine tag. This simplifies removal of the protease after cleavage of the fusion protein. The chemical and enzymatic reactions that have been used to achieve specific cleavage of peptide bonds in fusion proteins are shown in Table 15-3.

[a]Ala-64 subtilisin is a site-directed mutant of subtilisin in which the catalytic His-64 is replaced by alanine (H64A). The mutant enzyme is very specific for substrates containing a histidine (Carter and Wells 1987).

[b]The optimum cleavage sites for α-thrombin are (1) P4-P3-Pro-Arg-P1′-P2′, where P3 and P4 are hydrophobic amino acids and P1′ and P2′ are nonacidic amino acids, and (2) P2-Arg-P1′, where P2 or P1′ is Gly (Chang 1985).

[c]The Glu, Tyr, Gln, and Gly residues are required for cleavage (Carrington and Dougherty 1988; Dougherty et al. 1988; Dougherty and Parks 1989).

DEALING WITH INSOLUBLE PROTEINS

Overexpression of foreign proteins from cloned genes in heterologous hosts, such as *E. coli*, often leads to the formation of insoluble intracellular aggregates of the expressed protein (Williams et al. 1982; Schoner et al. 1985; for reviews, please see Marston 1986; Kane and Hartley 1988; Mitraki and King 1989; Schein 1989, 1991; Marston and Hartley 1990; Georgiou and Valax 1996). These so-called inclusion bodies are readily isolated by low-speed centrifugation and usually consist of almost pure accretions of denatured forms of the foreign protein. Inclusion bodies appear as amorphous granules in electron micrographs and as bright refractile particles in cells examined under phase-contrast illumination. No surrounding membranes are visible. Morphologically similar structures are observed in bacteria that have incorporated amino acid analogs into their proteins (Prouty and Goldberg 1972; Prouty et al. 1975) or are expressing high levels of endogenous genes (Marston 1986; Schein 1989).

Whether a foreign protein expressed to high levels in *E. coli* remains soluble or will accumulate in inclusion bodies is unpredictable. "Global" properties of proteins such as size, overall hydrophobicity, and charge are poor prognostic indicators. The quaternary structure of the native protein is also an unreliable guide since both monomeric proteins and subunits from oligomeric proteins can readily form inclusion bodies. The available evidence suggests that inclusion bodies arise by the inappropriate aggregation of partially folded or malfolded polypeptides, rather than as a consequence of the insolubility or instability of the native protein (Mitraki and King 1989; Schein 1989; Jaenicke 1991; Chrunyk et al. 1993). Thus, formation of inclusion bodies is (1) enhanced when mutant genes encoding thermolabile folding intermediates are expressed in *E. coli* (Haase-Pettingell and King 1988) and (2) partially suppressed when *E. coli* producing large quantities of foreign proteins is grown at low temperature (Lin et al. 1987; Schein and Noteborn 1988; Pan et al. 1991; Derbyshire et al. 1993). Several groups have used site-directed mutagenesis in an attempt to identify regions, domains, or motifs that are involved in inclusion body formation by particular proteins (Wetzel et al. 1991; Chrunyk et al. 1993). Mutations affecting the formation of inclusion bodies map in all areas of the proteins and are found in α helices, in both dynamically and statically disordered regions, in strands of β sheets, and in loops and turns. From these results, it seems that no single structural motif is responsible for the accumulation of folding intermediates and their aggregation into inclusion bodies. However, in one case — the polymerase domain of the Klenow fragment — problems of solubility were solved by two strategies: (1) reengineering the protein so as to remove both a solvent-exposed hydrophobic patch and a potentially unstructured region at the amino terminus of the protein (Derbyshire et al. 1993) and (2) changing the expression vector from one containing the λ p_L promoter to one containing the T7 promoter. Although the results of reengineering the protein are gratifyingly logical, it is impossible to understand why the expression system should dramatically influence the solubility of the protein product. As Derbyshire et al. (1993) point out, this result "emphasises the ignorance of the factors that influence protein overproduction and the need, in difficult cases...to test a range of expression systems, induction protocols and purification strategies."

As discussed earlier, a common strategy to avoid some of the problems associated with inclusion bodies and protein refolding is to express the protein of interest in a fusion system. In some cases, proteins that form inclusion bodies when expressed alone in *E. coli* are soluble when expressed as fusion proteins. The fusion partners of choice for production of soluble proteins are *Schistosoma* glutathione-*S*-transferase (Smith and Johnson 1988), *E. coli* maltose-binding protein (MalE) (Maina et al. 1988), and *E. coli* thioredoxin (*trxA*) (LaVallie et al. 1993; Sachdev and Chirgwin 1998). These systems have an additional advantage in that the fusion partner endows the foreign protein with specific biochemical properties that greatly simplify purification. For example, fusion proteins containing *E. coli* thioredoxin accumulate at zones of adhesion between

Lysozyme	Goliger and Roberts (1987)

the inner and outer membranes of the bacterial envelope, from where they can be released by osmotic shock or freezing and thawing.

An alternative method to circumvent formation of inclusion bodies is to express the protein from a vector that contains a prokaryotic signal sequence. The newly synthesized protein is then delivered to the periplasmic space, where it may be soluble. This method works best with proteins that are normally translocated into the secretory pathway of eukaryotic cells. For example, BiP, the major chaperone of the eukaryotic endoplasmic reticulum, is completely insoluble when expressed in the cytoplasm of bacteria, but it can be recovered in a biologically active form when expressed from a prokaryotic secretion vector (Blond-Elguindi et al. 1993).

Despite their complex structure, inclusion bodies sometimes offer opportunities to extract foreign proteins in an active and pure form. The basic steps in this procedure are outlined in Figure 15-3 and in Protocol 8. The difficult steps in this scheme are clearly the efficient solubilization of partially denatured aggregates and subsequent folding of the polypeptide into a native form. Because every protein is unique, no universal set of conditions exists to accomplish these goals. However, during the past 20 years, successful protocols have been devised to refold a large number of individual proteins, and from these, a set of basic guidelines of the methods most likely to succeed has emerged. For excellent sources of general advice on all stages of purification and recovery of proteins from inclusion bodies, please see the review articles by Marston (1986) and Marston and Hartley (1990).

Disruption of Bacteria Containing Inclusion Bodies

Lysis of bacteria containing inclusion bodies can generally be accomplished by standard methods, presented in Table 15-4. The choice among these methods is usually dictated by the range of equipment that is available and the previous experience of the investigator, rather than the properties of the protein under study. Whichever lysis method is chosen, it is very important to work quickly and to ensure that the temperature of the preparation does not exceed 4°C.

Centrifugation and Washing

In most cases, inclusion bodies can be recovered from the bacterial lysate by low-speed centrifugation (10,000–20,000*g* at 4°C). Contaminating proteins and nucleic acids can be removed by washing the pellet with solutions containing EDTA, detergents, and/or DNase. After washing, the inclusion bodies should be suspended in refolding buffer lacking the solubilization agent. Typically, these buffers contain Tris-Cl (pH 7.2), NaCl (50 mM), EDTA (1–5 mM), and a cocktail of protease inhibitors (see Table 15-5). If the native protein contains no disulfide bonds, dithiothreitol (2 mM) should also be included.

DNase	

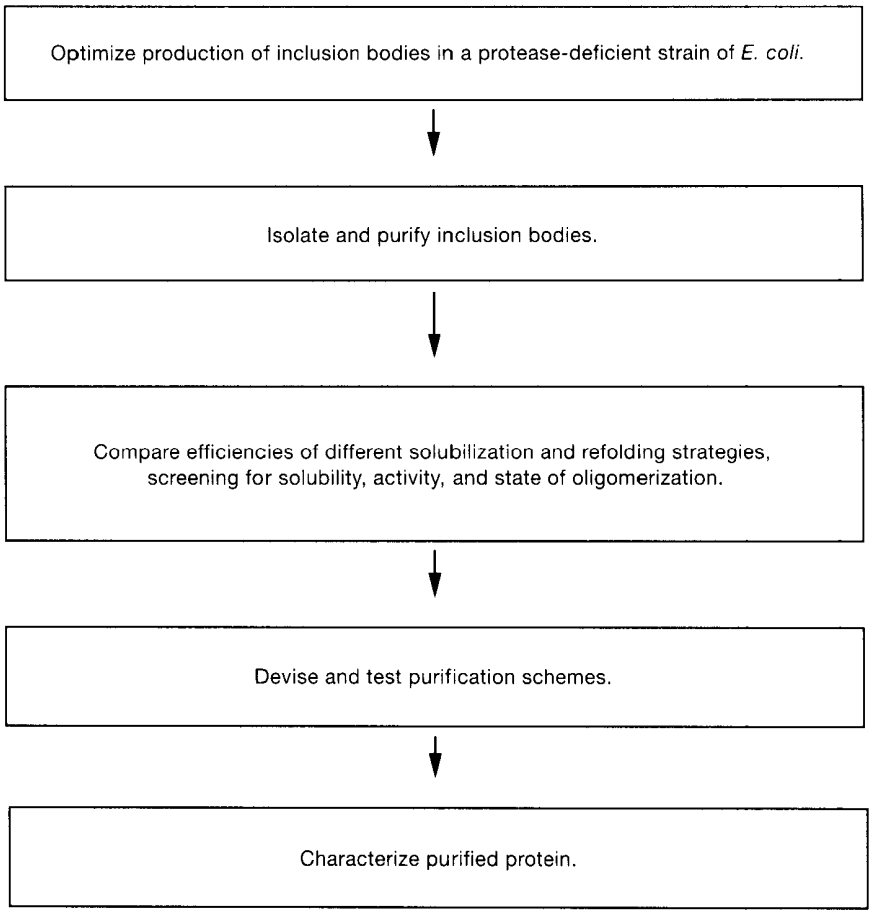

FIGURE 15-3 Flowchart: Purification of Protein from Inclusion Bodies

Solubilization and Refolding

Solubilization of the protein from the pellet generally requires exposure to strong chaotropic agents, such as urea (6–8 M) or guanidinium chloride (5–8 M), to detergents, such as SDS, and sometimes nonphysiological pH (Marston 1986; Marston and Hartley 1990). For further details on these agents, please see the information panel on **CHAOTROPIC AGENTS**. Usually, the aggregated protein isolated from washed inclusion bodies is ~50–75% pure and consists of denatured monomeric and oligomeric forms held together by disulfide bonds (Light 1985). The solubilized protein is almost always devoid of biological activity, which can be restored only if the protein can adopt a native or near-native configuration in vitro. Methods for solubilizing and refolding aggregated proteins isolated from inclusion bodies are described in Protocol 8.

OPTIMIZATION OF EXPRESSION OF FOREIGN PROTEINS IN *E. COLI*

Optimization of Translation Efficiency: Initiation

Efficient initiation of translation requires a ribosome-binding site upstream of the initiation codon (Huttenhofer and Noller 1994). During translation initiation, the Shine-Dalgarno

sequence, 5–9 nucleotides in length, interacts with the 3′ end of 16S RNA (Shine and Dalgarno 1974; Steitz and Jakes 1975; Steitz 1979). The distance between the Shine-Dalgarno sequence and the initiating ATG codon affects the translation efficiency. In vectors in which an open reading frame is inserted *downstream* from an initiating ATG, the distance between the Shine-Dalgarno sequence and the initiating codon will already have been optimized. However, if translation of the cloned open reading frame is initiated at its own ATG, then the initiating codon should be positioned 5–7 nucleotides downstream from the Shine-Dalgarno sequence (Ringquist et al. 1992).

The secondary structure of the translation initiation region also affects the efficiency of gene expression (de Smit and van Duin 1994a,b). In several cases, changing the sequences upstream and downstream from the Shine-Dalgarno sequence to reduce secondary structure has increased gene expression (e.g., please see Chen et al. 1994). Similarly, translational coupling, which involves placing the coding region of the gene of interest downstream from a translated sequence, has led to high-level expression of a number of genes (Makoff and Smallwood 1990; Rangwala et al. 1992).

Codon Usage

The genetic code is redundant, using 61 codons to specify 20 amino acids. Only two amino acids (Met and Trp) are specified by a single codon, whereas the remaining 18 are each specified by multiple codons. The synonymous codons that specify a single amino acid are not used with equal frequency (Grantham et al. 1980a,b, 1981).

If the coding region contains a high level or a cluster of rare codons, removal of the rare codons by resynthesis of the gene or by mutagenesis can increase expression (Rangwala et al. 1992). Particular problems have been observed when the target sequence contains the rare codons AGA and AGG, since they also can form fortuitous Shine-Dalgarno sequences within the coding region (Ivanov et al. 1992).

The DNA sequence encoding the amino terminus of the foreign protein can dramatically influence expression levels (Barnes et al. 1991). For this reason, it is sometimes necessary to use the polymerase chain reaction (PCR) or site-directed mutagenesis (Chapter 13, Protocols 4–6) to change the DNA sequences of the first seven or eight codons of the expressed gene to those most frequently used in *E. coli* (Bennetzen and Hall 1982). Wherever possible, the (G+C) content of the 5′ end of the target gene should be reduced to <40% by these procedures.

Optimization of Growth Conditions

Irrespective of the expression system used, dramatic differences in expression levels are often realized in different media (Weickert et al. 1996). A standard medium such as LB can be used to establish the general parameters of expression, but optimum expression, however, is usually achieved only after modification of the growth conditions, which may include using a minimal salts medium such as M9 (please see Appendix 2), defined salts medium such as induction medium (Protocol 4), or rich media such as Terrific Broth, YT, or NZCYM (Appendix 2). For further information, please see the panel on **TROUBLESHOOTING AND OPTIMIZATION OF PROTEIN EXPRESSION FROM AN INDUCIBLE PROMOTER** at the end of Protocol 1.

SUMMARY

This chapter describes methods for constructing and producing fusion proteins and intact nonfusion proteins in bacteria using a variety of different vectors. Nonfusion proteins can be produced in bacteria by placing a strong regulated promoter and an efficient ribosome-binding site upstream of the cloned gene. Fusion proteins can be made in large amounts, are easy to purify, and can be used to elicit a response in immunologic or biological assays.

Eukaryotic proteins expressed in bacterial systems may lack important processing or modification required for proper function. Expression systems based on the use of baculovirus vectors have proven to be tremendously useful for the faithful production of foreign proteins, fusion proteins, and simultaneous expression of two or more (up to four) proteins. For further details, please see the information panel on **BACULOVIRUSES AND BACULOVIRUS EXPRESSION SYSTEMS** in Chapter 17. Protocols for the use of the baculovirus expression system may be found in Spector et al. (1998; Chapter 66 of *Cells: A Laboratory Manual*).

Almost everything that distinguishes the modern world from earlier centuries is attributable to science, which achieved its most spectacular triumphs in the seventeenth century.

Bertrand Russell, *History of Western Philosophy*

Protocol 1

Expression of Cloned Genes in *E. coli* Using IPTG-inducible Promoters

PLASMIDS CARRYING ISOPROPYL-β-D-THIOGALACTOSIDE (IPTG)-inducible promoters are capable of expressing proteins at levels that exceed 30% of total mass of bacterial protein. These plasmids are well-suited for small-scale laboratory experiments, but the high cost of IPTG prevents their use for large-scale production of foreign proteins. Variables that influence the efficiency of expression of foreign proteins from these and other expression plasmids are discussed in the panel on **TROUBLESHOOTING AND OPTIMIZATION OF PROTEIN EXPRESSION FROM AN INDUCIBLE PROMOTER** at the end of this protocol.

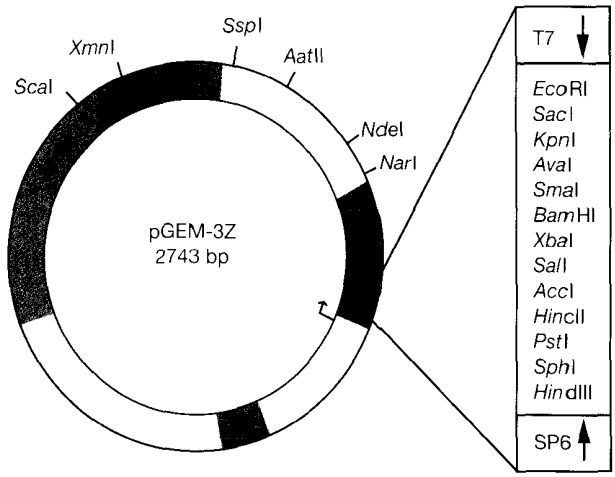

FIGURE 15-4 pGEM-3Z Vector

The pGEM-3Z vector may be used for in vitro transcription and protein expression. The vector encodes the LacZ α peptide preceded by *lac* operon sequences, the T7 and SP6 polymerase transcription initiation sequences flanking the multiple cloning site, and the β-lactamase-coding sequence that confers ampicillin resistance. (Modified, with permission, from Promega Corporation.)

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Coomassie Brilliant Blue stain or Silver stain
Please see Appendix 8.

IPTG (1 M)

1x SDS gel-loading buffer
Store 1x SDS gel-loading buffer lacking dithiothreitol at room temperature. Add dithiothreitol from a 1 M stock just before the buffer is used in Step 10.

Gels

Polyacrylamide gel (10%) containing SDS **<!>**
For the preparation of SDS-polyacrylamide gels used in the separation of proteins, please see Appendix 8.

Nucleic Acids and Oligonucleotides

Gene or cDNA fragment of interest

Media

LB agar plates containing 50 μg/ml ampicillin
LB medium containing 50 μg/ml ampicillin

Centrifuges and Rotors

Sorvall GSA rotor or equivalent

Special Equipment

Boiling water bath
Shaking incubator

Additional Reagents

Step 1 of this protocol requires the reagents listed in Chapter 8, Protocol 7.
Step 2 of this protocol requires the reagents listed in Chapter 1, Protocol 17 or 19.
Step 3 of this protocol requires the reagents listed in Chapter 1, Protocols 23–26.
Step 4 of this protocol requires the reagents listed in Chapter 12, Protocol 3.

Vectors and Bacterial Strains

E. coli *strain suitable for transformation and carrying either the* $lacI^q$ *or* $lacI^{q1}$ *allele*
Some IPTG-inducible expression vectors carry the *$lacI^q$* allele on the expression plasmid (e.g., pMAL and pGEX). These can be used in any laboratory strain of *E. coli* (e.g., JM101, DH5F′, and TG1). For details, please see the panel on **TROUBLESHOOTING AND OPTIMIZATION OF PROTEIN EXPRESSION FROM AN INDUCIBLE PROMOTER** at the end of this protocol.

IPTG-inducible expression vector
Other examples include pGEM-3Z (Promega; please see Figure 15-4), pGEX-1 (Pharmacia), pKK223-3 (Pharmacia), pMEX (U.S. Biochemicals), p*Trc* 99A (Pharmacia), and pMAL (New England Biolabs).

Positive control plasmid (e.g., an IPTG-inducible vector known to express a LacZ fusion protein of defined size)

METHOD

Construction of a Strain of *E. coli* Containing the Recombinant Expression Vector

1. Modify by PCR (Chapter 8, Protocol 7), or isolate by restriction enzyme digestion, a fragment of DNA carrying 5′- and 3′-restriction enzyme sites compatible with sites in an IPTG-inducible expression vector.

   Most IPTG-inducible expression vectors contain all of the controlling elements required for expression of foreign proteins. Use PCR to modify the ends of the cDNA/gene to be expressed so that no extraneous flanking sequences are included in the construct. Depending on the vector and preliminary results, other regulatory sequences can be added to the ends to facilitate expression (please see the panel on **TROUBLESHOOTING AND OPTIMIZATION OF PROTEIN EXPRESSION FROM AN INDUCIBLE PROMOTER** at the end of thie protocol).

   Constructs generated by PCR should be sequenced to ensure that no spurious mutations were introduced during the amplification reactions.

2. Ligate the DNA fragment containing the cDNA/gene of interest into the expression vector (Chapter 1, Protocol 17 or 19).

3. Transform an *E. coli* strain containing the *lacI*^{q} allele with the recombinant plasmid. If the plasmid vector itself carries the *lacI* gene, then any appropriate strain of *E. coli* can be used. Plate aliquots of the transformation reaction on LB agar containing 50 μg/ml ampicillin. Incubate the cultures overnight at 37°C.

   As controls, transform the same strain of *E. coli* with a plasmid such as pGEX-1 (positive control) and an empty expression plasmid (negative control).

4. Screen transformants by colony hybridization and/or restriction enzyme analysis, oligonucleotide hybridization, or direct DNA sequence analysis (please see Chapter 12, Protocol 3) of plasmid minipreparations.

Optimization of the Induction of Target Protein Expression

Many studies point to the importance of the rate of cell growth on foreign protein expression. For this reason, it is important to monitor the number of bacteria inoculated into the growth medium, the length of time cells are grown before induction, and the density to which cells are grown after induction. Overgrowth or too rapid growth can overload the bacterial synthetic apparatus and promote the formation of inclusion bodies.

5. Inoculate 1-ml cultures (LB medium containing 50 μg/ml ampicillin) with 1 or 2 colonies containing the empty expression vector, the positive control plasmid (pGEX-1), and the recombinant expression plasmid. Incubate the cultures overnight at the appropriate temperature (20–37°C).

   Because *E. coli* grows about four times more slowly at room temperature than at 37°C, the cultures may not reach saturation during overnight (~16 hours) incubation at ~20°C. However, the slower rate of bacterial metabolism at lower temperature may prevent formation of inclusion bodies. Please see the discussion on Dealing with Insoluble Proteins in the chapter introduction.

6. Inoculate 5 ml of LB medium containing 50 μg/ml ampicillin with 50 μl of each overnight culture. Incubate the cultures for >2 hours at 20–37°C in a shaking incubator until cells reach mid-log growth (A_{550} of 0.5–1.0).

7. Transfer 1 ml of each uninduced culture (zero-time aliquot) to microfuge tubes. Immediately process the zero-time aliquots as described in Steps 9 and 10.

8. Induce the remainder of each culture by adding IPTG to a final concentration of 1 mM and continue incubation at 20–37°C with aeration (but please see the notes below concerning optimization of the IPTG concentration and the induction temperature).

   The concentration of IPTG used to induce *lac* repressor-regulated promoters can dramatically influence expression. The suggested concentration of 1 mM IPTG is a starting point and is at the higher range of the scale. Establish the optimum concentration empirically by varying the IPTG concentration between 0.01 and 5.0 mM. With some proteins, it is important to induce transcription of the expression plasmid slowly (with low IPTG concentrations) so as not to overload the biosynthetic machinery of the bacterium.

   Perhaps the most important variable in obtaining high-level expression in *E. coli* is the temperature at which the bacteria are grown before and during induction. It is crucial to carry out trial studies to determine the optimum temperature for expression of a foreign protein. The temperature range over which successful expression has been obtained is 15–42°C. The optimum temperature for expression can be quite narrow, spanning 2–4°C. The reason for the sometimes all or none effect of different temperatures on expression levels is not known, but it could be due to a large number of factors, singly or in combination. These factors include: the growth rate of the cells, intracellular folding of the expressed protein, availability of prosthetic groups (heme, flavin adenine dinucleotide, biotin, etc.), thermal denaturation of the foreign protein, overloading of the secretory or folding machinery of the cell, the activity of endogenous proteases or other lytic enzymes, activation of the SOS response system of the bacterium, or other variables. Because of these uncertainties, gedanken experiments concerning optimum growth temperatures are of little use. Trial and error must be used.

9. At various time points during the induction period (e.g., 1, 2, 4, and 6 hours), transfer 1 ml of each culture to a microfuge tube, measure the A_{550} in a spectrophotometer, and centrifuge the tubes at maximum speed for 1 minute at room temperature in a microfuge. Remove the supernatants by aspiration.

10. Resuspend each pellet in 100 µl of 1x SDS gel-loading buffer, and heat the samples to 100°C for 3 minutes. Centrifuge the tubes at maximum speed for 1 minute at room temperature in a microfuge, and store them on ice until all of the samples are collected and ready to load on a gel.

11. Warm the samples to room temperature and load 0.15 OD_{550} units (of original culture) or 40 µg of each suspension on a 10% SDS-polyacrylamide gel.

12. Run the gel at 8–15 V/cm until the bromophenol blue reaches the bottom of the resolving gel.

13. Stain the gel with Coomassie Brilliant Blue or silver, or carry out an immunoblot to visualize the induced protein (please see Appendix 8).

    In extracts of cells expressing the positive control protein, glutathione *S*-transferase (GST) (i.e., pGEX-1-containing cells), a 26-kD protein should be visible ~30 minutes after induction at 37°C. The amount of GST should increase throughout the induction period. In extracts of cells expressing the recombinant gene, a protein of the predicted molecular weight should be visible at some time point after induction. The kinetics of induction and the stability of the foreign protein may differ from those of the GST control.

Large-scale Expression of the Target Protein

14. For large-scale expression and purification of the target protein, inoculate 50 ml of LB containing 50 µg/ml ampicillin in a 250-ml flask with a colony of *E. coli* containing the recombinant construct. Incubate the culture overnight at 20–37°C.

15. Inoculate 450–500 ml of LB containing 50 µg/ml ampicillin in a 2-liter flask with 5–50 ml of overnight culture of *E. coli*. Incubate with shaking at 20–37°C until the culture has reached the mid-log phase of growth (A_{550} = 0.5–1.0).

16. Induce expression of the target protein based on the optimal values of IPTG concentration, incubation time, and incubation temperature determined in the previous section.

17. After the induced cells have grown for the proper length of time, harvest the cells by centrifugation at 5000*g* (5500 rpm in a Sorvall GSA rotor) for 15 minutes at 4°C and proceed with a purification protocol:

    - Protocol 5 if the expressed protein is a fusion with glutathione S-transferase
    - Protocol 6 if the expressed protein is a fusion with maltose-binding protein
    - Protocol 7 if the expressed protein contains a polyhistidine tag

TROUBLESHOOTING AND OPTIMIZATION OF PROTEIN EXPRESSION FROM AN INDUCIBLE PROMOTER

- In addition to a strong bacterial promoter, an efficient ribosome-binding site is important for the expression of cloned DNA in *E. coli*. The ribosome-binding site includes an initiation codon (ATG) and a sequence 5–9 nucleotides in length located 3–11 nucleotides upstream of the initiation codon. This sequence, called the Shine-Dalgarno sequence, is complementary to the 3′ terminus of *E. coli* 16S rRNA. Binding of the ribosome to mRNA is thought to be promoted by base pairing between the Shine-Dalgarno sequence in the mRNA and the sequence at the 3′ terminus of the 16S rRNA (Shine and Dalgarno 1974; Steitz and Jakes 1975; Steitz 1979). Other sequences in the immediate 5′-untranslated region of the expressed gene may also contribute to expression levels (Gold 1988). (See also discussion on p. 15.12.)
- Placing sequences downstream from the inserted DNA that may stabilize the mRNA or improve the efficiency of translation (i.e., transcription terminators or RNase III sites) can also enhance expression (Panayotatos and Truong 1981; Studier and Moffatt 1986; Rosenberg et al. 1987).
- Use of an IPTG-inducible expression vector requires transformation of an *E. coli* strain that overexpresses the *lac* repressor. The *lac* repressor prevents transcription of foreign gene sequences in the absence of inducer. Since most IPTG-inducible expression plasmids are present at high copy number (30–600), excess repressor is needed to prevent titration of the protein and subsequent basal level (leaky) expression. The *lacI*^{q} allele, which overproduces the *lac* repressor by tenfold when present in single copy (Calos 1978), is most commonly used to overexpress this protein. However, if the foreign protein is especially toxic to *E. coli* and very low basal expression levels cannot be tolerated, or if a very high-copy-number plasmid vector is used (e.g., pUC-based plasmids), then a *lacI*^{q} gene should be cloned into the expression plasmid to ensure tight regulation. This precaution should also be considered when *E. coli* strains (e.g., JM101 and JM105) harboring the *lacI*^{q} allele on an F′ sex factor are used. The F′ sex factor is frequently lost (cured) from the bacterium with growth in rich medium, resulting in a gradual titration of the *lac* repressor and loss of regulation.
- Over and above the *lacI* requirement, the choice of which *E. coli* strain to use for the expression of a foreign protein must be made empirically. We strongly recommend transforming multiple common laboratory strains as well as a few more exotic strains to deduce the best *E. coli* host for a particular foreign protein. Although the known genotypes of some strains make them logical host choices (e.g., protease-deficient strains; please see below), there is usually no clear-cut reason why one strain fosters high-level expression of the protein of interest and another does not.
- The level of expression of the cloned gene may be low due to RNA instability, premature termination, inefficient initiation of translation, or protein instability. Protein instability is distinguished from the other potential problems by pulse-chase experiments. A culture of cells carrying the expression plasmid is grown to mid-log phase in M9 minimal media supplemented with 19 L-amino acids (minus methionine or cysteine) at 20 μg/ml, induced, and labeled for 10 minutes with 15 μCi/ml of [^{35}S]methionine or [^{35}S]cysteine (or Tran^{35}S-Label [ICN Biochemicals], which contains both radiolabeled amino acids), followed by the addition of excess (1 mM)

(*Continued on next page.*)

unlabeled methionine or cysteine. Samples taken every 10 minutes from immediately before induction to 1 hour after induction are analyzed by electrophoresis through an SDS-polyacrylamide gel. The gel is dried and subjected to autoradiography to determine whether the protein is unstable. The genetics and biochemistry of protein turnover in *E. coli* are quite well understood (Golberg 1992; Maurizi 1992), and a number of protease-deficient strains are available (Gottesman 1990). The most commonly used strains are those that harbor mutations in the *lon* gene, which encodes the Lon (or La) protease, an ATP-dependent endoprotease. This protease, working in conjunction with several heat shock proteins, degrades unfolded and abnormal (foreign) proteins in *E. coli* (Gottesman and Maurizi 1992). Representative Δ*lon* strains (Y1089 and Y1090) are available from The American Type Culture Collection (37196 and 37197, respectively) or from several commercial suppliers. A protease-deficient strain that has proven useful for both secreted and soluble proteins is *E. coli* RF6333, available from The American Type Culture Collection (ATCC # 55101). The RF6333 strain harbors *degP* and *ompT* mutations, which inactivate a periplasmic and an outer-membrane-localized protease, respectively. Increased yields of foreign protein in protease-deficient strains are a result of both decreased intracellular turnover and decreased proteolysis after cell lysis. Protease inhibitors (1 mM phenylmethylsulfonyl fluoride [PMSF], 1–5 mM EDTA, 1–5 mM EGTA, 1–20 mM benzamidine, 1–10 μg/ml leupeptin, 5 μg/ml pepstatin A, 1–10 μg/ml aprotinin, 1–20 mM tosyl-lysine-chloromethyl ketone, etc.) in the growth medium and harvest buffers may increase yields.

- The use of mutant strains defective in termination of transcription (*rho*) or altered in RNA metabolism (*pnp*, *rna*) may increase the amount of functional RNA transcribed from a foreign gene.
- Dramatic differences in expression levels are often realized in different media. LB medium can be used to establish the general parameters of expression as described above; however, for optimum expression, or in cases where no or very low expression is obtained in LB medium, other media should be tried. These include minimal salts medium such as M9, defined salts medium such as induction medium (Protocol 4), and other rich media such as Terrific Broth, YT, or NZCYM.
- As mentioned above, supplements to established media may enhance the expression of a given foreign protein. These supplements include NaCl at concentrations between 0.1 and 0.5 M (Jespers et al. 1991), nonmetabolizable sugars such as sucrose (0.2–0.6 M) (Bowden and Georgiou 1990), cofactors (heme), and antibiotics. The use of antibiotics such as chloramphenicol (1 μg/ml medium) and tetracycline (0.1 μg/ml) at sublethal concentrations is based on observations by Lee and Beckwith (1986), who noted that many suppressors of secretory pathway defects (sec mutants) mapped in genes encoding protein synthesis components. The net effect of these suppressor mutations was to decrease the overall rate of protein synthesis; in addition, low concentrations of antibiotics could mimic these effects in *E. coli*. When expressing a foreign protein, especially one destined for the membrane compartment of the cell, the decreased rate of protein synthesis in the presence of the antibiotic may prevent overloading of the secretion pathway. By the same token, soluble proteins may have greater access to chaperones and other molecules involved in formation of the native protein. Finally, the pH of the medium can affect expression of foreign proteins (Kopetzki et al. 1989). These authors noted a substantial increase in expression of the soluble protein α-glucosidase when the pH of the LB medium was decreased below pH 5.5. Extremes in pH probably act to slow overall cell growth and thereby prevent overloading of bacterial expression/processing systems.

Protocol 2

Expression of Cloned Genes in *E. coli* Using the Bacteriophage T7 Promoter

EXPRESSION SYSTEMS USING THE BACTERIOPHAGE T7 PROMOTER, first developed by Tabor and Richardson (1985) and Studier and Moffatt (1986), employ transcription signals derived from the bacteriophage T7 genome. These systems have the following advantages.

- Bacteriophage T7 RNA polymerase, unlike *E. coli* RNA polymerase, is not inhibited by rifampicin. The antibiotic can therefore be used to extinguish transcription of host cell genes.
- The bacteriophage-encoded enzyme recognizes only bacteriophage T7 promoters, which are not present in the *E. coli* chromosomal DNA.
- Bacteriophage T7 RNA polymerase is a processive enzyme that will transcribe around a circular plasmid several times and may therefore transcribe genes that are not efficiently transcribed by *E. coli* RNA polymerase.

Two components are required for the bacteriophage T7 expression system (please see Figure 15-5). The first component is bacteriophage T7 RNA polymerase, which is the product of bacteriophage T7 gene *1*. The polymerase can be provided by a cloned copy of the gene carried on an infecting bacteriophage λ vector, on a plasmid, or from a copy of the gene inserted into the *E. coli* chromosome (Tabor and Richardson 1985; Studier and Moffatt 1986). If the foreign protein is toxic to *E. coli*, the expression of bacteriophage T7 RNA polymerase must be curtailed during cell growth. This can be accomplished using the λ lysogen BL21(DE3), in which the bacteriophage T7 gene *1* is expressed under the control of the IPTG-inducible *lac*UV5 promoter. Alternatively, gene *1* can be placed under control of a temperature-inducible promoter such as the bacteriophage λ p_L sequence. In this situation, induction of the bacteriophage T7 RNA polymerase is accomplished by heat as described in Protocol 3. When attempting to express certain exquisitely toxic foreign gene products, it is necessary to use cells in which no bacteriophage T7 RNA polymerase is present until expression is induced. This goal is achieved by infecting the host cells (e.g., HMS174) harboring the expression plasmid with bacteriophage CE6 (λ*cIts*857 Sam7) carrying bacteriophage T7 gene *1* (Studier and Moffatt 1986).

The second component of the system is a plasmid vector equipped with a bacteriophage T7 promoter upstream of the gene to be expressed. The vector pET-3 is a derivative of pBR322 that carries the bacteriophage T7 gene *10* promoter (Pf_{10}), a *Bam*HI cloning site, and the bacteriophage T7 transcription terminator (Tf) (Studier et al. 1990). Derivatives of pET-3 (e.g., pET-3a) have been constructed that include a bacteriophage T7 gene *10* translation start (S_{10}) through

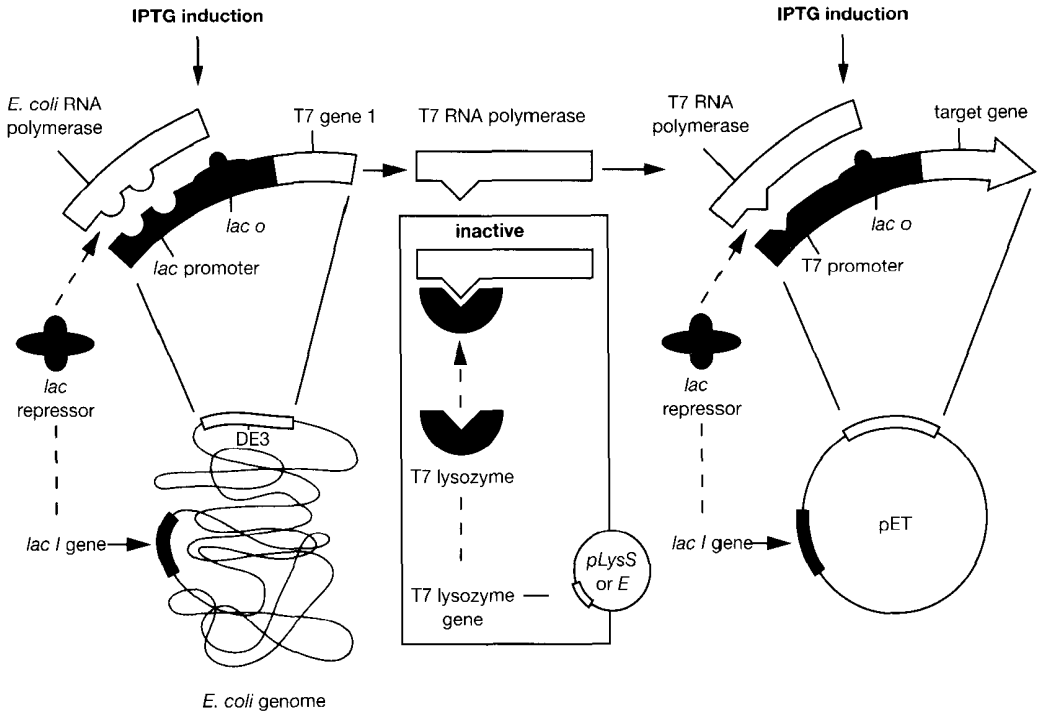

FIGURE 15-5 Control Elements of the pET System

Illustrated here are the host and vector elements that are available for control of T7 RNA polymerase levels and subsequent transcription of a target gene cloned in a pET vector. In λ DE3 lysogens, the T7 RNA polymerase gene is under control of the *lac*UV5 promoter, which allows low levels of transcription in the uninduced state. For more stringent control of expression, hosts carrying either pLysS or pLysE are available. The pLys plasmids encode T7 lysozyme, a natural inhibitor of T7 RNA polymerase, and thus reduces its ability to transcribe target genes in uninduced cells. (Redrawn, with permission, from Novagen, Inc.)

codon 11. DNA can be inserted in each of the three translation reading frames at this codon to express fusion proteins. Commercially available antibodies (Novagen) directed against the gene *10* portion of the fusion protein can then be used to detect the expressed protein by immunoblotting. Other frequently used vectors:

- ***Allow fusion to longer amino-terminal protein sequences,*** which can stabilize shorter foreign polypeptides in *E. coli* (e.g., pET-3xa-c from Novagen).
- ***Produce intact and secreted native proteins*** by inserting sequences coding for foreign polypeptides at the *Nde*I site immediately preceding the ATG of gene *10* or by fusion to an amino-terminal periplasmic localization signal (pET-12a-c).
- ***Generate proteins carrying a hexa-histidine sequence*** that can be purified by affinity chromatagraphy Ni^{2+} columns (e.g., pET-14b from Novagen).

In a lucid article describing the bacteriophage T7 promoter expression system, Studier et al. (1990) outline potential problems and solutions associated with the bacteriophage T7 system, discuss pros and cons of various bacterial strains, and describe the pET series of expression vectors. Because the T7 system expresses very high levels of the foreign gene/cDNA, the bacterial synthetic and processing apparatus can easily become overloaded. For this reason, methods that result in a slow induction or growth of cells often yield higher levels of foreign protein expression. The troubleshooting panel at the end of Protocol 1 provides further advice on these problems.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Coomassie Brilliant Blue stain or Silver stain
Please see Appendix 8.

IPTG (1 M)

1x SDS gel-loading buffer
Store 1x SDS gel-loading buffer lacking dithiothreitol at room temperature. Add dithiothreitol from a 1 M stock just before the buffer is used.

Gels

Polyacrylamide gel (10%) containing SDS **<!>**
For the preparation of SDS-polyacrylamide gels used in the separation of proteins, please see Appendix 8.

Nucleic Acids and Oligonucleotides

Gene or cDNA fragment of interest

Media

NZCYM agar plates containing 50 μg/ml ampicillin
NZCYM medium containing 50 μg/ml ampicillin

Centrifuges and Rotors

Sorvall GSA rotor or equivalent

Special Equipment

Boiling water bath

Additional Reagents

Step 1 of this protocol requires the reagents listed in Chapter 8, Protocol 7.
Step 2 of this protocol requires the reagents listed in Chapter 1, Protocol 17 or 19.
Step 3 of this protocol requires the reagents listed in Chapter 1, Protocols 23–26.
Step 4 of this protocol requires the reagents listed in Chapter 12, Protocol 3.

Vectors and Bacterial Strains

E. coli *strains HMS174(DE3) or BL21(DE3)*

pET vector or equivalent
For the many variations of this plasmid series, please refer to the Novagen catalog (or Web Site at www.novagen.com).

Positive control plasmid (e.g., carrying a bacteriophage T7 promoter that controls expression of a fusion protein of defined size)

METHOD

Preparation of Bacteria Containing the Recombinant Expression Vector

1. Modify by PCR (Chapter 8, Protocol 7), or isolate by restriction enzyme digestion, a fragment of DNA carrying 5′- and 3′-restriction enzyme sites compatible with sites in a bacteriophage T7 promoter expression plasmid (e.g., pET vectors; Studier et al. 1990).

   Constructs generated by PCR should be sequenced to ensure that no spurious mutations were introduced during the amplification reactions.

   If necessary, position a strong ribosome-binding site upstream of the ATG of the cDNA/gene.

2. Ligate the DNA fragment containing the cDNA/gene of interest into the expression vector (Chapter 1, Protocol 17 or 19).

3. Transform *E. coli* strain BL21(DE3) or HMS174(DE3) with aliquots of the ligation reaction. Select for ampicillin-resistant transformants by plating aliquots of the transformation reaction on NZCYM agar plates containing 50 µg/ml ampicillin. Incubate the plates overnight at 37°C.

   As a negative control, transform additional cells of the same strain of *E. coli* with an empty expression vector.

4. Screen the transformants by colony hybridization and/or restriction enzyme analysis, oligonucleotide hybridization, or direct DNA sequence analysis (please see Chapter 12, Protocol 3) of plasmid minipreparations.

Optimization of the Induction of Target Protein Expression

Many studies point to the importance of the rate of cell growth on foreign protein expression. For this reason, it is important to monitor the number of bacteria inoculated into the growth medium, the length of time cells are grown before induction, and the density to which cells are grown after induction. Overgrowth or too rapid growth can overload the bacterial synthetic apparatus and promote formation of inclusion bodies.

5. Inoculate 1-ml cultures (NZCYM medium containing 50 µg/ml ampicillin) with a transformed colony containing positive control vectors, negative control vectors, and one containing the recombinant vector. Incubate the cultures overnight at 37°C to obtain a saturated culture.

6. Inoculate 5 ml of NZCYM medium containing 50 µg/ml ampicillin in a 50-ml flask with 50 µl of a saturated culture. Incubate the cultures for 2 hours at 37°C.

7. Transfer 1 ml of each culture (zero-time aliquot) to a microfuge tube. Immediately process the zero-time aliquots as described in Steps 9 and 10.

8. Induce the remainder of each culture by adding IPTG to a final concentration of 1.0 mM and continue incubation at 20–37°C with aeration.

   Some vector systems express the bacteriophage T7 RNA polymerase from a heat-inducible promoter rather than from an IPTG-inducible promoter. For a discussion of factors that affect induction of protein expression, please see the note to Step 8 in Protocol 1.

9. At 0.5, 1, 2, and 3 hours after induction, transfer 1 ml of each culture to a microfuge tube, measure the A_{550} in a spectrophotometer, and centrifuge the tubes at maximum speed for 1 minute at room temperature in a microfuge. Remove the supernatants by aspiration.

10. Resuspend each pellet in 100 µl of 1x SDS gel-loading buffer, and heat the samples to 100°C for 3 minutes. Centrifuge the tubes at maximum speed for 1 minute at room temperature in a microfuge, and store them on ice until all of the samples are collected and ready to load on a gel.

11. Warm the samples to room temperature and load 0.15 OD_{550} units (of original culture) or 40 µg of each suspension on a 10% SDS-polyacrylamide gel.
12. Run the gel at 8–15 V/cm until the bromophenol blue reaches the bottom of the resolving gel.
13. Stain the gel with Coomassie Brilliant Blue or silver, or carry out an immunoblot to visualize the induced protein (please see Appendix 8).

    For cells expressing the vector alone, no difference in the protein pattern should be noted between untransformed *E. coli* cells and cells carrying the empty expression vector. For cells expressing the recombinant gene, a protein of the predicted molecular weight should be visible at some time point after induction.

Large-scale Expression of the Target Protein

14. For large-scale expression and purification of the target protein, inoculate 50 ml of NZCYM containing 50 µg/ml ampicillin in a 250-ml flask with individual colonies of *E. coli* containing the recombinant and control plasmids. Incubate the cultures overnight at 37°C.
15. Inoculate 450–500 ml of NZCYM containing 50 µg/ml ampicillin in a 2-liter flask with 5–50 ml of overnight culture of *E. coli* containing the recombinant plasmid. Incubate the culture with shaking at 37°C until the culture has reached the mid-log phase of growth (A_{550} = 0.5–1.0).
16. Induce expression of the target protein based on the optimal values of IPTG concentration, incubation time, and incubation temperature determined in the previous section.
17. After the induced cells have grown for the proper length of time, harvest the cells by centrifugation at 5000*g* (5500 rpm in a Sorvall GSA rotor) for 15 minutes at 4°C and proceed with a purification protocol:
    - Protocol 5 if the expressed protein is a fusion with glutathione *S*-transferase
    - Protocol 6 if the expressed protein is a fusion with maltose-binding protein
    - Protocol 7 if the expressed protein contains a polyhistidine tag

USING pLysS AND pLysE TO REGULATE BACTERIOPHAGE T7 RNA POLYMERASE ACTIVITY

Lysozyme encoded by bacteriophage T7, in addition to digesting peptidoglycan cell walls, has the ability to inhibit the virally encoded RNA polymerase. The former activity is not normally manifest in bacterial cells because the enzyme does not gain access to the cell wall. The latter activity can be used to inhibit the low level of RNA polymerase activity present in the uninduced state and therefore to stabilize plasmids that encode otherwise toxic foreign proteins.

The gene encoding bacteriophage T7 lysozyme is carried on two different plasmids termed pLysS and pLysE, which are compatible with the pET vectors and are commercially available (Novagen; please see Figure 15-5). Both plasmids encode resistance to chloramphenicol and are easily maintained by growth in the presence of 25 µg/ml of the antibiotic. Because of the arrangement of promoters on the plasmids, expression of lysozyme is low in cells carrying plasmid pLysS and high in cells carrying pLysE (Studier et al. 1990). Foreign genes encoding moderately toxic proteins are stable in the presence of pLysS, whereas genes encoding highly toxic proteins require pLysE for stability. Lysozyme expressed from these two plasmids increases the lag time between induction of the RNA polymerase and maximum expression of the foreign protein. This situation arises because enough RNA polymerase must be expressed to overcome inhibition by the lysozyme before the foreign gene can be transcribed.

The presence of the pLysS or pLysE plasmids and hence of viral lysozyme within an expressing *E. coli* cell can be exploited to facilitate lysis of cells at the time of harvest (please see Figure 15-5). Treatments that allow the intracellular lysozyme access to the cell wall lead to rapid cell lysis. Cells with these plasmids lyse spontaneously after resuspension in cell wash buffer and several cycles of freezing and thawing. Alternatively, lysis can be accomplished by resuspending the cells in wash buffer containing 0.1% (v/v) Triton X-100.

Protocol 3

Expression of Cloned Genes in *E. coli* Using the Bacteriophage λ p_L Promoter

THE POWERFUL BACTERIOPHAGE λ P_L PROMOTER IS REGULATED by a temperature-sensitive repressor, *cIts*857, which represses transcription at low, but not at elevated, temperatures. *E. coli* strains harboring the *cIts*857 gene must therefore be used as hosts with vectors carrying the λ p_L promoter. The repressor gene is usually present on a defective λ prophage, which also encodes the λ N protein, an antagonist of transcription termination. The antitermination function of the *N* gene product can enhance expression by facilitating RNA polymerase readthrough of spurious termination sites within the foreign cDNA/gene. The p_L vectors therefore have two useful properties: They are efficiently repressed at low temperatures and they are floridly induced at high temperatures.

A potential drawback of p_L vectors is that the temperature shift induces not only the p_L promoter, but also the cellular heat shock genes, some of which encode proteases (Buell et al. 1985). A related problem is that heat induction may cause thermal denaturation of the expressed protein and subsequent formation of aggregates or inclusion bodies. These problems can be alleviated by using a lysogenic host carrying a bacteriophage λ cI^+ lysogen that can be induced with mitomycin C or nalidixic acid (Shatzman and Rosenberg 1987). Alternatively, problems can be avoided by using a *cI* gene whose expression is controlled by the tryptophan promoter/operator (Mieschendahl et al. 1986; LaVallie et al. 1993). The use of tryptophan-inducible systems, including a vector system that employs thioredoxin fusion proteins, is discussed in more detail in the panel on **TRYPTOPHAN-INDUCIBLE EXPRESSION SYSTEMS** on the following page.

Several different p_L vectors are available, including the pHUB series (Bernard and Helinski 1979), pPLc series (Remaut et al. 1981), pKC30 (Rao 1984), pAS1 (Rosenberg et al. 1983), pRM1/pRM9 (Mieschendahl et al. 1986), and pTrxFus (LaVallie et al. 1993). The transcription/translation signals in these vectors vary considerably, and the primers used during PCR to modify the cDNA/gene to be expressed must therefore be designed appropriately. Other vector systems that rely on the *cIts*857 repressor to regulate expression from the bacteriophage λ p_R promoter and carry the repressor gene on the expression plasmid itself have been described previously (e.g., pCQV2; Queen 1983). These vectors are useful when complete shut off of the uninduced bacteriophage promoter is required. For a description of variables that affect the expression of foreign proteins in *E. coli*, please see the troubleshooting panel at the end of Protocol 1.

TRYPTOPHAN-INDUCIBLE EXPRESSION SYSTEMS

Mieschendahl et al. (1986) described a binary expression system consisting of a plasmid vector carrying a bacteriophage λ p_L promoter and an integrated copy of a wild-type cI gene whose expression is inducible by tryptophan. When cells carrying the plasmid vector are propagated in medium containing low concentrations of tryptophan, the wild-type bacteriophage repressor is efficiently expressed, and foreign genes controlled by the p_L promoter are repressed. Addition of tryptophan to the medium suppresses synthesis of the cI gene product and leads to an induction of the powerful p_L promoter and efficient expression of the foreign protein.

Tryptophan-inducible systems have several advantages over temperature-inducible systems. First, growth and induction are carried out at 37°C, a temperature at which synthesis of heat shock proteins is not markedly induced. Second, induction with tryptophan is accomplished by supplementation of the medium, a simpler task than heat induction. Third, regulation is tighter because the wild-type cI repressor has a higher affinity for the p_L operator than the cI*ts*857-encoded protein. Finally, *E. coli* strain GI724 contains the cI gene linked to the *Salmonella typhimurium trp* promoter/operon integrated into the *ampC* locus of the bacterial chromosome. This genetic arrangement is more stable than other tryptophan-regulated cI genes that are present on the F′ episome, and for this reason, GI724 is the host cell of choice.

LaVallie et al. (1993) have described a variation of the p_L-cI bacterial expression system in which the foreign protein of interest is expressed as a fusion protein with *E. coli* thioredoxin, a small (11.7 kD) cytoplasmic protein. This system combines a tryptophan-inducible cI gene, the bacteriophage λ p_L promoter, and fusion protein technology. All of the advantages associated with the expression of a foreign molecule as a fusion protein accrue in this system, including reduced formation of insoluble inclusion bodies containing the foreign protein, enhanced stability of the product, the ability to purify the fusion protein by simple procedures, and proteolytic release of the foreign protein from the fusion partner. Other examples of fusion-protein-based expression systems are the glutathione S-transferase system, the β-galactosidase system, and the maltose-binding protein.

Purification of fusion proteins produced in this system takes advantage of two properties of thioredoxin: (**1**) a unique subcellular association within the expressing cell (at adhesion zones) that usually allows release of the fusion protein into the medium after osmotic shock or freeze/thawing and (2) an enhanced thermal stability that allows enrichment of the fusion protein by incubation of cell lysates at high temperature (LaVallie et al. 1993). The components of the thioredoxin fusion protein expression system are available from Invitrogen Corp.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Coomassie Brilliant Blue stain or Silver stain

Please see Appendix 8.

1x SDS gel-loading buffer

Store 1x SDS gel-loading buffer lacking dithiothreitol at room temperature. Add dithiothreitol from a 1 M stock just before the buffer is used.

L-Tryptophan (10 mg/ml)

Gels

Polyacrylamide gel (10%) containing SDS **<!>**

For preparation of SDS-polyacrylamide gels used in the separation of proteins, please see Appendix 8.

Nucleic Acids and Oligonucleotides

Gene or cDNA fragment of interest

Media

LB agar plates

LB medium

Depending on the vector used, the LB medium and agar plates will require supplementation with various antibiotics.

LB medium heated to 65°C

Optional, please see Step 13.

M9 minimal medium

After sterilization, supplement this medium with 0.5% (w/v) glucose, 0.2% (w/v) casamino acids, and antibiotics as needed. This medium is used with tryptophan-inducible *c*I-gene-based p_L expression vectors.

Centrifuges and Rotors

Sorvall GSA rotor or equivalent

Special Equipment

Boiling-water bath

Shaking incubators preset to 30°C and 40°C

These incubators are required only if a temperature-sensitive allele of the bacteriophage λ *c*I gene is used.

Additional Reagents

Step 1 of this protocol requires the reagents listed in Chapter 8, Protocol 7.

Step 2 of this protocol requires the reagents listed in Chapter 1, Protocol 17 or 19.

Step 3 of this protocol requires the reagents listed in Chapter 1, Protocols 23–26.

Step 4 of this protocol requires the reagents listed in Chapter 12, Protocol 3.

Vectors and Bacterial Strains

E. coli *harboring either the* ts*857 allele or wild-type allele of the bacteriophage* λ *cI gene*

In strain M5219, the *cIts*857 allele is inducible by heat shock. Strain GI724 (ATCC 55151 cI gene) harbors a tryptophan-inducible wild-type *c*I gene.

p_L *Expression vector (e.g., pHUB, pPLc, pKC30, pAS1, pCQV2, pAL-781, and pTrxFus)*

Positive control (e.g., a p_L expression vector encoding a fusion protein of defined size)

METHOD

Preparation of Bacteria Containing the Recombinant Expression Vector

1. Modify by PCR (Chapter 8, Protocol 7), or isolate by restriction enzyme digestion, a fragment of DNA carrying 5′- and 3′-restriction enzyme sites compatible with sites in a p_L expression vector.

   If necessary, position a strong ribosome-binding site upstream of the initiating ATG of the cDNA/gene.

   Constructs generated by PCR should be sequenced to ensure that no spurious mutations were introduced during the amplification reactions.

2. Ligate the DNA fragment containing the cDNA/gene of interest into the expression vector (Chapter 1, Protocol 17 or 19).

3. Transform an *E. coli* strain containing the *cIts*857 allele or wild-type *c*I gene with aliquots of the ligation reaction. Plate aliquots of the transformation reaction on LB medium containing the appropriate selective antibiotic (usually ampicillin at 50 μg/ml), and incubate the cultures

overnight at 30°C (strains harboring the *cIts*857 allele) or at 37°C (strains harboring a tryptophan-inducible wild-type *c*I gene).

As a negative control, transform additional cells of the same strain of *E. coli* with the empty expression vector.

4. Screen the transformants by colony hybridization and/or restriction enzyme analysis, oligonucleotide hybridization, or direct DNA sequence analysis of plasmid minipreparations (please see Chapter 12, Protocol 3).

Optimization of the Induction of Target Protein Expression

Many studies point to the importance of the rate of cell growth on foreign protein expression. For this reason, it is important to monitor the number of bacteria inoculated into the growth medium, the length of time cells are grown before induction, and the density to which cells are grown after induction. Overgrowth or too rapid growth can overload the bacterial synthetic apparatus and promote formation of inclusion bodies.

5. Determine the optimum conditions for the induction of target protein expression, which is driven by the down-regulation of the *c*I repressor protein, either by an increase in temperature or by the presence of tryptophan.

For a discussion of factors that affect induction, please see the note to Step 8 in Protocol 1.

When using a temperature-inducible system

a. Inoculate 1-ml cultures of LB medium containing the appropriate antibiotics with 1 or 2 colonies of *E. coli* (carrying the *cIts*857 allele) containing the empty expression vector, and 1 or 2 colonies containing the recombinant expression vector. Incubate the cultures overnight at 30°C.

Include as positive control an expression vector encoding a protein of known size.

b. Inoculate 10 ml of LB medium containing antibiotic in a 50-ml flask with 50 µl of an overnight culture. Grow the culture to the mid-log phase of growth (A_{550} = 0.5–1.0) at 30°C.

c. Transfer 1 ml of each uninduced culture (zero-time aliquot) to microfuge tubes. Immediately process the zero-time aliquots as described in Steps 6 and 7.

d. Induce the remainder of each culture by shifting the incubation temperature to 40°C. Proceed to Step 6.

Although 42–45°C is used elsewhere in this manual to inactivate the bacteriophage λ *cIts*857 gene product, 40°C is used here to reduce the induction of heat shock proteins and to allow growth of the cells to continue.

When using a tryptophan-inducible system

a. Inoculate 1-ml cultures of supplemented M9 medium with 1 or 2 colonies of *E. coli* (carrying the *c*I wild-type allele) containing the empty expression vector, and 1 or 2 colonies containing the recombinant expression vector. Incubate the cultures overnight at 37°C.

Include as positive control an expression vector encoding a protein of known size.

b. Inoculate 10 ml of supplemented M9 medium in a 50-ml flask with 50 µl of the overnight cultures. Grow the cultures to the mid-log phase of growth (A_{550} = 0.5–1.0) at 37°C.

c. Transfer 1 ml of each uninduced culture (zero-time aliquot) to microfuge tubes. Immediately process the zero-time aliquots as described in Steps 6 and 7.

d. Induce the remainder of each culture by adding tryptophan to a final concentration of 100 μg/ml and continue incubation at 37°C.

6. At various time points during the induction period (e.g., 1, 2, 4, and 6 hours), transfer 1 ml of each culture to a microfuge tube, measure the A_{550} in a spectrophotometer, and centrifuge the tubes at maximum speed for 1 minute at room temperature in a microfuge. Remove the supernatants by aspiration.

7. Resuspend each pellet in 100 μl of 1x SDS gel-loading buffer, and heat the samples to 100°C for 3 minutes. Centrifuge the tubes at maximum speed for 1 minute at room temperature in a microfuge and store them on ice until all of the samples are collected and ready to load on a gel.

8. Warm the samples to room temperature and load 0.15 OD_{550} units (of original culture) or 40 μg of each suspension on a 10% SDS-polyacrylamide gel.

9. Run the gel at 8–15 V/cm until the bromophenol blue reaches the bottom of the resolving gel.

10. Stain the gel with Coomassie Brilliant Blue or silver, or carry out an immunoblot to visualize the induced protein (please see Appendix 8).

    For cells expressing the vector alone, no difference in the protein pattern should be noted between untransformed *E. coli* cells and cells carrying the empty expression vector. For cells expressing the recombinant gene, a protein of the predicted molecular weight should become visible at some time point after induction.

Large-scale Expression of the Target Protein

11. For large-scale expression and purification of the target protein, inoculate 50 ml of LB containing antibiotic or supplemented M9 medium in a 250-ml flask with a colony of *E. coli* containing the recombinant construct. Incubate the cultures overnight at 30°C or at 37°C, respectively.

12. Inoculate 450 ml of LB plus antibiotic or supplemented M9 medium in a 2-liter flask with 50-ml overnight cultures of *E. coli* containing the recombinant plasmids. Incubate the cultures with agitation at 30°C or 37°C, respectively, until the cultures have reached the mid-log phase of growth (A_{550} = 0.5–1.0). Induce the culture according to either Step 13 or 14, as appropriate.

13. Induce the *E. coli* culture carrying the *cIts*857 allele by the addition of 500 ml of LB medium heated to 65°C. Incubate the culture at 40°C for the optimum time period determined in the previous section.

    Alternatively, collect the bacterial cells by centrifugation at 12,000*g* (8600 rpm in a Sorvall GSA rotor) for 5 minutes at room temperature. Then resuspend the pellet in 500 ml of LB medium warmed to 40°C, and incubate the culture at 40°C for the optimum time period determined in Step 5.

14. Induce the *E. coli* culture carrying the *cI* allele by the addition of tryptophan to 100 μg/ml. Incubate the culture at 37°C for the optimum time period determined in the previous section.

15. After the induced cells have grown for the proper length of time, harvest the cells by centrifugation at 5000*g* (5500 rpm in a Sorvall GSA rotor) for 15 minutes at 4°C and proceed with a purification protocol:

    - Protocol 5 if the expressed protein is a fusion with glutathione *S*-transferase
    - Protocol 6 if the expressed protein is a fusion with maltose-binding protein
    - Protocol 7 if the expressed protein contains a polyhistidine tag

Protocol 4

Expression of Secreted Foreign Proteins Using the Alkaline Phosphatase Promoter (*phoA*) and Signal Sequence

FOR SOME PROTEINS, EXPORT TO THE PERIPLASMIC SPACE HAS ADVANTAGES over conventional expression in the cytosol:

- Some proteins that are degraded by intracellular proteases are stable in the periplasm (Talmadge et al. 1980).
- Some proteins that are inactive when produced intracellularly are active when exported; secretion may allow them to be properly folded (Gray et al. 1985). The *phoA* system has been used to export human epidermal growth factor (hEGF) into the periplasm of *E. coli* (Oka et al. 1985). The exported hEGF contained the correctly processed amino terminus and normal biological activity, indicating that the three disulfide bonds of hEGF were correctly formed.
- Proteins are produced that do not have an amino-terminal methionine, since cleavage occurs between the signal peptide and the coding sequence.

The two major problems encountered in the export of foreign proteins are that yields are often low, and cleavage of the signal peptide may not occur or may occur at an inappropriate position (Yuan et al. 1990). These problems may sometimes be remedied by inserting spacer amino acids between the signal sequence cleavage site and the foreign protein or by using *E. coli* strains that overexpress one or more of the signal peptidase genes.

In this protocol, export is accomplished by fusing the coding sequence to DNA encoding the *phoA* signal peptide, which is cleaved by the bacterial signal peptidase as the protein is exported into the space between the inner and outer membranes of *E. coli*. The *phoA* gene encodes the alkaline phosphatase component (the same enzyme used to dephosphorylate nucleic acids) of the phosphate scavenging system of *E. coli* and is repressed under conditions of excess phosphate. However, as phosphate becomes limiting in the medium (i.e., as the bacterial culture enters the lag phase of growth), the genes in the *pho* operon are gradually induced to high levels. The consequences of this regulation for *phoA* expression purposes are twofold. First, a gradual build up of the foreign protein occurs in the cell, instead of the acute induction that occurs with other regulated promoter systems. The slower build up decreases the chance of overloading components of the bacterial expression system and the formation of inclusion bodies. Second, the gradual build up allows the expression of foreign polypeptides that might be toxic if induced to high levels over a short period of time.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Coomassie Brilliant Blue stain or Silver stain

Please see Appendix 8.

Micronutrients (used in 10x MOPS salts)

37 mg $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$
84 mg $CoCl_2$
158 mg $MnCl_2\cdot 4H_2O$
247 mg H_3BO_3
25 mg $CuSO_4$
18 mg $ZnSO_4$

Dissolve in a final volume of 10 ml and sterilize by filtration. Store at 4°C.

10x MOPS salts (used in induction medium)

400 mM 3-(*N*-morpholino)propanesulfonic acid (pH 7.4) (MOPS) **<!>**
40 mM Tricine (pH 7.4)
0.1 mM $FeSO_4\cdot 7H_2O$
95 mM NH_4Cl
2.8 mM K_2SO_4
5 µM $CaCl_2\cdot 2H_2O$
5.3 mM $MgCl_2\cdot 6H_2O$
0.5 M NaCl

Dissolve in a final volume of 1 liter, and sterilize by filtration. Add 10 µl of micronutrients per liter before use.

Neutral phosphate buffer (1 M) (used in induction medium)

An equimolar mix of 1 M Na_2HPO_4 and 1 M NaH_2PO_4.

1x SDS gel-loading buffer

Store 1x SDS gel-loading buffer lacking dithiothreitol at room temperature. Add dithiothreitol from a 1 M stock just before the buffer is used in Step 8.

Gels

Polyacrylamide gel (10%) containing SDS **<!>**

For the preparation of SDS-polyacrylamide gels used in the separation of proteins, please see Appendix 8.

Nucleic Acids and Oligonucleotides

Gene or cDNA fragment of interest

Media

Induction medium

1x MOPS salts (for recipe, please see Buffers and Solutions above)
0.2% (w/v) glucose
0.2% (w/v) casamino acids (vitamin assay quality; DIFCO)
20 µg/ml adenine
0.5 µg/ml thiamine
0.1 M neutral phosphate buffer (for recipe, please see Buffers and Solutions above)

Combine the ingredients to a final volume of 1 liter in H_2O. Sterilize by filtration and store at 4°C.

This low-phosphate medium, which is used to induce transcription of the *phoA* promoter, was originally developed as a minimal salts medium for isotopic labeling (Neidhardt et al. 1974). Although difficult to prepare, this medium consistently provides the highest level of induction.

LB agar plates containing 50 µg/ml ampicillin
LB medium containing 50 µg/ml ampicillin

Centrifuges and Rotors

Sorvall GSA rotor or equivalent
Sorvall SS-34 rotor or equivalent

Special Equipment

Boiling water bath

Additional Reagents

Step 1 of this protocol requires the reagents listed in Chapter 8, Protocol 7.
Step 2 of this protocol requires the reagents listed in Chapter 1, Protocol 17 or 19.
Step 3 of this protocol requires the reagents listed in Chapter 1, Protocols 23–26.
Step 4 of this protocol requires the reagents listed in Chapter 12, Protocol 3.

Vectors and Bacterial Strains

E. coli *strain*

Essentially any strain of *E. coli* can be used to express genes cloned in *phoA* vectors. Oka et al. (1985) reported a fivefold higher yield of foreign protein in strain YK537 than strain C600. Strain YK537 carries the *phoA8* mutation, an internal deletion in the alkaline phosphatase gene. However, the difference in expression between these two strains is probably not due to this mutation, as the expression of foreign proteins in isogenic wild-type or *phoA8* strains does not differ (B.L. Wanner, pers. comm.).

If the foreign protein is not toxic, then bacterial strains containing *phoR* mutations can be used. Because wild-type *phoR* genes encode the repressor of the *pho* operon, *phoR* mutant strains constitutively express genes controlled by the *phoA* promoter (Wanner 1987). As with all bacterial expression systems, it may be necessary to try more than one *E. coli* strain to optimize synthesis/export of a given foreign protein (Weikert et al. 1998). The various strains should also be grown at different temperatures to maximize expression levels and protein stability (please see Protocol 1).

pTA1529 or pBAce

Plasmid pTA1529 is described by Oka et al. (1985). pBAce is available from C.C. Wang (Department of Pharmaceutical Chemistry, University of California, San Francisco).

METHOD

Preparation of Bacteria Containing the Recombinant Expression Vector

1. Modify by PCR (Chapter 8, Protocol 7), or isolate by restriction enzyme digestion, a fragment of DNA carrying 5′- and 3′-restriction enzyme sites compatible with the polycloning sites in pTA1529 or pBAce.

   Constructs generated by PCR should be sequenced to ensure that no spurious mutations were introduced during the amplification reactions.

2. Ligate the DNA fragment containing the cDNA/gene of interest into the expression vector (Chapter 1, Protocol 17 or 19).

3. Transform an appropriate *E. coli* strain with aliquots of the ligation reaction. Plate aliquots of the transformation reaction on LB agar containing 50 µg/ml ampicillin, and incubate the cultures overnight at 37°C.

   As a negative control, transform additional cells of the same strain of *E. coli* with the empty expression vector.

4. Screen the transformants by colony hybridization and/or restriction enzyme analysis, oligonucleotide hybridization, or direct DNA sequence analysis (please see Chapter 12, Protocol 3) of plasmid minipreparations.

Optimization of the Induction of Target Protein Expression

Numerous studies point to the importance of the rate of cell growth on foreign protein expression. For this reason, it is important to monitor the number of bacteria inoculated into the growth medium, the length of time cells are grown before induction, and the density to which cells are grown after induction. Overgrowth or too rapid growth can overload the bacterial synthetic apparatus and promote formation of inclusion bodies.

5. Inoculate 1-ml cultures of LB medium containing 50 µg/ml ampicillin with one to two colonies containing the empty expression vector, and one to two colonies containing the recombinant and control plasmids. Incubate the cultures overnight at 37°C.

6. Inoculate 5 ml of induction medium containing 50 µg/ml ampicillin in a 50-ml flask with 50 µl of an overnight culture. Incubate the cultures with shaking at 20–37°C.

   For a discussion of factors that affect induction, please see the note to Step 8 in Protocol 1.

7. At various time points after inoculation (e.g., 0, 6, 12, 18, and 24 hours), transfer 1 ml of each culture to a microfuge tube, measure the A_{550} in a spectrophotometer, and centrifuge the tubes at maximum speed for 1 minute at room temperature in a microfuge. Remove the supernatants by aspiration.

   The kinetics of induction from the *phoA* promoter are slower than those of other promoters, because induction occurs with gradual depletion of phosphate from the medium. The optimum growth temperature will vary with each foreign protein to be expressed and must be established empirically.

8. Resuspend each pellet in 100 µl of 1x SDS gel-loading buffer, and heat the samples to 100°C for 3 minutes. Centrifuge the tubes at maximum speed for 1 minute at room temperature in a microfuge, and store them on ice until all of the samples are collected and ready to load on a gel.

9. Warm the samples to room temperature and load 0.15 OD_{550} units (of original culture) or 40 µg of each suspension on a 10% SDS-polyacrylamide gel.

10. Run the gel at 8–15 V/cm until the bromophenol blue reaches the bottom of the resolving gel.

11. Stain the gel with Coomassie Brilliant Blue or silver, or carry out an immunoblot to visualize the induced protein (please see Appendix 8).

    When using the signal sequence of the *phoA* gene to direct secretion of the foreign protein, perform the additional protocol on **SUBCELLULAR LOCALIZATION OF PHOA FUSION PROTEINS** (p. 15.35) to determine the subcellular location of the protein by cell fractionation.

Large-scale Expression of the Target Protein

12. For large-scale expression and purification of the target protein, inoculate 25 ml of LB medium containing 50 µg/ml ampicillin in a 125-ml flask with a colony of *E. coli* containing the recombinant *phoA* construct. Incubate the culture overnight with agitation at 37°C.

13. Collect the cells by centrifugation at 5000*g* (6500 rpm in a Sorvall SS-34 rotor) for 15 minutes. Resuspend the cell pellet in 25 ml of induction medium, and collect the cells again by centrifugation.

14. Resuspend the washed cells in 2.5 ml of fresh induction medium, and inoculate the cells into 500 ml of induction medium in a 2-liter flask. Incubate the large-scale culture at the optimum temperature and for the optimum time determined in the previous section.

15. After the cells have grown for the proper length of time, harvest the cells by centrifugation at 4000*g* (5000 rpm in a Sorvall GSA rotor) for 15 minutes at 4°C.

    If a *phoA* expression vector with a signal sequence was used and if the results of the additional protocol indicate that the foreign protein is efficiently exported to the periplasm, then the expressed protein can be purified by osmotic shock as described in the additional protocol. If a *phoA* expression vector without a signal sequence was used, then the foreign protein must be purified by conventional chromatography.

ADDITIONAL PROTOCOL: SUBCELLULAR LOCALIZATION OF PHOA FUSION PROTEINS

Accurate measurements of the distribution of PhoA fusion proteins among different cellular compartments requires the use of marker enzymes to assay purification of each of the subcellular fractions (periplasmic space, membrane, and cytoplasm) (Guzman-Verduzco and Kupersztoch 1990). This protocol, although not quantitative, should provide preliminary information on the cellular location of PhoA fusion proteins.

Additional Materials

Cell lysis buffer
- 1 mg/ml lysozyme
- 20% (w/v) sucrose
- 30 mM Tris-Cl (pH 8.0)
- 1 mM EDTA (pH 8.0)

2x SDS Gel-loading buffer
- 100 mM Tris-Cl (pH 6.8)
- 200 mM dithiothreitol
- 4% SDS (w/v) (electrophoresis grade)
- 0.2% (w/v) bromophenol blue
- 20% (v/v) glycerol

Store 2x SDS gel-loading buffer lacking dithiothreitol at room temperature. Add dithiothreitol from a 1 M stock just before the buffer is used.

Tris-Cl (0.1 M, pH 8.0)

Methods

1. Transfer 1 ml of the induced culture containing the highest quantity of the foreign protein to a microfuge tube. Recover the cells by centrifugation at maximum speed for 1 minute at 4°C in a microfuge.

   Check the supernatant medium for the presence of secreted protein. To do so, add an equal volume of ice-cold 20% (w/v) trichloroacetic acid to the supernatant. Incubate the acidified solution on ice for at least 20 minutes. Centrifuge the solution at maximum speed for 20 minutes in a microfuge and discard the supernatant. Wash the pellet with 1 ml of ethanol and recover the pellet by centrifugation at maximum speed for 5 minutes in a microfuge. Repeat the ethanol wash and resuspend the pellet in 40 µl of 1x SDS gel-loading buffer. Analyze 20 µl of the sample on an SDS-polyacrylamide gel (Step 7).

2. Suspend the cell pellet in 100 µl of a freshly prepared solution of cell lysis buffer and store the suspension on ice for 10 minutes.

   The use of lysozyme to generate spheroplasts has two potential drawbacks. First, contaminating lytic enzymes in some commercial preparations of lysozyme can lyse the bacterial cells. Second, if the foreign protein of interest has a molecular weight similar to that of lysozyme (~15,000), the presence of lysozyme in the buffer can obscure visualization of the expressed protein on stained polyacrylamide gels. Other methods for the preparation of spheroplasts can be tried, including those using reduced concentrations of lysozyme (Marvin and Witholt 1987), osmotic shock, treatment with chloroform (Ames et al. 1984), and use of the peptide antibiotic polymyxin B (Cerny and Teuber 1971). To release polypeptides into the periplasmic space by the latter method, resuspend the cells at Step 1 in 100 µl of 400 µg/ml polymyxin B and incubate on ice for 2 hours. Centrifuge the treated cells as in Step 1. The supernatant contains the periplasmic proteins and the cell pellet contains the cytoplasmic and membrane proteins, which can be further fractionated as described in Steps 4 and 5.

3. Recover the cells by centrifugation as in Step 1. The supernatant is the periplasmic fraction, which should be stored on ice until Step 6.

4. Resuspend the cell pellet in 100 µl of 0.1 M Tris-Cl (pH 8.0) and lyse the cells by freezing and thawing (i.e., place the cells on dry ice to freeze and then thaw them at 37°C; repeat this process twice more).

5. Centrifuge the suspension at maximum speed for 5 minutes at 4°C in a microfuge. The cytoplasmic proteins are found mainly in the supernatant. Resuspend the pellet, which contains the membrane fraction and insoluble inclusion bodies, in 100 µl of 0.1 M Tris-Cl (pH 8.0).

   To release the PhoA fusion proteins from the periplasmic space, please see the panel on page 15.43.

6. Add an equal volume of 2x SDS gel-loading buffer to each of the subcellular fractions, mix the solutions well, and then heat the samples to 100°C for 3 minutes. Centrifuge the boiled samples at maximum speed for 1 minute at room temperature in a microfuge.

7. Load an equal volume from each of the fractions on a 10% SDS-polyacrylamide gel.

8. Run the gel at 8–15 V/cm until the bromophenol blue reaches the bottom of the resolving gel.

9. Stain the gel with Coomassie Brilliant Blue to determine the subcellular location of the foreign protein and how effectively the protein is secreted into the periplasm.

Protocol 5

Purification of Fusion Proteins by Affinity Chromatography on Glutathione Agarose

FUSION PROTEINS EXPRESSED FROM PGEX VECTORS CONTAIN A GLUTATHIONE *S*-transferase (GST) moiety and can therefore be purified to near homogeneity by affinity chromatography on glutathione-agarose. GSTs are a class of enzymes that utilize glutathione (γ-glutamylcysteinylglycine) as a substrate to inactivate toxic small molecules via formation of mercapturic acids (Jakoby and Ziegler 1990). Because the affinity of GST for its substrate is in the submillimolar range, immobilization of glutathione on an agarose matrix makes a highly efficient affinity chromatography resin. Bound GST fusion proteins are readily displaced from the column by elution with buffers containing free glutathione. The glutathione-agarose resin can then be regenerated by treatment with buffers containing 3 M NaCl.

The capacity of the glutathione-agarose for GST fusion proteins is high (8 mg of fusion protein per 1 ml of bed volume of resin). With fusion protein production in the range of 0.1–10 mg/liter of *E. coli* culture, this capacity means that lysate from 1 liter of *E. coli* can be fractionated on 1 ml of resin.

This protocol uses a batch method to bind, wash, and release the fusion protein from the affinity resin. Although the method is rapid, conventional chromatography using small disposable columns is sometime preferable because it allows smaller amounts of elution buffer to be used, resulting in a higher concentration of protein in the eluate.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Dithiothreitol (1 M)

Glutathione elution buffer

10 mM reduced glutathione
50 mM Tris-HCl (pH 8.0)

Phosphate-buffered saline (PBS) (4°C)

Triton X-100 (0.2% v/v)

Enzymes and Buffers

DNase (5 mg/ml)
Lysozyme
RNase (5 mg/ml)
Thrombin, Enterokinase, or Factor Xa solution
Follow the manufacturer's instructions for the preparation and storage of these proteases.

Gels

Polyacrylamide gel (10%) containing SDS **<!>**
For preparation of SDS-polyacrylamide gels used in the separation of proteins, please see Appendix 8.

Centrifuges and Rotors

Sorvall SS-34 rotor or equivalent

Special Equipment

Glutathione-agarose resin
If necessary, adjust the concentration of the resin with 20% ethanol to make a 50% (v/v) slurry.
Hypodermic needles (18-, 22-, and 25-gauge)

Vectors and Bacterial Strains

E. coli *cells expressing a recombinant GST fusion protein (cell pellet generated in Step 17 of Protocol 1 or 2)*

METHOD

Preparation of the Glutathione-Agarose Resin

1. Gently invert the container of the glutathione-agarose resin to mix the slurry.
2. Transfer an aliquot of the slurry to a 15-ml polypropylene tube (2 ml of the slurry will be needed for each 100 ml of the original bacterial culture).
3. Centrifuge the tube at 500*g* (2100 rpm in a Sorvall SS-34 rotor) for 5 minutes at 4°C. Carefully remove and discard the supernatant.
4. Add 10 bed volumes of cold PBS to the resin, and mix the slurry by inverting the tube several times. Centrifuge the tube at 500*g* (2100 rpm in a Sorvall SS-34 rotor) for 5 minutes at 4°C. Carefully remove and discard the supernatant.
5. Add 1 ml of cold PBS per milliliter of resin to make a 50% slurry. Mix the slurry by inverting the tube several times. Keep the suspension on ice until the cell extract has been prepared.

Preparation of Cell Extract

6. Resuspend the cell pellet (e.g., from Protocol 1, Step 17) in 4 ml of PBS per 100 ml of cell culture.

7. Add lysozyme to a final concentration of 1 mg/ml and incubate the cell suspension on ice for 30 minutes.

   Several protocols use sonication or a French press to lyse cells before affinity purification of the GST fusion protein. Lysozyme is more reproducible and avoids the cataclysmic lysis that can release outer membrane proteins and other molecules that cause aggregation of the GST fusion protein or copurify with it on glutathione-agarose chromatography.

8. Add 10 ml of 0.2% Triton X-100. Use a syringe to inject the solution forcibly into the viscous cell lysate. Shake the tube vigorously several times to mix the solution of detergent and cell lysate. Add DNase and RNase to the tube each to a final concentration of 5 μg/ml, and continue the incubation with rocking for 10 minutes at 4°C. Remove the insoluble debris by centrifugation at 3000*g* (5000 rpm in a Sorvall SS-34 rotor) for 30 minutes at 4°C. Collect the supernatant (cell lysate) in a fresh tube. Add dithiothreitol to a final concentration of 1 mM.

   It may be necessary to pass the supernatant through a 0.45-μm filter to prevent clogging of the resin during purification of the GST fusion protein.

   Triton X-100 is added to the slurry of lysed cells to prevent aggregation. Detergents that have been reported to solubilize GST fusion proteins and not interfere with the glutathione-agarose affinity purification step include 1% (v/v) Triton X-100, 1% (v/v) Tween-20 plus 10 mM dithiothreitol, 0.03% (w/v) SDS, and 1.5% (w/v) *N*-lauroylsarcosine (Smith and Johnson 1988; Frankel et al. 1991; Grieco et al. 1992). Tween-20, SDS, and *N*-lauroylsarcosine can be added in place of, or simultaneously with, the Triton X-100. Please see the panel on **TROUBLESHOOTING: INSOLUBLE PROTEINS**.

Purification of the Fusion Protein

9. Combine the cell lysate with an appropriate amount of the 50% slurry of glutathione-agarose resin in PBS. Use 2 ml of slurry for each 100 ml of bacterial culture used to make the protein extract. Shake the mixture gently for 30 minutes at room temperature.

10. Centrifuge the mixture at 500*g* (2100 rpm in a Sorvall SS-34 rotor) for 5 minutes at 4°C. Carefully remove the supernatant. Save a small amount of the supernatant to analyze by SDS-polyacrylamide gel electrophoresis.

11. Wash unbound proteins from the resin by adding 10 bed volumes of PBS to the pellet, and mix by inverting the tube several times.

12. Centrifuge at 500*g* (2100 rpm in a Sorvall SS-34 rotor) for 5 minutes at 4°C. Carefully remove the supernatant. Save a small amount of the supernatant to analyze by SDS-polyacrylamide gel electrophoresis.

13. Repeat Steps 11 and 12 two more times.

14. Bound GST fusion protein may be eluted from the resin using glutathione elution buffer. Alternatively, GST fusion proteins may be cleaved while still bound to the gel with thrombin, enterokinase, or Factor Xa, liberating the protein of interest from the GST moiety.

ELUTION OF THE FUSION PROTEIN USING GLUTATHIONE

a. Elute the bound protein from the resin by adding 1 bed volume of glutathione elution buffer to the pellet. Incubate the tube with gentle agitation for 10 minutes at room temperature.

b. Centrifuge the tube as in Step 12. Transfer the supernatant (which contains the eluted fusion protein) to a fresh tube.

c. Repeat Steps a and b twice more, pooling all three supernatants.

Depending on the particular fusion protein being purified, a significant amount of protein may remain bound to the gel following the elution steps. The volume of elution buffer and the elution times may vary among fusion proteins. Additional elutions may be required. Monitor the eluates for GST protein by SDS-polyacrylamide gel electrophoresis. Estimate the yield of fusion protein by measuring the absorbance at 280 nm. As a general rule for proteins containing a GST tag, 1 A_{280} = 0.5 mg/ml. The yield of protein may also be determined by standard chromogenic methods (e.g., Lowry or Bradford). If the Lowry method is used, the sample must first be dialyzed against 2000 volumes of 1x PBS to remove the glutathione, which can interfere with protein measurement. The Bradford method can be performed in the presence of glutathione.

PROTEOLYTIC CLEAVAGE OF THE TARGET PROTEIN FROM THE BOUND GST MOIETY

a. Add thrombin, enterokinase or Factor Xa (as appropriate for the cleavage site within the fusion protein) to the beads. Use 50 units of the appropriate protease in 1 ml of PBS for each milliliter of resin volume. Mix the solution by inverting the tube several times, and incubate the mixture with shaking for 2–16 hours at room temperature. The exact time should be determined empirically using small-scale reactions.

b. Centrifuge the tube at 500*g* (2100 rpm in a Sorvall SS-34 rotor) for 5 minutes at 4°C. Carefully transfer the supernatant to a fresh tube.

The GST should still be bound to the matrix and the protein of interest should be in the supernatant. The thrombin or the Factor Xa will also be in the supernatant. The protein of interest can be separated from the protease by conventional chromatography or by SDS-polyacrylamide gel electrophoresis.

15. Analyze the protein profile of each step (cell extract, washes, and elution) on a 10% SDS-polyacrylamide gel.

TROUBLESHOOTING: INSOLUBLE PROTEINS

Insoluble GST fusion proteins (detected by the presence of fusion protein in the preliminary induction experiments and by the absence of the polypeptide after affinity chromatography, or in cell fractionation experiments) can also be solubilized with the following detergents: 1% (v/v) Triton X-100, 1% (v/v) Tween-20 plus 10 mM dithiothreitol, 0.03% (w/v) SDS, and especially 1.5% (w/v) *N*-lauroylsarcosine (Smith and Johnson 1988; Frankel et al. 1991; Grieco et al. 1992).

1. Follow the main protocol through Step 7.
2. Centrifuge the cell lysate at 10,000*g* (7300 rpm in a Sorvall SS-34 rotor) for 10 minutes at 4°C, remove and save the supernatant, and resuspend pellet in 8 ml of 1.5% *N*-lauroylsarcosine, 25 mM triethanolamine, 1 mM EDTA (pH 8.0).
3. Mix the solution for 10 minutes at 4°C and then centrifuge as in Step 2 above.
4. Combine supernatants from the initial detergent-free cell lysate and the resolubilized cell pellet.
5. Proceed with the remainder of the protocol (from Step 9).

Protocol 6

Purification of Maltose-binding Fusion Proteins by Affinity Chromatography on Amylose Resin

MALTOSE-BINDING PROTEIN (MBP) FUSIONS GENERATE RECOMBINANT PROTEINS in a form that can be purified to near homogeneity by affinity chromatography (Hennig and Schafer 1998). MBP, a periplasmic protein encoded by the *malE* gene of *E. coli*, is a component of the maltose transport system of the bacterium. MBP has an affinity in the micromolar range for maltose and maltodextrins and can thus be purified on matrices consisting of sugars cross-linked to an agarose matrix. The *malE* gene product tolerates a wide variety of fusions and is therefore a useful pack horse in expression studies (Schatz and Beckwith 1990).

The pMAL-c2 or pMAL-p2 vectors (di Guan et al. 1988; Maina et al. 1988; New England Biolabs) contain the IPTG-inducible *tac* promoter adjacent to an extensive polycloning site and an *rrnB* terminator. The polylinker spans the amino terminus of the α-complementation fragment of β-galactosidase, allowing blue/white screening of bacterial colonies when cloning into these vectors. Because the plasmids also contain the cI^q allele of the *lacI* gene, expression of MBP fusion proteins can be induced by IPTG in most strains of *E. coli*. A spacer sequence of ten asparagine residues separating the *malE* sequence from the polycloning site facilitates cleavage of the fusion protein by Factor X protease and, in addition, may enhance the ability of the MBP fusion protein to bind to the affinity resin. The Factor X protease cleavage site (Ile-Glu-Gly-Arg) lies immediately adjacent to the first restriction enzyme site (*Eco*RI) in the polycloning site. The Factor X protease cleavage site may be replaced as desired by a sequence encoding a cleavage site for other proteases, such as thrombin or enterokinase. pMAL-c2 lacks the MBP signal sequence, whereas pMAL-p2 contains the MBP signal sequence that directs MBP fusion proteins to the periplasmic space. Export into this compartment allows rapid isolation by osmotic shock, decreases exposure of the fusion protein to proteases, and in some cases, allows the formation of disulfide bonds in the foreign protein. Not all fusion proteins, however, are exported efficiently into the periplasm. Thus, any advantage of targeting to the periplasmic space must be established empirically.

MBP fusions have a potential advantage over GST fusions: the *malE* gene sequence is derived from *E. coli* and should therefore contain the appropriate codons and elements of mRNA secondary structure that are required for efficient expression in the bacterium. By contrast, the effectiveness in *E. coli* of the analogous GST sequence, which is derived from a parasitic organism, is unknown. However, no direct comparisons have been published of the efficiency with which the two types of vectors express a series of fusion proteins.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Cell lysis buffer (~150 ml)
30 mM Tris-Cl (pH 7.1)
0.1 mM EDTA
20% (w/v) sucrose

Cell wash buffer (~250 ml)
10 mM Tris-Cl (pH 7.1)
30 mM NaCl

Column elution buffer (~100 ml)
10 mM Tris-Cl (pH 7.5)
10 mM maltose

Column wash buffer (~250 ml)
10 mM Tris-Cl (pH 7.1)
1 M NaCl

$MgCl_2$ (0.1 mM, ~250 ml)

PMSF (100 mM) **<!>**

Add 17.4 mg of PMSF per milliliter of isopropanol. Store at –20°C.

PMSF is inactivated in aqueous solutions. The rate of inactivation increases with increasing pH and is faster at 25°C than at 4°C. The half-life of a 20 mM aqueous solution of PMSF is ~35 minutes at pH 8.0 (James 1978). This short half-life means that aqueous solutions of PMSF can be safely discarded after they have been rendered alkaline (pH >8.6) and stored for several hours at room temperature.

An alternative to PMSF (4-[2-aminoethyl]-benzenesulfonylfluoride, hydrochloride; Pefabloc SC) is available from Boehringer Mannheim. Pefabloc is an irreversible serine protease inhibitor, is used at the same concentration as PMSF, but is nontoxic and stable in aqueous buffer solutions.

1x SDS gel-loading buffer
Store 1x SDS gel-loading buffer lacking dithiothreitol at room temperature. Add dithiothreitol from a 1 M stock, just before the buffer is used.

Tris-Cl (10 mM, pH 7.1)

Enzymes and Buffers

DNase (5 mg/ml)

Lysozyme

RNase (5 mg/ml)

Thrombin, Enterokinase, or Factor Xa solution
Follow the manufacturer's instructions for the preparation and storage of these proteases.

Gels

Polyacrylamide gel (10%) containing SDS **<!>**
For preparation of SDS-polyacrylamide gels used in the separation of proteins, please see Appendix 8.

Centrifuges and Rotors

Beckman Ti60 rotor or equivalent

Sorvall GSA rotor or equivalent

Sorvall SS-34 rotor or equivalent

Special Equipment

Amylose Agarose
This affinity chromatography matrix can be synthesized as described by Kellermann and Ferenci (1982) or purchased from New England Biolabs (binding capacity 2–4 mg MBP/ml bed volume).

Boiling water bath

Equipment for sonication
Please see Appendix 8.

Disposable Nalgene filter (0.45-μm nitrocellulose)

Vectors and Bacterial Strains

E. coli *cells expressing a recombinant MBP fusion protein (cell pellet generated in Step 17 of Protocol 1 or 2)*

METHOD

Preparation of Amylose Agarose

1. Pour a 3 x 6-cm column of amylose agarose. Equilibrate in 10 mM Tris-Cl (pH 7.1) at 4°C.

Preparation of the Cell Extract

2. Resuspend the cell pellet in 1/10 original culture volume (typically 50 ml) of ice-cold cell wash buffer. Collect the cells by centrifugation at 5000*g* (5500 rpm in a Sorvall GSA rotor) for 15 minutes at 4°C and again resuspend the pellet in 1/10 original culture volume (typically 50 ml) of ice-cold cell wash buffer.
3. Prepare the cell lysate.

IF AN MBP VECTOR WITHOUT A SIGNAL SEQUENCE WAS USED (PMAL-C2)

a. Lyse cells by sonication with a microtip sonicator, using three bursts of 10 seconds each. Use a power setting of ~30 W and keep the cells cold (0°C) during sonication.
b. Add PMSF to a final concentration of 1 mM and clarify the solution by centrifugation at 87,000*g* (35,000 rpm in a Beckman Ti60 rotor) for 30 minutes at 4°C.

Proceed to purify the fusion protein from the supernatant by amylose-agarose chromatography as described in Step 4.

IF AN MBP VECTOR WITH A SIGNAL SEQUENCE WAS USED (PMAL-P2)

a. Collect the cells by centrifugation at 5000*g* (5500 rpm in a Sorvall GSA rotor) for 15 minutes at 4°C and resuspend the cell pellet in 1/20 original culture volume (typically 25 ml) of ice-cold cell wash buffer.
b. Add PMSF to 1 mM. Stir the cell suspension for 15 minutes at room temperature. Collect the cells by centrifugation at 17,200*g* (12,000 rpm in a Sorvall SS-34 rotor) for 10 minutes at 4°C.

c. Spread the cell pellet around the sides of the centrifuge tube. Add ice-cold 0.1 mM $MgCl_2$ solution (100 ml/liter original culture volume) and stir the suspension for 10 minutes at 4°C.

d. Centrifuge the shocked cells at 17,200*g* (12,000 rpm in a Sorvall SS-34 rotor) for 10 minutes at 4°C. Add 10 mM Tris-Cl (pH 7.1) until the pH of the supernatant is 7.1.

e. Filter the supernatant through a 100-ml disposable Nalgene filter (0.45-µm nitrocellulose membrane), and dialyze the filtered solution against 100 volumes 10 mM Tris-Cl (pH 7.1) at 4°C.

Proceed to purify the fusion protein from the supernatant by amylose-agarose chromatography as described in Step 4.

4. Pour the supernatant from Step 3 over the column. Rinse the column with 100 ml of 10 mM Tris-Cl (pH 7.1). Pass 100 ml of column wash buffer through the column.

5. Elute the bound fusion protein with 50 ml of column elution buffer and collect 1-ml fractions.

6. Analyze aliquots of the collected fractions by SDS-polyacrylamide gel electrophoresis to determine the location of the fusion protein in the series of elution fractions. Pool the fractions containing the fusion protein, and store them at –70°C.

7. Use the appropriate protease to cleave the fusion protein from the MBP moiety.

a. Add thrombin, enterokinase or Factor Xa (as appropriate for the cleavage site within the fusion protein) to the beads. Use 50 units of the appropriate protease in 1 ml of PBS for each milliliter of resin volume. Mix the solution by inverting the tube several times, and incubate the mixture with shaking for 2–16 hours at room temperature.

The time required to obtain maxiumum yield of the foreign protein should be determined empirically using small-scale reactions.

b. Centrifuge the tube at 500*g* (2100 rpm in a Sorvall SS-34 rotor) for 5 minutes at 4°C. Carefully transfer the supernatant to a fresh tube.

The protein of interest can be separated from the protease by conventional chromatography or by SDS-polyacrylamide gel electrophoresis.

Proteins secreted into the periplasmic space of *E. coli* can be readily released from cells by osmotic shock as described in Step 3. Treatment of bacteria with hypertonic solutions containing EDTA (i.e., cell lysis buffer) changes membrane/cell wall permeability, and subsequent incubation in a hypotonic solution (i.e., 0.1 mM $MgCl_2$) causes permeabilization of the cell wall and release of components from the periplasmic space (Nossal and Heppel 1966). Cells harvested from exponentially growing cultures are more readily shocked than are stationary cells. Typically, ~4% of the total protein mass of *E. coli* is secreted into the periplasmic space. The proteins secreted include a number of degradative enzymes such as alkaline phosphatase, acid phosphatase, RNase, DNase, and nucleotide metabolizing enzymes. Because proteases are also secreted, the use of a protease-deficient *E. coli* strain or the addition of a protease inhibitor cocktail (please see Protocol 1), together with the 10 mM Tris-Cl (pH 7.1) buffer after the shock treatment, may enhance the yield of intact MBP fusion proteins.

Some foreign proteins are not translocated efficiently into the periplasmic space and, as a consequence, are not isolated in high yield by the procedures described in this protocol. Because these fusion proteins generally remain attached to the cytoplasmic membrane, they cannot be efficiently isolated from cells lysed by sonication. For this reason, it is a good idea to determine the distribution of the MBP fusion protein among different cellular fractions (periplasm, cytoplasm, or membrane) (please see Protocol 4). If an expressed protein is found associated with the inner membrane, include 1% Triton X-100 in the cell wash buffer of Step 3a above. The use of other detergents for solubilization of fusion proteins is discussed in Protocol 4.

Protocol 7

Purification of Histidine-tagged Proteins by Immobilized Ni^{2+} Absorption Chromatography

POLYHISTIDINE TRACTS BIND TIGHTLY TO A NUMBER OF TRANSITION METALS and transition metal chelate complexes, such that a protein carrying an exposed His-6 region will bind to a resin charged with divalent nickel ions. Contaminating proteins can be removed with appropriate washing, and the protein of interest can then be eluted by a soluble competing chelator. Because few natural proteins bind with significant affinities to such matrices, His-6-labeled proteins generated by recombinant techniques can be purified substantially in a single step by metal chelate affinity chromatography. Those natural proteins that do bind to these matrices can almost always be removed in a second chromatography step. Metal chelate chromatography has become popular because it is both highly effective and relatively insensitive to proper protein folding, ionic strength, chaotropes, and detergents (Hochuli et al. 1988). Because of the high efficiency, high capacity, concentrating power, and speed of this technique, it should be used as a first (and sometimes only) step in a purification protocol.

To perform metal chelate chromatography, the protein of interest must first be engineered to contain a His-6 sequence in an exposed and relatively flexible site, frequently found at the amino or carboxyl terminus (Van Reeth et al. 1998). It can be helpful to place one or two glycine residues between the His-6 sequence and the rest of the protein. Unique protease cleavage sites also can be inserted to allow removal of the His-6 sequence after purification (please see Table 15-3). Proteases may also be used to desorb proteins from the affinity matrix by cleavage at the linker/His-6 insertion. Coexpression of an unmodified protein of interest together with a His-6-tagged binding partner can allow isolation of the binary complex on the affinity matrix and selective elution of the native target protein (Kozasa and Gilman 1995). This method can be particularly effective if the two proteins can be dissociated gently such that contaminating proteins that bind to the matrix are not eluted (please see Chapter 18, Protocols 2 and 3).

Purification can be performed under both native and denaturing conditions (e.g., in buffers containing 8 M urea or 6 M guanidine hydrochloride). Because any chelator can interfere with metal chelate chromatography, buffers used for extraction and chromatography should be free of EDTA or EGTA. Submillimolar concentrations of dithiothreitol may not interfere significantly. Nevertheless, it is preferable to use buffers containing 1–5 mM of a monothiol such as β-mercaptoethanol or β-mercaptoacetic acid. The target protein is eluted by a chelator such as imidazole or EDTA. Imidazole is the more selective eluant and should be used whenever possible. Efficient elution is usually achieved with 50–100 mM imidazole at pH 7–8. The lowest effective concentra-

tion should be established using a linear gradient of 10–150 mM imidazole. EDTA is more effective, but it may strip Ni^{2+} from the NTA-agarose. In this case, the Ni^{2+} must then be removed for many applications, either by dialysis or by a second chromatographic step.

The Ni^{2+} resin can be easily regenerated and reused many times (please see the additional protocol at the end of this protocol). Because of its large binding capacity, as much as 20 mg of recombinant protein may be purified on a 2.5-ml column. The following protocol is adapted from methods contributed by Elliot Ross (University of Texas Southwestern Medical Center, Dallas) and Tzu-Ching Meng in Nick Tonks' group at Cold Spring Harbor Laboratory.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Binding buffer (pH 7.8)
20 mM sodium phosphate
500 mM NaCl

Imidazole elution buffer (pH 6.0)
20 mM sodium phosphate
500 mM NaCl
Create a series of four elution buffers containing imidazole at concentrations of 10 mM, 50 mM, 100 mM, and 150 mM by adding the appropriate amount of 3 M imidazole to wash buffer (pH 6.0).

Triton X-100 (10% v/v)

Wash buffer (pH 6.0)
20 mM sodium phosphate
500 mM NaCl

Enzymes and Buffers

DNase (1 mg/ml)
Lysozyme
RNase (1 mg/ml)

Gels

Polyacrylamide gel (10%) containing SDS **<!>**
For preparation of SDS-polyacrylamide gels used in the separation of proteins, please see Appendix 8.

Centrifuges and Rotors

Sorvall SS-34 rotor or equivalent

Special Equipment

Chromatography column (glass or polypropylene)

Ni^{2+}-charged chromatography resin (e.g., ProBond, Invitrogen; HisTrap, Pharmacia; His•Bind Resin, Novagen; NTA-Ni^{2+}-agarose, Qiagen)

Currently, the most common metal chelate affinity support is nitrilotriacetate (NTA)-Ni^{2+}-agarose, available from the suppliers described above. Other matrices with different properties are also available. A proprietary Co^{2+} chelate (Talon) is said to bind His-6-tagged proteins with higher affinity, and somewhat higher selectivity, but it cannot be conveniently regenerated in the laboratory and is consequently much more expensive.

Rocking platform

Vectors and Bacterial Strains

E. coli *cells expressing a polyhistidine-tagged protein (generated in Protocol 1, 2, 3, or 4)*

METHOD

Preparation of the Ni^{2+} Affinity Column

1. Gently invert the bottle of Ni^{2+}-charged chromatography resin to mix the slurry, and transfer 2 ml to a small polypropylene or glass column. Allow the resin to pack under gravity flow.
2. Wash the resin with 3 column volumes of sterile H_2O.

   One column volume is equivalent to the volume of the settled bed of resin.
3. Equilibrate the resin with 3 column volumes of binding buffer (pH 7.8). The column is now ready for use in Step 9.

Preparation of Cell Extract

4. Resuspend the cell pellet (e.g., from Protocol 1, Step 17) in 4 ml of binding buffer (pH 7.8) per 100 ml of cell culture.
5. Add lysozyme to a final concentration of 1 mg/ml and incubate the cell suspension on ice for 30 minutes.

   Several protocols use sonication or a French press to lyse cells before affinity purification of the polyhistidine-tagged protein. The use of lysozyme, as described here, is somewhat more reproducible and avoids the cataclysmic lysis that can release membrane proteins and other molecules that cause aggregation of the polyhistidine-tagged protein.

   ▲ **IMPORTANT** Protease inhibitors may be added, but do not add EDTA or other chelators, which will remove the Ni^{2+} from the affinity resin, destroying its ability to bind histidine.
6. Incubate the mixture on a rocking platform for 10 minutes at 4°C.
7. Add Triton X-100, DNase, and RNase to the tube to final concentrations of 1%, 5 µg/ml, and 5 µg/ml, respectively, and continue the incubation with rocking for another 10 minutes at 4°C.
8. Remove the insoluble debris by centrifugation at 3000*g* (5000 rpm in a Sorvall SS-34 rotor) for 30 minutes at 4°C. Collect the supernatant (cell lysate) in a fresh tube.

   It may be necessary to pass the supernatant through a 0.45-µm filter to prevent clogging of the resin during purification of the polyhistidine-tagged protein.

Purification of the Polyhistidine-tagged Protein

9. Allow the binding buffer above the resin to drain to the top of the column.
10. Immediately load the cell lysate (Step 8) onto the column. Adjust the flow rate to 10 column volumes per hour.

    Ni^{2+} affinity resins will typically bind ~8–12 mg of protein per milliliter of resin. The amount of polyhistidine-tagged protein produced in *E. coli* will vary depending on the target protein, but it is typically in the range of 1–10 mg of protein per 100 ml of cell culture.
11. Wash the column with 6 column volumes of binding buffer (pH 7.8).
12. Wash the column with 4 volumes of wash buffer (pH 6.0). Continue washing the column until the A_{280} of the flowthrough is <0.01.
13. Elute the bound protein with 6 volumes of 10 mM imidazole elution buffer. Collect 1-ml fractions from the column, and monitor the A_{280} of each fraction.
14. Repeat Step 13 using imidazole elution buffers containing increasing concentrations of imidazole (i.e., 50 mM, 100 mM, and 150 mM imidazole).

    Alternatively, elute the protein using a continuous gradient of increasing imidazole concentration from 10 mM to 100 mM. Most His-tagged proteins will elute between 50 mM and 100 mM imidazole. Instead of using imidazole, the bound protein can be eluted using buffers of decreasing pH (please see the panel on **ALTERNATIVE PROTOCOL: ELUTION OF POLYHISTIDINE-TAGGED PROTEINS FROM METAL AFFINITY COLUMNS USING DECREASING pH**).
15. Assay the fractions of interest for the presence of the polyhistidine-tagged protein by analyzing 20-µl aliquots by electrophoresis through a 10% SDS-polyacrylamide gel.

ALTERNATIVE PROTOCOL: ELUTION OF POLYHISTIDINE-TAGGED PROTEINS FROM METAL AFFINITY COLUMNS USING DECREASING pH

As an alternative to imidazole, polyhistidine-tagged proteins may be eluted from the affinity column using a series of buffers of decreasing pH.

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Additional Materials

Low pH elution buffer (pH 4.0)
20 mM sodium phosphate
500 mM NaCl
Use phosphoric acid <!> to lower the pH to 4.0.

Wash buffer II (pH 5.5)
20 mM sodium phosphate
500 mM NaCl

Method

1. Carry out the main protocol through Step 12.
2. Wash the column with 6 volumes of Wash buffer II (pH 5.5).
3. Elute the bound protein with 6 volumes of low pH elution buffer (pH 4.0). Collect 1-ml fractions from the column, and monitor the A_{280} of each fraction.
4. Assay the fractions of interest for the presence of the polyhistidine-tagged protein by analyzing 20-µl aliquots by electrophoresis through a 10% SDS-polyacrylamide gel.

ADDITIONAL PROTOCOL: REGENERATION OF NTA-Ni^{2+}-AGAROSE

NTA-Ni^{2+}-agarose can be reused almost indefinitely if it is washed well and regenerated. If the column has not been oxidized or depleted (loss of light blue color or appearance of yellow/brown color), the manufacturer recommends washing with 0.2 M acetic acid in 30% glycerol. We routinely strip and regenerate the matrix after every use according to the manufacturer's recommendation (Qiagen in this case).

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Additional Materials

6 M guanidinium chloride/0.2 M acetic acid <!>
2% (w/v) SDS
25%, 50%, and 75% ethanol (all v/v)
100 mM EDTA
0.1 M $NiSO_4$ <!>

Method

1. Wash the column successively with

   2 volumes of 6 M guanidinium chloride/0.2 M acetic acid (or other stripping agent)
   5 volumes of H_2O
   2 volumes of 2% SDS
   1 volume each of 25%, 50%, and 75% ethanol
   5 volumes of ethanol
   1 volume each of 75%, 50%, and 25% ethanol
   1 volume of H_2O
   5 volumes of 100 mM EDTA
   1 volume of H_2O

2. Regenerate the column with <2 volumes 0.1 M $NiSO_4$, wash with H_2O, and equilibrate with the appropriate chromatographic buffer.

   The column should be white after the EDTA wash (or after elution of protein with EDTA) and should return to a pale blue color after regeneration.

Protocol 8

Purification of Expressed Proteins from Inclusion Bodies

THE EXPRESSION OF FOREIGN PROTEINS AT HIGH LEVELS IN *E. COLI* often results in the formation of cytoplasmic granules or inclusion bodies composed of insoluble aggregates of the expressed protein. These inclusion bodies can be seen with a phase-contrast microscope and are readily separated from most soluble and membrane-bound bacterial proteins as described in this protocol. Briefly, cells expressing high levels of foreign protein are concentrated by centrifugation and lysed by mechanical techniques, sonication, or lysozyme plus detergents. The inclusion bodies are recovered by centrifugation and washed with Triton X-100 and EDTA (Marston et al. 1984) or urea (Schoner et al. 1985). The purpose of the washing steps is to remove as much soluble, adherent bacterial protein as possible from the aggregated foreign protein. In most cases, adjusting the washing conditions allows the isolation of inclusion bodies that contain >90% pure foreign protein. The material extracted from the purified inclusion body can be used directly as an antigen (Harlow and Lane 1988).

To obtain soluble, active protein, the washed inclusion bodies are solubilized and the denatured target protein is then refolded. Various conditions (e.g., guanidine HCl [5–8 M], urea [6–8 M], SDS, alkaline pH, or acetonitrile/propanol) may be used to solubilize the inclusion bodies (Marston 1987). Other methods such as passage of cell suspensions through a French Press or sonication can also be used to lyse cells containing inclusion bodies. Proteins expressed from T7 RNA polymerase vectors in cells containing pLys plasmids can be lysed by methods described in Protocol 2. With all of these procedures, it is crucial to obtain maximum cell lysis in order to obtain inclusion bodies in high yields. Each protein may require a slightly different procedure, which must be determined empirically (please see Mitraki and King 1989). The procedure given below has been used to solubilize prorennin inclusion bodies and is adapted from Marston et al. (1984). Various options for refolding solubilized proteins are outlined in the panel on **ADDITIONAL PROTOCOL: REFOLDING SOLUBILIZED PROTEINS RECOVERED FROM INCLUSION BODIES** at the end of this protocol.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Cell lysis buffer I

50 mM Tris-Cl (pH 8.0)
1 mM EDTA (pH 8.0)
100 mM NaCl

Cell lysis buffer II, ice cold

50 mM Tris-Cl (pH 8.0)
10 mM EDTA (pH 8.0)
100 mM NaCl
0.5% (v/v) Triton X-100

Deoxycholic acid

Use a protein grade of this bile acid/detergent.

HCl (12 M) (concentrated HCl) <!>

Inclusion-body solubilization buffer I

50 mM Tris-Cl (pH 8.0)
1 mM EDTA (pH 8.0)
100 mM NaCl
8 M urea
0.1 M PMSF

Prepare the buffer fresh just before use.

Inclusion-body solubilization buffer II

50 mM KH_2PO_4 (pH 10.7)
1 mM EDTA (pH 8.0)
50 mM NaCl

KOH (10 N) <!>

PMSF (100 mM) <!>

1x and 2x SDS gel-loading buffer

Store 1x and 2x SDS gel-loading buffer lacking dithiothreitol at room temperature. Add dithiothreitol from a 1 M stock just before the buffer is used.

Tris-Cl (0.1 M, pH 8.5) with urea

For use in Method 2 only; please see Step 7. Prepare 0.1 M Tris-Cl (pH 8.5) with increasing concentrations of urea (e.g., 0.5, 1, 2, and 5 M). Make the solution fresh from solid urea and use immediately. Do not use solutions containing urea that have been stored for any period of time, because the urea decomposes.

Enzymes and Buffers

DNase I (1 mg/ml)

Lysozyme (10 mg/ml)

Prepare the solution fresh in Tris-Cl (pH 8.0).

Gels

Polyacrylamide gels (10%) containing SDS <!>

For preparation of SDS-polyacrylamide gels used in the separation of proteins, please see Appendix 8.

Centrifuges and Rotors

Sorvall GSA rotor or equivalent

Special Equipment

pH paper

Optional, please see Step 10.

Polished glass rod

Vectors and Bacterial Strains

E. coli *cells expressing the protein of interest*

Grow 1 liter of *E. coli* cells that have been transformed by any of the methods in Protocols 1–4 and now expresses the protein of interest as inclusion bodies.

METHOD

Preparation of Cell Extract

1. Centrifuge 1 liter of the cell culture of *E. coli* expressing the protein of interest at 5000*g* (5500 rpm in a Sorvall GSA rotor) for 15 minutes at 4°C in preweighed centrifuge bottles.

   ▲ **IMPORTANT** Perform Steps 2–4 at 4°C.

2. Remove the supernatant and determine the weight of the *E. coli* pellet. For each gram (wet weight) of *E. coli*, add 3 ml of Cell lysis buffer I. Resuspend the pellet by gentle vortexing or by stirring with a polished glass rod.

3. For each gram of *E. coli*, add 4 µl of 100 mM PMSF and then 80 µl of 10 mg/ml lysozyme. Stir the suspension for 20 minutes.

   Other cocktails of protease inhibitors may be added at this step (please see Protocol 1).

4. Stirring continuously, add 4 mg of deoxycholic acid per gram of *E. coli*.

5. Store the suspension at 37°C and stir it occasionally with a glass rod. When the lysate becomes viscous, add 20 µl of 1 mg/ml DNase I per gram of *E. coli*.

6. Store the lysate at room temperature until it is no longer viscous (~30 minutes).

Purification and Washing of Inclusion Bodies

7. Purify and wash the inclusion bodies using one of the following two methods.

METHOD 1: RECOVER INCLUSION BODIES USING TRITON X-100

The following procedure is adapted from Marston et al. (1984).

a. Centrifuge the cell lysate at maximum speed for 15 minutes at 4°C in a microfuge.

b. Decant the supernatant. Resuspend the pellet in 9 volumes of Cell lysis buffer II at 4°C.

c. Store the suspension for 5 minutes at room temperature.

d. Centrifuge the tube at maximum speed for 15 minutes at 4°C in a microfuge.

e. Decant the supernatant and set it aside for the next step. Resuspend the pellet in 100 µl of H_2O.

f. Remove 10-µl samples of the supernatant and of the resuspended pellet. Mix each sample with 10 µl of 2× SDS gel-loading buffer and analyze the samples by SDS-polyacrylamide gel electrophoresis to determine which fraction contains the protein of interest.

g. If necessary, proceed with Step 8 to solubilize the inclusion bodies.

METHOD 2: RECOVER INCLUSION BODIES USING UREA

The following procedure, adapted from Schoner et al. (1985), involves washing and solubilization of inclusion bodies with buffers containing different concentrations of urea.

a. Centrifuge the cell lysate at maximum speed for 15 minutes at 4°C in a microfuge.

▲ **IMPORTANT** Perform Steps b, d, and f at 4°C.

b. Decant the supernatant. Resuspend the pellet in 1 ml of H_2O per gram of *E. coli*. Transfer 100-µl aliquots to four microfuge tubes and store the remainder of the suspension at 4°C.

c. Centrifuge the 100-µl aliquots at maximum speed for 15 minutes at 4°C in a microfuge.

d. Discard the supernatants. Resuspend each pellet in 100 µl of 0.1 M Tris-Cl (pH 8.5) containing a different concentration of urea (e.g., 0.5, 1, 2, and 5 M).

e. Centrifuge the tubes at maximum speed for 15 minutes at 4°C in a microfuge.

f. Decant the supernatants and set them aside for the next step. Resuspend each pellet in 100 µl of H_2O.

g. Remove 10-µl samples of each supernatant and each resuspended pellet. Mix each sample and resuspended pellet with 10 µl of 2X SDS gel-loading buffer and analyze by SDS-polyacrylamide gel electrophoresis to determine which concentration of urea yields the best recovery of the inclusion bodies.

h. Use the appropriate concentration of urea, determined in Step g, to wash the remaining pellet (from Step b) as described in this method.

i. If necessary, proceed with Step 8 to solubilize the inclusion bodies.

Solubilization of Inclusion Bodies

8. Centrifuge the appropriate resuspended pellets from Step 7 at maximum speed for 15 minutes at 4°C in a microfuge, and suspend them in 100 µl of Inclusion-body solubilization buffer I containing 0.1 mM PMSF (freshly added).

9. Store the solution for 1 hour at room temperature.

10. Add this solution to 9 volumes of Inclusion-body solubilization buffer II and incubate the mixture for 30 minutes at room temperature. Check that the pH is maintained at 10.7 by spotting small aliquots onto pH paper. If necessary, readjust the pH to 10.7 with 10 N KOH.

11. Adjust the pH of the solution to 8.0 with 12 M HCl, and store the adjusted solution for at least 30 minutes at room temperature.

12. Centrifuge the solution at maximum speed for 15 minutes at room temperature in a microfuge.

13. Decant the supernatant and set it aside for the next step. Resuspend the pellet in 100 µl of 1X SDS gel-loading buffer.

14. Remove 10-µl samples of the supernatant and resuspended pellet. Mix the supernatant sample with 10 µl of 2X SDS gel-loading buffer. Analyze both samples by SDS-polyacrylamide gel electrophoresis to determine the degree of solubilization. Proceed with the additional protocol.

ADDITIONAL PROTOCOL: REFOLDING SOLUBILIZED PROTEINS RECOVERED FROM INCLUSION BODIES

Renaturation and refolding of solubilized protein occur during gradual removal of denaturing agents and/or detergents. Of necessity, this involves exposure of hydrophobic regions of the protein to solvent, a process which, unless conditions are carefully controlled, can lead to the formation of insoluble aggegates and/or soluble but inactive multimers. In many cases, considerable work is required to suppress formation of these off-pathway aggregates and thereby allow protein monomers to fold into a fully native conformation. The yield of active protein or of protein with the native structure depends on many factors including the size, number, and distribution of hydrophobic amino acids; the number of repeat structures in the polypeptide; the concentration, purity, and size of the polypeptide; the pH and ionic strength of the solvent; the number of disulfide bonds in the molecule; and, finally, the rate of refolding.

Few general guidelines are possible because the conditions that promote efficient refolding vary widely from protein to protein. Common sense, however, suggests that it would be best to establish a basic set of conditions that minimizes chemical modification of amino acid side chains, inhibits proteolysis, and, in the case of cytosolic proteins, suppresses formation of intermolecular disulfide bonds during purification of the denatured protein. The refolding process can then be optimized by gradually reducing the concentration of denaturing agents and, for secreted proteins, by shifting the balance between oxidizing and reducing conditions at various stages during solubilization and renaturation (Wulfing and Pluckthun 1994). For details of several protocols that have been used successfully with different proteins, please see Marston (1987) and Burgess (1996). The sequence of recovery, solubilization, and refolding of expressed protein from inclusion bodies is diagrammed in Figure 15-6.

Various commercial resources are available for determining the most appropriate refolding strategy for the particular protein under study (e.g., please see the protocols and reagents provided with the Protein Refolding Kit, available from Novagen at www.novagen.com). Although no refolding method is perfect, a technique that yields even a few percent of the expressed protein in an active form will usually provide enough material for subsequent biochemical experimentation. It is often possible to separate the refolded protein from the unfolded and aggregated forms of the polypeptide by gel filtration chromatography (Lin et al. 1989).

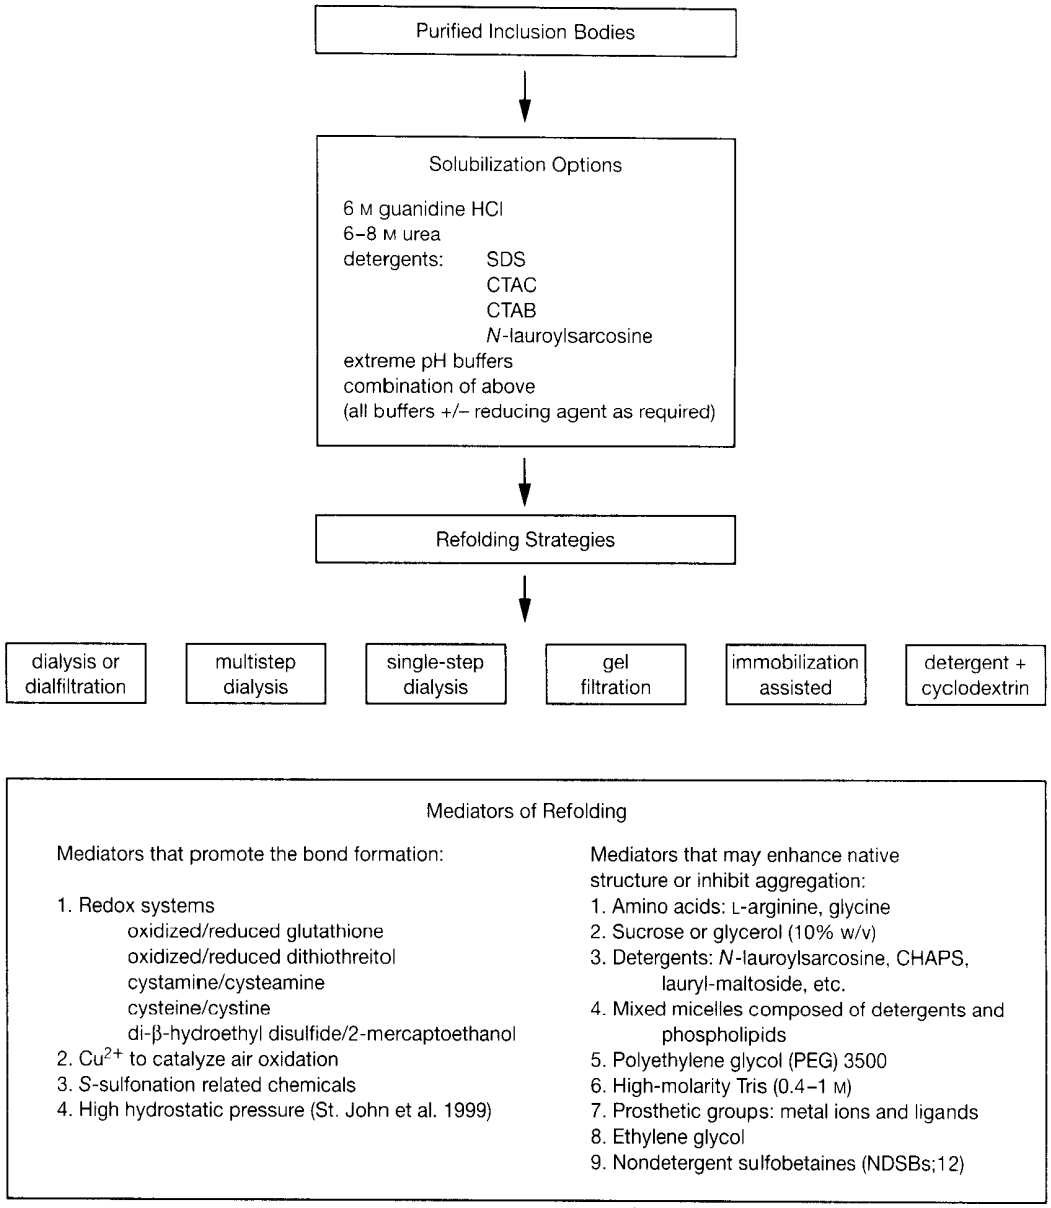

FIGURE 15-6 Methods for Protein Refolding

A number of strategies are presented that are used to optimize the recovery of functional target protein. Inclusion bodies may be solubilized by exposure to high molarity denaturants, detergents, acidic or alkali buffers, or a combination of reagents. Following solubilization, the target protein may be subjected to any of various strategies for refolding that result in the removal of the solubilizing agent. The most effective strategy for a particular protein must be determined empirically. In general, the presence of cysteine residues in the target protein, or specific requirements for proper formation of essential disulfides, will dictate the use of a reducing agent in the solubilization and refolding buffers. (Reprinted, with permission, from Novagen, Inc.)

EXPRESSION OF CLONED GENES

Expression of cloned genes is perhaps the last area of molecular cloning that retains some vestige of the pioneering spirit. Because the routes for isolating genes and cDNAs are now so well-mapped and because enzymes and reagents of high quality are available at almost every step of the way, cloners can usually travel from protein to gene in comfort and with reasonable confidence. However, there is one region of molecular cloning — expression of cloned genes — of which travellers must beware. It is a maze of mirages where success depends on chance and experience may be of little benefit. It is the one area in molecular cloning where investigators can do everything perfectly and still see the experiments fail.

The reasons for this are clear. Too little is known about the mechanism of folding of proteins in different organisms to predict which host-vector system might be best for a given protein, and few methods are available to increase the efficiency of folding or to prevent the aggregation, denaturation, and/or degradation of foreign proteins expressed in environments that are unnatural to them. In the absence of any useful guiding principles, the expression of every cDNA or gene presents a unique set of problems, which must be solved empirically.

Selection of an Expression System

Five major expression systems have been developed to a point where they are reasonably portable from one laboratory to another, where the necessary components and vectors are readily available from commercial sources or public repositories, and where success can be documented with more than a handful of proteins. The host cells for these systems are *E. coli, Bacillus subtilis, Saccharomyces cerevisiae*, cultured insect cells, and cultured mammalian cells. Very few, if any, laboratories have all five of these systems running and most investigators will have to choose among the various options.

- ***Expression in* E. coli**. Please see Chapter 15.
- ***Expression in mammalian systems***. Please see Chapter 17.
- ***Expression in* Saccharomyces cerevisiae.** Although the range of available expression vectors is extensive (Emr 1990), few foreign proteins have been produced in yeast at levels that are more than modest. *S. cerevisiae* is generally a fairly inefficient factory for recombinant proteins. However, the extremely powerful genetic systems of the organism have been exploited in two important ways, neither of which requires massive overproduction of foreign proteins: First, because many mutants of *S. cerevisiae* can be complemented by expression of the homologous mammalian proteins, yeasts may be used as hosts for the isolation of mammalian cDNAs by complementation. Second, the powerful genetics of yeast have been elegantly exploited to develop selective systems for the isolation of genes that encode pairs of interacting proteins (please see Chapter 18, Protocol 1).
- ***Expression in* Bacillus subtilis.** *B. subtilis* has a well-developed secretory system, and recombinant proteins can often be delivered to the medium in high yield in a soluble and active form. However, this is not necessarily a great advantage since *B. subtilis* also secretes a number of proteases with powerful degradative activities. In addition, the range of vectors is rather limited, and there are few examples of proteins that can be expressed more efficiently in *B. subtilis* than in *E. coli*.
- ***Expression in cultured insect cells.*** The baculovirus expression system is used to generate large quantities of recombinant proteins in cultured insect cells. A potential advantage of the system is that proteins secreted from insect cells undergo a form of complex glycosylation. However, a major disadvantage is that expression of the foreign protein occurs during acute lytic infection of cells with a recombinant baculovirus stock. Protein production therefore occurs for only a short period of time and results in cell death. Consequently, there is a constant need to generate new virus stocks and new cells for infection. Please see the information panel on **BACULOVIRUSES AND BACULOVIRUS EXPRESSION SYSTEMS** in Chapter 17.

E. COLI EXPRESSION SYSTEMS

Expression of foreign genes in bacteria has always been the Grail of molecular cloning. The early cloners were remarkably confident that *E. coli* could be reprogrammed to elaborate any desired protein in quantities sufficient for any desired purpose. During the Great Recombinant DNA debate of the early 1970s, the idea that there might be problems in constructing strains of *E. coli* that would make proteins to order was hardly questioned. In fact, much of the discussion centered around the degrees of physical and biological containment that would be required to protect the world from bacteria that expressed this or that foreign gene. Synthesis of foreign proteins in prokaryotes was feared as the approaching apocalypse by the Luddite fringe and was simultaneously peddled to Wall Street as an apotheosis by the more entrepreneurial of the molecular biologists.

As it turned out, neither the dark paranoia nor the day-glo optimism of those times was justified. The doomsayers were spectacularly wrong, as they since have been about other perceived dangers in molecular cloning. In the 20 years since the Asilomar conference, many thousands of strains of *E. coli* have been constructed that express foreign proteins, without untoward consequences. In recognition of this fact, most of the regulations that restricted expression work in *E. coli* were dropped in the United States a few years after Asilomar, with only token opposition from the hard-core pessimists. As for the entrepreneurs, only a few of them became rich from proteins that were synthesized in *E. coli*. For the most part, these proteins were small cytokines and growth factors whose secretion into medium could be easily engineered. Larger secreted proteins and cytosolic proteins of all sizes proved to be far more difficult to produce. After several years of effort to solve problems of prokaryotic expression, most genetic engineering companies abandoned *E. coli* in favor of eukaryotic cells as the means to produce larger secreted proteins.

Although the solutions remain elusive, the reasons for these problems are clear enough. Too little is known about the mechanism of folding of proteins in *E. coli*, and few infallible methods are available either to increase the efficiency of folding or to prevent the aggregation, denaturation, and/or degradation of foreign proteins expressed at high levels in an environment that is unnatural to them. In some cases, the use of mutants of *E. coli* (e.g., *lon* mutants) that are defective in degradation has proven helpful; in many other cases, solubility problems have been alleviated by expressing the polypeptide of interest as part of a hybrid protein. However, most nonsecreted proteins synthesized in *E. coli* accumulate as denatured aggregates, called inclusion bodies, which can be purified by differential centrifugation (for review, please see Marston 1986; Cousens et al. 1987). These aggregates are insoluble in aqueous buffers at neutral pH, but they usually can be dissolved in buffers that are markedly acidic or alkaline or contain high concentrations of detergents, organic solvents, or denaturants. In a few cases, it has then been possible to fold the solubilized protein in vitro into an active or native state (for reviews, please see Marston 1986; Kohno et al. 1990).

Most success with *E. coli* expression systems has been achieved with small secretory proteins (Goeddel 1990), which can be translocated into the periplasmic space of *E. coli*, from where they can be recovered and purified, sometimes in an active form. To achieve maximum efficiency, however, it is usually necessary to replace the eukaryotic hydrophobic signal sequences with a bacterial signal sequence and cleavage site. It is unreasonable to expect secretory proteins that depend on glycosylation or specific proteolytic cleavage to be recovered in an active state.

As indicated above, small cytosolic proteins and polypeptides (<100 residues in length) are best expressed in *E. coli* as fusion proteins. The carrier sequences often stabilize the protein of interest against intracellular degradation and provide a binding site that can be used for affinity purification. The protein of interest can sometimes be recovered in an active form by including a proteolytic cleavage site at an appropriate location in the fusion protein.

During the last 20 years, many different carrier sequences have been used in hybrid proteins. Any one of them may work well in a specific construct or in a particular bacterial strain, but none of them is a universal panacea. However, newly developed expression systems that utilize *E. coli* protein thioredoxin as a carrier appear to be a significant improvement over more traditional fusion partners, such as β-galactosidase. The following are the two most problematic groups of proteins.

- ***Cytosolic proteins*** >100 residues are sometimes toxic, often unstable, and frequently form insoluble inclusion bodies.

- ***Large cell-surface proteins and secretory proteins*** are translocated inefficiently across the inner membrane of *E. coli*, and only a small fraction of the molecules that reach the periplasmic space are able to fold into an active configuration. Perhaps this is not surprising in view of the fact that in mammalian cells, transport, folding, and biological activity of cell surface and large secretory proteins are often dependent on the correct constellation of chaperone proteins, as well as glycosylation and/or other forms of posttranslational modification.

In the absence of any informing principles that would help to find a general solution to the problems of intracellular protein folding, the expression of every cDNA encoding "difficult" proteins in *E. coli* presents a unique set of problems, which must be solved empirically.

LACZ FUSIONS

Gene fusions are created by joining together two pieces of DNA that were not previously connected. Often, the regulatory sequences of the gene of interest are placed upstream of sequences coding for a reporter molecule whose level of expression can be easily measured, for example, β galactosidase. This type of gene fusion allows rapid experimental analysis of the physiological conditions affecting the expression of the gene of interest; and it facilitates mutational analysis of the upstream regulatory region. Gene fusions are also used to create hybrid proteins in which the protein of interest is attached to the amino terminus or the carboxyl terminus of a carrier protein. Many vector systems have been developed for the expression of *lacZ* fusion genes. Some of these are listed in Table 15-6. LacZ fusion proteins have several advantages:

- Their expression is placed under the dominion of a well-characterized promoter whose activity can be increased by several orders of magnitude by simple manipulation of the bacterial culture. Transcription of LacZ is subject to both negative and positive regulation. Negative regulation is exerted by the Lac repressor, which binds to the operator (LacO) and prevents synthesis of *lac* mRNA. The *lac* repressor, a tetrameric protein of 150 kD, is encoded by the *lacI* gene. Normally, there are about ten molecules of repressor per cell, sufficient to smother, but not completely strangle, transcription of the Lac operon. In the absence of inducer, basal expression generates ~60 molecules of the monomer of β-galactosidase per cell when *lacZ* is carried as a chromosomal F′ gene, and higher levels when the gene is carried on a multicopy plasmid. Because this level of basal expression may lead to problems if a LacZ fusion protein is expressed that is toxic to *E. coli*, many LacZ fusion systems make use of a mutant *lacI* gene (*lacI*^{q}; Müller-Hill et al. 1968) that synthesizes about tenfold more repressor than wild type. This overproduction of repressor suppresses the basal level of transcription of the Lac operon in the absence of inducer. Repression of the LacZ operon is relieved by inducers, such as IPTG, which bind to the repressor and cause a conformational change that lowers the affinity of the repressor for the *lac* operator. A fully induced culture of *E. coli* contains ~60,000 molecules of *lacZ* β-galactosidase per cell.

  In addition to an inducer such as IPTG, the efficient expression of *lacZ* requires cAMP and an activator protein, CAP. The cAMP-bound form of CAP binds with high affinity to a site in the *lac* promoter (Majors 1975) and facilitates binding of RNA polymerase. Because CAP acts in a positive fashion, this type of regulation is called positive control. In the absence of CAP, the levels of *lac* gene products are reduced up to 50-fold (Beckwith et al. 1972). The activity of CAP is controlled by the intracellular level of cAMP, which is, in turn, regulated by the concentration of glucose. Growth of cells on glucose reduces the intracellular concentration of cAMP and inhibits induction of the *lac* operon.
- The fusion protein inherits a ribosome-binding site and initiation sequence whose efficiency is proven. *lacZ* does not have a particularly good Shine-Dalgarno sequence, and the sequences immediately surrounding the start codon are not optimal for initiation of translation (Hui et al. 1984). Nevertheless, ini-

tiation of protein synthesis occurs efficiently enough that it is not normally a limiting factor in expression of LacZ fusion proteins.

- The *lacZ* segment of the fusion protein serves as an identification tag that can be used for affinity purification on Sepharose columns containing the immobilized inhibitor of β-galactosidase, *p*-aminophenyl-β-D-thio-galactoside (also known as TPEG or APTG) (Steers et al. 1971; Germino et al. 1983; Ullmann 1984).
- Fusion to *lacZ* offers some protection against the intracellular proteolysis that lays waste to many foreign proteins expressed in *E. coli*. Produced on their own, these proteins evidently fold into conformations that are susceptible to degradation by ATP-dependent proteases such as *lon* and *clp* (Gottesman 1989). This fate is particularly true of small polypeptides such as somatostatin (Itakura et al. 1977), insulin (Goeddel et al. 1979), and β-endorphin (Shine et al. 1980). When attached to *lacZ* or another carrier, these proteins are stabilized to the point where the fusion protein can comprise 20% of the total cell protein (for review, please see Marston 1986).
- Finally, the high levels of expression that can be achieved with LacZ fusion proteins promote the formation of insoluble aggregates or inclusion bodies, which can be isolated easily (Marston 1987). However, to obtain active fusion protein, the inclusion bodies must be dissolved in strongly denaturing buffers, and the fusion protein must then be purified and refolded. These steps are not trivial, and conditions for each of them must be developed empirically. For reasons that are not understood, foreign proteins attached to the carboxyl terminus of *lacZ* are usually sequestered into inclusion bodies; amino-terminal fusion proteins are generally soluble and can be directly purified from cell lysates by affinity chromatography.

Like other expression systems, LacZ fusions have some disadvantages. First, only a small fraction of the amino acid residues of the fusion proteins may belong to a foreign protein. Second, to obtain biologically active material, the foreign protein usually must be cleaved, either enzymatically or chemically, from its LacZ carrier. This cleavage can be accomplished by building a unique cleavage site between β-galactosidase and the fusion protein. However, if the fusion protein is insoluble, cleavage may be possible only after denaturation or in the presence of denaturant. This feature places restrictions on the types of enzymatic cleavage that can be used. Third, β-galactosidase is not a secreted protein and cannot be translocated across the membrane of *E. coli* even if it is equipped with a signal sequence. Typically, LacZ fusion proteins that carry functional signal sequences become jammed in the membrane and are toxic to the cell (Bassford et al. 1979; Moreno et al. 1980).

Despite these disadvantages, *lacZ* fusions were used successfully in the 1980s to express more than 50 proteins in *E. coli*. Nowadays, however, *lacZ* would probably not be the system of choice. Vectors containing promoters for bacteriophage T7 RNA polymerase have tighter transcription control and can drive higher levels of expression (Studier et al. 1990). Polyhistidine tracts (Smith et al. 1988) may now be the first choice for protein tags since they generally do not destroy protein function and allow affinity purification to be carried out under gentle conditions.

TABLE 15-6 Systems for Expression of LacZ Fusion Proteins

Plasmid Vector	Site of Insertion of Foreign DNA	Promoter	Comments	References
pUR series	carboxyl terminus of *lacZ*	UV5*lac*	Contains multiple cloning sites in all three reading frames.	Rüther and Müller-Hill (1983)
pUK series	amino terminus of *lacZ*	UV5*lac*	Contains cloning sites in all three reading frames.	Koenen et al. (1985)
pEX series	carboxyl terminus of *lacZ*	bacteriophage λp_R	Contains a cloning site in all three reading frames.	Stanley and Luzio (1984)
pMR100		UV5*lac* (2 copies)	When foreign DNA is inserted into the polycloning site, a fusion protein is synthesized that has the amino terminus of the bacteriophage λ cI gene, a central segment of foreign protein, and β-galactosidase at the carboxyl terminus.	Gray et al. (1982)
pAX series	carboxyl terminus of *lacZ*	*lac*	At the end of the *lacZ* gene, PAX vectors contain (1) a hinge region of 187 bp encoding a fragment of collagen, (2) an endoproteinase Xa recognition site followed by (3) a multiple cloning site and (4) the bacteriophage λ transcriptional terminator.	Germino and Bastia (1984)
pUC series, pGEMZ series, Bluescript series, and many others	amino terminus of α-fragment of β-galactosidase	*lac*	Contains multiple cloning sites in all three reading frames; insertion of foreign DNA in any frame abolishes α-complementation; insertion in the correct reading frame generates a LacZ–α-fragment fusion protein.	Messing (1983); Norrander et al. (1983); Yanisch-Perron et al. (1985) Product literature from Stratagene and Promega

UV5*lac* is a double mutant of the *lac* promoter in which a G to A transition lies adjacent to a T to A transversion in the RNA polymerase-binding site. UV5*lac* is an "up" promoter that allows transcription of the *lac* operon in the absence of the CAP-AMP complex (Dickson et al. 1975).

CHAOTROPIC AGENTS

In molecular cloning, chaotropic agents are used chiefly to destroy the three-dimensional structure of proteins. The most powerful of the commonly used protein denaturants are guanidinium isothiocyanate and guanidinium chloride, which convert most proteins to a randomly coiled state (Tanford 1968; Gordon 1972). The mechanism of this conversion is unclear, although it seems to involve binding of progressively greater amounts of the guanidinium salt to the protein as denaturation proceeds (Gordon 1972).

The first guanidinium salt to be used as a deproteinization agent during isolation of RNA was chloride (Cox 1968). Although it is a strong inhibitor of ribonuclease, guanidinium chloride (also known as guanidine chloride or aminoformamidine hydrochloride) is not a powerful enough denaturant to allow extraction of intact RNA from tissues that are rich in RNase, such as the pancreas. Guanidinium isothiocyanate (also known as guanidinium rhodanide or guanidine thiocyanate) is a stronger chaotropic agent because it contains a reductant to break protein disulfide bonds and potent cationic and anionic groups that form strong hydrogen bonds. The procedure of Chirgwin et al. (1979), which involves lysis of cells by guanidinium isothiocyanate and ultracentrifugation of the cell lysates through CsCl gradients (Glisin et al. 1973), has become a standard method for isolation of undegraded RNA. More recently, procedures have been developed that combine guanidinium thiocyanate and extraction with phenol/chloroform (Chomczynski and Sacchi 1987; Puissant and Houdebine 1990; please see Chapter 7, Protocol 1). Because the ultracentrifugation step is eliminated, many samples can be processed simultaneously at modest cost.

In a perverse fashion, chaotropic agents, such as guanidine hydrochloride, can also be used to enhance the renaturation of a denatured protein. This use finds two major applications in molecular biology. First, the overexpression of foreign proteins in heterologous hosts, such as *E. coli*, often leads to the formation of aggregates of the expressed protein. These so-called inclusion bodies are readily isolated by low-speed centrifugation and usually consist of almost pure accretions of denatured forms of the foreign protein. The inclusion bodies can sometimes be solubilized with 6 M solutions of guanidine hydrochloride, which acts by dissociating the aggregates and completely denaturing the protein. The unfolded foreign protein will often refold into its native conformation if the chaotropic agent is slowly removed from the solution by dialysis against buffer. This renaturation procedure has been used to refold hundreds of recombinant proteins (Marston 1987).

Second, a similar denaturation/renaturation protocol is useful when screening bacteriophage λ expression libraries with antibody or DNA-binding-site probes (Vinson et al. 1988). In this case, intact or fusion proteins expressed from cDNA inserts are transferred to nitrocellulose filters (Young and Davis 1983). The filters are then incubated in a series of buffers containing 6 M, 3 M, and 0 M guanidinium hydrochloride to denature and renature the expressed proteins. Finally, the filters are probed with an antibody specific for the protein of interest or with a concatenated DNA probe made up of repeats of a DNA sequence specifically recognized by the target protein (e.g., a DNA-binding transcription factor). Vinson et al. (1988) found that the inclusion of a denaturation/renaturation step in the screening procedure could make all or no difference in the identification of a particular cDNA.

Chapter 16

Introducing Cloned Genes into Cultured Mammalian Cells

A VARIETY OF STRATEGIES ARE AVAILABLE FOR THE DELIVERY of genes into eukaryotic cells. These techniques fall into three categories: transfection by biochemical methods, transfection by physical methods, and virus-mediated transduction. This chapter deals with the first two categories; the third approach is covered extensively in Section 8 of *Cells: A Laboratory Manual* (Spector et al. 1998b). The choice of a particular transfection method is determined by the experimental goal (e.g., the type of assay to be used for screening, the ability of the cell line to survive the stress of transfection, and the efficiency required of the system).

Biochemical methods of transfection, including calcium-phosphate-mediated and diethylaminoethyl (DEAE)-dextran-mediated transfection, have been used for nearly 30 years to deliver nucleic acids into cultured cells. The work of Graham and van der Eb (1973) on transformation of mammalian cells by viral DNAs in the presence of calcium phosphate laid the foundation for the biochemical transformation of genetically marked mouse cells by cloned DNAs (Maitland and McDougall 1977; Wigler et al. 1977), for the transient expression of cloned genes in a variety of mammalian cells (e.g., please see Gorman et al. 1983b), and for the isolation and identification of cellular oncogenes, tumor-suppressing genes, and other single-copy mammalian genes (e.g., please see Wigler et al. 1978; Perucho and Wigler 1981; Weinberg 1985; Friend et al. 1988). More recently, a collection of cationic lipid (liposome) reagents has been used successfully for gene delivery into a wider range of cell types. In all three of these chemical methods (calcium phosphate, DEAE-dextran, and cationic lipids), the chemical agent forms a complex with the DNA that facilitates its uptake into cells.

Two physical methods of transfection are in common use: Biolistic particle delivery and direct microinjection work by perforation of the cell membrane and subsequent delivery of the DNA into the cell; electroporation uses brief electrical pulses to create transient pores in the plasmid membrane through which nucleic acids enter.

TRANSIENT VS. STABLE TRANSFECTION

Two different approaches are used to transfer DNA into eukaryotic cells: transient transfection and stable transfection. In transient transfection, recombinant DNA is introduced into a recipient cell line in order to obtain a temporary but high level of expression of the target gene. The transfected DNA does not necessarily become integrated into the host chromosome. Transient transfection is the method of choice when a large number of samples are to be analyzed within a short period of time. Typically, the cells are harvested between 1 and 4 days after transfection, and the resulting lysates are assayed for expression of the target gene.

Stable or permanent transfection is used to establish clonal cell lines in which the transfected target gene is integrated into chromosomal DNA, from where it directs the synthesis of moderate amounts of the target protein. In general (depending on the cell types), the formation of stably transfected cells occurs with an efficiency that is one to two orders of magnitude lower than the efficiency of transient transfection. Isolation of the rare stable transformant from a background of nontransfected cells is facilitated by the use of a selectable genetic marker. The marker may be present on the recombinant plasmid carrying the target gene, or it may be carried on a separate vector and introduced with the recombinant plasmid into the desired cell line by cotransfection (for further details, please see the information panels on **COTRANSFORMATION** and **SELECTIVE AGENTS FOR STABLE TRANSFORMATION**). In general, all of the methods described below are suitable for use in transient transfection assays, and all, with the exception of DEAE-dextran, may be used for stable transfection.

TRANSFECTION METHODS

Until recently, cloned DNA has been introduced into cultured eukaryotic cells chiefly by biochemical methods. During the past 10 years, the range of cell types that can be transfected efficiently has been extended with the development of liposome methods, which work well with suspension cultures, and with the use of physical methods such as electroporation and biolistic particle delivery, which may be used successfully with many cell lines that are resistant to transfection by other means. A brief summary of transfection methods is given in Table 16-1.

TABLE 16-1 Transfection Methods

Method	Expression		Cell Toxicity	Cell Types	Comments
	Transient	Stable			
Lipid-mediated **Protocol 1**	yes	yes	varies	adherent cells, primary cell lines, suspension cultures	Cationic lipids are used to create artificial membrane vesicles (liposomes) that bind DNA molecules. The resulting stable cationic complexes adhere to and fuse with the negatively charged cell membrane (Felgner et al. 1987; Felgner et al. 1994).
Calcium-phosphate-mediated **Protocols 2 and 3**	yes	yes	no	adherent cells (CHO, 293); suspension cultures	Calcium phosphate forms an insoluble coprecipitate with DNA, which attaches to the cell surface and is absorbed by endocytosis (Graham and van der Eb 1973).
DEAE-dextran-mediated **Protocol 4**	yes	no	yes	BSC-1, CV-1, and COS	Positively charged DEAE-dextran binds to negatively charged phosphate groups of DNA, forming aggregates that bind to the negatively charged plasma membrane. Uptake into the cell is believed to be mediated by endocytosis, which is potentiated by osmotic shock (Vaheri and Pagano 1965).
Electroporation **Protocol 5**	yes	yes	no	many	Application of brief high-voltage electric pulses to a variety of mammalian and plant cells leads to the formation of nanometer-sized pores in the plasma membrane (Neumann et al. 1982; Zimmermann 1982). DNA is taken directly into the cell cytoplasm either through these pores or as a consequence of the redistribution of membrane components that accompanies the closure of the pores. Electroporation can be extremely efficient and may be used for both transient and stable transfection.
Biolistics **Protocol 6**	yes	yes	no	primary cell lines; tissues, organs, plant cells	Small particles of tungsten or gold are used to bind DNA, in preparation for delivery into cells, tissues, or organelles by a particle accelerator system (Sanford et al. 1993). This process has been variously called the microprojectile bombardment method, the gene gun method, and the particle acceleration method. Biolistics is used chiefly to transform cell types that are impossible or very difficult to transform by other methods.
Polybrene **Protocol 7**	yes	yes	varies	CHO and keratinocyte	The polycation Polybrene allows the efficient and stable introduction of low-molecular-weight DNAs (e.g., plasmid DNAs) into cell lines that are relatively resistant to transfection by other methods (Kawai and Nishizawa 1984; Chaney et al. 1986; Aubin et al. 1997). The uptake of DNA is enhanced by osmotic shock and dimethylsulfoxide (DMSO), which may permeabilize the cell membrane.

TRANSFECTION CONTROLS

All transfection experiments should include controls to test individual reagents and plasmid DNA preparations, and to test for toxicity of the gene or construct being introduced.

Controls for Transient Expression

Negative Controls

In transient transfection experiments, one or two dishes of cells should be transfected with the carrier DNA and/or buffer used to dilute the test plasmid or gene. Typically, salmon sperm DNA or another inert carrier such as the vector used to construct the recombinant is transfected into adherent cells in the absence of the test gene. After transfection, the cultured cells should not detach from the dish nor become rounded and glassy in appearance.

Positive Controls

One or two dishes of cells are transfected with a plasmid encoding a readily assayed gene product such as chloramphenicol acetyl transferase, luciferase, *Escherichia coli* β-galactosidase, or green fluorescent protein, whose expression is driven by a pan-specific promoter such as the human cytomegalovirus immediate early gene region promoter and enhancer. Tracer plasmids of this kind are available from many different commercial suppliers who sell kits containing the enzymes and reagents needed for detection of the encoded protein. Because the endogenous levels of these reporter activities are typically low, the increase in enzyme activity provides a direct indication of the efficiency of the transfection and the quality of the reagents used for a particular experiment. This control is especially important when comparing results of transfection experiments carried out at different times. Cotransfecting the reporter plasmid with the test plasmid or genomic DNA also provides a control for nonspecific toxicity in the overall transfection process.

Controls for Stable Expression

Negative Controls

One or two dishes should be transfected with an inert nucleic acid such as salmon sperm DNA, in the absence of the selectable marker. After culturing for 2–3 weeks in the presence of the selected agent (G418, hygromycin, mycophenolic acid), no colonies should be visible.

Positive Controls

One or two dishes of cells should be transfected with the plasmid encoding the selectable marker in the absence of any other DNA. The number of viable colonies present at the end of the 2–3-week selection period is a measure of the efficiency of the transfection/selection process. A similar number of colonies should be present on dishes into which both the selectable marker and the test plasmid or gene were introduced. A marked discrepancy in the number of colonies on these two sets of dishes can be an indication of a toxic gene product (or in rare instances of a gene product that enhances survival of the transfected cells). If a particular cDNA or gene proves toxic to

recipient cells, consider the use of a regulated promoter such as metallothionein (a Zn^{2+}- or Cd^{2+}-responsive DNA), the mouse mammary tumor virus long terminal repeat promoter (a glucocorticoid-responsive DNA), a tetracycline-regulated promoter (Gossen and Bujard 1992; Gossen et al. 1995; Shockett et al. 1995), or an ecdysone-regulated system (No et al. 1996). Alternatively, conditional alleles of some genes can be constructed (Picard et al. 1988).

OPTIMIZATION AND SPECIAL CONSIDERATIONS

Irrespective of the method used to introduce DNA into cells, the efficiency of transient or stable transfection is determined largely by the cell type that is used (please see Table 16-1). Different lines of cultured cells vary by several orders of magnitude in their ability to take up and express exogenously added DNA. Furthermore, a method that works well for one type of cultured cell

may be useless for another. Many of the protocols described in this chapter have been optimized for the standard lines of cultured cells. When using more exotic lines of cells, it is important to compare the efficiencies of several different methods. The protocols in this chapter present commonly used transfection techniques as well as methods that have proven successful with cell lines that are resistant to transfection by standard techniques. Commercial kits are available that provide collections of reagents for many types of transfections (please see Table 16-2).

Many techniques used in eukaryotic cell culture are not discussed in detail in this manual (for specific information on cell culture, please see Volume 1 of *Cells: A Laboratory Manual* [Spector et al. 1998a]). In particular, it is assumed that the conditions for optimal growth and passage of the cell lines to be used in this protocol have already been established.

The students study molecules now, spinning models across their computer screens and splicing the genes of one creature into those of another. The science of genetics is utterly changed.... Sometimes I wonder where we have misplaced our lives.

Andrea Barrett
"*The Behavior of the Hawkweeds.*"

Protocol 1

DNA Transfection Mediated by Lipofection

BECAUSE A LARGE NUMBER OF VARIABLES AFFECT THE EFFICIENCY of lipofection, we suggest that the conditions outlined in the following protocol be used as a starting point for systematic optimization of the system (for further details, please see the information panel on **LIPOFECTION** at the end of this chapter). Alternatively, a protocol recommended by a commercial manufacturer of a particular lipofectant can be used to begin the optimization process. Once a positive signal has been obtained with a plasmid carrying a standard reporter gene, each of the parameters discussed in the information panel on **LIPOFECTION** may be changed systematically to obtain the maximal ratio of signal to background and to minimize variability between replicate assays. From these results, optimal protocols can be developed to assay the expression of the genes of interest.

To explore the suitability of a wide variety of lipids for the task at hand, we recommend purchasing an optimization kit containing a series of individual lipids or combinations of lipids. Examples of such kits include the Tfx Reagents Transfection Trio (Promega), PerFect Lipid Transfection Kit (Invitrogen), and the Transfection Reagent Optimization System (Life Technologies).

The following protocol is a modification of a method provided by Mark Evans (Alexion Pharmaceuticals, New Haven, Connecticut).

MATERIALS

Buffers and Solutions

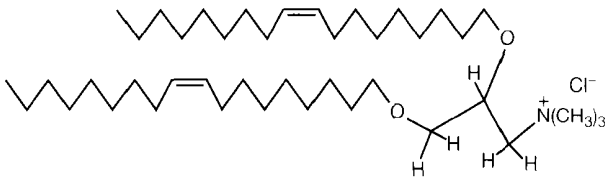
Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Lipofection reagent

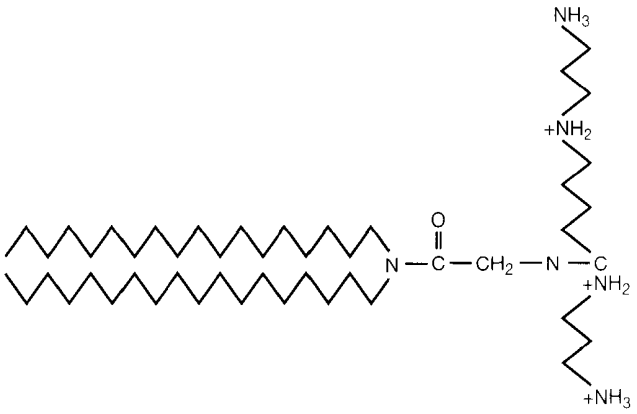
As illustrated in Table 16-4 and described in the information panel on **LIPOFECTION**, several types of lipofection reagents are available. This protocol describes the use of two common lipids:

- Lipofectin (*N*-[1-(2,3-dioleoyloxy)propyl]-*N*,*N*,*N*-trimethylammonium chloride [DOTMA]) (Figure 16-1). This monocationic lipid mixed with a helper lipid is usually purchased at a concentration of 1 mg/ml. DOTMA can also be synthesized with the help of an organic chemist (Felgner et al. 1987). If synthesized in-house, dissolve 10 mg each of dried DOTMA and the helper lipid dioleoyl phosphatidylethanolamine (DOPE, purchased from Sigma) in 2 ml of sterile deionized H_2O in a polystyrene tube (do not use polypropylene tubes). Sonicate the turbid solution to form liposomes before diluting to a final concentration of 1 mg/ml. Store the solution at 4°C.

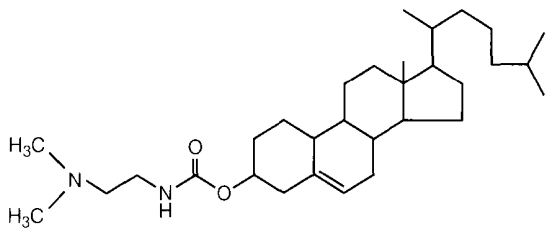
A. DOTMA



B. DOGS



C. DC-cholesterol



D. DOPE

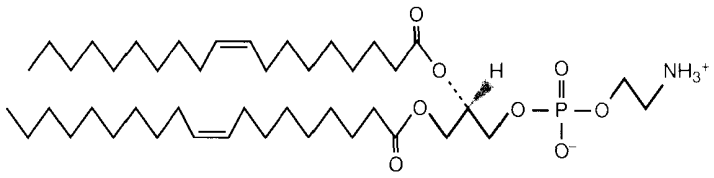


FIGURE 16-1 Structures of Lipids Used in Lipofection

For further descriptions of each of these lipids, please see Table 16-4.

TABLE 16-3 Dimensions of Dishes Used for Cell Culture

SIZE OF PLATE	GROWTH AREA (cm^2)	RELATIVE AREA[a]	RECOMMENDED VOLUME
96-well	0.32	0.04x	200 µl
24-well	1.88	0.25x	500 µl
12-well	3.83	0.5x	1.0 ml
6-well	9.4	1.2x	2.0 ml
35-mm	8.0	1.0x	2.0 ml
60-mm	21	2.6x	5.0 ml
10-cm	55	7x	10.0 ml
Flasks	25	3x	5.0 ml
	75	9x	12.0 ml

[a]Relative area is expressed as a factor of the growth area of a 35-mm culture plate.

- Transfectam (Spermine-5-carboxy-glycinedioctadecyl-amide [DOGS]) (Figure 16-1). Polycationic lipids such as DOGS may be substituted for Lipofectin in the protocol. DOGS can be purchased and reconstituted as directed (Promega) or the lipid may be synthesized in-house to save money (Loeffler and Behr 1993). If synthesized in the laboratory, prepare a stock solution as follows: Dissolve 1 mg of polyamine in 40 µl of 96% (v/v) ethanol for 5 minutes at room temperature with frequent vortexing. Add 360 µl of sterile H_2O and store the solution at 4°C. Vortex the solution just before use. Polyamines, such as DOGS, do not require the use of polystyrene tubes; polypropylene tubes (i.e., standard microfuge tubes) can be safely used with these reagents. Polystyrene tubes must be used with DOTMA, because the lipid can bind nonspecifically to polypropylene.

NaCl (5 M) (optional)

Use as the diluent for DOGS.

Sodium citrate (pH 5.5, 20 mM) containing 150 mM NaCl (optional)

Use instead of sterile H_2O as the diluent for the plasmid DNA if DOGS is the lipofection reagent (Kichler et al. 1998).

Nucleic Acids and Oligonucleotides

Plasmid DNA

If carrying out lipofection for the first time or if using an unfamiliar cell line, obtain an expression plasmid encoding *E. coli* β-galactosidase or green fluorescent protein (please see the information panel on **GREEN FLUORESCENT PROTEIN** in Chapter 17). These can be purchased from several commercial manufacturers (e.g., pCMV-SPORT-β-gal, Life Technologies, or pEGFP-F, CLONTECH; please see Figures 16-2 and 16-3).

Purify closed circular plasmid DNAs by column chromatography or ethidium bromide-CsCl gradient centrifugation as described in Chapter 1. Dissolve the DNAs in H_2O at 1 µg/µl.

Media

Cell culture growth medium (complete, serum-free, and [optional] selective)

Special Equipment

Test tubes, polystyrene or polypropylene

Polystyrene tubes must be used with DOTMA, because the lipid can bind nonspecifically to polypropylene.

Tissue culture dishes (60 mm)

This protocol is designed for cells grown in 60-mm culture dishes. If multiwell plates, flasks, or dishes of a different diameter are used, scale the cell density and reagent volumes accordingly. Please see Table 16-3.

Additional Reagents

Step 9 of this protocol may require the reagents listed in Chapter 17, Protocol 7.

Cells and Tissues

Exponentially growing cultures of mammalian cells

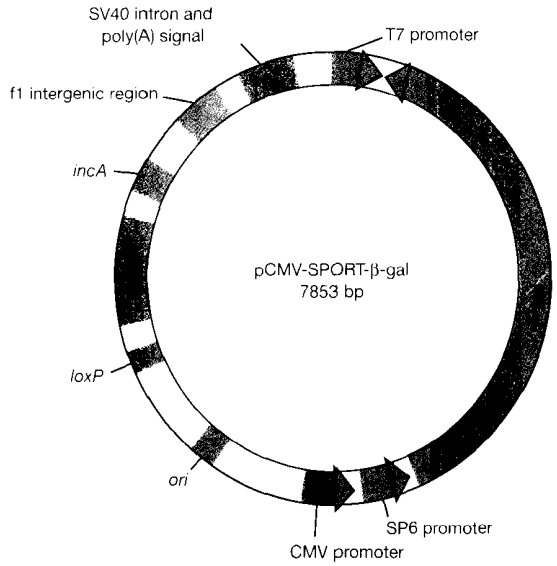

FIGURE 16-2 pCMV-SPORT-β-gal

pCMV-SPORT-β-gal is a reporter vector that may be used to monitor transfection efficiency. It carries the *E. coli* gene encoding β-galactosidase preceded by the CMV (cytomegalovirus) promoter that drives high levels of transcription in mammalian cells. The SV40 polyadenylation signal downstream from the β-galactosidase sequence directs proper processing of the mRNA in eukaryotic cells. (Reproduced, with permission, from Life Technologies, Inc.)

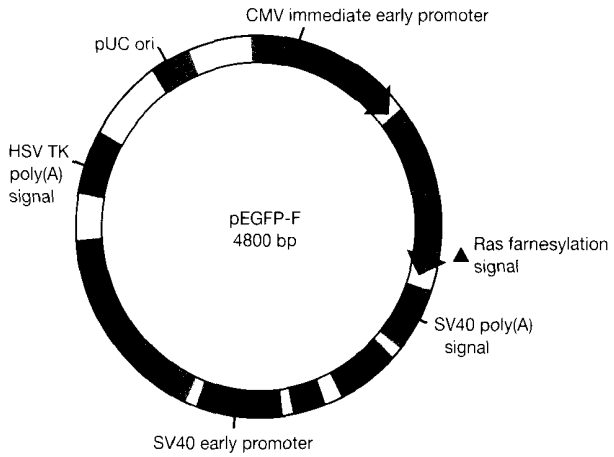

FIGURE 16-3 pEGFP-F

pEGFP-F is a reporter vector that may be used both to monitor transfection efficiency and as a cotransfection marker. The vector encodes a modified form of the green fluorescent protein, a farnesylated enhanced GFP (EGFP-F) that remains bound to the plasma membrane in both living and in fixed cells. The EGFP-F-coding sequence is preceded by the CMV (cytomegalovirus) promoter that drives high levels of transcription and is followed by the SV40 polyadenylation signal to direct proper processing of the mRNA in eukaryotic cells. The plasmid carries sequences that allow replication in prokaryotic (pUC ori) as well as eukaryotic (SV40 ori) cells and markers that facilitate selection for the plasmid in prokaryotic (kanamycin) cells as well as eukaryotic (neomycin) cells. The presence of EGFP-F can be detected by fluorescence microscopy. (Adapted, with permission, from CLONTECH.)

METHOD

1. Twenty-four hours before lipofection, harvest exponentially growing mammalian cells by trypsinization and replate them on 60-mm tissue culture dishes at a density of 10^5 cells/dish (or at 5×10^4 cells/35-mm dish). Add 5 ml (or 3 ml for 35-mm dish) of growth medium, and incubate the cultures for 20–24 hours at 37°C in a humidified incubator with an atmosphere of 5–7% CO_2.

   The cells should be ~75% confluent at the time of lipofection. If the cells are grown for fewer than 12 hours before transfection, they will not be well anchored to the substratum and are likely to detach during exposure to lipid.

2. For each 60-mm dish of cultured cells to be transfected, dilute 1–10 µg of plasmid DNA into 100 µl of sterile deionized H_2O (if using Lipofectin) or 20 mM sodium citrate containing 150 mM NaCl (pH 5.5) (if using Transfectam) in a polystyrene or polypropylene test tube. In a separate tube, dilute 2–50 µl of the lipid solution to a final volume of 100 µl with sterile deionized H_2O or 300 mM NaCl.

   ▲ **IMPORTANT** When transfecting with Lipofectin, use polystyrene test tubes; do not use polypropylene tubes, because the cationic lipid DOTMA can bind nonspecifically to polypropylene. For other cationic lipids, use the tubes recommended by the manufacturer.

3. Incubate the tubes for 10 minutes at room temperature.

4. Add the lipid solution to the DNA, and mix the solution by pipetting up and down several times. Incubate the mixture for 10 minutes at room temperature.

5. While the DNA-lipid solution is incubating, wash the cells to be transfected three times with serum-free medium. After the third rinse, add 0.5 ml of serum-free medium to each 60-mm dish and return the washed cells to a 37°C humidified incubator with an atmosphere of 5–7% CO_2.

   It is very important to rinse the cells free of serum before the addition of the lipid-DNA liposomes. In some cases, serum is a very effective inhibitor of the transfection process (Felgner and Holm 1989). Similarly, extracellular matrix components such as sulfated proteoglycans can also inhibit lipofection, presumably by binding the DNA-lipid complexes and preventing their interaction with the plasma membranes of the recipient cells.

6. After the DNA-lipid solution has incubated for 10 minutes, add 900 µl of serum-free medium to each tube. Mix the solution by pipetting up and down several times. Incubate the tubes for 10 minutes at room temperature.

7. Transfer each tube of DNA-lipid-medium solution to a 60-mm dish of cells. Incubate the cells for 1–24 hours at 37°C in a humidified incubator with an atmosphere of 5–7% CO_2.

8. After the cells have been exposed to the DNA for the appropriate time, wash them three times with serum-free medium. Feed the cells with complete medium and return them to the incubator.

9. If the objective is stable transformation of the cells, proceed to Step 10. Examine the cells 24–96 hours after lipofection using one of the following assays.

   - If a plasmid DNA expressing *E. coli* β-galactosidase was used, follow the steps outlined in Chapter 17, Protocol 7 to measure enzyme activity in cell lysates. Alternatively, carry out a histochemical staining assay as detailed in the panel on **ADDITIONAL PROTOCOL: HISTOCHEMICAL STAINING OF CELL MONOLAYERS FOR β-GALACTOSIDASE.**
   - If a green fluorescence protein expression vector was used, examine the cells with a microscope under 450–490-nm illumination.

- For other gene products, newly synthesized protein may be analyzed by radioimmunoassay, by immunoblotting, by immunoprecipitation following in vivo metabolic labeling, or by assays of enzymatic activity in cell extracts.

  To minimize dish-to-dish variation in transfection efficiency, it is best to (i) transfect several dishes with each construct, (ii) trypsinize the cells after 24 hours of incubation, (iii) pool the cells, and (iv) replate them on several dishes.

10. To isolate stable transfectants: After the cells have incubated for 48–72 hours in complete medium, trypsinize the cells and replate them in the appropriate selective medium. Change this medium every 2–4 days for 2–3 weeks to remove the debris of dead cells and to allow colonies of resistant cells to grow. Thereafter, individual colonies may be cloned and propagated for assay (for methods, please see Jakoby and Pastan 1979 or Spector et al. 1998b [Chapter 86 in *Cells: A Laboratory Manual*]).

    A permanent record of the numbers of colonies may be obtained by fixing the remaining cells with ice-cold methanol for 15 minutes followed by staining with 10% Giemsa for 15 minutes at room temperature before rinsing in tap water. The Giemsa stain should be freshly prepared in phosphate-buffered saline or H_2O and filtered through Whatman No. 1 filter paper before use.

ADDITIONAL PROTOCOL: HISTOCHEMICAL STAINING OF CELL MONOLAYERS FOR β-GALACTOSIDASE

This method, designed for cells growing in 60-mm culture dishes, was adapted from Sanes et al. (1986). Kits that contain all of the necessary reagents for immunohistochemical detection of β-galactosidase are available from several manufacturers.

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Additional Materials

Cell fixative

2% (v/v) formaldehyde <!>
0.2% (v/v) glutaraldehyde <!>
1x phosphate-buffered saline

▲ **WARNING** Prepare the cell fixative solution in a chemical fume hood and store at room temperature.

Histochemical stain

5 mM potassium ferricyanide ($K_3Fe[CN]_6$) <!>
5 mM potassium ferrocyanide ($K_4Fe[CN]_6$) <!>
2 mM $MgCl_2$
1x phosphate-buffered saline
1 mg/ml X-gal (5-bromo-4-chloro-3-indolyl-β-galactoside) <!>

Store the staining solution in the dark at 4°C.

▲ **IMPORTANT** Add the X-gal immediately before applying the stain to the cell monolayer.

Phosphate-buffered saline

Method

1. Wash the transfected cells twice with 2–3 ml of phosphate-buffered saline at room temperature.
2. Add 5 ml of cell fixative to the cells.
3. Wash the cells once with phosphate-buffered saline.
4. Add 3–5 ml of histochemical stain to the cells.
5. Incubate the cells for 14–24 hours at 37°C.
6. Wash the cell monolayer several times with phosphate-buffered saline.
7. Cover the cell monolayer with a small amount of phosphate-buffered saline and examine under a light microscope.

   Cells that have expresssed the β-galactosidase expression vector should be a brilliant blue. The transfection frequency can be estimated by counting the relative numbers of stained and unstained cells.

Protocol 2

Calcium-phosphate-mediated Transfection of Eukaryotic Cells with Plasmid DNAs

THE UPTAKE OF DNA BY CELLS IN CULTURE IS MARKEDLY ENHANCED when the nucleic acid is presented as a coprecipitate of calcium phosphate and DNA. Graham and van der Eb (1973) initially described this method, and their work laid the foundation for the introduction of cloned DNAs into mammalian cells and led directly to reliable methods for both stable transformation of cells and transient expression of cloned DNAs. For further details on the procedure, please see the information panel on **TRANSFECTION OF MAMMALIAN CELLS WITH CALCIUM PHOSPHATE–DNA COPRECIPITATES** at the end of this chapter.

Since the publication of the original method, increases in the efficiency of the procedure have been achieved by incorporating additional steps, such as a glycerol shock (Parker and Stark 1979) and/or a chloroquine treatment (Luthman and Magnusson 1983) in the transfection protocol. Treatment with sodium butyrate has been shown to enhance the expression of plasmids that contain the SV40 early promoter/enhancer in simian and human cells (Gorman et al. 1983a,b). Transfection kits, which frequently include these and other modifications to the original protocol, are available from a number of companies (please see Table 16-2).

This protocol, which describes a calcium-phosphate-mediated transfection method for use with plasmid DNAs and adherent cells, was modified from Jordan et al. (1996), who rigorously optimized calcium-phosphate-based transfection methods for Chinese hamster ovary cells and human embryonic kidney 293 cells. Following this protocol are variations on this basic method:

- For high-efficiency generation of stable transfectants, please see the alternative method at the end of this protocol.
- For use with high-molecular-weight genomic DNAs (Protocol 3) and for use with adherent cells that have been released from the substratum with trypsin, please see the alternative method at the end of Protocol 3.
- For use with nonadherent cells, please see the alternative method at the end of Protocol 3.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

$CaCl_2$ (2.5 M)

Chloroquine (100 mM) (optional)

Dissolve 52 mg of chloroquine diphosphate in 1 ml of deionized distilled H_2O. Sterilize the solution by passing it through a 0.22-µm filter; store the filtrate in foil-wrapped tubes at –20°C. Please see Step 5.

Giemsa stain (10% w/v)

The Giemsa stain should be freshly prepared in phosphate-buffered saline or H_2O and filtered through Whatman No. 1 filter paper before use.

Glycerol (15% v/v) in 1x HEPES-buffered saline (optional)

Add 15% (v/v) autoclaved glycerol to filter-sterilized HEPES-buffered saline solution just before use. Please see Step 5.

2x HEPES-buffered saline

140 mM NaCl

1.5 mM $Na_2HPO_4 \cdot 2H_2O$

50 mM HEPES

Dissolve 0.8 g of NaCl, 0.027 g of $Na_2HPO_4 \cdot 2H_2O$, and 1.2 g of HEPES in a total volume of 90 ml of distilled H_2O. Adjust the pH to 7.05 with 0.5 N NaOH **<!>**, and then adjust the volume to 100 ml with distilled H_2O. Sterilize the solution by passing it through a 0.22-µm filter; store the filtrate in 5-ml aliquots at –20°C for periods of up to 1 year.

Methanol **<!>**

Phosphate-buffered saline

The solution should be sterilized by filtration before use and stored at room temperature.

Sodium butyrate (500 mM) (optional)

In a chemical fume hood, bring an aliquot of stock butyric acid solution to a pH of 7.0 with 10 N NaOH. Sterilize the solution by passing it through a 0.22-µm filter; store in 1-ml aliquots at –20°C. Please see Step 5.

0.1x TE (pH 7.6)

1 mM Tris-Cl (pH 7.6)

0.1 mM EDTA (pH 7.6)

Sterilize the solution by passing it through a 0.22-µm filter; store the filtrate in aliquots at 4°C.

Nucleic Acids and Oligonucleotides

Plasmid DNA

Dissolve the DNA in 0.1x TE (pH 7.6) at a concentration of 25 µg/ml; 50 µl of plasmid solution is required per milliliter of medium.

To obtain the highest transformation efficiencies, plasmid DNAs should be purified by column chromatography (please see Chapter 1, Protocol 9) or by equilibrium centrifugation in CsCl-ethidium bromide density gradients (please see Chapter 1, Protocol 10). If the starting amount of plasmid DNA is limiting, then add carrier DNA to adjust the final concentration to 25 µg/ml. Eukaryotic carrier DNA prepared in the laboratory usually gives higher transfection efficiencies than commercially available DNA such as calf thymus or salmon sperm DNA. Sterilize the carrier DNA before use by ethanol precipitation or extraction with chloroform.

Media

Cell culture growth medium (complete and [optional] selective)

Special Equipment

Tissue culture dishes (60-mm) or 12-well plates

This protocol is designed for cells grown in 60-mm culture dishes or 12-well plates. If other multiwell plates, flasks, or dishes of a different diameter are used, scale the cell density and reagent volumes accordingly. Please see Table 16-3.

Additional Reagents

Step 6 of this protocol requires the reagents listed in Chapter 6, Protocol 10, and Chapter 7, Protocol 8.

Cells and Tissues

Exponentially growing cultures of mammalian cells

METHOD

1. Twenty-four hours before transfection, harvest exponentially growing cells by trypsinization and replate them at a density of 1×10^5 to 4×10^5 cells/cm^2 in 60-mm tissue culture dishes or 12-well plates in the appropriate complete medium. Incubate the cultures for 20–24 hours at 37°C in a humidified incubator with an atmosphere of 5–7% CO_2. Change the medium 1 hour before transfection.

   To obtain optimum transfection frequencies, it is important to use exponentially growing cells. Cell lines used for transfection should never be allowed to grow to >80% confluency.

2. Prepare the calcium phosphate–DNA coprecipitate as follows: Combine 100 µl of 2.5 M $CaCl_2$ with 25 µg of plasmid DNA in a sterile 5-ml plastic tube and, if necessary, bring the final volume to 1 ml with 0.1x TE (pH 7.6). Mix 1 volume of this 2x calcium-DNA solution with an equal volume of 2x HEPES-buffered saline at room temperature. Quickly tap the side of the tube to mix the ingredients and allow the solution to stand for 1 minute.

   The precipitation reaction mixture can be doubled or quadrupled in volume if a larger number of cells are to be transfected. Normally, 0.1 ml of the calcium phosphate–DNA coprecipitate is added per 1 ml of medium in the culture dish, well, or flask.

3. Immediately transfer the calcium phosphate–DNA suspension into the medium above the cell monolayer. Use 0.1 ml of suspension for each 1 ml of medium in a well or 60-mm dish. Rock the plate gently to mix the medium, which will become yellow-orange and turbid. Carry out this step as quickly as possible because the efficiency of transfection declines rapidly once the DNA precipitate is formed. If the cells will be treated with chloroquine, glycerol, and/or sodium butyrate, proceed directly to Step 5.

   In some instances, higher transfection frequencies are achieved by first removing the medium and then directly adding the calcium phosphate–DNA suspension to the exposed cells. Thereafter, incubate the cells for 15 minutes at room temperature, and then add medium to the dish.

4. Transfected cells that will not be treated with transfection facilitators should be incubated at 37°C in a humidified incubator with an atmosphere of 5–7% CO_2. After 2–6 hours incubation, remove the medium and DNA precipitate by aspiration. Add 5 ml of warmed (37°C) complete growth medium and return the cells to the incubator for 1–6 days. Proceed to Step 6 to assay for transient expression of the transfected DNA, or proceed directly to Step 7 if the objective is stable transformation of the cells.

5. The uptake of DNA can be increased by treatment of the cells with chloroquine in the presence of the calcium phosphate–DNA coprecipitate or exposure to glycerol and sodium butyrate following removal of the coprecipitate solution from the medium.

TREATMENT OF CELLS WITH CHLOROQUINE

Chloroquine is a weak base that is postulated to act by inhibiting the intracellular degradation of the DNA by lysosomal hydrolases (Luthman and Magnusson 1983). The concentration of chloroquine added to the growth medium and the time of treatment are limited by the sensitivity of the cells to the toxic effect of the drug. The optimal concentration of chloroquine for the cell type used should be determined empirically (please see the information panel on **CHLOROQUINE DIPHOSPHATE**).

a. Dilute 100 mM chloroquine diphosphate 1:1000 directly into the medium either before or after the addition of the calcium phosphate–DNA coprecipitate to the cells.

b. Incubate the cells for 3–5 hours at 37°C in a humidified incubator with an atmosphere of 5–7% CO_2.

Most cells can survive in the presence of chloroquine for 3–5 hours. Cells often develop a vesicularized appearance during treatment with chloroquine.

c. After the treatment with DNA and chloroquine, remove the medium, wash the cells with phosphate-buffered saline, and add 5 ml of warmed complete growth medium. Return the cells to the incubator for 1–6 days. Proceed to Step 6 to assay for transient expression of the transfected DNA, or proceed directly to Step 7 if the objective is stable transformation of the cells.

TREATMENT OF CELLS WITH GLYCEROL

This procedure may be used following treatment with chloroquine. Because cells vary widely in their sensitivity to the toxic effects of glycerol, each cell type must be tested in advance to determine the optimum time (30 seconds to 3 minutes) of treatment.

a. After cells have been exposed for 2–6 hours to the calcium phosphate–DNA coprecipitate in growth medium (± chloroquine), remove the medium by aspiration and wash the monolayer once with phosphate-buffered saline.

b. Add 1.5 ml of 15% glycerol in 1x HEPES-buffered saline to each monolayer, and incubate the cells for the predetermined optimum length of time at 37°C.

c. Remove the glycerol by aspiration, and wash the monolayers once with phosphate-buffered saline.

d. Add 5 ml of warmed complete growth medium, and incubate the cells for 1–6 days. Proceed to Step 6 to assay for transient expression of the transfected DNA, or proceed directly to Step 7 if the objective is stable transformation of the cells.

TREATMENT OF CELLS WITH SODIUM BUTYRATE

The mechanism through which sodium butyrate acts is not known with certainty; however, the compound is an inhibitor of histone deacetylation (Lea and Randolph 1998), which suggests that treatment may lead to histone hyperacetylation and a chromatin structure on the incoming plasmid DNA that is predisposed to transcription (Workman and Kingston 1998).

a. Following the glycerol shock, dilute 500 mM sodium butyrate directly into the growth medium (Step d, treatment of cells with glycerol). Different concentrations of sodium butyrate are used depending on the cell type. For example:

CV-1	10 mM
NIH-3T3	7 mM
HeLa	5 mM
CHO	2 mM

The correct amount for other cell lines that may be transfected should be determined empirically.

b. Incubate the cells for 1–6 days. Proceed to Step 6 to assay for transient expression of the transfected DNA, or proceed directly to Step 7 if the objective is stable transformation of the cells.

6. To assay the transfected cells for transient expression of the introduced DNA, harvest the cells 1–6 days after transfection. Analyze RNA or DNA using hybridization. Analyze newly synthesized protein by radioimmunoassay, by immunoblotting, by immunoprecipitation following in vivo metabolic labeling, or by assays of enzymatic activity in cell extracts.

To minimize dish-to-dish variation in transfection efficiency, it is best to (i) transfect several dishes with each construct, (ii) trypsinize the cells after 24 hours of incubation, (iii) pool the cells, and (iv) replate them on several dishes.

7. To isolate stable transfectants:

a. Incubate the cells for 24–48 hours in nonselective medium to allow time for expression of the transferred gene(s).

b. Either trypsinize and replate the cells in the appropriate selective medium or add the selective medium directly to the cells without further manipulation.

c. Change the selective medium with care every 2–4 days for 2–3 weeks to remove the debris of dead cells and to allow colonies of resistant cells to grow.

d. Clone individual colonies and propagate for assay (for methods, please see Jakoby and Pastan 1979 or Spector et al. 1998b [Chapter 86 of *Cells: A Laboratory Manual*]).

e. Obtain a permanent record of the numbers of colonies by fixing the remaining cells with ice-cold methanol for 15 minutes followed by staining with 10% Giemsa for 15 minutes at room temperature before rinsing in tap water.

The dilution at which the transfected cells should be replated to yield well-separated colonies is determined by the efficiency of stable transformation, which can vary over several orders of magnitude (e.g., please see Spandidos and Wilkie 1984). The efficiency is dependent on the recipient cell type (significant differences have been observed even between different clones or different passage numbers of the same cell line [Corsaro and Pearson 1981; Van Pel et al. 1985]), the nature of the introduced gene and the efficacy of the transcriptional control signals associated with it, and the amount of DNA used in the transfection.

ALTERNATIVE PROTOCOL: HIGH-EFFICIENCY CALCIUM-PHOSPHATE-MEDIATED TRANSFECTION OF EUKARYOTIC CELLS WITH PLASMID DNAs

A modification of the classical calcium phosphate transfection method that greatly enhances the efficiency of the procedure was developed by Hiroto Okayama and colleagues (Chen and Okayama 1987, 1988). Their method works particularly well when stable transfectants are to be isolated using supercoiled plasmid DNAs and differs from the classical procedure in that the calcium phosphate–DNA coprecipitate is allowed to form in the tissue culture medium during prolonged incubation (15–24 hours) under controlled conditions of pH (6.96) and reduced CO_2 tension (2–4%).

Variables Affecting the Efficiency of Transfection

Variables that affect transfection include the purity, form, and amount of the DNA; the pH of the 2x BES buffer; and the concentration of CO_2 in the incubator.

- Impure plasmid DNAs transfect poorly because of the inhibitory effects of bacterial contaminants. For this reason, the best results are obtained with scrupulously clean DNA, preferably purified through specialized chromatography resins or two rounds of CsCl centrifugation (please see Chapter 1, Protocols 9 and 10). If necessary, the plasmid can be further purified by phenol:chloroform extraction in the presence of 1% (w/v) SDS.
- Linear DNAs yield very low transformation frequencies, perhaps because the slow formation of the calcium phosphate–DNA coprecipitate leaves the DNA exposed for long periods of time to cell nucleases.
- The nature of the precipitate is affected by the amount of DNA used. A transition (visible under the microscope) from a coarse precipitate to a fine precipitate occurs at the optimal DNA concentration (usually 2–3 µg/ml in the growth medium). The optimum DNA concentration encompasses a narrow range and should be determined empirically for individual cell lines.
- The slow formation of the calcium phosphate–DNA coprecipitate requires a slightly acidic pH and incubation in an atmosphere containing low concentrations of CO_2. The pH curve is very sharp with a clearly defined optimum at 6.96, whereas the CO_2 concentration is optimal between 2% and 4%.

Chen and Okayama (1987) reported that this method could be used for transient analysis of gene expression and that the simultaneous introduction of two or more plasmids reduced the overall efficiency of transfection. The overall frequency was still much higher than that obtained with other calcium phosphate methods. When cotransfecting with a selectable marker, it is usually necessary to optimize the system using mixtures containing different ratios of plasmids carrying the selectable marker of the gene of interest (e.g., 1:2, 1:5, and 1:10).

Additional Materials

2x BES-buffered saline (BBS)

50 mM BES (*N,N*-bis[2-hydroxyethyl]-2-aminoethanesulfonic acid)
280 mM NaCl
1.5 mM $Na_2HPO_4 \cdot 2H_2O$
Dissolve 1.07 g of BES, 1.6 g of NaCl, and 0.027 g of Na_2HPO_4 in a total volume of 90 ml of distilled H_2O. Adjust the pH of the solution to 6.96 with HCl at room temperature, and then adjust the volume to 100 ml with distilled H_2O. Sterilize the solution by passing it through a 0.22-µm filter; store the filtrate in aliquots at –20°C.

$CaCl_2$ (0.25 M)

Dissolve 1.1 g of $CaCl_2 \cdot 6H_2O$ in 20 ml of distilled H_2O. Sterilize the solution by passing it through a 0.22-µm filter. Store the filtrate in 1-ml aliquots at –20°C.

Superhelical plasmid at 1 µg/µl in 0.1x TE (pH 7.6)

Tissue culture dishes (90-mm)

This protocol is designed for cells grown in 90-mm culture dishes. If other multiwell plates, flasks, or dishes of a different diameter are used, scale the cell density and reagent volumes accordingly. Please see Table 16-3.

Method

1. Twenty-four hours before transfection, harvest exponentially growing cells by trypsinization and replate aliquots of 5×10^5 cells onto 90-mm tissue culture dishes. Add 10 ml of complete growth medium, and incubate the cultures overnight at 37°C in a humidified incubator with an atmosphere of 5–7% CO_2.

2. Mix 20–30 μg of superhelical plasmid DNA with 0.5 ml of 0.25 M $CaCl_2$. Add 0.5 ml of 2x BES-buffered saline (BBS) and incubate the mixture for 10–20 minutes at room temperature. Do not expect a visible precipitate to form during this time.
3. Add the $CaCl_2$-DNA-BBS solution dropwise to the dishes of cells, swirling gently to mix well. Incubate the cultures for 15–24 hours at 37°C in a humidified incubator in an atmosphere of 2–4% CO_2.
4. Remove the medium by aspiration, and rinse the cells twice with medium. Add 10 ml of nonselective medium, and incubate the cultures for 18–24 hours at 37°C in a humidified incubator in an atmosphere of 5% CO_2.
5. Following 18–24 hours of incubation in nonselective medium, to allow expression of the transfected gene(s) to occur, trypsinize and replate the cells in the appropriate selective medium. Change the selective medium with care every 2–4 days for 2–3 weeks to remove the debris of dead cells and to allow colonies of resistant cells to grow.

   The dilution at which the transfected cells should be replated to yield well-separated colonies is determined by the efficiency of stable transformation, which can vary over several orders of magnitude (e.g., please see Spandidos and Wilkie 1984). The efficiency is dependent on the recipient cell type (significant differences have been observed even between different clones or different passage numbers of the same cell line [Corsaro and Pearson 1981; Van Pel et al. 1985]), the nature of the introduced gene and the efficacy of the transcriptional control signals associated with it, and the amount of donor DNA used in the transfection.
6. Thereafter, clone individual colonies and propagate for assay (for methods, please see Jakoby and Pastan 1979 or Spector et al. 1998b [Chapter 86 in *Cells: A Laboratory Manual*]).

   A permanent record of the number of colonies may be obtained by fixing the remaining cells with ice-cold methanol for 15 minutes followed by staining with 10% Giemsa for 15 minutes at room temperature before rinsing in tap water. The Giemsa stain should be freshly prepared in phosphate-buffered saline or H_2O and filtered through Whatman No. 1 filter paper before use.

Protocol 3

Calcium-phosphate-mediated Transfection of Cells with High-molecular-weight Genomic DNA

MAMMALIAN GENES HAVE BEEN SUCCESSFULLY ISOLATED by transfecting cultured mammalian cells with genomic DNA, followed by selection for the gene of interest. This includes dominant cellular oncogenes, genes that encode cell surface molecules, and, as selection/identification strategies and techniques have improved, genes that encode intracellular proteins. Target genes are recovered from the chromosomal DNA of stably transfected cells by virtue of their species-specific repetitive DNA elements or by linkage to cotransfected plasmid DNAs.

The method outlined below is a modification of the calcium phosphate procedure described by Graham and Van der Eb (1973), using high-molecular-weight genomic DNA instead of plasmid DNA. The procedure works especially well to generate stable lines of cells carrying transfected genes that complement mutations in the hosts' chromosomal genes (Sege et al. 1984; Kingsley et al. 1986). This protocol was supplied by P. Reddy and M. Krieger (Massachusetts Institute of Technology).

MATERIALS

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

$CaCl_2$ (2 M)

Sterilize by filtration, and store frozen as 5-ml aliquots.

Glycerol (15% v/v) in 1x HEPES-buffered saline

Add 15% (v/v) autoclaved glycerol to filter-sterilized HEPES-buffered saline solution just before use.

HEPES-buffered saline

21 mM HEPES
0.7 mM Na_2HPO_4
137 mM NaCl
5 mM KCl
6 mM dextrose

Adjust the pH of the solution to 7.10. Sterilize the solution by filtration and store frozen in 25–50-ml aliquots. Thaw a fresh aliquot before each transfection and check the pH of a small volume. Readjust pH if necessary to 7.10.

Isopropanol

NaCl (3 M)

Sterilize by filtration, and store at room temperature.

Nucleic Acids and Oligonucleotides

Genomic DNA

Prepare high-molecular-weight DNA in TE from appropriate cells as described in Chapter 6, Protocol 3. Dilute the DNA to 100 µg/ml in TE (pH 7.6). Approximately 20–25 µg of genomic DNA is required to transfect each 90-mm plate of cultured cells.

The genomic DNA must be sheared to a size range of 45–60 kb before using it to transfect cells (please see Steps 2 and 3). The appropriate conditions for shearing the genomic DNA are best determined in preliminary experiments as follows: Shear 2-ml aliquots of high-molecular-weight DNA by passing each aliquot through a 22-gauge needle for a different number of times (e.g., three, four, five, or six times). Examine the DNA by electrophoresis on a 0.6% (w/v) agarose gel followed by staining with either ethidium bromide or SYBR Gold. As markers, use monomeric and dimeric forms of linear bacteriophage λ DNA. To optimize the remaining steps, sheared DNA of the proper size should then be taken through Step 9 of the protocol using dishes without cells.

Plasmid with selectable marker

Optional, please see notes to Steps 3 and 12.

Media

Cell culture growth medium (complete and selective)

Special Equipment

Polyethylene tubes (12-ml)

Shepherd's crook

Siliconized glass Pasteur pipette containing a hook at the end.

Tissue culture dishes (90-mm)

Cells and Tissues

Exponentially growing cultures of mammalian cells

METHOD

1. On day 1 of the experiment, plate exponentially growing cells (e.g., CHO cells) at a density of 5 x 10^5 cells per 90-mm culture dish in appropriate growth medium containing serum. Incubate the cultures for ~16 hours at 37°C in a humidified incubator with an atmosphere of 5% CO_2.

2. On day 2, shear an appropriate amount of high-molecular-weight DNA into fragments ranging in size from 45 kb to 60 kb, by passing it through a 22-gauge needle for the predetermined number of times (please see the note to the Genomic DNA entry above in Materials).

   Cells should be transfected with 20–25 µg of genomic DNA per 90-mm dish.

3. Precipitate the sheared DNA by adding 0.1 volume of 3 M NaCl and 1 volume of isopropanol. Collect the DNA on a Shepherd's crook. Drain the precipitate briefly against the side of the tube and transfer it to a second tube containing HEPES-buffered saline (1 ml per 12–15 µg of DNA). Redissolve the DNA by gentle rotation for 2 hours at 37°C. Make sure that all of the DNA has dissolved before proceeding.

   When cotransfecting with a selectable marker (please see the note below Step 12), add to the genomic DNA a sterile solution of the appropriate plasmid to a final concentration of 0.5 µg/ml.

4. Transfer 3-ml aliquots of sheared genomic DNA into 12-ml polyethylene tubes (one aliquot per two dishes to be transfected).

   The number of dishes required and transfectants obtained will vary from one cell line to another and on the efficiency of the selection method. As a guide, ~15–20 dishes of CHO cells must be transfected to obtain 3–10 stable transformants.

5. To form the calcium phosphate–DNA coprecipitate, gently vortex an aliquot of sheared genomic DNA, and add 120 µl of 2 M $CaCl_2$ in a dropwise fashion. Incubate the tube for 15–20 minutes at room temperature.

   The solution should turn hazy, but it should not form visible clumps of precipitate.

6. Aspirate the medium from two dishes of cells (from Step 1) and gently add 1.5 ml of the calcium phosphate–DNA coprecipitate to each dish. Carefully rotate the dishes to swirl the medium and spread the precipitate over the monolayer of cells. Incubate the cells for 20 minutes at room temperature, rotating the dishes once during the incubation.

7. Gently add 10 ml of warmed (37°C) growth medium to each dish and incubate for 6 hours at 37°C in a humidified incubator with an atmosphere of 5% CO_2.

8. Repeat Steps 5–7 until all of the dishes of cells contain the calcium phosphate–DNA precipitate.

9. After 6 hours of incubation, examine each dish under a light microscope. A "peppery" precipitate should be seen adhering to the cells. The precipitate should be neither too fine nor clumpy.

   Experience will dictate how a "peppery" precipitate looks under the microscope. Terminate the experiment with cells if a very fine or clumpy precipitate is visualized at this step. The failure to form a peppery precipitate at this step or a hazy solution at Step 5 could be due to the use of a HEPES-buffered saline solution of improper pH, an overly long incubation at Step 5, or a suboptimal concentration of $CaCl_2$ or DNA.

10. In most cases, treatment with glycerol at this step will enhance the transfection frequency. To shock the cells with glycerol:

    a. Aspirate the medium containing the calcium phosphate–DNA coprecipitate.

    b. To each dish of cells, add 3 ml of 15% glycerol in 1× HEPES-buffered saline that has been warmed to 37°C. Incubate for *no longer than 3 minutes* at room temperature.

       It is important that the glycerol in the HEPES-buffered saline *not* be left in contact with the cells for too long. The optimum time period usually spans a narrow range and varies from one cell line to another and from one laboratory to the next. For these reasons, treat only a few dishes at a time and take into account the length of time to aspirate the glycerol in the HEPES-buffered saline. Do not to exceed the optimum incubation period. Seconds can count!

    c. Aspirate the glycerol in the HEPES-buffered saline and rapidly wash the dishes twice with 10 ml of warmed growth medium.

    d. Add 10 ml warmed growth medium and incubate the cultures for 12–15 hours at 37°C in a humidified incubator with an atmosphere of 5% CO_2.

11. Replace the medium with 10 ml of fresh growth medium. Continue the incubation overnight at 37°C in a humidified incubator with an atmosphere of 5% CO_2.

12. Microscopic examination of cells at this point (day 4) should reveal a normal morphology. Cells can be trypsinized and replated in selective medium on day 4. Continue the incubation for 2–3 weeks to allow growth of complemented and/or resistant colonies. Change the medium every 2–3 days.

The length of the selection period, the cell density of replating, and the selection conditions all depend on the mutation or gene being complemented or selected. Optimum cell density for replating at Step 12 usually varies between 2.5×10^5 and 1×10^6 cells per 90-mm dish. Determine this parameter empirically by plating different numbers of cells without transfection and applying the selection procedure. For logistical reasons, use the highest density that still allows efficient cell killing.

Cotransfection (e.g., with a plasmid conferring G418 resistance) can be used to distinguish between transfectants and revertants. Because the reversion frequency for some mutant cell lines can be as high as 10^{-6} (i.e., 1 per 1 million cells plated), false positives can be a problem. The transfection frequency is usually 2×10^{-7}, and the cotransfection frequency is $\sim 10^{-8}$. The use of a selection (e.g., G418 resistance) in conjunction with the mutation/gene selection should eliminate false positives. For further details, please see the information panel on **COTRANSFORMATION.**

13. Thereafter, clone individual colonies and propagate them for assay (for methods, please see Jakoby and Pastan 1979 and Step 7d, p. 16.18).

A permanent record of the numbers of colonies may be obtained by fixing the remaining cells with ice-cold methanol for 15 minutes followed by staining with 10% Giemsa for 15 minutes at room temperature before rinsing in tap water. The Giemsa stain should be freshly prepared in PBS or H_2O and filtered through Whatman No. 1 filter paper before use.

ALTERNATIVE PROTOCOL: CALCIUM-PHOSPHATE-MEDIATED TRANSFECTION OF ADHERENT CELLS

This protocol can be used with all types of adherent cells, but is particularly useful for polarized epithelial cells, which do not efficiently take up material by endocytosis through the apical plasma membrane.

Additional Materials

Exponentially growing adherent mammalian cells
Sorvall H1000B rotor or equivalent

Method

1. Harvest exponentially growing adherent cells by trypsinization. Resuspend the cells in growth medium containing serum, and centrifuge aliquots containing ~10^6 cells at 800*g* (2000 rpm in a Sorvall H1000B rotor) for 5 minutes at 4°C. Discard the supernatants.
2. Form the calcium phosphate–DNA coprecipitate as described in Protocol 2, Step 2 if plasmid DNA is used or as described in Protocol 3, Step 5 if genomic DNA is used.

   Note that the coprecipitate with plasmid DNA takes only ~5 minutes to prepare, whereas the coprecipitate containing genomic DNA takes ~25 minutes to prepare. Execute the initial two steps of this protocol so that cells and coprecipitate are ready at the same time.
3. Resuspend each aliquot of 10^6 cells in 0.5 ml of the calcium phosphate–DNA suspension, and incubate for 15 minutes at room temperature.

   This protocol can be easily modified to accommodate greater numbers of cells. For example, Chu and Sharp (1981) used 10^8 cells in 2 ml of calcium phosphate–DNA suspension containing 25 μg of DNA. In this case, after 15 minutes, dilute the mixture with 40 ml of complete growth medium supplemented with 0.05x HEPES-buffered saline and 6.25 mM $CaCl_2$. Plate the cells at a density of 5 x 10^7 cells per 150-mm dish.
4. To each aliquot, add 4.5 ml of warmed growth medium (with or without chloroquine; please see Protocol 2, Step 5), and plate the entire suspension (~5 ml) in a single 90-mm tissue culture dish. Incubate the cells for up to 24 hours at 37°C in a humidified incubator with an atmosphere of 5–7% CO_2.
5. Some types of cells may be further treated with glycerol and sodium butyrate to facilitate transfection. Please follow the procedures in Protocol 2, Step 5.
6. Thereafter, assay the cells for transient expression or place in the appropriate selective medium for the isolation of stable transformants (please see Protocol 2, Steps 6 and 7).

ALTERNATIVE PROTOCOL: CALCIUM-PHOSPHATE-MEDIATED TRANSFECTION OF CELLS GROWING IN SUSPENSION

A few cell lines grown as suspension cultures (e.g., HeLa cells) can be transfected using the modified calcium phosphate procedure described in this protocol. However, most lines of cells grown in suspension are resistant to calcium-phosphate-mediated transfection methods. Intransigent cell lines are best transfected using electroporation (Protocol 5) or lipofection (Protocol 1).

Additional Materials

Exponentially growing mammalian suspension cells
Phosphate-buffered saline (PBS)
Sorvall H1000B rotor or equivalent

Method

1. Collect cells from an exponentially growing suspension culture by centrifugation at 800*g* (2000 rpm in a Sorvall H1000B rotor) for 5 minutes at 4°C. Discard the supernatant, and resuspend the cell pellet in 20 volumes of ice-cold PBS. Divide the suspension into aliquots containing 1 x 10^7 cells each. Recover the washed cells by centrifugation as before, and again discard the supernatant.
2. Form the calcium phosphate–DNA coprecipitate as described in Protocol 2, Step 2 if plasmid DNA is used for transfection or as described in Protocol 3, Step 5 if genomic DNA is used.

   Note that preparation of the coprecipitate with plasmid DNA takes only ~5 minutes to prepare, whereas the coprecipitate containing genomic DNA takes ~25 minutes to prepare. Execute the initial two steps of this protocol so that cells and coprecipitate are ready at the same time.
3. Gently resuspend 1 x 10^7 cells in 1 ml of calcium phosphate–DNA suspension (containing ~20 µg of DNA), and allow the suspension to stand for 20 minutes at room temperature.
4. Add 10 ml of complete growth medium (with or without chloroquine; please see Protocol 2, Step 5) to a tube of cells, and plate the entire suspension in a single 90-mm tissue culture dish. Incubate the cells for 6–24 hours at 37°C in a humidified incubator with an atmosphere of 5–7% CO_2.
5. (*Optional for cells known to survive a glycerol shock*) At 4–6 hours after beginning Step 4, carry out the following (otherwise, proceed to Step 6):
   a. Collect the cells by centrifugation at 800*g* (2000 rpm in a Sorvall H1000B rotor) for 5 minutes at room temperature, and wash them once with PBS.
   b. Resuspend the washed cells in 1 ml of 15% glycerol in 1x HEPES-buffered saline, and incubate the cells for 30 seconds to 3 minutes at 37°C.

      Please see the note to Step 10b in the main protocol.
   c. Dilute the suspension with 10 ml of PBS, and recover the cells by centrifugation as described in Step a. Wash the cells once in PBS.
   d. Resuspend the washed cells in 10 ml of complete growth medium, and plate them in a 90-mm tissue culture dish. Incubate the culture for 48 hours at 37°C in a humidified incubator with an atmosphere of 5–7% CO_2.
6. Recover the cells by centrifugation at 800*g* (2000 rpm in a Sorvall H1000B rotor) for 5 minutes at room temperature, and wash them once with PBS.
7. Resuspend the cells in 10 ml of complete growth medium warmed to 37°C. Return the cells to the incubator for 48 hours before assaying for transient expression of transfected genes (Protocol 2, Step 6) or replating the cells in selective medium for isolation of stable transformants (Protocol 2, Step 7).

Protocol 4

Transfection Mediated by DEAE-Dextran: High-efficiency Method

THE FIRST TRANSFECTION METHODS, DEVELOPED IN THE LATE 1950s, used hyperosmotic and polycationic proteins to promote entry of DNA into cells (for review, please see Felgner 1990). The results were erratic, and the efficiency of transfection was, at best, very poor. The situation improved dramatically in the mid 1960s when DEAE-dextran (diethylaminoethyl-dextran) was used to introduce poliovirus RNA (Pagano and Vaheri 1965) and SV40 and polyomavirus DNAs (McCutchan and Pagano 1968; Warden and Thorne 1968) into cells. The procedure, with slight modifications, continues to be widely used for transfection of cultured cells with viral genomes and recombinant plasmids. Although the mechanism of action of DEAE-dextran is not understood in detail, it seems likely that the high-molecular-weight positively charged polymer serves as a bridge between the negatively charged nucleic acid and the negatively charged surface of the cell (Lieber et al. 1987; Holter et al. 1989). After the DEAE-dextran/DNA complexes have been internalized by endocytosis (Ryser 1967; Yang and Yang 1997), the DNA somehow escapes from the increasingly acidic endosomes and is transported by unknown mechanisms across the cytoplasm and into the nucleus.

Transfection mediated by DEAE-dextran differs from calcium phosphate coprecipitation in three important respects. First, it is used for transient expression of cloned genes and not for stable transformation of cells (Gluzman 1981). Second, it works very efficiently with lines of cells such as BSC-1, CV-1, and COS but is unsatisfactory with many other types of cells. Third, smaller amounts of DNA are used for transfection with DEAE-dextran than with calcium phosphate coprecipitation. Maximal transfection efficiency of 10^5 simian cells is achieved with 0.1–1.0 μg of supercoiled plasmid DNA; larger amounts of DNA (>2–3 μg) can be inhibitory. By contrast to transfection mediated by calcium phosphate, where high concentrations of DNA are required to promote the formation of a coprecipitate, carrier DNA is rarely used with the DEAE-dextran transfection method.

Since the method was introduced more than 20 years ago, many variants of DEAE-dextran transfection have been described. In most cases, the cells are exposed to a preformed mixture of DNA and high-molecular-weight DEAE-dextran (m.w. >500,000). However, a modified procedure has been described in which the cells are exposed first to DEAE-dextran and then to DNA (al-Moslih and Dubes 1973; Holter et al. 1989). All of these methods seek to maximize the uptake of DNA and to minimize the cytotoxic effects of DEAE-dextran. The following are among the variables that influence the efficiency of transfection.

- ***Concentration of DEAE-dextran used and length of time cells are exposed to it.*** It is possible to use either a relatively high concentration of DEAE-dextran (1 mg/ml) for short periods (30 minutes to 1.5 hours) or a lower concentration (250 μg/ml) for longer periods of time (up to

8 hours). The first of these transfection procedures is the more efficient, but it involves monitoring the cells for early signs of distress when they are exposed to the DNA/DEAE-dextran mixture. The second technique is less demanding and more reliable, but slightly less efficient. However, it can be combined with shock treatments (see below) that can raise the efficiency of transfection to very high levels.

- ***Use of facilitators such as DMSO, chloroquine, or glycerol.*** The efficiency of transient expression of genes introduced by DEAE transfection is increased ~50-fold if cells are exposed to DMSO, glycerol, polyethyleneimine, or other substances such as Starburst dendrimers that perturb osmosis and increase the efficiency of endocytosis (Lopata et al. 1984; Sussman and Milman 1984; Kukowska-Latello et al. 1996; Zauner et al. 1996; Godbey et al. 1999). A similar increase in efficiency of transfection of some lines of cultured cells may be obtained by exposing the transfected cells to chloroquine, which prevents acidification of endosomes and promotes early release of DNA into the cytoplasm (Luthman and Magnusson 1983). In the best cases, 80% of the cells in a transfected population can express foreign genes when DEAE-dextran and facilitators are used in combination (e.g., please see Kluxen and Lübbert 1993). However, the efficiency of DNA transfection using DEAE-dextran with a facilitator varies greatly from cell line to cell line. Conditions that are optimal for one cell line may not work at all for another. To obtain consistently high efficiencies of transformation with a particular cell line, the following factors should be standardized:

  Density of cells and their state of growth.

  Amount of transfecting DNA.

  Concentration and molecular weight of DEAE-dextran.

  Length of time cells are exposed to DNA.

  Whether the DEAE-dextran and DNA are added to the cells simultaneously or sequentially (al-Moslih and Dubes 1973; Holter et al. 1989).

  Length and temperature of the posttransfection facilitation and the concentration of the facilitating agent.

  Whether the cells are transfected while growing on a solid support or are first removed from the solid support and transfected in suspension (Golub et al. 1989).

For publications that analyze the effects of some or all of these conditions on transfection efficiency, please see Holter et al. (1989), Fregeau and Bleackley (1991), Kluxen and Lübbert (1993), and Luo and Saltzman (1999).

In addition to its use as a primary agent for transfection, DEAE-dextran can also be used as an adjuvant to enhance the efficiency of electroporation. Although the effects appear to vary from one cell line to another, the combination of electroporation and DEAE-dextran in some cases can improve the efficiency of transfection by a factor of 10–100 (Gauss and Leiber 1992).

DNA transfected into cells by the DEAE-dextran method is prone to mutation. This is particularly true of sequences cloned in vectors that can replicate in transfected mammalian cells. For example, when the *E. coli lacI* gene, cloned in a plasmid containing an SV40 origin of replication, was introduced into COS-7 cells, allowed to replicate for several generations, and then returned to *E. coli*, mutations occurred at a frequency of one to several percent (Calos et al. 1983). Stunning in their variety, mutations induced during replication in mammalian cells include deletions, insertions, and base substitutions (Razzaque et al. 1983; Lebkowski et al. 1984; Ashman and Davidson 1985). These mutations are thought to arise as a consequence of damage caused by the action of degradative enzymes and low pH in the lysosomes and also perhaps by the lack of a complete chromatin structure after the transfecting DNA enters the nucleus (Miller et al. 1984; Reeves et al. 1985).

Here, we describe two variations on the classical DEAE-dextran transfection procedure. The first (main protocol) involves a brief exposure of cells to a high concentration of DEAE-dextran and yields higher transfection frequencies but elevated cellular toxicity. The second (please see the panel on **ALTERNATIVE PROTOCOL: TRANSFECTION MEDIATED BY DEAE-DEXTRAN: INCREASED CELL VIABILITY** at the end of this protocol) involves a longer exposure of cells to a lower concentration of DEAE-dextran, which produces lower transfection frequencies but increased cell survival.

TRANSFECTION OF COS CELLS

The DEAE-dextran procedure is most often used to transfect simian COS cells. These cells were developed by Gluzman (1981) and express the SV40 large T antigen (please see the information panel on **COS CELLS** in Chapter 11). Introduction of the SV40 origin of replication, typically by use of the SV40 early region promoter-enhancer/origin to express the gene or cDNA of interest, results in the amplification of the origin-containing plasmid to very high copy number (Gluzman 1981). This amplification in turn produces a high level of expression of the transfected cDNA or gene, but severely stresses and eventually kills cells that take up the plasmid. COS cells are thus usually used as transient transfection hosts and analyzed 48–72 hours posttransfection.

The efficiency of DEAE-dextran-mediated transfection of COS cells is very high, often approaching 50% of the cells on a dish. For this reason, COS cells are frequently used in expression cloning (please see Chapter 11, Protocol 2). The high efficiency of transfection also allows multiple plasmids to be introduced simultaneously into the cells. For example, entire intermediary metabolism pathways can be reconstituted in COS cells by introducing expression plasmids encoding individual enzymes in the pathway (Zuber et al. 1988).

MATERIALS

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Chloroquine diphosphate (100 mM)

Dissolve 60 mg of chloroquine diphosphate in 1 ml of deionized distilled H_2O. Sterilize the solution by passing it through a 0.22-μm filter. Store the filtrate in foil-wrapped tubes at –20°C.

Please see the information panel on **CHLOROQUINE DISPHOSPHATE**.

DEAE-dextran (50 mg/ml)

Dissolve 100 mg of DEAE-dextran (M_r = 500,000; Pharmacia) in 2 ml of distilled H_2O. Sterilize the solution by autoclaving for 20 minutes at 15 psi (1.05 kg/cm^2) on liquid cycle. Autoclaving also assists dissolution of the polymer.

The molecular weight of the DEAE-dextran originally used for transfection was >2 x 10^6 (McCutchan and Pagano 1968). Although this material is no longer available commercially, it is still occasionally found in chemical storerooms. The older batches of higher-molecular-weight DEAE-dextran are more efficient for transfection than the lower-molecular-weight polymers currently available.

Phosphate-buffered saline (PBS)

Sterilize the solution by filtration before use and store it at room temperature.

Tris-buffered saline with dextrose (TBS-D)

Immediately before use, add 20% (w/v) dextrose (prepared in H_2O and sterilized by autoclaving or filtration) to the TBS solution. The final dextrose concentration should be 0.1% (v/v).

Nucleic Acids and Oligonucleotides

Plasmid DNA

To obtain the highest transformation efficiencies, purify the plasmid DNAs by column chromatography (please see Chapter 1, Protocol 9) or by equilibrium centrifugation in CsCl–ethidium bromide density gradients (please see Chapter 1, Protocol 10).

Media

Cell culture growth medium (complete and serum-free)

Special Equipment

Tissue culture dishes (60-mm or 35-mm)

This protocol is designed for cells grown in 60-mm or 35-mm culture dishes. If multiwell plates, flasks, or dishes of a different diameter are used, scale the cell density and reagent volumes accordingly. Please see Table 16-3.

Additional Reagents

Step 8 of this protocol requires the reagents listed in Chapter 6, Protocol 1, and Chapter 7, Protocol 8.

Cells and Tissues

Exponentially growing cultures of mammalian cells

DEAE-DEXTRAN TRANSFECTION KITS

Several manufacturers sell kits that provide all of the materials listed in this protocol (e.g., ProFection Mammalian Transfection System from Promega). These kits are somewhat expensive (reagent cost is about $1 per 60-mm dish), but they serve as a useful source of control reagents when performing DEAE-dextran transfection experiments for the first time.

METHOD

1. Twenty-four hours before transfection, harvest exponentially growing cells by trypsinization and transfer them to 60-mm tissue culture dishes at a density of 10^5 cells/dish (or 35-mm dishes at a density of 5×10^4 cells/dish). Add 5 ml (or 3 ml for 35-mm dish) of complete growth medium, and incubate the cultures for 20–24 hours at 37°C in a humidified incubator with an atmosphere of 5–7% CO_2.

   The cells should be ~75% confluent at the time of transfection. If the cells are grown for <12 hours before transfection, they will not be well anchored to the substratum and are more likely to detach during exposure to DEAE-dextran.

2. Prepare the DNA/DEAE-dextran/TBS-D solution by mixing 0.1–4 μg of supercoiled or circular plasmid DNA into 1 mg/ml DEAE-dextran in TBS-D.

   0.25 ml of the solution is required for each 60-mm dish; 0.15 ml is required for each 35-mm dish.

   The amount of DNA required to achieve maximal levels of transient expression depends on the exact nature of the construct and should be determined in preliminary experiments. If the construct carries a replicon that will function in the transfected cells (e.g., the SV40 early region promoter/origin of replication), 100–200 ng of DNA per 10^5 cells should be sufficient; if no replicon is present, larger amounts of DNA may be required (up to 1 μg per 10^5 cells).

3. Remove the medium from the cell culture dishes by aspiration, and wash the monolayers twice with warmed (37°C) PBS and once with warmed TBS-D.

4. Add the DNA/DEAE-dextran/TBS-D solution (250 μl per 60-mm dish, 150 μl per 35-mm dish). Rock the dishes gently to spread the solution evenly across the monolayer of cells. Return the cultures to the incubator for 30–90 minutes (the time will depend on the sensitivity of each batch of cells to the DNA/DEAE-dextran/TBS-D solution). At 15–20-minute intervals, remove the dishes from the incubator, swirl them gently, and check the appearance of the cells under the microscope. If the cells are still firmly attached to the substratum, continue the incubation. Stop the incubation when the cells begin to shrink and round up.

5. Remove the DNA/DEAE-dextran/TBS-D solution by aspiration. Gently wash the monolayers once with warmed TBS-D and then once with warmed PBS, taking care not to dislodge the transfected cells.

6. Add 5 ml (per 60-mm dish) or 3 ml (per 35-mm dish) of warmed medium supplemented with serum and chloroquine (100 μM final concentration), and incubate the cultures for 3–5 hours at 37°C in a humidified incubator with an atmosphere of 5–7% CO_2.

   The efficiency of transfection is increased severalfold by treatment with chloroquine, which may act by inhibiting the degradation of the DNA by lysosomal hydrolases (Luthman and Magnusson 1983). Note, however, that the cytotoxic effects of a combination of DEAE-dextran and chloroquine can be severe. It is therefore important to carry out preliminary experiments to determine the maximum permissible length of exposure to chloroquine after treatment of cells with DEAE-dextran (for further details, please see the information panel on **CHOROQUINE DIPHOSPHATE**).

7. Remove the medium by aspiration, and wash the monolayers three times with serum-free medium. Add to the cells 5 ml (per 60-mm dish) or 3 ml (per 35-mm dish) of medium supplemented with serum, and incubate the cultures for 36–60 hours at 37°C in a humidified incubator with an atmosphere of 5–7% CO_2 before assaying for transient expression of the transfected DNA.

   The time of incubation should be optimized for the particular cell line and construct under study.

8. To assay the transfected cells for transient expression of the introduced DNA, harvest the cells 36–60 hours after transfection. Analyze RNA or DNA using hybridization. Analyze newly synthesized protein by radioimmunoassay, by immunoblotting, by immunoprecipitation following in vivo metabolic labeling, or by assays of enzymatic activity in cell extracts.

   To minimize dish-to-dish variation in transfection efficiency, it is best to (i) transfect several dishes with each construct, (ii) trypsinize the cells for 24 hours of incubation, (iii) pool the cells, and (iv) replate them on several dishes.

ALTERNATIVE PROTOCOL: TRANSFECTION MEDIATED BY DEAE-DEXTRAN: INCREASED CELL VIABILITY

By contrast to the DEAE-dextran method described in the main protocol, this alternative protocol uses a lower concentration of DEAE-dextran (250 μg/ml) that remains in contact with the cells for longer periods of time (up to 8 hours). Although transfection frequencies are not as high as those obtained in the presence of elevated DEAE-dextran concentrations, the use of reduced levels of DEAE-dextran is associated with less cell toxicity.

Additional Materials

Dulbecco's modified Eagle's medium

This is standard DMEM buffered with $NaHCO_3$ and supplemented with serum.

Dulbecco's modified Eagle's medium, buffered with HEPES (HEPES-buffered DMEM)

This is DMEM lacking $NaHCO_3$ but containing 10 mM HEPES (pH 7.15). No serum should be added to this reagent.

Method

1. Twenty-four hours before transfection, harvest exponentially growing cells by trypsinization and transfer them to 60-mm tissue culture dishes with 10^5 cells/dish (or 35-mm dishes with 5×10^4 cells/dish). Add 5 ml (or 3 ml for 35-mm dish) of complete growth medium, and incubate the cultures for 20–24 hours at 37°C in a humidified incubator with an atmosphere of 5–7% CO_2.

   The cells should be ~75% confluent at the time of transfection. If the cells are grown for <12 hours before transfection, they will not be well anchored to the substratum and are more likely to detach during exposure to DEAE-dextran.

2. Mix 0.1–1 μg of supercoiled or circular plasmid DNA and 250 μg of DEAE-dextran per 1 ml of HEPES-buffered DMEM. The resulting solution will be used at 500 μl per 60-mm dish or 250 μl per 35-mm dish.

   The amount of DNA required to achieve maximal levels of transient expression depends on the exact nature of the construct and should be determined in preliminary experiments. If the construct carries a replicon that will function in the transfected cells (e.g., the SV40 early region promoter/origin of replication), 100–200 ng of DNA per 10^5 cells should be sufficient; if no replicon is present, larger amounts of DNA may be required (up to 1 μg per 10^5 cells).

3. Remove the medium from the cell culture dishes by aspiration, and wash the monolayers twice with warmed (37°C) HEPES-buffered DMEM.

4. Add the DNA/DEAE-dextran/DMEM solution to the cells (500 μl per 60-mm dish, 250 μl per 35-mm dish), and return the cells to the incubator for up to 8 hours. Gently rock the dishes every 2 hours to ensure even exposure to the DNA/DEAE-dextran/DMEM solution.

   The efficiency of transfection is increased severalfold by concurrent treatment of the cells with chloroquine diphosphate. If used, add the drug (100 μM final concentration) to the DNA/DEAE-dextran solution just before it is applied to the cells. Because chloroquine is toxic to the cells, the time of incubation must then be limited to 3–5 hours.

   A simple variation on this step is reported to double the transfection frequency obtained with COS cells (Gonzales and Joly 1995): Plate the cells in small culture flasks with screw caps at the beginning of the experiment and tightly screw the cap after addition of the DNA/DEAE-dextran/DMEM solution in Step 4. Continue the incubation for 8 hours, during which time the medium alkalinizes slowly, due to the metabolism of the small amount of CO_2 remaining in the flask. This change, which is marked by the gradual deepening in color from crimson to burgundy of the phenol red indicator in the medium, may stimulate transfection in a manner similar to the use of a reduced CO_2 atmosphere within the incubator (please see the **ALTERNATIVE PROTOCOL: HIGH-EFFICIENCY CALCIUM-PHOSPHATE-MEDIATED TRANSFECTION OF EUKARYOTIC CELLS WITH PLASMID DNAs** in Protocol 2).

5. Remove the DNA/DEAE-dextran/DMEM solution from the cells by aspiration, and gently wash the cell monolayers twice with warmed (37°C) HEPES-buffered DMEM. Take care not to dislodge the transfected cells.

6. Wash the cells once with warmed DMEM (buffered with $NaHCO_3$, not HEPES) supplemented with serum. Add to the cells 5 ml (per 60-mm dish) or 3 ml (per 35-mm dish) of complete growth medium, and incubate the cultures for 36–60 hours at 37°C in a humidified incubator with an atmosphere of 5–7% CO_2 before assaying for transient expression of the transfected DNA.

7. To assay the transfected cells for transient expression of the introduced DNA, harvest the cells 36–60 hours after transfection. Analyze RNA or DNA using hybridization. Analyze newly synthesized protein by radioimmunoassay, by immunoblotting, by immunoprecipitation following in vivo metabolic labeling, or by assays of enzymatic activity in cell extracts.

   To minimize dish-to-dish variation in transfection efficiency, it is best to (i) transfect several dishes with each construct, (ii) trypsinize the cells after 24 hours of incubation, (iii) pool them, and (iv) replate them on several dishes.

Protocol 5

DNA Transfection by Electroporation

PULSED ELECTRICAL FIELDS CAN BE USED TO INTRODUCE DNA into a variety of animal cells (Neumann et al. 1982; Wong and Neumann 1982; Potter et al. 1984; Sugden et al. 1985; Toneguzzo et al. 1986; Tur-Kaspa et al. 1986), plant cells (Fromm et al. 1985, 1986; Ecker and Davis 1986), and bacteria. Electroporation works well with cell lines that are refractive to other techniques, such as calcium phosphate–DNA coprecipitation. But, as with other transfection methods, the optimal conditions for electroporating DNA into untested cell lines must be determined empirically.

The efficiency of transfection by electroporation is influenced by a number of factors as described below.

- ***Strength of the applied electric field.*** At low voltage, the plasma membranes of cultured cells are not sufficiently altered to allow passage of DNA molecules; at higher voltage, the cells are irreversibly damaged. For most lines of mammalian cells, the maximal level of transient expression is reached when voltages between 250 V/cm and 750 V/cm are applied. Typically, between 20% and 50% of the cells survive this treatment (as measured by exclusion of trypan blue [Patterson 1979; Baum et al. 1994]).

- ***Length of the electric pulse.*** Usually, a single electric pulse is passed through the cells. The length, field shape, and strength of the pulse are determined by the capacitance of the power supply and the dimensions of the cuvette. Some electroporation devices grant the investigator control over the characteristics of the pulse; others do not. The optimal length of the electric pulse required for electroporation is 20–100 msec.

- ***Temperature.*** Some investigators report that maximal levels of transient expression are obtained when the cells are maintained at room temperature during electroporation (Chu et al. 1987); others have obtained better results when the cells are maintained at 0°C (Reiss et al. 1986). These discrepancies may result from differences in the responses of various types of mammalian cells to the passage of electric current or in the amount of heat generated during electroporation when large electrical voltages (>1000 V/cm) and/or extended electric pulses (>100 msec) are used. The efficiency of transient expression is increased if the cells are incubated for 1–2 minutes in the electroporation chamber after exposure to the electric pulse (Rabussay et al. 1987).

- ***Conformation and concentration of DNA.*** Although both linear and circular DNAs can be transfected by electroporation, higher levels of both transient expression and stable transformation are obtained when linear DNA is used (Neumann et al. 1982; Potter et al. 1984; Toneguzzo et al. 1986). Effective transfection has been obtained with concentrations of DNA ranging from 1 μg/ml to 40 μg/ml.

- ***Ionic composition of the medium.*** The efficiency of transfection is manyfold higher when the cells are suspended in buffered salt solutions (e.g., HEPES-buffered saline) rather than in buffered solutions of nonionic substances such as mannitol or sucrose (Rabussay et al. 1987).

A number of different electroporation instruments are available commercially, and the manufacturers supply detailed protocols for their use. The following method is adapted from a protocol provided by Jennifer Cuthbert and Rhonda Bassel-Duby (University of Texas Southwestern Medical Center, Dallas) and from Baum et al. (1994).

For a review of methods for the introduction of DNA molecules into eukaryotic cells by electroporation, please see Andreason and Evans (1988); for a discussion of the use of electroporation to introduce DNA into bacterial cells, please see Chapter 1, Protocol 26; and for further information on the mechanism of electroporation and optimization, please see the information panel on **ELECTROPORATION.**

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Giemsa stain (10% w/v)

The Giemsa stain should be freshly prepared in phosphate-buffered saline or H_2O and filtered through Whatman No. 1 filter paper before use.

Methanol <!>

Phosphate-buffered saline (PBS)

Sterilize the solution by filtration before use and store it at room temperature.

Sodium butyrate (500 mM) (optional)

In a chemical fume hood, bring an aliquot of stock butyric acid solution to a pH of 7.0 with 10 N NaOH. Sterilize the solution by passing it through a 0.22-μm filter; store the filtrate at −20°C.

Nucleic Acids and Oligonucleotides

Carrier DNA (10 mg/ml; e.g., sonicated salmon sperm DNA) (optional)
Linearized or circular plasmid DNA (1 μg/μl in sterile deionized H_2O)

Media

Cell culture growth medium (complete and [optional] selective)

Centrifuges and Rotors

Sorvall H1000B rotor or equivalent

Special Equipment

Electroporation device and cuvettes

Gene Pulser II (Bio-Rad Cat. no. 165-2105 for 110-V U.S. Systems and Cat. no. 165-2106 for 220-V European Systems).

Tissue culture dishes (35-mm)

This protocol is designed for cells grown in 35-mm culture dishes. If multiwell plates, flasks, or dishes of a different diameter are used, scale the cell density and reagent volumes accordingly. Please see Table 16-3.

Additional Reagents

Step 10 of this protocol may require the reagents listed in Chapter 17, Protocol 7, or in the additional protocol in Protocol 1.

Cells and Tissues

Exponentially growing cultures of mammalian cells

METHOD

1. Harvest the cells to be transfected from cultures in the mid- to late-logarithmic phase of growth. Use either a rubber policeman or trypsin to release adherent cells. Centrifuge at 500g (1500 rpm in a Sorvall H1000B rotor) for 5 minutes at 4°C.

2. Resuspend the cell pellet in 0.5x volume of the original growth medium and measure the cell number using a hemocytometer (please see Appendix 8).

3. Collect the cells by centrifugation as described in Step 1, and resuspend them in growth medium or phosphate-buffered saline at room temperature at a concentration of 2.5×10^6 to 2.5×10^7 cells/ml.

4. Transfer 400-µl aliquots of the cell suspension (10^6 to 10^7 cells) into as many labeled electroporation cuvettes as needed. Place the loaded cuvettes on ice.

5. Set the parameters on the electroporation device. A typical capacitance value is 1050 µF. Voltages range from 200 to 350 V, depending on the cell line, but generally average 260 V. Use an infinite internal resistance value. Discharge a blank cuvette containing phosphate-buffered saline at least twice before beginning electroporation of cells.

6. Add 10–30 µg of plasmid DNA in a volume of up to 40 µl to each cuvette containing cells. (Some investigators add carrier DNA [e.g., salmon sperm DNA] to bring the total amount of DNA to 120 µg.) Gently mix the cells and DNA by pipetting the solution up and down. Proceed to Step 7 without delay.

   ▲ **IMPORTANT** Do not introduce air bubbles into the suspension during the mixing step.

7. Immediately transfer the cuvette to the electroporator and discharge the device. After 1–2 minutes, remove the cuvette, place it on ice, and proceed immediately to the next step.

8. Transfer the electroporated cells to a 35-mm culture dish using a micropipettor equipped with a sterile tip. Rinse out the cuvette with a fresh aliquot of growth medium, and add the washings to the culture dish. Transfer the dish to a humidified incubator at 37°C with an atmosphere of 5–7% CO_2.

   To incorporate a sodium butyrate shock (please see Protocol 2, Step 5), rinse the cuvette with growth medium containing an appropriate amount of sodium butyrate, and combine the rinse with the electroporated cells in the dish before its transfer to an incubator. After 24 hours, remove butyrate-containing medium and replace with normal growth medium.

9. Repeat Steps 6–8 until all of the DNA cell samples in cuvettes are shocked. Record the actual pulse time for each cuvette to facilitate comparisons between experiments.

10. If the objective is stable transformation of the cells, proceed directly to Step 11. For transient expression, examine the cells 24–96 hours after electroporation using one of the following assays:

    - If a plasmid DNA expressing *E. coli* β-galactosidase was used, follow the steps outlined in Chapter 17, Protocol 7 to measure enzyme activity in cell lysates. Alternatively, carry out a histochemical staining assay as detailed in the additional protocol in Protocol 1.
    - If a green fluorescence protein expression vector was used, examine the cells with a microscope under 450–490-nm illumination.
    - For other gene products, analyze the newly synthesized protein by radioimmunoassay, by immunoblotting, by immunoprecipitation following in vivo metabolic labeling, or by assays of appropriate enzymatic activity in cell extracts.

      To minimize dish-to-dish variation in transfection efficiency, it is best to (i) transfect several dishes with each construct, (ii) trypsinize the cells after 24 hours of incubation, (iii) pool the cells, and (iv) replate them on several dishes.

11. To isolate stable transfectants: After incubation for 48–72 hours in complete medium, trypsinize the cells and replate them in the appropriate selective medium. The selective medium should be changed every 2–4 days for 2–3 weeks to remove the debris of dead cells and to allow colonies of resistant cells to grow. Thereafter, clone individual colonies and propagate for assay (for methods, please see Jakoby and Pastan 1979 or Spector et al. 1998b [Chapter 86 in *Cells: A Laboratory Manual*]).

    A permanent record of the numbers of colonies may be obtained by fixing the remaining cells with ice-cold methanol for 15 minutes, followed by staining with 10% Giemsa for 15 minutes at room temperature before rinsing in tap water. The Giemsa stain should be freshly prepared in phosphate-buffered saline or H_2O and filtered through Whatman No. 1 filter paper before use.

Protocol 6

DNA Transfection by Biolistics

DESPITE THE MYRIAD AND INGENIOUS METHODS developed to introduce cloned DNAs into cells, some cell types, tissues, and intracellular organelles remain impermeable to foreign DNA. This problem, which is particularly acute with plant cells, was solved to a large degree with the invention of the "gene gun" by John Sanford, Ed Wolf, and their colleagues at Cornell University. The gene gun was of greatest interest to plant geneticists, whose attempts to introduce DNA into plant cells by conventional methods had been frustratingly inefficient. The gun solved the problem by the crude but efficient strategy of drilling holes through the thick cell walls with DNA-coated metal particles. Despite the initial enormous sketicism of other scientists, Sanford and Wolf published papers on the subject (Klein et al. 1987; Shark et al. 1991; Smith et al. 1992; Sanford et al. 1993), obtained patents on the gene gun and its uses as an instrument to deliver DNA to cells, and formed a company with the apt name of Biolistics, Inc. This method has revolutionized plant genetics: Most of the world's transgenic crops have been produced using biolistic technology. The travails of Sanford and Wolf and the scientific and commercial rewards of their work are beautifully described by Sanford in a publication available from his philanthropic organization (Feed My Sheep Foundation, Waterloo, New York).

The efficiency with which foreign DNA is introduced into cells by biolistic transformation depends on a large number of variables, including:

- ***Cell type.*** Cells ranging from bacteria to plants to hepatocytes within the livers of living rodents have been successfully shot with DNA-coated microprojectiles. In each case, the conditions that produced a successful experiment were different.
- ***Cell growth.*** The density at which cultured cells are bombarded affects the transfection frequency, with greater efficiency realized at low cell density in some cases (e.g., when introducing DNA into intracellular organelles) and at high cell density in others (e.g., when cells of *Bacillus megaterium* are the target). Some cells are best transfected while in the early log phase of their growth cycle, whereas others succumb after being grown to saturation.
- ***Culture medium.*** The efficiencies with which many bacterial and plant cells can be transfected by biolistic methods can be increased considerably by bombarding the cells in a medium of high osmolarity. Agents such as sorbitol and/or mannitol in concentrations ranging from 0.05 to 1.5 M are used, with the optimum osmoticum and concentration differing between species and cell type.
- ***Gene gun settings.*** Important parameters include the amount of vacuum applied to the shooting chamber, the helium pressure used to drive the DNA-coated particles, and the distance between the gun and the target cells.

- ***Type of ammunition.*** Blasting subcellular organelles with inappropriately large-diameter gold or tungsten particles produces only a mess. The optimum particle size for each application differs between cell types and ranges from 0.6 μm for subcellular organelles to 1.6 μm for cultured mammalian cells. Particles made of tungsten or gold are used to deliver the DNA to cells and each metal has its idiosyncrasies. Tungsten particles are irregular in size and some cells are sensitive to the toxic effects of this transition metal. Tungsten is also susceptible to oxidation, which promotes the degradation of DNA. Gold is less toxic and more malleable and consequently can be shaped into particles that are more uniform in diameter. However, gold binds DNA less efficiently and is more expensive than tungsten.

As with many other methods of transfection, the bewildering array of variables that affect the efficiency of biolistic transformation requires that the optimum conditions for gene delivery be determined empirically in each laboratory and for each cell type. Optimization is best achieved by applying a matrix of variables in the initial series of experiments as described by Sanford et al. (1993). From these results, a reproducible method of biolistic transformation can be established for experimental purposes. The following protocol is an amalgam derived from Horch et al. (1999), Sanford et al. (1993), publications from the principal gene gun manufacturer (US/EG Bulletins 1688 and 2087; Bio-Rad), and a method contributed by Steve Finkbeiner (University of California, San Francisco).

MATERIALS

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

$CaCl_2$ (2.5 M)

Ethanol

Use a fresh bottle of absolute ethanol that has not been opened previously. Ethanol is hygroscopic and with exposure to air picks up small amounts of water. In the method described below, the presence of water in the ethanol washes of Steps 1, 2, and 3 can interfere with effective bombardment of cells and tissues.

Glycerol (50% in H_2O)

Sterilize the solution by autoclaving.

Spermidine (0.1 M)

Dissolve an appropriate amount of spermidine (free-base form) in deionized H_2O and sterilize the solution by passing it through a 0.22-μm filter. Store the solution in small aliquots at −20°C. Make a fresh stock solution of this reagent every month.

Nucleic Acids and Oligonucleotides

Plasmid DNA

When carrying out a gene gun experiment for the first time or if a new cell line or tissue is to be transfected, obtain an expression plasmid encoding an appropriate marker gene for use in optimizing delivery. Examples include vectors that express *E. coli* β-galactosidase, green fluorescent protein, and β-glucuronidase (for plants) or selectable markers such as neomycin resistance. Plasmids expressing a gene or cDNA of interest can be used after the process has been optimized.

Investigators debate whether plasmid DNAs purified on various chromatographic resins (please see Chapter 1, Protocol 9), which contain varying amounts of lipopolysaccharide, can be used in biolistic gene delivery. Apparently, even minor contamination of the plasmid DNA with endotoxin/ lipopolysaccharide reduces the frequency of transfection. We thus recommend purification of plasmid DNAs by CsCl-ethidium bromide centrifugation (Chapter 1, Protocol 10). Dissolve the purified plasmid DNA in H_2O at a concentration of 1 μg/μl.

Media

Cell culture growth medium (complete and [optional] selective)

Special Equipment

Gene gun

A popular model is the Biolistic PDS-1000/He Particle Delivery System, sold by Bio-Rad, which includes a bombardment chamber with separate connections for vacuum and helium lines. A pump capable of pulling a vacuum of 5 inches of mercury is required. In general, house vacuum lines are unsuitable for this task. A high-pressure (2400–2600 psi) tank of helium gas (>99.999% pure) that is safely anchored to the bench or wall should be connected to the device.

Gold or tungsten particles (microcarriers)

The DNA to be transfected is delivered to cells on tungsten or gold particles that vary in diameter from 0.6 to 5 μm. The optimum pellet diameter for a given cell or tissue type must be determined empirically. The beads are purchased from commercial sources (e.g., Bio-Rad and Sylvania) and prepared for DNA coating as described in Step 1.

Lens paper

Microfuge tubes (1.5 ml)

Use high-quality microfuge tubes. Some brands or batches of microfuge tubes bind excessive amounts of the colloidal particles used as ammunition for gene gun experiments.

Additional Reagents

Step 8 of this protocol may require the reagents listed in Chapter 17, Protocol 7.

Cells and Tissues

Cells or tissue to be transfected

Adherent cultured cells from various species should be bombarded at 50–80% confluency. Collect plant cells grown in suspension by sterile filtration onto Whatman No. 1 filter papers (7-cm diameter) using a Buchner funnel, and place them on sterile filter papers soaked with culture medium of high osmolarity before bombardment (for details, please see Sanford et al. 1993).

Freshly dissect the mammalian tissue, section at ~400 μm, and maintain the slices in culture dishes as described by McAllister et al. (1995).

Culture bacteria and yeast to mid- to late-logarithmic growth depending on the species and strain, collect by centrifugation, resuspend in a small volume of culture medium of high osmolarity, and plate (1×10^8 to 2×10^9 cells) on a thin layer of agar atop a piece of filter paper in a Petri dish before being shot.

METHOD

1. Prepare tungsten or gold particles.
   a. Weigh 60 mg of gold or tungsten particles into a 1.5-ml microfuge tube.
   b. Add 1 ml of 70% ethanol to the particles and vortex the tube continuously for 5 minutes at room temperature. Store the tube on the bench top for 15 minutes.
   c. Collect the particles by centrifugation at maximum speed for 5 seconds in a microfuge.
   d. Gently remove the supernatant. Resuspend the metal particles in 1-ml of sterile H_2O and vortex the suspension for 1 minute. Store the tube on the bench top for 1 minute.
   e. Collect the metal particles by centrifugation at maximum speed for 5 seconds in a microfuge.

f. Repeat the H_2O wash (Steps d and e) three more times.

g. Remove the supernatant after the fourth H_2O wash. Resuspend the particles in 1 ml of sterile 50% glycerol.

The washed particles are assumed to have a concentration of 60 mg/ml and may be stored at room temperature for 1–2 weeks. Longer storage can result in oxidation of the metal beads and a decline in transfection efficiency.

2. For every six dishes of cells or slices of tissue to be shot, prepare an aliquot of DNA-coated particles as follows:

a. While continuously vortexing the stock solution of microcarrier particles, remove a 50-µl aliquot (~3 mg).

b. Transfer the aliquot to a fresh microfuge tube, and while vortexing, add the following to the tube:

plasmid DNA (~2.5 µg)	2.5 µl
2.5 M $CaCl_2$	50 µl
0.1 M spermidine	20 µl

After all ingredients are added, continue vortexing the tube for an additional 3 minutes.

It is very important that the microfuge tube be continuously vortexed during this procedure to ensure uniform coating of the particles with plasmid DNA.

c. Stand the tube on the bench for 1 minute to allow the particles to settle, and then collect them by centrifugation at maximum speed for 2 seconds in a microfuge.

Longer centrifugation times can cause agglomeration of the metal particles, reducing transfection efficiency.

d. Remove the supernatant and carefully layer 140 µl of 70% ethanol over the pelleted particles. Remove the 70% ethanol, and add 140 µl of 100% ethanol, again without disturbing the particles. Remove the supernatant and replace with 50 µl of ethanol.

e. Resuspend the particle pellet by tapping the side of the tube, followed by gentle vortexing for 2–3 seconds.

3. Place a macrocarrier in the metal holder of the gene gun apparatus using the seating device supplied by the manufacturer. Wash the sheet twice with 6-µl aliquots of ethanol. Between washes, blot the sheet dry with lens paper.

4. Vortex the pellet sample from Step 2e for 1 minute. While vortexing, withdraw 6 µl of the pellet slurry (~500 µg of particles) and, as quickly as possible, spread the aliquot around the central 1 cm of the macrocarrier.

5. Repeat Steps 3 and 4 until the desired number of loaded macrocarriers has been prepared. Allow the ethanol solution containing the DNA-coated particles to dry on the macrocarrier.

6. Load a macrocarrier into the gene gun, and following the manufacturer's directions, shoot a plate of cells or tissue slice.

7. After the vacuum has returned to atmospheric pressure, remove the wounded cells or tissue and place in appropriate culture conditions. Remove the ruptured macrocarrier and repeat Steps 6 and 7 until all plates are shot.

8. If the objective is stable transformation of the cells, proceed directly to Step 9. For transient expression, examine the cells 24–96 hours after shooting, using one of the following assays.

   - If a plasmid DNA expressing *E. coli* β-galactosidase was used, follow the steps outlined in Chapter 17, Protocol 7, to measure enzyme activity in cell lysates. Alternatively, carry out a histochemical staining assay as detailed in the additional protocol in Protocol 1 of this chapter.
   - If a green fluorescence protein expression vector was used, examine the cells with a microscope under 450–490-nm illumination.
   - If a plasmid DNA expressing β-glucuronidase was used, assay for β-glucuronidase activity as detailed in the panel on **ADDITIONAL PROTOCOL: HISTOCHEMICAL STAINING OF CELL MONOLAYERS OR TISSUE FOR β-GLUCURONIDASE.**
   - For other gene products, analyze the newly synthesized protein by radioimmunoassay, by immunoblotting, by immunoprecipitation following in vivo metabolic labeling, or by assays of appropriate enzymatic activity in cell extracts.

     To minimize dish-to-dish variation in transfection efficiency, it is best to (i) transfect several dishes with each construct, (ii) trypsinize the cells after 24 hours of incubation, (ii) pool the cells, and (iv) replate them on several dishes.

9. To isolate stable transfectants: After the cells have incubated for 48-72 hours in complete medium, transfer the bombarded cells to selective medium. The concentration of selective agent and the culture conditions will vary depending on the cell type.

ADDITIONAL PROTOCOL: HISTOCHEMICAL STAINING OF CELL MONOLAYERS OR TISSUE FOR β-GLUCURONIDASE

β-glucuronidase is often used as a reporter gene in transfected plant cells because the endogenous levels of this hydrolase are very low. The enzyme cleaves many β-glucuronide linkages with high efficiency, including those β-glucuronidases conjugated with fluorescent and histochemical tags that are readily visualized within cells or lysates. This protocol was adapted from Jefferson et al. (1987).

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Additional Materials

Formaldehyde (0.3% v/v) **<!>**
X-GlcA solution
10 mM EDTA (pH 8.0)
100 mM sodium phosphate
0.5 mM potassium ferrocyanide **<!>**
0.1% (v/v) Triton X-100
0.5 mg/ml X-GlcA (5-bromo-4-chloro-3-indolyl-β-D-glucuronide)

Dissolve an appropriate amount of X-GlcA (Sigma) in a small volume of DMSO before adding it to the buffer.
Mannitol (0.3 M)
MES (10 mM, pH 5.6)
NaH_2PO_4 (50 mM)

Method

1. Remove the medium in which the plant cells or tissue are maintained and replace with just enough X-GlcA solution to cover the biological material.

   With some plant tissues, the intensity of β-glucuronidase staining can be enhanced by fixing the tissue before addition of the X-GlcA solution. Incubate the section in 0.3% (v/v) formaldehyde/10 mM MES (pH 5.6)/0.3 M mannitol for 30–60 minutes, rinse the section several times with 50 mM NaH_2PO_4, and then cover it with X-GlcA staining solution.

2. Incubate the plates for 12–24 hours at 37°C.

3. Examine the bombarded cells under a light microscope and count the number of blue cells or blue clusters of cells. Cells that have taken up the β-glucuronidase expression plasmid and are synthesizing the enzyme should be a dark blue.

   The number of blue spots per dish can be considered to be at best a semiqualitative estimate of transfection efficiency. This number is most useful in determining the optimum conditions for gene bombardment experiments and should not be taken as a quantitative readout of gene expression. If a quantitative measurement of gene expression is needed, then it is best to establish an in vitro biochemical assay using a fluorescent β-glucuronidase substrate and cell lysates prepared from transfected cells or tissue slices. For a detailed description of this type of assay, please see Jefferson et al. (1987).

Protocol 7

DNA Transfection Using Polybrene

SEVERAL POLYCATIONS, INCLUDING POLYBRENE (1,5-dimethyl-1,5-diazaundecamethylene polymethobromide) (Kawai and Nishizawa 1984; Chaney et al. 1986) and poly-L-ornithine (Bond and Wold 1987; Dong et al. 1993; Nead and McCance 1995), have been used in the presence of DMSO to facilitate DNA transfection of cells that are insensitive to transfection by other methods.

Variables that influence the efficiency of transfection by Polybrene are the concentrations of DMSO and polycation, the amount of DNA, the temperature of incubation with DMSO, and the length of time the cells are left in contact with the polycation-DNA mixture (Bond and Wold 1987; Aubin et al. 1988; Nead and McCance 1995). The original protocol, which was developed using chicken embryo fibroblasts, had optimal levels of transfection with 30% DMSO and 30 µg of Polybrene. Optimal transfection into other cell lines requires different amounts of these reagents.

- Permanent transfection of human epidermal keratinocytes using Polybrene was found to be optimal after a 27% DMSO shock (Jiang et al. 1991).
- Murine NIH-3T3 cells required 15% DMSO (Aubin et al. 1988, 1997) for stable transfection, but 25% DMSO for optimal transient transfection.
- Human keratinocytes were transfected using 12 µg/ml poly-L-ornithine during a 6-hour incubation followed by a 4-minute shock with 25% DMSO (Nead and McCance 1995).

The mechanism by which DMSO enhances the uptake of DNA is not known, but may involve a combination of permeabilization of the cell membrane and the osmotic shock. In some experiments using Polybrene (e.g., please see Ogawa et al. 1988), DMSO has been replaced by solutions containing 5–7% NaCl. DNA toxicity is generally not a problem in the Polybrene method of transfection. However, the linear relationship between DNA concentration and transformation efficiency breaks down when using very high concentrations of DNA (Kawai and Nishizawa 1984).

The method outlined below using Polybrene and DMSO was adapted from Aubin et al. (1997). This procedure works efficiently for stable transformation of Chinese hamster ovary and keratinocyte cells by plasmid DNA, yielding ~15-fold more transformants than calcium phosphate–DNA coprecipitation. However, there is no difference between the two methods in the efficiency of transformation of cells by high-molecular-weight DNA.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

DMSO (30%) in serum-containing medium <!>

Dilute high-performance liquid chromatography (HPLC)-grade or tissue-culture-grade DMSO to a final concentration of 30% (v/v) in the cell growth medium containing serum just before use in Step 3.

Giemsa stain (10% w/v)

The Giemsa stain should be freshly prepared in phosphate-buffered saline or H_2O and filtered through Whatman No. 1 filter paper before use.

Methanol <!>

Polybrene (10 mg/ml)

Dissolve Polybrene (Aldrich) at a concentration of 10 mg/ml in H_2O and sterilize the solution by passing it through a 0.22-µm filter. Store the solution as small aliquots (0.25-ml) at –20°C until needed. Discard aliquots after use.

Sodium butyrate (500 mM) (optional)

In a chemical fume hood, bring an aliquot of stock butyric acid solution to a pH of 7.0 with 10 N NaOH. Sterilize the solution by passing it through a 0.22-µm filter. Store the filtrate in 1-ml aliquots at –20°C.

Nucleic Acids and Oligonucleotides

DNA to be transformed, e.g., plasmid DNA (1 µg/µl) in H_2O

Media

Minimum essential medium (MEM)-α (containing 10% fetal calf serum, serum-free, and [optional] selective agents)

Special Equipment

Tissue culture dishes (90-mm)

This protocol is designed for cells grown in 90-mm culture dishes. If multiwell plates, flasks, or dishes of a different diameter are used, scale the cell density and reagent volumes accordingly. Please see Table 16-3.

Additional Reagents

Step 6 of this protocol may require the reagents listed in Chapter 17, Protocol 7, or in the additional protocol in Protocol 1.

Cells and Tissues

Exponentially growing cultures of mammalian cells

METHOD

1. Harvest exponentially growing cells (e.g., CHO cells) by trypsinization, and replate them at a density of 5×10^5 cells per 90-mm tissue culture dish in 10 ml of MEM-α containing 10% fetal calf serum. Incubate the cultures for 18–20 hours at 37°C in a humidified incubator in an atmosphere of 5–7% CO_2.

2. Replace the medium with 3 ml of warmed (37°C) medium containing serum, DNA (5 ng to 40 μg; no carrier DNA), and 30 μg of Polybrene. Mix the DNA with the medium before adding the 10 mg/ml Polybrene. Return the cells to the incubator for 6–16 hours. Gently rock the dishes every 90 minutes during the early stages of this incubation to ensure even exposure of the cells to the DNA-Polybrene mixture.

3. Remove the medium containing the DNA and Polybrene by aspiration. Add 5 ml of 30% DMSO in serum-containing medium. Gently swirl the DMSO medium around the dish to ensure even exposure of the cells to the solvent and place the dishes in the incubator.

4. After 4 minutes of incubation, remove the dishes from the incubator and immediately aspirate the DMSO solution. Wash the cells once or twice with warmed (37°C) serum-free medium, and add 10 ml of complete medium containing 10% fetal calf serum. If a sodium butyrate boost is to be included, then proceed to Step 5. If not, incubate the cultures for 48 hours at 37°C in a humidified incubator with an atmosphere of 5–7% CO_2. Then proceed directly to either Step 6 (to assay for transient expression) or Step 7 (to establish stable transformants).

   Cells treated with DMSO are prone to detach from the dish. For this reason, the washing steps to remove the solvent-containing medium and the additions of fresh medium should be done as gently as possible, e.g., by slowly pipetting the medium against the side of the dish with each change.

5. (*Optional*) To facilitate the transfection of cells treated with DMSO and Polybrene:

   a. Add 500 mM sodium butyrate directly to the growth medium to a final concentration of 2.5–10 mM.

      The exact concentration of sodium butyrate added depends on the cell type and must be determined empirically.

   b. Incubate the cells for 20–24 hours at 37°C in a humidified incubator with an atmosphere of 5–7% CO_2.

   c. Remove the medium containing sodium butyrate, and replace it with butyrate-free medium containing 10% fetal bovine serum. Return the cells to the incubator.

      Sodium butyrate treatment of DMSO-permeabilized cells can enhance the transient (but not permanent) expression from certain recombinant plasmids (Aubin et al. 1997), especially those carrying the SV40 early promoter/enhancer, in simian and human cells (Gorman et al. 1983a).

6. If the objective is stable transformation of the cells, proceed directly to Step 7. For transient expression, examine the cells 1–2 days after transfection using one of the following assays:

   - If a plasmid DNA expressing *E. coli* β-galactosidase was used, follow the steps outlined in Chapter 17, Protocol 7, to measure enzyme activity in cell lysates. Alternatively, carry out a histochemical staining assay as detailed in the additional protocol in Protocol 1.
   - If a green fluorescence protein expression vector was used, examine the cells with a microscope under 450–490-nm illumination.
   - For other gene products, analyze the newly synthesized protein by radioimmunoassay, by immunoblotting, by immunoprecipitation following in vivo metabolic labeling, or by assays of enzymatic activity in cell extracts.

     To minimize dish-to-dish variation in transfection efficiency, it is best to (i) transfect several dishes with each construct, (ii) trypsinize the cells after 24 hours of incubation, (iii) pool the cells, and (iv) replate them on several dishes.

7. To isolate stable transfectants: After the cells have incubated for 48 hours in nonselective medium (to allow expression of the transferred gene[s] to occur [Step 4]), either trypsinize or replate the cells in the appropriate selective medium or add the selective medium directly to the cells without further manipulation. Change this medium every 2–4 days for 2–3 weeks to remove the debris of dead cells and to allow colonies of resistant cells to grow.

8. Thereafter, clone individual colonies and propagate for assay (for methods, please see Jakoby and Pastan 1979 or Spector et al. 1998b [Chapter 86 of *Cells: A Laboratory Manual*]).

   A permanent record of the numbers of colonies may be obtained by fixing the remaining cells with ice-cold methanol for 15 minutes, followed by staining with 10% Giemsa for 15 minutes at room temperature before rinsing in tap water. The Giemsa stain should be freshly prepared in phosphate-buffered saline or H_2O and filtered through Whatman No. 1 filter paper before use.

COTRANSFORMATION

Analysis of function and expression of transfected genes may require the stable integration of the transfected DNA into the host chromosome. After entering the cell, some of the transfected nucleic acid is transferred from the cytoplasm to the nucleus. Depending on the cell type, up to 80% of a population of cells will then express the transfected gene in a transient fashion. At some point within the first few hours after transfection, the incoming DNA undergoes a series of nonhomologous intermolecular recombination and ligation events to form a large concatemeric structure that eventually integrates into the cellular chromosome. Each transformed cell usually contains only one of these packages, which can exceed 2 Mb in size (Perucho et al. 1980). Stable cell lines can then be isolated that carry integrated copies of the transfected DNA. Transformation rates vary widely from cell type to cell type. In the best cases, ~1 cell in 10^3 in the original transfected population stably expresses a gene(s) carried by the transfected DNA.

Because the uptake, integration, and expression of DNA are relatively rare events, stable transformants are usually isolated by selection of cells that have acquired a new phenotype. Typically, this phenotype is conferred by the presence in the transfection mixture of a gene encoding antibiotic resistance. Cells transformed for a genetic marker present on one piece of DNA frequently express another genetic marker that was originally carried on a separate DNA molecule. Therefore, cells that stably express selectable (e.g., antibiotic-resistant) markers are also likely to have incorporated other DNA sequences present among the carrier DNA. This phenomenon, in which physically unlinked genes are assembled into a single integrated array and expressed in the same transformed cell, is known as cotransformation.

The first gene to be used extensively for selection in mammalian cells was a viral (herpes simplex) gene encoding thymidine kinase (TK; Wigler et al. 1977). Although many mammalian cell lines express thymidine kinase, several TK^- lines were created by selection for growth in the presence of 5-bromodeoxyuridine (BrdU). When transfected and stably integrated into the host genome of cell lines lacking thymidine kinase, the viral gene confers the TK^+ phenotype, thereby allowing growth in the presence of aminopterin (for a discussion of the basis for selection, please see the information panel on **SELECTIVE AGENTS FOR STABLE TRANSFORMATION**). Thereafter, this strategy was used to introduce foreign DNA in mammalian cells by cotransfection with a plasmid encoding the *tk* gene (Perucho et al. 1980; Robins et al. 1981). The difficulties or additional efforts involved in creating tk^- mutants promoted the search for other selection schemes. Therefore, other possibilities for selection in cotransformation studies were explored, leading to the development of vectors that express bacterial proteins which confer drug resistance in mammalian cell lines. These selectable markers include, for example, aminoglycoside phosphotransferase (resistance to G418 or neomycin), hygromycin-B phosphotransferase (resistance to hygromycin-B), xanthine-guanine phosphoribosyltransferase (resistance to mycophenolic acid and aminopterin), and puromycin-*N*-acetyl transferase (resistance to puromycin). All have been used with considerable success to establish stably transformed lines of mammalian cells.

In addition to providing a means to introduce exogenous genes into mammalian cells in a stable manner, it is often desirable to increase the stringency of the selective conditions in order to obtain higher levels of expression of the transfected genes. This enhancement in expression can be achieved as a result of increase in copy number, or coamplification, of the target gene and the gene conferring the resistance. A target gene that has been cotransfected with (and become integrated near) a particular marker gene is highly likely to undergo amplification with the marker under selection. Thus, the amplification of the dihydrofolate reductase (*dhfr*) gene resulting from exposure to increasing levels of methotrexate has been used successfully to overexpress cotransfected foreign genes (Schimke 1984). Similarly, the gene encoding adenosine deaminase (ADA) can be amplified through the stepwise increase in concentrations of 2′-deoxycoformycin (dCF; Kaufman et al. 1986) (for further details on gene amplification, please see Stark and Wahl 1984).

For further details on the basis for selection as well as selective conditions required for these systems, please see the information panel on **SELECTIVE AGENTS FOR STABLE TRANSFORMATION**.

SELECTIVE AGENTS FOR STABLE TRANSFORMATION

Resistance to antibiotics has proven to be effective in selecting cotransformants and, in some cases, as a driver for gene amplification.

Aminopterin

- ***Mode of action.*** Thymidine kinase catalyzes a reaction in an alternative pathway for the synthesis of dTTP from thymidine. The enzyme is not required under normal conditions of growth, as cells typically synthesize dTTP from dCDP. However, cells grown in the presence of aminopterin (an analog of dihydrofolate) are unable to utililize the usual pathway for synthesizing dTTP, and thus require thymidine kinase to make use of the alternative pathway.
- ***Selective conditions.*** Cell lines lacking endogenous thymidine kinase activity are grown in a complete medium supplemented with 100 μM hypoxanthine, 0.4 μM aminopterin, 16 μM thymidine, and 3 μM glycine (HAT medium).

G418

- ***Mode of action.*** This aminoglycoside antibiotic, similar in structure to neomycin, gentamycin, and kanamycin, is the most commonly used selective agent in permanent transfection experiments. G418 and its relatives block protein synthesis through interference with ribosomal functions. The bacterial enzyme aminoglycoside phosphotransferase, carried on the transposon sequence Tn5, converts G418 to a nontoxic form.
- ***Selective conditions.*** Because each eukaryotic cell line demonstrates a different sensitivity to this antibiotic (and some are completely resistant to it), the optimum amount required to kill nontransfected cells must be established empirically for each new cell line or strain used for permanent transfection. This optimum is established by determining a killing curve for the cell line of interest. In this type of experiment, a plasmid conferring resistance to G418 (e.g., pSV2*neo* or pSV3*neo*; Southern and Berg 1982) is transfected into the cells, and plates of transfected cells are subjected to different concentrations of G418. After a 2–3-week selection period, the concentration of G418 giving rise to the largest number of viable colonies is determined by visual inspection, or better by actual counting of the colonies after staining with Giemsa or gentian violet.

  Commercial preparations of G418 vary in their concentration of active antibiotic, with the average purity being ~50%. For this reason, each batch of G418 should be titrated before use in tissue culture. Despite this variation, the amount of G418 used to obtain optimal numbers of transfected colonies is constant for well-characterized cell lines. Table 16-5 gives the optimum G418 concentration ranges for use with several commonly used cell lines.

TABLE 16-5 Selective G418 Concentration Ranges

Cell Line or Organisms	G418 Concentration (μg/ml)
Chinese hamster ovary cells	700–800
Madin-Darby canine kidney cells	500
Human epidermoid A431 cells	400
Simian CV-1 cells	500
Dictyostelium	10–35
Plant	10
Yeast	125–500

TABLE 16-6 Selective Concentrations of Hygromycin B

Organism	Inhibitory Concentration of Hygromycin B	References
Escherichia coli	200 μg/ml	Gritz and Davies (1983)
Saccharomyces cerevisiae	200 μg/ml	Gritz and Davies (1983)
Mammalian cells	12–400 μg/ml, depending on the cell line	Sugden et al. (1985); Palmer et al. (1987)

Hygromycin B <!>

- ***Mode of action.*** Hygromycin B is an aminocyclitol antibiotic produced by *Streptomyces hygroscopicus* (Pittenger et al. 1953). Hygromycin B inhibits protein synthesis in both prokaryotes and eukaryotes by interfering with translocation (Cabañas et al. 1978; Gonzalez et al. 1978) and causing mistranslation in vivo and in vitro (Singh et al. 1979).

  A bacterial plasmid-borne gene has been identified and sequenced (Gritz and Davies 1983), which encodes a 341-amino-acid hygromycin-B phosphotransferase (Rao et al. 1983) that inactivates the antibiotic. This gene has been used as a selectable marker in *E. coli*, and chimeric genes constructed with the appropriate promoters act as dominant selectable markers in *Saccharomyces cerevisiae* (Gritz and Davies 1983; Kaster et al. 1984), mammalian cells (Santerre et al. 1984; Sugden et al. 1985), and plants (van den Elzen 1985; Waldron et al. 1985).
- ***Selective conditions.*** The concentrations of antibiotic required to inhibit growth of various organisms are presented in Table 16-6.

Methotrexate (MTX) <!>

- ***Mode of action.*** An analog of dihydrofolate, methotrexate is a powerful inhibitor of dihydrofolate reductase (DHFR), an enzyme required for purine biosynthesis. Increasing levels of methotrexate can result in amplification of the gene encoding DHFR with concomitant increase in its levels of expression. The system is therefore extremely effective for amplification of cotransfected genes (Simonsen and Levinson 1983).
- ***Selective conditions.*** The medium is typically supplemented with 0.01–300 μM methotrexate.

Mycophenolic Acid

- ***Mode of action.*** Mycophenolic acid, a weak dibasic acid with antibiotic properties, specifically inhibits inosinate (IMP) dehydrogenase, an enzyme of mammalian cells that converts IMP to xanthine monophosphate (XMP). This block to synthesis of guanosine monophosphate (GMP) can be relieved by supplying cells with xanthine and a functional *E. coli gpt* gene, which encodes an enzyme, xanthine-guanine phosphoribosyltransferase, that converts xanthine to XMP. *E. coli gpt* can therefore be used in the presence of mycophenolic acid as a dominant selectable marker for cotransformation of mammalian cells of any type (Mulligan and Berg 1981a,b). The selection can be made more efficient by the addition of aminopterin, which blocks the endogenous pathway of purine biosynthesis (for further details, please see Gorman et al. 1983b).
- ***Selective conditions.*** The concentration of antibiotic required to inhibit growth in mammalian cells is ~25 μg/ml.

Puromycin

- ***Mode of action.*** Puromycin, acting as an analog of aminoacyl tRNA, inhibits protein synthesis by causing premature chain termination. The antibiotic becomes acetylated, and thereby inactivated, by the action of puromycin-*N*-actyl transferase (de la Luna et al. 1988).
- ***Selective conditions.*** The concentrations of antibiotic required to inhibit growth of mammalian cell lines is typically in the range of 0.5–10 μg/ml; many transformed cell lines are effectively selected at 2 μg/ml.

LIPOFECTION

Lipofection is the generic name of a set of techniques used to introduce exogenous DNAs into cultured mammalian cells. Many variants of the basic method have been developed, but they all adhere to the same general principle: The DNA to be transfected is coated by a lipid, which either interacts directly with the plasma membrane of the cell (Bangham 1992) or is taken into the cell by nonreceptor-mediated endocytosis (Zhou and Huang 1994; Zabner et al. 1995), presumably as a prelude to membrane fusion in endosomes (Pinnaduwage et al. 1989; Leventis and Silvius 1990; Rose et al. 1991). However, as with other transfection techniques, only a small percentage of liposomes deliver their cargo of DNA into the nucleus (Tseng et al. 1997). As judged from microscopy, most of the DNA remains associated with the membrane compartments of the cell, where it is unavailable for transport into the cytoplasm and subsequent movement to the nucleus (Zabner et al. 1995). Nevertheless, when working at its best, lipofection can deliver DNA into cells more efficiently than precipitation with polycations such as calcium phosphate and at lower cost than electroporation.

Like other transfection techniques, lipofection is not universally successful: The efficiency of both transient expression and stable transformation by exogenously added genes varies widely from cell line to cell line. Different types of cells may show a range of quantitative responses to the same lipofection protocol. Different protocols used on the same cell line may generate results that span an extensive range. However, lipofection works very well in many situations where standard methods are notoriously inefficient, for example, transfection of primary cultures or cultures of differentiated cells (e.g., please see Thompson et al. 1999) or introduction of very high-molecular-weight DNA into standard cell lines (e.g., please see Strauss 1996). Lipofection is therefore the method of choice for introducing genes into differentiated cells in vitro and is the technique of first resort when older methods of transfection are inadequate.

The Chemistry of Lipofection

There are two general classes of liposomal transfection reagents: those that are anionic and those that are cationic. Transfection with anionic liposomes, which was first used in the late 1970s to deliver DNA and RNA to cells in a biologically active form, requires that the DNA be trapped in the internal aqueous space of large artificial lamellar liposomes (for reviews of this early work, please see Fraley and Papahadjopoulos 1981, 1982; Fraley et al. 1981; Straubinger and Papahadjopoulos 1983). However, the technique in its basic form never entered widespread use, perhaps because of its time-consuming nature and problems with reproducibility by investigators who were not expert in lipid chemistry.

The lipofection techniques in common use today stem from a seminal discovery by Peter Felgner that cationic lipids react spontaneously with DNA to form a unilamellar shell which can fuse with cell membranes (Felgner et al. 1987; Felgner and Ringold 1989). The formation of DNA-lipid complexes is due to ionic interactions between the head group of the lipid, which carries a strongly positive charge that neutralizes the negatively charged phosphate groups on the DNA (please see Figure 16-1).

The first generation of cationic lipids were monocationic double-chain amphiphiles with a positively charged quaternary amino head group (Duzgunes et al. 1989), linked to the lipid backbone by ether or ester linkages. Such monocationic lipids suffer from two major problems: They are toxic to many types of mammalian and insect cells, and their ability to promote transfection is restricted to a small range of cell lines (Felgner et al. 1987; Felgner and Ringold 1989). The later generations of cationic lipids are polycationic, have a far wider host range, and are considerably less toxic than their predecessors (for review, please see Gao and Huang 1993). In most cases, preparations of cationic lipids used for transfection consist of a mixture of synthetic cationic lipid and a fusogenic lipid (phosphatidylethanolamine or DOPE). Several cationic and polycationic lipids active in transfection are described in Table 16-4. Depending on the composition of the lipid mixture, the DNA to be transfected becomes incorporated either into multilamellar structures composed of alternating layers of lipid bilayer and hydrated DNA or into hexagonal columns arranged in a honeycomb structure (Labat-Moleur et al. 1996; Koltover et al. 1998). Each column or tube in the honeycomb consists of a central core of hydrated DNA molecules and a surrounding hexagonal shell of lipid monolayers. Experiments with model systems suggest that honeycomb arrangements of this type deliver DNA across lipid bilayers more efficiently than multilamellar structures.

A Plethora of Lipofectants Is Available

The same properties of lipids that facilitate the formation of transfection-competent structures with DNA also bring unwanted side effects. Chief among these are a generalized toxicity, which is manifested by cells rounding up and detaching from the dish. In addition, lipofection is vulnerable to interference by fats and lipoproteins in serum and by charged components of the extracellular matrix such as chondroitin sulfate (Felgner and Holm 1989). Systematic modifications of the cationic and neutral lipids have been made in an effort to overcome these drawbacks (e.g., please see Behr et al. 1989; Felgner et al. 1994), resulting in a wealth of effective lipofection reagents. Unfortunately, these reagents, many of which are commercially available, work with varying efficiencies with different types of cells. Although few head-to-head comparisons of efficiency are available, the companies that market these reagents for lipofection provide useful bibliographies and lists of cell lines that can be efficiently transfected with the help of their particular products. The toxicity of these compounds varies from cell line to cell line, as does inter alia, the optimal ratio of cationic lipids:DNA and the amount of cationic lipid that can be added to a given number of cells (e.g., please see Felgner et al. 1987; Ho et al. 1991; Ponder et al. 1991; Farhood et al. 1992; Harrison et al. 1995).

Optimizing Lipofection

In addition to the properties and chemical composition of the cationic and neutral lipids, several other variables affect the efficiency of lipofection, including:

- ***Initial density of the cell culture.*** Cell monolayers should be in mid-log phase and should be between 40% and 75% confluent.
- ***Amount of DNA added per dish.*** Depending on the concentration of the sequences of interest, as little as 50 ng and as much as 40 μg of DNA might be required to obtain maximum signal from a reporter gene.
- ***Medium and serum used to grow the cells.***
- ***Time of exposure of cells to the cationic lipid-DNA complex,*** which varies from 0.1 to 24 hours.
- ***Purity of the DNA preparation.*** Wherever possible, the DNA should be dissolved in H_2O rather than buffers containing EDTA. Plasmid preparations used for lipofection should be free of bacterial lipopolysaccharides and should preferably be purified by chromatography on anion exchange resins or by CsCl–ethidium bromide equilibrium density centrifugation.

All of these variables must be optimized in order to establish optimum transfection frequencies for a target cell line.

TRANSFECTION OF MAMMALIAN CELLS WITH CALCIUM PHOSPHATE–DNA COPRECIPITATES

DNA can be introduced into many lines of cultured mammalian cells as a coprecipitate with calcium phosphate. After entering the cell by endocytosis, some of the coprecipitate escapes from endosomes or lysosomes and enters the cytoplasm, from where it is transferred to the nucleus. Depending on the cell type, up to 50% of a population of cells then express transfected genes in a transient fashion. Transformed cell lines that carry integrated copies of the transfected DNA can also be selected, although at a much lower frequency. Transformation rates vary widely from cell type to cell type. In the best cases, ~1 cell in 10^3 permanently expresses a selectable marker(s) carried by the transfected DNA.

Calcium-phosphate-mediated DNA transfection was developed by Frank Graham and Alex van der Eb (1973) as a method to introduce adenovirus and SV40 DNA into adherent cultured cells. Graham and van der Eb worked out optimal conditions for the formation of calcium phosphate–DNA coprecipitates and for subsequent exposure of cells to the coprecipitate. Their work laid the foundation for the biochemical transformation of genetically marked mouse cells by cloned DNAs (Maitland and McDougall 1977; Wigler et al. 1977); for the transient expression of cloned genes in a variety of mammalian cells (e.g., please see Gorman 1985); and for the isolation and identification of cellular oncogenes, tumor-suppressing genes, and other single-copy mammalian genes (e.g., please see Wigler et al. 1978; Perucho and Wigler 1981; Weinberg 1985; Friend et al. 1988). However, Graham and van der Eb never profited financially from their discovery. That was left to Wigler, Axel, and their colleagues who in 1983 were awarded a lucrative patent for cotransformation of unlinked segments of DNA by the calcium phosphate method (please see the information panel on **COTRANSFORMATION**).

Published procedures differ widely in the manner in which calcium phosphate–DNA coprecipitates are formed prior to their addition to cells. Some methods advise against anything but the gentlest agitation and suggest, for example, that air bubbled gently from an electric pipetting device should be used to mix the DNA and the buffered solution of calcium phosphate. Other methods advocate slow mixing during addition of the DNA solution, followed by gentle vortexing. Whatever technique is chosen, the aim should be to avoid creation of coarse precipitates that are endocytosed and processed inefficiently by cells. In addition to the speed of mixing, the following are other factors that affect the efficiency of transfection:

- ***Size and concentration of the DNA.*** The inclusion of high-molecular-weight genomic DNA in the coprecipitate increases the efficiency of transformation by small DNAs (e.g., plasmids) (e.g., please see Chen and Okayama 1987). Soon after transfection, the small DNAs integrate in the carrier DNA, often forming an array of head-to-tail tandems. This assemblage subsequently integrates into the chromosome of the transfected cell (Perucho and Wigler 1981).
- ***Exact pH of the buffer and the concentration of calcium and phosphate ions*** (Jordan et al. 1996). Some investigators make up several batches of HEPES-buffered saline over the pH range 6.90–7.15 and test each batch for the quality of the calcium phosphate–DNA precipitates and for the efficiency of transformation.
- ***Use of facilitators.*** Increases in the efficiency of transient expression and transformation can be achieved by exposing cells to glycerol (Parker and Stark 1979), chloroquine (Luthman and Magnusson 1983), commercially available "transfection maximizers" (e.g., please see Zhang and Kain 1996), or certain inhibitors of cysteine proteases (Coonrod et al. 1997). In general, these agents are toxic to cells, and their effects on viability and transfection efficiently vary from one type of cell to another. For example, chloroquine, an amine that prevents acidification of endosomes and lysosomes and inhibits lysosomal protease cathepsin B (Wibo and Poole 1974), improves the transfection efficiency of some types of cells and decreases the efficiency of others (Chang 1994). The optimal time, length, and intensity of treatment with facilitators must therefore be determined empirically for each cell line.

The level of transient expression is determined chiefly by the intensity of transcription from the promoter and its associated *cis*-acting control elements. In specific cases, it may be possible to increase the level of expression by exposing the transfected cells to hormones, heavy metals, or other substances that activate the appropriate cellular transcription factors. In addition, expression of genes carried on plasmids that contain the SV40 enhancer can be enhanced by treating transfected simian and human cells with sodium butyrate (Gorman et al. 1983a,b). Transfection kits, which frequently include these and other modifications to the original protocol, are available from a number of companies (please see Table 16-2).

DNA transfected as a calcium phosphate coprecipitate or with DEAE-dextran as a facilitator is mutated at a high frequency (~1% per gene) in all mammalian cells examined (Calos et al. 1983; Lebkowski et al. 1984). This effect is confined to the transfected sequences and does not affect the chromosomal DNA of the host cell (Razzaque et al. 1983). The mutations, which are predominantly base substitutions and deletions, appear to occur shortly after the transfecting DNA arrives in the nucleus (Lebkowski et al. 1984). However, replication of the incoming DNA is not necessary. Because almost all of the base substitutions occur at G:C base pairs, it seems likely that the major premutational events are hydrolysis of the sugar base glycosyl bond of deoxyguanosine residues and deamination of cytosine residues. Both of these reactions occur readily at acid pH and would take place as the incoming DNA passes through endosomes, which maintain a pH of ~5 (de Duve et al. 1974). Linear DNA is especially prone to deletions (Razzaque et al. 1983; Miller et al. 1984) presumably because it serves as an attractive substrate for exonucleases. Although these mutation rates are extraordinarily high, they have little relevance to transient expression of transfected genes unless the gene of interest is large and/or has a very high content of G+C. Most of the work on mutation rates was carried out with *lacI*, which is encoded by a 750-bp segment of DNA. A gene that is 10 kb in length might therefore be expected to suffer a mutation rate of 12% or more depending on its content of G+C.

CHLOROQUINE DIPHOSPHATE

Chloroquine (F.W. = 519.5), an amine that prevents acidification of endosomes and lysosomes and inhibits lysosomal protease cathepsin B (Wibo and Poole 1974), increases the efficiency of transfection of some types of cells and decreases the efficiency of others (Chang 1994). By inhibiting acidification of lysosomes, chloroquine may prevent or delay the degradation of transfecting DNA by lysosomal hydrolases (Luthman and Magnusson 1983). Unfortunately, the beneficial effects of chloroquine are modest and do not extend to all cell lines. In fact, although treatment with chloroquine improves the transfection efficiency of some types of cells, it decreases the efficiency of others (Chang 1994). Because the balance between the benefits and disadvantages of chloroquine varies so widely from cell line to cell line, there is simply no way to predict whether the drug will lead to a useful increase in transfection frequency in a particular circumstance. However, if low frequencies of transfection are a problem, it is certainly worth exploring whether chloroquine can help. The optimal time, length, and intensity of treatment must be determined empirically for each cell line. Typically, however, cells will be exposed to chloroquine diphosphate at a final concentration of 100 μM for 3–5 hours either before, during, or after the cells are exposed to a calcium phosphate–DNA coprecipitate, or during exposure of cells to a mixture of DNA and DEAE-dextran. In the presence of chloroquine, the cells develop a vesicularized appearance. After the treatment, the cells are washed with phosphate-buffered saline and medium and then incubated for 24–60 hours before assaying for expression of the transfected DNA. Chloroquine diphosphate is prepared as a 100 mM stock solution (52 mg/ml in H_2O), which should be sterilized by filtration and stored in foil-covered tubes at –20°C.

ELECTROPORATION

Nucleic acids do not enter cells under their own power; they require assistance in crossing physical barriers at the cell boundary and in reaching an intracellular site where they can be expressed and/or replicated. Exposure of many types of cells to an electrical discharge reversibly destabilizes their membranes and transiently induces the formation of aqueous pathways or membrane pores (Neumann and Rosenheck 1972; Neumann et al. 1982; Wong and Neumann 1982; for reviews, please see Zimmermann 1982; Andreason and Evans 1988; Tsong 1991; Weaver 1993) that potentiate the entry of DNA molecules (Neumann et al. 1982). This method, which is known as electroporation, has been developed into a rapid, simple, and efficient technique for introducing DNA into a wide variety of cells, including bacteria, yeasts, plant cells, and a large number of cultured mammalian cell lines. The chief practical advantages of electroporation are that it can be applied to a wide variety of cells, both prokaryotic and eukaryotic, and that it is extremely simple to carry out.

The Mechanism of Electroporation

Because the changes in membrane structure that accompany electroporation cannot be visualized in real time by microscopy, our understanding of the mechanism is based on evidence that is both patchy and circumstantial. While evidence for many of the steps is lacking, the following model (Weaver 1993) nevertheless provides a plausible account of the sequence of events that are initiated by increasing the transmembrane voltage from its physiological value of ~0.1 to 0.5–1.0 V. Figure 16-4 shows the following sequence of events:

- ***The onset of electroporation causes a membrane dimple*** followed by formation of transient hydrophobic pores whose diameter fluctuates from a minimum of 2 nm to a maximum of several nanometers.
- ***Some of the larger hydrophobic pores are converted to hydrophilic pores*** because the energy needed to form an aqueous pore is reduced as the transmembrane voltage is increased and the energy required to maintain the circumference of a large hydrophilic pore is significantly lower than that required to maintain a large hydrophobic pore. For this reason, hydrophilic pores have an extended half-life and may be further stabilized by attachment to underlying cytoskeletal elements. The generation of such long-lived metastable pores allows small ions and molecules to enter and leave the cell long after the transmembrane voltage has returned to low values (Rosenheck et al. 1975; Zimmermann et al. 1976; Lindner et al. 1977). The detailed mechanism by which molecules pass through hydrophilic pores is not known, but may include electrophoresis (Chermodnick et al. 1990) electroendo-osmosis, diffusion, and endocytosis (Weaver and Barnett 1992). Reclosing of the pores appears to be a stochastic process that can be delayed by keeping the cells at 0°C. While the pores remain open, up to 0.5 pg of DNA can enter the cell (Bertling et al. 1987). Size seems to be no impediment since DNA molecules up to 150 kb in size can easily pass through the pores (Knutson and Yee 1987). Because the DNA enters directly into the cytoplasm, it is not exposed to acid conditions in endosomes and lysosomes. This route may explain why the rate of mutation in DNA introduced to mammalian cells by electroporation is apparently very low (Drinkwater and Kleindienst 1986; Bertling et al. 1987) compared with DNA transfected as calcium phosphate coprecipitates or DEAE-dextran complexes (e.g., please see Calos et al. 1983). For *E. coli*, electroporation is currently the most efficient method available for transformation with plasmids. In excess of 80% of the cells in a culture can be transformed to ampicillin resistance by this method and efficiencies of transformation approaching the theoretical maximum of one transformant per molecule of plasmid DNA have been reported (Smith et al. 1990). However, the number of transformants obtained is marker-dependent. When pBR322, which carries genes conferring resistance to two antibiotics (ampicillin and tetracycline), is introduced into *E. coli* by electroporation, the number of tetracycline-resistant transformants is ~100-fold less than the number of ampicillin-resistant transformants (Steele et al. 1994). This effect is not seen when the plasmid is introduced to the bacteria by the calcium chloride method. One possible explanation is that electroporation damages or changes the bacterial membrane so that it can no longer interact efficiently with the tetracycline resistance protein.

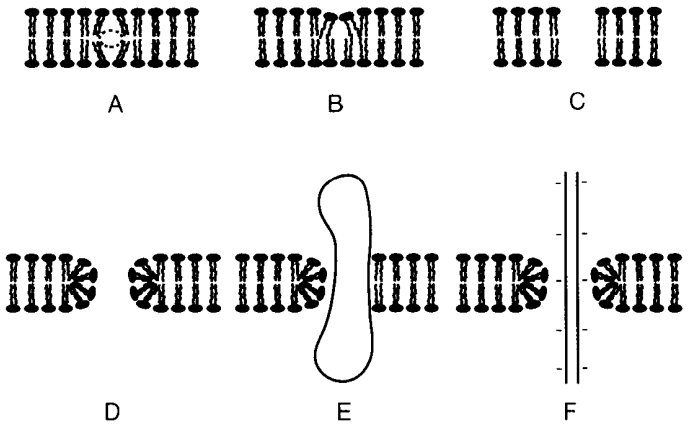

FIGURE 16-4 Changes in the Membrane during Electroporation

Drawings of hypothetical structures for transient and metastable membrane conformations believed to be relevant to electroporation. (*A*) Fredd volume fluctuation; (*B*) aqueous protrusion or "dimple"; (*C,D*) hydrophobic pores usually regarded as the "primary pores" through which ions and molecules pass; (*E*) composite pore with "foot in the door" charged macromolecule inserted into a hydrophilic pore. The transient aqueous pore model assumes that transitions from A→B→C or D occur with increasing frequency as U is increased. Type F may form by entry of a tethered macromolecule, while the transmembrane voltage is significantly elevated, and then persist after U has decayed to a small value through pore conduction. It is emphasized that these hypothetical structures have not been directly observed and that support for them derives from the interpretation of a variety of experiments involving electrical, optical, mechanical, and molecular transport behavior. (Redrawn, with permission, from Weaver 1993 [copyright Wiley-Liss, Inc.].)

Typically, between 50% and 70% of cells exposed to high electric field strengths are killed. The lethal effects, which vary in intensity from one cell type to another, are not due to heating or electrolysis and are independent of the current density and energy input. Instead, cell killing is dependent on field strength and the total time of treatment (Sale and Hamilton 1967). The most likely cause of cell killing is the rupture of cell membranes, which leads to rapid loss of ionic balance and massive efflux of cellular components.

Electrical Conditions Required for Electroporation

Electroporation of almost all mammalian cells is induced when the transmembrane voltage, $\Delta U(t)$, is increased to 0.5–1.0 V for durations of microseconds to milliseconds. This translates to an electric field strength of ~7.5–15.0 kV/cm. Because this value is constant and is independent of the biochemical nature of the cell membrane, it seems likely that variations in the efficiency of electroporation from cell line to cell line are due to differences in the rate and efficiency of membrane recovery at the end of the pulse.

The transmembrane voltage, $\Delta U(t)$, induced by electric fields varies in direct proportion to the diameter of the cell that is the target for transfection (Knutson and Yee 1987). Electroporation of mammalian cells, for example, requires smaller electric fields (<10 kV/cm) than does electroporation of yeasts or bacteria (12.5–16.5 kV/cm). Most of the commercial suppliers of electroporation machines provide literature describing the approximate voltages required for transfection of specific types of cells in their particular apparatus.

Three important characteristics of the pulse affect the efficiency of electroporation: the *length* of the pulse, its *field-strength*, and its *shape*. Most of the commercial electroporation machines use capacitative discharge to produce controlled pulses whose length is mainly determined by the value of the capacitor and the conductivity of the medium. Thus, the time constant of the pulse can be altered by switching capacitors according to the manufacturer's instructions or by changing the ionic strength of the medium. When the

charge from the capacitor is directed to a sample placed between two electrodes, the voltage across the electrodes rises rapidly to a peak (V_0) and declines over time (t) according to the equation:

$$V_t = V_0[e^{-F(t,\tau)}]$$

where t is the time constant, which is equal to the time over which the voltage declines to ~37% of peak value. τ (measured in seconds) is also equal to the product of the resistance (R, measured in ohms [Ω]) and the capacitance (C, in Farads [F]):

$$\tau = RC$$

From this equation, it follows (1) that a larger capacitor requires more time to discharge through a medium of a given resistance and (2) that a capacitor of a given size discharges more slowly as the resistance of the medium increases. Electroporation of mammalian cells is usually carried out in buffered saline solutions or culture media using a capacitor of 25.0 μF whose discharge has a time constant of ~0.5 msec.

The *field strength* (E) of the pulse varies in direct proportion to the applied voltage (V) and in inverse proportion to the distance (d) between the two electrodes, which is usually determined by the size of the cuvette through which the pulse travels.

$$E = F(V,d)$$

Most manufacturers provide cuvettes in three sizes, where the interelectrode distances are, respectively, 0.1 cm, 0.2 cm, and 0.4 cm. When 1000 V are discharged into these cuvettes, E_0 is 10,000 V/cm in the 0.1-cm cuvette, 5000 V/cm in the 0.2-cm cuvette, and 2500 V/cm in the 0.4-cm cuvette.

The *shape* of the pulse is determined by the design of the electroporation device. The wave form produced by most commercial machines is simply the exponential decay pattern of a discharging capacitor. In some types of electroporation apparatuses, square waves can be generated by rapidly increasing the voltage, maintaining it at the desired level for a specified time (pulse width), and then rapidly reducing the voltage to zero. Square pulses can be grouped into two general categories: very high field strength of very short duration (typically 8 kV/cm for 5.4 msec) (Neumann et al. 1982), and low field strength of medium to long duration (e.g., <2 kV/cm for >10 msec) (e.g., please see Potter et al. 1984). Although differences in the effectiveness of these various waveforms have been reported from time to time (e.g., please see Knutson and Yee 1987), there is no evidence that any one of them is consistently better than any other. For all practical purposes, the exponential wave forms produced by commercial electroporation machines are perfectly satisfactory.

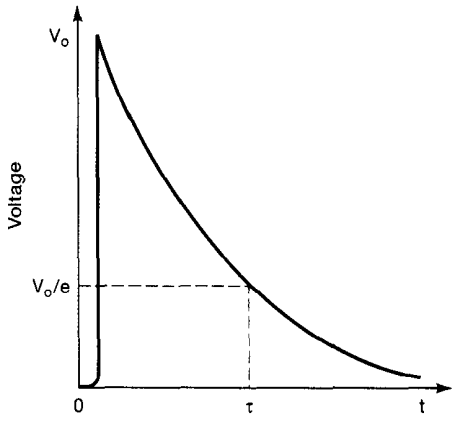

FIGURE 16-5 Changes in the Electric Field during Electroporation

Time course of the electric field generated by capacitor discharge. V_0 represents the time constant for the decay of the electric field; (τ)*RC*, where *C* is the capacitance of the discharge capacitor and *R* is the resistance of the discharge unit; the resistance of the sample cell usually determines the circuit resistance. (*t*) Time.

Optimizing Conditions for Electroporation

A major advantage of electroporation over other methods of transfection is that it works for a very wide variety of mammalian cells, including those that are difficult to transfect by other means (e.g., please see Potter et al. 1984; Tur-Kaspa et al. 1986; Chu et al. 1987). However, despite its advantages, electroporation is not always the most efficient way to introduce DNA into a particular cell line. For example, COS cells are transfected most efficiently by the DEAE-dextran/DNA method (Kluxen and Lübbert 1993), whereas for other cell lines, lipofection or polybrene treatment are the techniques of choice (e.g., please see Jiang et al. 1991). To find out whether electroporation is a useful method of transfection for a particular cell line, it is important to use a range of field strengths and pulse lengths and thereby to establish conditions that generate the maximum numbers of transfectants. Such conditions have been reported for >50 types of mammalian cells, and it is sometimes possible to save a lot of work by simply reading the relevant literature. Most of the companies that sell electroporation devices produce excellent up-to-date lists of papers in which electroporation has been used for transfection. These bibliographies are often the easiest way to gain access to information about the properties of a particular cell line or its close relatives. However, because of variation in properties between different cultivars of the same cell line, it is important for investigators to confirm that the conditions described in the literature are optimal for cells grown in their laboratory.

Because transfection and cell killing are independently determined by field strength (Chu et al. 1987), it is best to expose aliquots of cells to electric fields of increasing strength with time constants between 50 and 200 msec. For each field strength, measure (1) the number of cells that express a transfected reporter gene (10–40 μg/ml of linearized plasmid DNA in the electroporation buffer) and (2) the proportion of cells that survive exposure to the electric field. Plating efficiency is a more accurate measure of cell survival than staining with vital dyes since, after electroporation, cells can remain permeable to vital dyes such as trypan blue for an hour or two. The following are other variables that have been reported to affect the efficiency of electroporation.

- ***The temperature of the cells before, during, and after electroporation*** (e.g., please see Potter et al. 1984; Chu et al. 1987). Usually, electroporation is carried out on cells that have been prechilled to 0°C. The cells are held at 0°C after electroporation (to maintain the pores in an an open position) and are diluted into warm medium for plating (Rabussay et al. 1987).
- ***The concentration and conformation of the DNA*** (e.g., please see Neumann et al. 1982; Potter et al. 1984; Tonneguzzo and Keating 1986). Linear DNA is preferred for stable transformation; circular DNA is for transient transfection. Preparations containing DNA at a concentration of 1 μg/ml to 80 μg/ml are optimal.
- ***The state of the cells.*** The best results are obtained with cell cultures in the mid-log phase of growth that are actively dividing.

Chapter 17

Analysis of Gene Expression in Cultured Mammalian Cells

THIS CHAPTER DEALS WITH FOUR EXPERIMENTAL METHODS that are commonly used to measure the transcriptional activity of mammalian genes and to regulate their expression in transfected cells.

- ***Identifying DNA-protein complexes.*** *cis*-acting regulatory regions of genes bind *trans*-acting factors that can either protect target sequences from experimental attack by deoxyribonuclease or can enhance their sensitivity to the enzyme. Protocol 1 describes methods for "footprinting" regulatory elements of DNA to identify regions that bind nuclear proteins. Target sequences also can be identified by forming DNA-protein complexes and analyzing the products by gel retardation assays, as described in Protocol 2. For further information, please see the information panels on **FOOTPRINTING DNA** and **GEL RETARDATION ASSAYS** at the end of this chapter. Protocol 3 describes a method to scan regions within and distal to genes for potential regulatory sequences whose sensitivity to digestion with exogenous DNase I changes as a function of transcriptional activity. These so-called hypersensitive sites are detected by Southern hybridization of the products of digestion of genomic DNA in isolated nuclei using a probe derived from the target gene.

- ***Analyzing primary transcripts by transcriptional run-on.*** Protocol 4 describes a method to measure the intensity of transcription of a target gene under different experimental conditions. Nuclei isolated from cells expressing the gene of interest are radiolabeled in vitro, and the resulting labeled RNAs are hybridized to a vast excess of the cloned gene. The amount of radioactivity specifically bound to the target sequences is a measure of its transcriptional activity. Please note that methods to measure and analyze steady-state mRNA levels are described in Chapters 7 and 8 of this book. These methods include ribonuclease protection, primer extension, northern blotting, and real time PCR.

- ***Using reporter genes as markers to map regulatory elements and to quantify their power.*** Protocols 5, 6, and 7 describe the use of three different reporter genes encoding easily assayed enzyme activities: chloramphenicol acetyltransferase (CAT), luciferase, and β-galactosidase. The strengths and weaknesses of these three systems are compared in the introduction preceding Protocol 5.

- ***Regulating expression of target genes.*** Regulatory systems controlled by small diffusible ligands can be imported into mammalian cells and used to control the expression of target genes. Protocol 8 describes the use of tetracycline-responsive systems to regulate expression of transiently transfected genes. Protocol 9 describes how analogs of the insect hormone ecdysone can be used as a inducer of gene expression in mammalian cells.

Expression systems based on the use of baculovirus vectors have proven to be tremendously useful for the production of foreign proteins, fusion proteins, and simultaneous expression of two or more (up to four) proteins. For further details, please see the information panel on **BACULOVIRUSES AND BACULOVIRUS EXPRESSION SYSTEMS.** Protocols for the use of the baculovirus expression system may be found in Spector et al. (1998; Chapter 66 of *Cells: A Laboratory Manual*).

Science is built up with facts, as a house is with stones. But a collection of facts is no more a science than a heap of stones is a house.

Henri Poincare (1854–1912)

Protocol 1

Mapping Protein-binding Sites on DNA by DNase I Footprinting

DNASE I FOOTPRINTING IS A METHOD TO VISUALIZE DIRECTLY the binding of a protein to a specific DNA sequence (please see Figure 17-1) (Galas and Schmitz 1978). The assay is usually used in combination with gel retardation assays (please see Protocol 2) to identify nuclear factors that bind to sequences in the regulatory regions of genes. A DNase I "footprint" is generated when a bound transcription factor protects a segment of DNA from the nucleolytic activity of DNase I. In a typical experiment, the pattern of DNase I cleavage obtained for a target DNA fragment in the presence and absence of nuclear extract is compared. Footprints appear as tracts where no cleavage occurs in the presence of nuclear extract. By comparing the electrophoretic mobility of the DNase I cleavage products to those of a sequence ladder derived from the same DNA fragment, the position of the footprint, and hence the DNA sequence recognized by a DNA-binding protein, can be determined. Overall, the method is fast and sensitive and provides resolution at the nucleotide level.

In this protocol, we describe methods for mapping protein-binding sites on a radiolabeled fragment of DNA. The protocol uses DNase I to fragment the DNA, whereas an alternative protocol uses hydroxyl radicals to fragment the DNA. For suggestions on how to optimize the footprinting reactions, please see the panel on **TROUBLESHOOTING AND OPTIMIZATION OF DNASE I FOOTPRINTING** at the end of this protocol.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Cell homogenization buffer

10 mM HEPES-KOH (pH 7.9) <!>
1.5 mM $MgCl_2$
10 mM KCl
0.5 mM dithiothreitol
0.5 mM phenylmethylsulfonyl fluoride <!>

Cell homogenization buffer containing 0.05% (v/v) Nonidet P-40

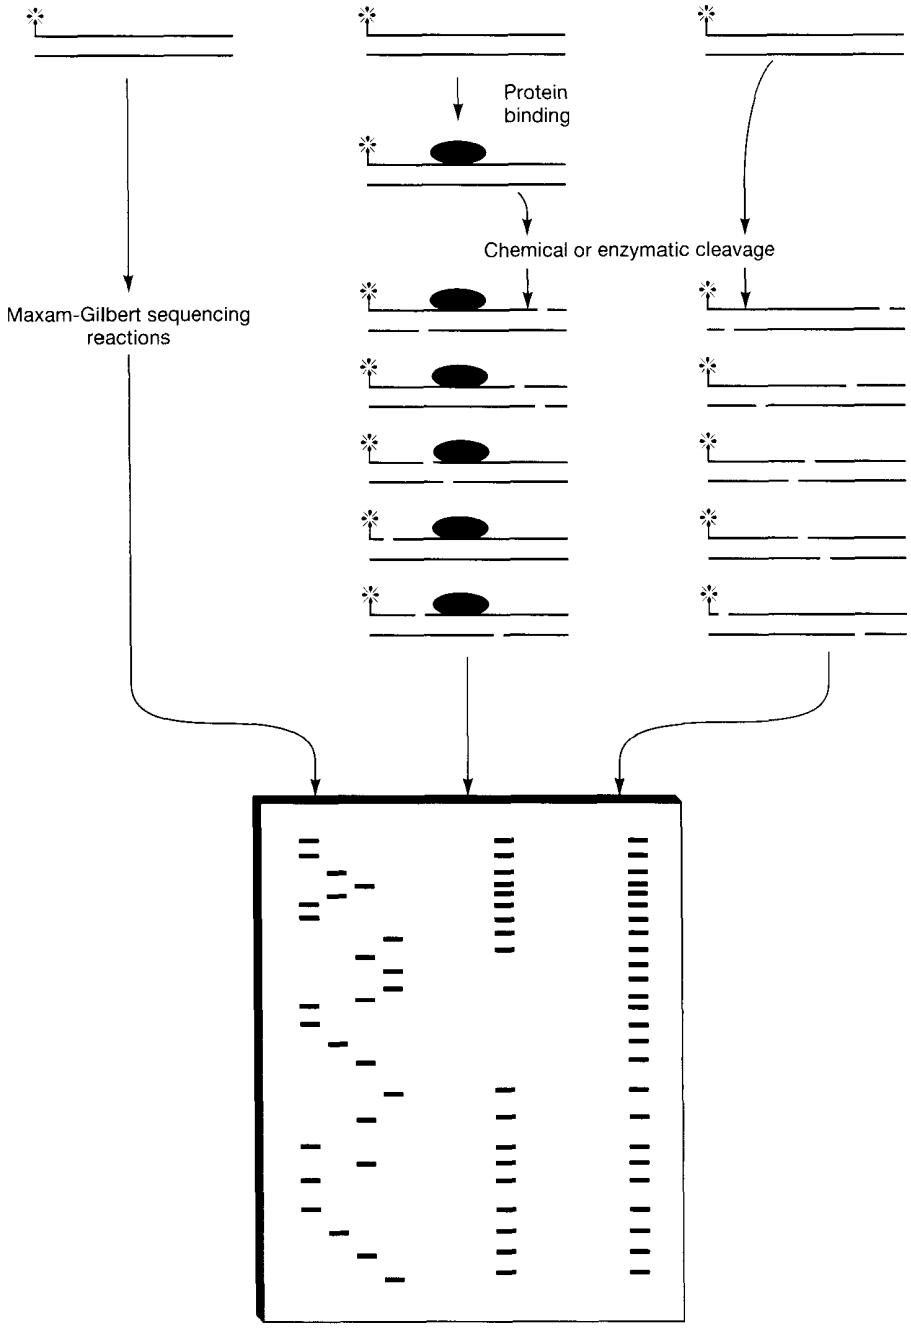

FIGURE 17-1 Steps Involved in DNA Footprinting

A fragment of double-stranded DNA of defined length is first labeled at one end of one strand, incubated with a putative DNA-binding protein and then incubated with a cleavage reagent under conditions that result in an average of one cleavage event per labeled molecule. The DNA is purified and analyzed by electrophoresis through a denaturing polyacrylamide gel. If cleavage occurs randomly, the resulting populations of radiolabeled single-stranded DNA fragments will differ in length by a single nucleotide and will appear as a semicontinuous ladder after autoradiography of the gel. However, if a region of DNA is protected from cleavage by a bound protein, there will be a gap in the ladder of radioactive fragments. This "footprint" can be precisely located by aligning the gap with a set of Maxam-Gilbert sequencing reactions, carried out on the same radiolabeled DNA.

Cell resuspension buffer

40 mM HEPES-KOH (pH 7.9)
0.4 M KCl
1 mM dithiothreitol
10% (v/v) glycerol
0.1 mM phenylmethylsulfonyl fluoride
0.1% (w/v) aprotinin

Store the buffer at 0°C until needed.

Cell rinse buffer

40 mM Tris-Cl (pH 7.4)
1 mM EDTA
0.15 M NaCl

Store the buffer at 0°C until needed.

Ethanol

Ficoll 400 (20% w/v)

Dissolve the Ficoll in sterile H_2O and store the solution frozen in 100-µl aliquots at –20°C.

Formamide dye mix <!>

10 ml of formamide
10 mg of xylene cyanol FF
10 mg of bromophenol blue

Store at room temperature.

$MgCl_2/CaCl_2$ solution

10 mM $MgCl_2$
5 mM $CaCl_2$

Sterilize the solution by filtration and store the filtrate at room temperature.

NaCl (5 M)

Nonidet P-40 (0.05% v/v)

Phenol:chloroform <!>

Phosphate-buffered saline without calcium and magnesium salts

Polyvinyl alcohol (10% w/v)

Dissolve the polyvinyl alcohol in sterile H_2O and store the solution frozen in 100-µl aliquots at –20°C.

Stop mix

20 mM EDTA (pH 8.0)
1% (w/v) SDS
0.2 M NaCl
125 µg/ml yeast tRNA

Tissue homogenization buffer

10 mM HEPES-KOH (pH 7.6)
25 mM KCl
0.15 mM spermine
0.5 mM spermidine
1 mM EDTA (pH 8.0)
2 M sucrose
10% (v/v) glycerol

The buffer should be ice cold at the time of use. Add protease inhibitors such as 0.5 mM phenylmethylsulfonyl fluoride (PMSF), 1 µg/ml leupeptin, 1 µg/ml pepstatin, or others as needed, just before Step 1.

Tissue resuspension buffer

5 mM HEPES-KOH (pH 7.9)
1.5 mM $MgCl_2$
0.5 mM dithiothreitol
0.5 mM phenylmethylsulfonyl fluoride
26% (v/v) glycerol

Store the buffer at 0°C until needed.

Trypan Blue dye (0.4% w/v)

Dissolve an appropriate amount of dye in phosphate-buffered saline without calcium and magnesium salts. Store the solution at room temperature.

Enzymes and Buffers

DNase I (1 mg/ml)

Dissolve the enzyme in 10 mM Tris-Cl (pH 8.0). Store the solution frozen in small aliquots at –20°C. Dilute the solution 1:100 in ice-cold 10 mM Tris-Cl (pH 8.0) just before Step 3.

Gels

Denaturing 6% or 8% polyacrylamide sequencing gel (Chapter 12, Protocol 8) <!>

Nucleic Acids and Oligonucleotides

Poly(dI-dC) (1 mg/ml)

Dissolve an appropriate amount of poly(dI-dC) in sterile H_2O and store the solution in 100-µl aliquots at –20°C. The nucleic acid copolymer is added to decrease nonspecific binding of proteins to the radiolabeled DNA fragment. The optimum concentration (usually between 0 and 100 µg/ml) of poly(dI-dC) in a binding reaction should be determined empirically. Other nucleic acids that can be used to decrease nonspecific binding include sheared genomic DNA (e.g., from *E. coli*, salmon sperm, or calf thymus), tRNAs, sheared or restricted plasmid DNA, poly(dA-dT), and poly(dG-dC).

Sequencing gel size standards

These typically consist of the (A+G) reactions of a Maxam and Gilbert sequencing experiment derived from the target DNA fragment. For a method to perform chemical sequencing reactions, please see Chapter 12, Protocol 7. Alternatively, use a dideoxy terminator sequencing reaction (Chapter 12, Protocols 3–6), of a DNA whose 5′ end is identical to the radiolabeled end of the DNA fragment digested with DNase I.

Radioactive Compounds

^{32}P-end-labeled DNA (200–500 bp in length, specific activity ≥2.5 x 10^7 cpm/µg/≥5000 cpm/fmole) <!>

End labeling of the DNA fragment can be accomplished by phosphorylation (Chapter 9, Protocols 13–16, or Chapter 10, Protocol 2), by filling in of a 3′-recessed end using a DNA polymerase (Chapter 9, Protocols 10 and 11, or Chapter 10, Protocol 7), or by using an end-labeled primer in a polymerase chain reaction (PCR; Chapter 8, Protocol 1). Of these, the latter method is fastest, independent of restriction sites, and allows the positioning of the DNA-binding site at multiple positions relative to the end label. Whatever method of radiolabeling is used, purify the DNA fragment by electrophoresis through an agarose or polyacrylamide gel before use in the footprinting reaction.

The DNA fragment used in the reaction should be 200–500 bp in length, with the binding site of interest at least 30 bp from the radiolabeled end. Resolution on the sequencing gel deteriorates when longer DNA fragments are used. Sites that are too close to an end may not be recognized by the DNA-binding protein or by DNase I.

Centrifuges and Rotors

Beckman SW28 rotor or equivalent, chilled to 4°C
Sorvall H1000B rotor or equivalent, chilled to 4°C

Special Equipment

Boiling water bath
Dounce homogenizer with type-B pestle
Polyallomer or ultraclear swinging-bucket centrifuge tubes
Rubber policeman

Additional Reagents

Steps 7–10 of this protocol require the reagents listed in Chapter 12, Protocols 8, 11, and 12.

Cells and Tissues

Fresh tissue, Cultured cells, or Protein fractions derived from cells or tissues

CONTROL REACTIONS FOR DNASE I FOOTPRINTING

At least two control reactions (described in Step 2) should be included in every experiment. A control lacking any DNA-binding protein is required to identify regions of the naked DNA fragment that are resistant to digestion with DNase I or that are only partially digested. A control reaction lacking DNase I but including DNA-binding protein(s) exposes endogenous endonucleases that can give rise to overdigestion and/or nonrandom cleavage patterns. When using partially or highly purified fractions of proteins, the latter control may be unnecessary, provided a contaminating nuclease does not cofractionate with the DNA-binding protein of interest.

When carrying out DNA footprinting for the first time, it is useful to have a positive control in which a ubiquitously expressed DNA-binding protein of high abundance and affinity is assayed. Examples include the nuclear factors Sp1 and NF-1, which bind avidly to DNA fragments containing variations on the sequences CCGCCC and TGGN$_7$ACC, respectively. Both of these factors are present in nuclear extracts from cultured HeLa cells, a cell line that is easy to procure and grow. It is worthwhile obtaining these or other positive control reagents before carrying out a DNA footprinting study. Alternatively, several companies sell partially purified preparations of nuclear transcription factors that can be used as positive controls.

METHOD

1. Prepare nuclear extracts using one of the following three methods. Alternatively, fractions derived from purification of cellular proteins can be used directly in Step 2.

PREPARATION OF NUCLEAR EXTRACTS FROM TISSUE

a. Dissect and mince 10–15 g of tissue. Adjust the volume of minced tissue to 30 ml with ice-cold tissue homogenization buffer. Homogenize in a tight-fitting Dounce homogenizer until >80–90% of the cells are broken as determined by microscopy.

b. To monitor lysis, mix 10 µl of the cell suspension with an equal volume of 0.4% Trypan Blue dye and examine the solution under a microscope equipped with a 20x objective. Lysed cells take up the dye and stain blue, whereas intact cells exclude dye and remain translucent. Continue to homogenize the tissue until >80–90% of the cells are broken.

c. Dilute the homogenate to 85 ml with ice-cold tissue homogenization buffer. Layer 27-ml aliquots over 10-ml cushions of ice-cold tissue homogenization buffer in ultraclear or polyallomer swinging-bucket centrifuge tubes. Centrifuge the tubes at 103,900*g* (24,000 rpm in a Beckman SW28 rotor) for 40 minutes at 4°C.

d. Decant the supernatant and allow the tubes to drain in an inverted position for 1–2 minutes. Place the tubes on ice.

   (*Optional*) Use a razor blade to cut off the top two thirds of the tube and place the bottom one third containing the nuclei on ice.

e. Resuspend the pellet of nuclei in 2 ml of ice-cold tissue resuspension buffer. Accurately measure the volume of the resuspended nuclei and add ice-cold 5 M NaCl to a final concentration of 300 mM. Mix the suspension gently. Incubate the suspension for 30 minutes on ice.

f. Recover the nuclei by centrifugation at 103,900*g* (24,000 rpm in a Beckman SW28 rotor) for 20 minutes at 4°C. Carefully transfer the supernatant to a fresh tube. Divide the supernatant into aliquots of 100–200 µl. Reserve an aliquot for protein concentration determination. Snap-freeze the remainder of the aliquots in liquid nitrogen, and store them in liquid nitrogen.

g. Determine the protein concentration of the supernatant by the Bradford method.

PREPARATION OF NUCLEAR EXTRACTS FROM CULTURED MAMMALIAN CELLS

a. Harvest 0.5×10^8 to 1×10^8 cells from their culture flasks, plates, or wells. Collect the cells by centrifugation at 250*g* (1100 rpm in a Sorvall H1000B rotor) for 10 minutes at room temperature. Rinse the cells several times with phosphate-buffered saline without calcium and magnesium salts.

b. Resuspend the cell pellet in 5 volumes of ice-cold cell homogenization buffer. Incubate the cells for 10 minutes on ice, and then collect them by centrifugation as before.

c. Resuspend the cell pellet in 3 volumes of ice-cold cell homogenization buffer containing 0.05% (v/v) Nonidet P-40, and homogenize the cells with 20 strokes of a tight-fitting Dounce homogenizer. The body of the homogenizer should be buried in ice during the homogenization process, during which the swollen cells lyse and release intact nuclei.

d. Collect the nuclei by centrifugation at 250*g* (1100 rpm in a Sorvall H1000B rotor) for 10 minutes at 4°C. Remove the supernatant, and resuspend the pellet of nuclei in 1 ml of cell resuspension buffer. Accurately measure the volume of the resuspended nuclei and add 5 M NaCl to a final concentration of 300 mM. Mix the suspension gently and incubate for 30 minutes on ice.

e. Recover the nuclei by centrifugation at 103,900*g* (24,000 rpm in a Beckman SW28 rotor) for 20 minutes at 4°C. Carefully transfer the supernatant to a chilled, fresh tube. Divide the supernatant into aliquots of 100–200 µl. Reserve an aliquot for protein concentration determination. Quick freeze the aliquots in liquid nitrogen, and store them in liquid nitrogen. Determine the protein concentration of the supernatant by the Bradford method.

PREPARATION OF NUCLEAR EXTRACTS FROM SMALL NUMBERS OF CULTURED MAMMALIAN CELLS

This procedure is suitable for cells transfected with plasmids expressing cDNAs encoding transcription factors.

a. Rinse the cells with several changes of cell rinse buffer. Add 1 ml of the cell rinse buffer to each dish, and scrape the cells into the buffer using a rubber policeman.

b. Transfer the cell suspension to a 1.5-ml microfuge tube, and pellet the cells by centrifuging at maximum speed for 2 minutes at room temperature in a microfuge.

c. Resuspend the cell pellet in 300 µl of cell resuspension buffer per 150-mm dish of original cells. Subject the resuspended cells to three cycles of freezing and thawing.

d. Remove the cellular debris by centrifuging the tubes at maximum speed for 5 minutes at 4°C in a microfuge. Store the supernatant (i.e., the cell lysate) in small aliquots at –70°C.

2. To an appropriate number of 1.5-ml microfuge tubes add:

nuclear extract or protein fraction	1–23 µl
^{32}P-end-labeled DNA	1–10 fmoles
1 mg/ml poly(dI-dC)	1 µl
H_2O	to 25 µl
Optional additions:	
20% Ficoll 400	12 µl
or	
10% polyvinyl alcohol	10 µl

Centrifuge the tubes for 5 seconds at 4°C in a microfuge to deposit the reaction mixtures at the bottom of the tubes. Incubate the reaction mixtures for 10–30 minutes on ice.

> For each DNA fragment or fraction to be assayed, set up two control reactions. One control without the nuclear extract, the other without addition of DNase I in Step 3.

3. Add 50 µl of $MgCl_2/CaCl_2$ solution at room temperature and mix gently. Incubate the reactions for 1 minute at room temperature. Add 1–8 µl of diluted DNase I solution to the microfuge tubes, mix gently, and incubate the reactions for 1 minute at room temperature.

4. Stop the reactions by adding 75 µl of stop mix. Vortex briefly and extract the reactions with an equal volume of phenol:chloroform.

5. Transfer the aqueous phases to fresh microfuge tubes, and precipitate the nucleic acids with 2.5 volumes of ethanol. Chill the ethanolic solution for 15 minutes at –70°C, and collect precipitates by centrifugation at maximum speed for 10 minutes at 4°C in a microfuge. Rinse the pellets with 1 ml of 70% ethanol, centrifuge again, and dry in the air to remove the last traces of ethanol.

6. Solubilize the DNA pellets in 5–10 µl of formamide dye mix by vigorous vortexing. Denature the DNA solutions by boiling for 3–5 minutes.

7. Set up a denaturing 6% or 8% polyacrylamide sequencing gel and run the gel for at least 30 minutes before loading the DNA samples.

8. Load the DNA samples in the following order:

   sequence ladder
   control DNA digested with DNase I in the absence of nuclear extract
   target DNA from reactions digested with DNase I in the presence of nuclear extract
   target DNA incubated with nuclear extract and no DNase I

9. Run the gel at sufficient constant power to maintain a temperature of 45–50°C.

   The time required to achieve optimal resolution of the sequence of interest must be determined empirically. Monitor the progress of the electrophoretic run by following the migration of the marker dyes in the formamide gel-loading buffer.

10. After electrophoresis is complete, pry the glass plates apart and transfer the gel to a piece of thick blotting paper. Dry the gel under vacuum for ~1 hour, and expose it to X-ray film without an intensifying screen for 12–16 hours at –20°C. Alternatively, subject the dried gel to phosphorimage analysis for 1–3 hours.

TROUBLESHOOTING AND OPTIMIZATION OF DNASE I FOOTPRINTING

- The concentration of monovalent cations in the reaction mixture (Step 2) should be <200 mM and is typically in the 50 mM range. Higher concentrations are almost always inhibitory, disrupting interactions between proteins and negatively charged DNA. High-salt fractions from chromatography steps should be diluted appropriately, dialyzed against low-salt buffers, or passed through a Centricon or desalting column before assaying.
- Buffering in the DNase I footprinting assay is provided by the ingredients of the nuclear extract. If this proves unsatisfactory, then in Step 2, include the following components at the listed final concentrations: 20 mM HEPES-KOH (pH 7.9)/50 mM KCl/2 mM $MgCl_2$/0–4 mM spermidine/0–0.02 mM zinc acetate/0.1 µg/ml bovine serum albumin/10% (v/v) glycerol/0.5 mM dithiothreitol.
- The optimum concentration of magnesium should be determined empirically for each DNA fragment. With each new binding site or DNA fragment, a magnesium titration curve should be set up by varying the concentration of magnesium (try a range of 0.1–10 mM) while keeping all other variables constant. Similarly, the optimum temperature (from 0°C to 37°C) of binding and protection should be determined in trial reactions.
- The amount of protein extract required to visualize a footprint depends on the abundance of the factor of interest and the affinity of the protein for the DNA. Relatively abundant transcription factors such as Sp1 (Dynan and Tjian 1983) and NF-1 (Rosenfeld and Kelly 1986) can be detected in 1–20 µg of crude nuclear extract protein obtained from cultured mammalian cells (e.g., HeLa cells). In worst case scenarios, such as the sterol regulatory element-binding proteins (SREBPs), nuclear extract must be purified blindly through one or more chromatographic steps before footprinting activity can be detected (Briggs et al. 1993; Wang et al. 1993). The standard methods of preparing nuclear extracts described in Protocol 1 derived from the classical procedures of Dignam et al. (1983) and Manley et al. (1983).
- The concentration of DNase I required to produce a convincing ladder of DNA fragments usually varies between 50 and 500 ng/ml. The exact concentration must be determined empirically and can vary from one DNA fragment to another and among different preparations of the same fragment. Cleavage depends on the specific activity of the DNase I, the purity of the DNA fragment, and, to a lesser extent, the sequence of the DNA fragment in question. Some investigators find it easier to vary the incubation time or temperature in Step 3, rather than to vary the amount of DNase I added to the reaction.

ALTERNATIVE PROTOCOL: MAPPING PROTEIN-BINDING SITES ON DNA BY HYDROXYL RADICAL FOOTPRINTING

DNase I does not cleave DNA at random, and as a consequence, the pattern of bands detected in a footprinting experiment will not represent cleavage at every phosphodiester bond in the probe. As long as the enzyme cleaves at one or more points within the sequence protected by a DNA-binding protein, a binary complex can be inferred. However, an interaction can be missed if the protein of interest binds between two points of DNase I cleavage. To avoid this problem and to increase the resolution of footprinting to the nucleotide level, Tullius and Dombroski (1986) introduced a chemical cleavage method termed hydroxyl radical footprinting that relies on the ability of hydroxyl radicals generated by Fe(II)-catalyzed reduction of O_2 or H_2O_2 to cleave the DNA backbone. The method is straightforward; the chemical reagent cleaves essentially all phosphodiester bonds equally and is inert to most buffer components. Unlike DNase I footprinting, the method can sometimes provide detailed information regarding relative affinities between a protein and individual nucleotides within a recognition sequence.

Additional Materials

Fe(II)-EDTA solution

Prepare a solution of 0.4 mM Fe(II) by dissolving an appropriate amount of $(NH_4)_2Fe(SO_4)_2 \cdot 6H_2O$ in H_2O. Prepare a 0.8 mM solution of EDTA. Mix equal volumes of the 0.4 mM Fe(II) and 0.8 mM EDTA solutions to make the Fe(II)-EDTA solution; 1 µl of this solution is used per reaction.

0.6% hydrogen peroxide
20 mM sodium ascorbate
3 M sodium acetate (pH 5.5)
TE (pH 8.0)
0.1 M thiourea

▲ **IMPORTANT** Prepare all of the additional materials just before beginning Step 3 below.

Timer

Method

1. Prepare nuclear extracts as described in Step 1 of the main protocol, or use fractions derived from purification of cellular proteins.
2. Form protein-DNA complexes as described in Step 2 of the main protocol, making sure that the final concentration of glycerol (a hydroxyl radical scavenger) in the reaction is <0.5% (v/v).

   Glycerol is a component of the homogenization or resuspension buffer used in Step 1.
3. Carefully pipette 1 µl of the Fe(II)-EDTA solution, 1 µl of 0.6% hydrogen peroxide, and 1 µl of 20 mM sodium ascorbate at a single position on the side of the tube containing the protein-DNA complex. Mix these reagents by pipetting up and down. Start a timer and tap the side of the tube to mix the cleavage reagents and the protein-DNA solution. Allow the cleavage reaction to proceed for 1–2 minutes at room temperature.

   The time and temperature of incubation can be varied to optimize detection of a footprint.
4. Stop the reaction by the addition of 2 µl of 0.1 M thiourea and 2.5 µl of 3 M sodium acetate (pH 5.5). Mix the contents of the tube and add 100 µl of ethanol. Precipitate the DNA on ice for 15 minutes. Recover the nucleic acids by centrifugation at maximum speed for 10 minutes in a microfuge.
5. Dissolve the DNA pellet in 100 µl of TE (pH 8.0). Extract the DNA with 100 µl of phenol:chloroform and then with chloroform alone. Precipitate the aqueous phase with ethanol and collect the precipitated DNA by centrifugation at maximum speed for 10 minutes in a microfuge. Rinse the pellet with 1 ml of 70% ethanol, centrifuge briefly, and dry in air to remove the last traces of ethanol.
6. Analyze the samples by gel electrophoresis as described in Steps 6–10 of the main protocol.

   Autoradiography or phosphorimaging should reveal a ladder corresponding to cleavage at adjacent phosphodiester bonds in the control reaction without protein; an intact DNA fragment in the control that was not exposed to the Fe(II)-EDTA solution; and footprints in the test lanes containing target DNA.

Protocol 2

Gel Retardation Assays for DNA-binding Proteins

GEL RETARDATION ASSAYS FOR DNA-BINDING PROTEINS, developed by Fried and Crothers (1981), provided the first kinetic analyses of the interactions of the *Escherichia coli* lactose repressor with its DNA-binding site. The simplicity and sensitivity of the reaction and the quantitative nature of the assay led to its rapid adoption by the growing community of researchers studying transcription and gene regulation. The assay is now routinely used to follow the purification of DNA (or RNA)-binding proteins, to determine the sequence requirements of a known or suspected DNA-binding protein, to establish reaction constants (e.g., affinity binding constants and on/off rates), and to study protein-protein assembly or the interactions of multiple proteins on gene sequences (please see the information panel on **GEL RETARDATION ASSAYS**).

The assay, which is straightforward, exploits electrophoretic mobility differences between a rapidly migrating DNA containing a binding site and a more slowly migrating complex of protein bound to DNA. Typically, the DNA fragment is radiolabeled with ^{32}P, whereas the proteins are unlabeled. Binding of the DNA by a protein leads to a complex with an electrophoretic mobility characteristic of the protein. The method is exquisitely sensitive, because high-specific-activity DNA probes can be used and because a phenomenon known as "caging" occurs within the polyacrylamide gel (Cann 1989). Caging is thought to occur because the protein–nucleic acid complexes migrate through the pores of the gel during electrophoresis, which transiently increases their concentrations over and above that in an aqueous solution. This concentration in turn shifts the binding equilibrium in favor of complex formation and allows the detection of even very weak binding interactions. The following method for gel retardation assays is derived in part from a protocol provided by Michael Briggs (Pharmacia Corp., St. Louis).

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Ficoll 400 (20% w/v)

Dissolve the solute in sterile H_2O and store the solution in 100-µl aliquots at –20°C.

Polyvinyl alcohol (10% w/v)

Dissolve the solute in sterile H_2O and store the solution in 100-µl aliquots at –20°C.

Sucrose dye solution

0.25% (w/v) bromophenol blue
0.25% (w/v) xylene cyanol
40% (w/v) sucrose (dextrose)
Dissolve the solutes in H_2O and pass the solution through a 0.22-µm filter; store the filtrate at room temperature or 4°C.

10x Tris-glycine or Tris-borate-EDTA (TBE) buffer

Gels

Neutral 4–7% polyacrylamide gel (≤ 1.5 mm in thickness) **<!>**

Nucleic Acids and Oligonucleotides

Poly(dI-dC) (1 mg/ml)

Dissolve an appropriate amount of poly(dI-dC) in sterile H_2O and store the solution in 100-µl aliquots at –20°C. For additional information on the role of poly(dI-dC) in gel retardation experiments, please see the panel on **POLY(dI-dC)**.

Radioactive Compounds

^{32}P-labeled control DNA **<!>**

^{32}P-labeled target DNA of >20 bp (specific activity ≥2.5 x 10^7 cpm/µg[≥5000 cpm/fmole])

Labeling of the DNA fragment can be accomplished by phosphorylation (Chapter 9, Protocols 13–16, or Chapter 10, Protocol 2), filling in of a 3′-recessed end using a DNA polymerase (Chapter 9, Protocols 10 and 11, or Chapter 10, Protocol 7), or by using PCR to incorporate radiolabeled nucleotides into the body of the probe (Chapter 8, Protocol 1). Of these, the latter method is fastest and provides probes of the highest specific activity. For suggestions on how to radiolabel the DNA probe, please see the panel on **TROUBLESHOOTING AND OPTIMIZATION OF GEL RETARDATION ASSAYS** at the end of this protocol.

Special Equipment

Blotting paper

Cells and Tissues

Control nuclear extract or protein fraction

Nuclear extract or Protein fraction(s)

Prepare the extract by one of the methods described in Protocol 1. In-vitro-translated protein made in rabbit reticulocyte lysates or wheat germ extracts can also be used as a source of DNA-binding proteins. In the latter cases, aliquots of 1–20 µl are typically used in place of a nuclear extract.

POLY(dI-dC)

This nucleic acid polymer is added to gel retardation assays to reduce nonspecific binding of proteins to the radiolabeled DNA fragment. The amount recommended in Step 1 (50 µg/ml of reaction) is a median value. The optimum amount (usually between 0 and 100 µg/ml) of poly(dI-dC) added to a reaction should be determined empirically for each DNA-binding activity. Other nucleic acids that can be used to decrease nonspecific binding include sheared genomic DNA (e.g., from *E. coli*, salmon sperm, or calf thymus), tRNAs, sheared or restricted plasmid DNA, poly(dA-dT), or poly(dG-dC). When assaying for binding proteins whose recognition sites are immediately adjacent to one another, using one binding site as a competitor can reveal the presence of protein binding to the adjacent site. This approach can be crucial when one DNA-binding protein is present in the nuclear extract at a much lower concentration than the other (e.g., a basal transcription factor such as Sp1 vs. a rare regulatory protein). Once specific binding of a nuclear protein to a target DNA sequence has been established in a gel retardation assay, it is a good idea to vary the nonspecific competitor. For example, if a protein of interest binds to a particular sequence in the presence of 10 µg/ml of poly(dI-dC), substitute 10 µg/ml of poly(dG-dC) for the poly(dI-dC) in the reaction and determine the consequences for binding. Many examples exist in the literature in which changing the concentration or identity of the carrier nucleic acid dramatically affects the results, sometimes simply enhancing binding, or, in more extreme cases, revealing completely different binding activities.

METHOD

1. To a sterile 1.5-ml microfuge tube add:

^{32}P-labeled target DNA	1 ng (1–10 fmole)
1 mg/ml poly(dI-dC)	1 µl
nuclear extract (5–10 µg)	≤10 µl
or	
protein fraction ≤10 µl	
20% Ficoll 400	5 µl
or	
10% polyvinyl alcohol	4 µl
H_2O	to 20 µl

Include control reactions with every experiment. Positive control reactions contain a nuclear extract (or protein fraction) and a radiolabeled DNA fragment carrying a sequence recognized by a DNA-binding protein that is abundant in the extract and has high affinity for the DNA sequence. Examples are a DNA fragment containing an Sp1, C/EBP, or NF-1 site and mammalian cell nuclear extract, or a *lacI* recognition site and extract derived from a *lacI*^{q} strain of *E. coli*. The negative control reactions contain the radiolabeled target DNA fragment, but no nuclear extract.

2. Centrifuge the reaction tubes for several seconds in a microfuge to deposit the reaction mixtures at the bottom of the tubes. Incubate the reactions for 10–30 minutes on ice.
3. Add 3 µl of sucrose dye solution to each tube. Load the samples into the slots of a neutral 4–7% polyacrylamide gel.
4. Run the gel in either 0.5x Tris-glycine buffer or 0.5x TBE buffer at 200–250 V and 20 mA for ≥2 hours.

   Depending on the lability of the binding protein(s) and the affinity of the binding reaction(s), it may be necessary to run the gel at 4°C.

5. After electrophoresis is complete, pry the gel plates apart, transfer the gel to a piece of sturdy blotting paper, and dry the gel for ~1 hour on a gel dryer.
6. Expose the dried gel to X-ray film for ≥1 hour at –20°C to visualize radiolabeled DNA fragments. Less abundant DNA-protein complexes can be detected after 1–3-hours on a phosphorimager.

TROUBLESHOOTING AND OPTIMIZATION OF GEL RETARDATION ASSAYS

- The concentration of monovalent cations in the reaction mixture (Step 1) should be <200 mM and is typically in the 50 mM range. Higher concentrations are almost always inhibitory. High-salt fractions from chromatography steps should be diluted appropriately, dialyzed against low-salt buffers, or passed through a Centricon or desalting column before assaying.
- Buffering in the gel retardation assay is provided by the ingredients of the nuclear extract. If buffering proves to be unsatisfactory, include the following components at the listed final concentrations: 20 mM HEPES-KOH (pH 7.9)/50 mM KCl/2 mM $MgCl_2$/0–4 mM spermidine/0–0.02 mM zinc acetate/0.1 μg/ml bovine serum albumin/10% (v/v) glycerol/0.5 mM dithiothreitol.
- The DNA fragment used in the reaction should be longer than 20 bp, with the recognition sequence at least 4 bp away from each end of the fragment. Polymerizing the recognition sequence by ligation of monomer sites or by chemical synthesis may enhance detection of rare or low-affinity binding proteins.
- Phosphatases or exonucleases present in crude nuclear extracts can remove radioactive nucleotides from the ends of DNA probes, generating unlabeled binding sites that can act as competitors of the binding reaction. Probes should have blunt ends to avoid high backgrounds caused by the abundant and nonspecific single-stranded nucleic-acid-binding proteins present in many cells. For this reason, double-stranded probes formed by annealing single-stranded oligonucleotides should be checked by polyacrylamide gel electrophoresis for completion of annealing. If a significant proportion of single-stranded oligonucleotides remain, then adjust the concentrations of the oligonucleotides in subsequent annealing reactions. An advantage to using the Klenow fragment of *E. coli* DNA polymerase I to fill and radiolabel a probe is that the enzyme will only act on double-stranded DNAs. Single-stranded DNA or unhybridized oligonucleotides from an incomplete annealing reaction will not be radiolabeled by Klenow enzyme, and thus any protein-DNA complexes involving them will not be visualized in the autoradiogram or phosphorimage of the gel.
- The optimum concentration of Mg^{2+} should be determined empirically for each DNA-binding protein. With a new binding site or DNA probe, an Mg^{2+} titration curve should be set up by varying the concentration of Mg^{2+} (try a range of 0.1–10.0 mM) while keeping all other variables unchanged. Similarly, the optimum temperature (from 0°C to 37°C) of binding and the effects of exogenously added stabilizing proteins (e.g., albumin and cytochrome *c*) should be determined in trial reactions.
- Addition of bystander proteins to the reaction mixture can sometimes stabilize a given protein-DNA interaction. Proteins that have been used in this way include bovine serum albumin, milk proteins (BLOTTO, which is non-fat dried milk), cytochrome *c*, fetuin, bovine milk casein, thyroglobulin, asialofetuin, and bovine submaxillary mucin (type 1), all at 0.015–1 mg/ml. These proteins sometimes act by stabilizing a dilute transcription factor or DNA-binding protein. More often than not, however, the mechanism is unknown and the best additive must be determined by trial and error. Steroid hormone receptors and certain other transcription factors are stimulated by the addition of sodium molybdate at concentrations between 0.1 and 5.0 mM. The addition of standard reagents that enhance protein stability (e.g., protease inhibitors, phosphatase inhibitors, kinase inhibitors, and glycerol) may improve the binding between protein and DNA.
- As with DNA footprinting, the amount of protein extract required to visualize a retained band depends on the abundance of the factor of interest and the affinity of the protein for the DNA. It may be necessary to purify the protein through several chromatographic steps to remove inhibitors or to increase factor abundance to detectable levels. The use of DNA affinity chromatography to purify a DNA-binding protein should be delayed until a given fraction is substantially free of endogenous nucleases.
- The best resolution of retained protein-DNA complexes is usually obtained on polyacrylamide gels that contain between 4% and 7% polyacrylamide. A ratio of acrylamide to bis-acrylamide of 29:1 provides good resolution. An optimum gel size is 20 x 20 cm with 1.5-mm spacers. The choice of buffer used in the gel is often a matter of convenience. Laboratories that keep concentrated stocks of TBE for use in agarose and polyacrylamide gel electrophoresis use 0.5x TBE in gels to separate bound and free probes, whereas laboratories that spend more time doing protein gel electrophoresis will typically use Tris-glycine buffers. These buffers can also be used at 0.25x concentration in the polyacrylamide gel.

ADDITIONAL PROTOCOL: SUPERSHIFT ASSAYS

The identity of a DNA-binding protein in a particular band detected in a gel retardation assay can often be identified by using specific antibody probes to "supershift" the complex (Kristie and Roizman 1986). In this type of experiment, an antibody against the suspected protein is added to the reaction mixture before, during, or after formation of the complex, and the reaction mixture is separated on the gel. If the antibody recognizes the band in question, then the mobility of the complex will shift to a larger size due to the formation of a ternary complex between the antibody, DNA-binding protein, and the DNA probe. In some cases, addition of antibody disrupts the formation of the complex rather than increasing its molecular weight. A similar experimental design can be used to study interactions between different protein components of transcription factor complexes that assemble on eukaryotic promoters (Lieberman and Berk 1991).

Antibodies directed against a variety of eukaryotic transcription factors are available from several companies. These antibodies can be used both to identify a known factor and as positive controls in the supershift assay.

Additional Materials

Antibody against the protein of interest

This is usually an IgG fraction arising from a rabbit polyclonal antiserum (Harlow and Lane 1988).

Method

1. Incubate varying amounts of antibody with the nuclear extract preparation to be used in Step 1 of the main protocol for 10–30 minutes at room temperature. The amount of antibody to add depends on the affinity of the antiserum and the abundance of the transcription factor. Try a range between 1 and 100 μg of antibody per standard gel retardation reaction.
2. After the incubation, add the DNA probe and the other ingredients listed in Step 1 of the main protocol, and carry out the remaining procedures in the main protocol. Addition of antibody should disrupt or shift the mobility of the complex in question.

   Although a particular antibody may recognize the transcription factor of interest in an immunoblotting or immunoprecipitation experiment, the same antibody may not work in a supershift assay. This discrepancy is usually due to the inability of the antibody to recognize the native protein. The best solution is to use another antiserum that recognizes a different epitope on the binding protein. Other solutions to consider are increasing the salt concentration in the binding buffer, adding low concentrations (0.01–0.5%) of nonionic detergents (e.g., Tween-20, Nonidet P-40, and Triton X-100) to the binding buffer, or increasing the amount of antibody in the reaction. The temperature at which the preincubation step is performed can be varied between 0°C and 37°C to facilitate antibody recognition and complex stability. Finally, experiments can be carried out to determine if addition of the antibody before or after the DNA probe affects the supershift.

ADDITIONAL PROTOCOL: COMPETITION ASSAYS

The specificity of an observed DNA-binding reaction can be tested in competition assays in which an excess of unlabeled probe is added together with the radiolabeled probe during Step 1 of the main protocol. Specific DNA binding is usually defined as that which is competed by a reasonable excess of unlabeled probe. For most transcription factors that exhibit high-affinity binding to a target DNA sequence, a 10–100-fold molar excess of unlabeled probe should eliminate the radiolabeled complex.

Competition assays can also be used to identify a protein that is present in a given retained band. For example, if a probe encompassing the 5′-flanking region of a gene is used that contains several different recognition elements within its sequence and thus gives rise to multiple DNA-protein complexes with different mobilities, then addition of a 100-fold molar excess of an oligonucleotide containing a known recognition sequence such as that bound by the Sp1 factor should eliminate the band corresponding to Sp1-DNA complexes. Similar competition assays with oligonucleotides containing other recognition sequences can identify the proteins present in other complexes, and antibodies against the suspected transcription factors can be used in supershift assays (please see the panel on **ADDITIONAL PROTOCOL: SUPERSHIFT ASSAYS**) to confirm a tentative identification.

Finally, competition assays can be used to identify important nucleotides in the binding site of a given transcription factor. By carrying out a series of competition assays using oligonucleotides that differ in a single nucleotide from that used to identify the binding protein, crucial nucleotides within the recognition element can be quickly identified.

Protocol 3

Mapping DNase-I-hypersensitive Sites

THE CONTROL REGIONS IN A EUKARYOTIC GENE CAN OFTEN BE LOCALIZED by mapping DNase-I-hypersensitive sites. For reasons that are not well understood, genes contain discrete sequences of DNA that are sensitive to DNase I cleavage, and the pattern of these so-called hypersensitive sites changes depending on the activation state of the gene (Weintraub and Groudine 1976). By comparing the pattern of hypersensitive sites obtained by cleavage of a quiescent gene with that obtained when the gene is actively transcribed, regions that participate in gene regulation (either induction or suppression) can be identified. A major strength of the method is that it makes no a priori assumptions about the locations of control sequences and thus allows an investigator to examine many hundreds of kilobases of DNA for potential regulatory sequences.

A case that illustrates the power of DNase I hypersensitivity mapping is the identification of the locus control region, a master regulatory sequence that directs the complicated temporal and cell-type-specific transcription patterns of multiple linked hemoglobin genes and that maps ~10 kb away from the first gene in the cluster (Tuan et al. 1985; Forrester et al. 1986). These sequences, which contain several DNase-I-hypersensitive sites, are both necessary and sufficient for the expression of globin genes in erythroid cells (Grosveld et al. 1987; Townes and Behringer 1990). Similar success stories have been realized with many other genes (for review, please see Gross and Garrard 1988).

Several theories have been proposed to explain the occurrence of DNase-I-hypersensitive sites (Gross and Garrard 1988). The best of these ideas is that the sites represent regions of the DNA from which nucleosomes have been displaced by the binding of transcription factors and/or DNA unwinding proteins. In turn, the bound proteins are thought to lead to enhanced transcription of the gene, either directly by interacting with components of the basal transcription apparatus or indirectly by establishing a conformation conducive to transcription (Wallrath et al. 1994). A variety of functional sequences are associated with DNase-I-hypersensitive sites, including enhancers, silencers, developmental control regions, and tissue-specific regulatory regions. For this reason, mapping hypersensitive sites in the nuclei of different tissues or at different times of development can provide a wealth of information about the expression of a target gene.

The most popular method of mapping hypersensitive sites involves the isolation of nuclei from a cell or tissue of interest followed by incubation of the intact nuclei with varying amounts of DNase I. A control incubation is also carried out that contains no exogenous DNase I. The genomic DNA from the treated and control nuclei is then purified by phenol:chloroform extraction and incubated with a restriction enzyme. The fragments of DNA are separated by agarose gel

electrophoresis, transferred to a membrane filter, and hybridized to a labeled probe derived from the target gene. If the probe corresponds to the 5′ end of the gene, then only the restriction fragments arising from that region will be detected by the probe in the no-DNase-I control. If DNase I was included in the initial incubation and a hypersensitive site exists in one or more of the DNA fragments recognized by the probe, then shorter DNAs will be detected on the Southern blot corresponding to fragments that were cleaved at one end by the restriction enzyme and at the other end by the DNase I. By determining the size of the doubly cleaved DNAs, the position of the hypersensitive site can be deduced and the location of a potential control sequence inferred. The exact location of the regulatory region can be mapped to within ±50 nucleotides by using different restriction enzymes and probes. With additional effort and the use of the polymerase chain reaction (PCR), the position of a hypersensitive site can be pinpointed to within a few nucleotides of the site (Pfeifer 1992).

In summary, DNase I hypersensitivity mapping is an excellent method to map potential regulatory regions both within and distal to a target gene. The technique is especially useful (1) in the early stages of promoter analysis when the locations of the regulatory sequences are unknown and (2) in analyzing genes that exhibit tissue-specific regulation (for further details on the activities and properties of DNase I, please see Appendix 4). The following protocol originated in Bob Tjian's laboratory (University of California at Berkeley) and was provided by Tim Hoey (Tularik, Inc., South San Francisco, California).

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Buffer A

50 mM Tris-Cl (pH 7.9)
100 mM NaCl
3 mM $MgCl_2$
1 mM dithiothreitol
0.2 mM phenylmethylsulfonyl fluoride**<!>**
Store Buffer A at 4°C. Add dithiothreitol and PMSF to Buffer A just before use.

EDTA (0.5 M, pH 8.0)

Ethanol

Lysis buffer

50 mM Tris-Cl (pH 7.9)
100 mM KCl
5 mM $MgCl_2$
0.05% (v/v) saponin
50% (v/v) glycerol
200 mM β-mercaptoethanol **<!>**
Store lysis buffer at 4°C. Add β-mercaptoethanol to the lysis buffer just before use.

Phenol:chloroform **<!>**

Phosphate-buffered saline without calcium and magnesium salts

SDS buffer

20 mM Tris-Cl (pH 7.9)
100 mM NaCl
70 mM EDTA (pH 8.0)
2% (w/v) SDS
Store the SDS buffer at room temperature.

TE

Trypan Blue dye (0.4% w/v)

Dissolve an appropriate amount of dye in phosphate-buffered saline without calcium and magnesium salts. Store the solution at room temperature.

Enzymes and Buffers

DNase I dilution buffer

10 mM HEPES-KOH (pH 7.9)<!>
30 mM $CaCl_2$
30 mM $MgCl_2$
50% (v/v) glycerol

DNase I solution

Dilute a preparation of RNase-free DNase I to a concentration of 10 units/µl using DNase dilution buffer. Store the solution at –20°C. One unit is defined as the amount of DNase that will cause a change in A_{260} of 0.001/minute/ml of a reaction using a calf thymus DNA substrate.

Proteinase K solution

Dissolve proteinase K at 0.2 mg/ml in a solution of 50 mM Tris-Cl (pH 7.9) and 100 mM NaCl. Store the solution in small aliquots at –20°C.

RNase solution

Dissolve a preparation of DNase-free RNase at a concentration of 0.5 mg/ml in TE (pH 8.0).

Centrifuges and Rotors

Sorvall H1000B rotor or equivalent

Special Equipment

Screw-cap tubes (50 ml)
Shaking water baths preset to 50°C and 55°C

Additional Reagents

Step 18 of this protocol requires the reagents listed in Chapter 6, Protocols 8 and 10.

Cells and Tissues

Eukaryotic cells

Approximately 10^8 cells are required per DNase I hypersensitivity mapping experiment.

METHOD

1. Harvest ~10^8 cells from spinner cultures, flasks, or dishes, and wash the cells twice with 25-ml aliquots of ice-cold phosphate-buffered saline without calcium and magnesium salts.

   Alternatively, if starting with fresh tissue, isolate the nuclei as described in Protocol 1, Step 1.

2. Resuspend the cell pellet from the final wash in 1.5 ml of ice-cold lysis buffer. Incubate the cells for 10 minutes on ice to allow cell lysis to occur.

3. Mix a 10-µl aliquot of cell lysate with an equal volume of 0.4% Trypan Blue dye and examine the solution under a microscope equipped with a 20x objective. Lysed cells and nuclei take up the dye and appear blue, whereas unlysed cells are impermeable to the dye and remain translucent. Continue the incubation on ice until >80% of cells are lysed.

4. Recover nuclei from the lysed cells by centrifugation of the suspension at 1300*g* (2500 rpm in a Sorvall H1000B rotor) for 15 minutes at 4°C.

5. Carefully remove the supernatant and resuspend the pellet of nuclei in 1.5 ml of ice-cold Buffer A. Collect the nuclei by centrifugation as described in Step 4.

6. Resuspend the nuclear pellet in 4 ml of ice-cold Buffer A.
7. Set up a series of dilutions of the standard DNase I solution (1/40, 1/80, 1/160, 1/320, 1/640, 1/1280, and 1/2560 in DNase dilution buffer). Store the dilutions on ice.
8. Label a series of tubes 1 through 9 and add 180 µl of resuspended nuclei from Step 6 to each tube.
9. To Tube 1, add 20 µl of DNase I dilution buffer containing no DNase I and store the tube on ice until Step 12, below. To Tube 2, add 20 µl of DNase I dilution buffer containing no DNase and incubate as described in Step 11, below. Tubes 1 and 2 are controls.
10. To Tubes 3 through 9, add 20 µl of each of the progressive dilutions, i.e., to Tube 3, add 20 µl of the 1/2560 dilution, to Tube 4, add 20 µl of the 1/1280 dilution, etc.
11. Incubate Tubes 2–9 for 20 minutes at 37°C.
12. Terminate the reactions by adding three individual aliquots of 16.6 µl of 0.5 M EDTA to each tube, with vortexing between additions. When all of the tubes have been treated, add 12 µl of RNase solution to each tube. Incubate the reactions for 30 minutes at 37°C to allow digestion of nuclear RNA.
13. Digest nuclear proteins by adding 40 µl of proteinase K solution to each tube. Mix the solution gently by pipetting the mixture up and down. Add 100 µl of SDS buffer to each tube and mix once more. Incubate the tubes for 16 hours at 50°C with rotation or rocking.
14. Add an additional aliquot of 100 µl of proteinase K solution and continue the digestion for a further 2–3 hours at 50°C.
15. Extract the digestion mixtures three times with phenol:chloroform. Be gentle. Precipitate the DNA with the addition of 3 volumes of ice-cold ethanol, incubate for 30 minutes on ice, and collect the DNA precipitates by centrifugation at 1200*g* (2400 rpm in a Sorvall H1000B rotor) in a benchtop centrifuge. Decant the supernatant and drain the last dregs of ethanol from the tubes on a paper towel.
16. Add 200 µl of TE to each tube and allow the DNA to redissolve with rocking or rotation overnight at 55°C.

    ▲ **IMPORTANT** An extended incubation is required for complete solubilization and recovery of the DNase-treated DNA.
17. Determine the A_{260} of the resuspended DNA and estimate the concentration.
18. Digest the DNA with a restriction enzyme(s), followed by Southern blotting and hybridization as described in Chapter 6, Protocols 8 and 10. Load 15–30 µg of restricted genomic DNA per lane on the agarose gel.

HYBRIDIZATION PROBES

DNA fragments produced by DNase I cleavage can be present in substoichiometric mass relative to the parental uncleaved fragment. This situation can arise due to incomplete cleavage of sensitive sites, incomplete occupation of a binding site by a nuclear regulatory factor, intercellular variations in gene expression, or, when working with tissues, the presence of diverse cell types with different gene expression patterns. For these reasons, it is crucial to use high-specific-activity radioactive probes when mapping hypersensitive sites. The specific activity of the probe, as determined using methods described in Appendix 8, should be $>5 \times 10^8$ cpm/µg. Single-stranded DNA probes derived from bacteriophage M13 templates (Chapter 3, Protocol 4) are sensitive high-specific-activity probes that are complementary to short regions (~200 nucleotides of the target DNA). They are thus ideal for high-resolution hypersensitivity mapping experiments.

CONTROLS FOR DNASE I HYPERSENSITIVITY MAPPING

After completion of Southern blotting and visualization of the hybridized probe by autoradiography or phosphorimaging analysis, one or more additional bands should be seen in lanes containing DNA digested with DNase I. These bands are shorter than the intact, undigested fragment detected by the labeled probe, usually not as sharp, and, sometimes, not as intense. They should not be present in the controls lacking DNase I (Tubes 1 and 2 in the protocol). If the correct range of DNase I concentrations was used, the additional bands will be absent in the low end of the titration range, clearly visible in the mid-range, and lost in a broad smear at the high end of the range of nucleolytic enzyme. The amount of DNase I added to the nuclei can be increased or decreased to compensate for under- or overdigestion in order to obtain the perfect cosmetic result. Sites that appear at relatively low concentrations of DNase I enzyme are sometimes referred to as "major" sites, whereas those that appear at higher enzyme concentrations are labeled "minor" hypersensitive sites (e.g., please see Tuan et al. 1985).

To obtain results of this sort requires that the appropriate regulatory regions of the gene be examined with the appropriate probe. When starting the analysis of regulatory regions in a new gene, it is a good idea to set up a series of control reactions in which a DNase-I-hypersensitive site in a control gene is examined with a defined restriction digest and probe. Ideally, the control gene should be regulated by the same physiological events as the target gene. The choice of probes should be made without assuming where regulatory sequences might lie. Thus, probes should be designed to allow examination of all regions of a target gene. Although most regulatory regions occur immediately 5′ to the gene, it is not uncommon for control sequences to map to the extreme 5′- and 3′-flanking regions of a gene or in an intron.

DNase-I-hypersensitive site mapping suffers from several inherent limitations. Small DNA fragments (<1 kb) arising from the action of DNase on a unique gene in a complex mammalian genome are difficult to visualize by blotting and Southern hybridization. Furthermore, there is a good deal of variation in signal strength between experiments. These problems can usually be overcome by using more than one restriction enzyme and probe in the experiments, by using more than one cell source of nuclei (e.g., expressing and nonexpressing cells, stimulated or nonstimulated cells, and different cell lines), and by simply repeating successful experiments. By using restriction enzyme double digests and various probes, it is possible to position the undigested and digested DNA fragments in the range of maximum resolution (1–10 kb) on the Southern blot. In addition, these conditions allow fine-structure mapping and ultimate positioning of the hypersensitive site on the gene map.

As mentioned in the introduction to this protocol, hypersensitive sites often mark sequences that are important for target gene expression. Once a hypersensitive site has been identified, then higher-resolution techniques such as DNase footprinting (Protocol 1) and gel retardation assays (Protocol 2) can be used to define the proteins that bind to the DNA. When these methods are combined with expression analyses using transfected reporter genes (e.g., please see Protocols 5–7), a complete picture of the regulatory regions of a gene can be assembled.

Protocol 4

Transcriptional Run-on Assays

NUCLEAR RUN-ON ASSAYS ARE USED TO DETERMINE WHETHER A CLONED GENE is transcriptionally regulated. Ideally, nuclear run-on assays should be done *after* hybridization experiments that examine changes in steady-state mRNA levels and *before* analysis of the promoter.

In the simplest of terms, nuclear run-on assays allow the measurement of the number of RNA polymerases traversing the gene at a given time in cells subject to one or more regulatory inputs. A typical experiment involves the isolation of nuclei from cells expressing the gene of interest and their subsequent incubation with [^{32}P]UTP. The radiolabeled UTP is incorporated into nascent RNA transcripts by RNA polymerase molecules that were actively transcribing the gene at the time the cells were harvested (very little initiation of transcription occurs in isolated nuclei). The transcriptional activity of the target gene in the nuclei is measured by hybridizing the radiolabeled RNAs to an excess of the target gene immobilized on a nitrocellulose or nylon membrane. The fraction of radioactivity that hybridizes to the immoblized DNA reflects the contribution of the target gene to the total transcriptional activity of the cell (Srivastava and Schonfeld 1998).

Regulatory inputs that change the transcriptional activity of the gene are detected by an increase or decrease in hybridization in a nuclear run-on experiment. A change in hybridization generally means that a larger or smaller number of transcription complexes are traversing the gene and that the stimulus affected the number of initiation events at the promoter of the target gene. If this type of result is obtained, it is probable that *cis*-acting DNA sequences underlie the observed changes in gene activity and that subsequent identification of these elements might be accomplished by transfection of appropriate reporter gene constructs. However, changes in hybridization are not necessarily synonymous with regulation of transcription at the level of initiation. In certain isolated cases, changes in hybridization can also be associated with more complex regulatory mechanisms, such as effects on the rate of RNA polymerase movement along the gene (attenuation) (e.g., please see Bentley and Groudine 1986).

Regulatory inputs that affect posttranscriptional events such as mRNA stability, transport, or translation do not alter the level of hybridization of primary transcripts of the target gene. Sequences that affect posttranscriptional processes can often be identified by analyzing the sequence of the mRNA itself. The function of such *cis*-acting elements can be analyzed in detail by construction and expression of genes encoding appropriate mRNAs.

Because the number of nascent RNA transcripts from a single-copy gene is very low, large amounts of cDNA or gene must be applied to the membrane, copious quantities of [^{32}P]UTP are

required to radiolabel the nascent RNA, and hybridization should be carried out for extended periods of time. The following methods were derived from protocols provided by Dorothy Yuan, Diane Jelinek, and Karl Normington (all of University of Texas Southwestern Medical Center, Dallas).

MATERIALS

▲ **IMPORTANT** All test tubes and solutions must be prepared RNase-free.

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Chloroform **<!>**

Chloroform:isoamyl alcohol **<!>**

DNA denaturation solution

2 M NaCl

0.1 M NaOH **<!>**

Ethanol

Glycerol storage buffer

50 mM Tris-Cl (pH 8.3)

5 mM $MgCl_2$

0.1 mM EDTA (pH 8.0)

40% (v/v) glycerol

Store the buffer at 4°C.

HSB buffer

10 mM Tris-Cl (pH 7.4)

50 mM $MgCl_2$

2 mM $CaCl_2$

0.5 M NaCl

Store the buffer at room temperature.

Labeling buffer

20 mM Tris-Cl (pH 8.0 at 4°C)

140 mM KCl

10 mM $MgCl_2$

1 mM $MoCl_2$

20% (v/v) glycerol

14 mM β-mercaptoethanol **<!>**

1 mM each of ATP, GTP, and CTP

10 mM phosphocreatine

100 μg/ml phosphocreatine kinase

0.1 μM [^{32}P]UTP, 500–5000 μCi/ml **<!>**

Just before use, add the last five ingredients and keep the solution at 4°C. Exercise extreme care after the radioactive UTP has been added.

LiCl (5 M)

Lysis buffer

10 mM Tris-Cl (pH 8.4 at 4°C)

1.5 mM $MgCl_2$

0.14 M NaCl

Store the buffer at 4°C.

NaCl (2 M)

NaOH (0.1 M) **<!>**

Nonidet P-40 (5% v/v)

Nuclei wash buffer

20 mM Tris-Cl (pH 8.0 at 4°C)
140 mM KCl
10 mM $MgCl_2$
1 mM $MoCl_2$
20% (v/v) glycerol
14 mM β-mercaptoethanol

Store the buffer at 4°C. Just before use, add the β-mercaptoethanol to the buffer from a concentrated stock solution.

Phenol **<!>**

Phosphate-buffered saline (PBS)

Prehybridization/Hybridization solution **<!>**

Hybridization buffer containing formamide is generally used in nuclear run-on assays, e.g., 50% (v/v) formamide, 6x SSC, 5 mM sodium pyrophosphate, 2x Denhardt's solution, 0.5% (w/v) SDS, 10 μg/ml poly(A), and 100 μg/ml salmon sperm DNA (please see Chapter 6, Protocol 10).

2x Reaction buffer

10 mM Tris-Cl (pH 8.0)
5 mM $MgCl_2$
0.3 M KCl

Store the buffer at 4°C. Just before use, add 5 μl of 1 M dithiothreitol, 100 μl of 100 mM ATP, 10 μl of 100 mM CTP, and 10 μl of 100 mM GTP to 1 ml of 2x reaction buffer.

RNasin

RNasin is a generalized term for the rat liver RNase inhibitor protein. Preparations of this enzyme are available from several companies (please see the information panel on **INHIBITORS OF RNASES** in Chapter 7).

SDS (0.5% w/v)

6x SSC

Stop buffer

50 mM Tris-Cl (pH 7.5)
20 mM EDTA (pH 8.0)
0.8% (w/v) SDS

Store the buffer at room temperature.

Tissue homogenization buffer

10 mM HEPES-KOH (pH 7.6)
25 mM KCl
0.15 mM spermine
0.5 mM spermidine
1 mM EDTA (pH 8.0)
2 M sucrose
10% (v/v) glycerol

Store the buffer at 4°C. Just before use in Step 1, add dithiothreitol to 1 mM and protease inhibitors (0.5 mM phenylmethylsulfonyl fluoride, 1 μg/ml leupeptin, 1 μg/ml pepstatin, or others as needed).

Trypan Blue dye (0.4% w/v)

Dissolve an appropriate amount of dye in phosphate-buffered saline without calcium and magnesium salts. Store the solution at room temperature.

Enzymes and Buffers

DNase solution

Dissolve 2 mg of RNase-free DNase (e.g., Worthington) in 1 ml of 0.0025 N HCl, 50% (v/v) glycerol. Store the solution at –20°C.

Proteinase K (optional)

Restriction enzyme(s)

Please see Step 9.

Radioactive Compounds

[α-^{32}P]UTP (500–5000 μCi/ml) **<!>**

Use 100 μCi for each sample of nuclei to be radiolabeled.

Centrifuges and Rotors

Beckman SW28 rotor or equivalent
Sorvall H1000B rotor or equivalent
Sorvall SS-34 rotor or equivalent
▲ **IMPORTANT** Chill all rotors to 4°C.

Special Equipment

Boiling water bath
Dounce homogenizer with type-B pestle
Polyallomer or ultraclear swinging-bucket centrifuge tubes
Polypropylene tubes (17 x 100 mm)
Razor blades
Shaking water bath preset to 30°C
Water baths preset to 4°C and 65°C

Additional Reagents

Step 11 of this protocol requires the reagents and equipment listed in Chapter 7, Protocol 9.
Step 13 of this protocol requires the reagents listed in Chapter 6, Protocol 8.
Steps 14–16 of this protocol require the reagents listed in Chapter 6, Protocols 8 and 10.

Vectors and Bacterial Strains

Nonrecombinant plasmid vector
Recombinant plasmid containing the cDNA or gene of interest

Cells and Tissues

Cultured cells or Fresh tissue

METHOD

Isolation of Nuclei and Radiolabeling of RNA Transcripts

1. Isolate nuclei from either cultured cells or fresh tissue.

ISOLATION OF NUCLEI FROM CULTURED CELLS

a. Scrape the cells from culture dishes and wash them twice with ice-cold PBS. Resuspend 1×10^7 to 1×10^8 cells in 1 ml of ice-cold lysis buffer in a 17 x 100-mm polypropylene tube. Add 2–4 µl of 5% Nonidet P-40 and incubate the suspension for 10 minutes on ice.

b. Mix 10 µl of the suspension with an equal volume of 0.4% Trypan Blue dye and examine the solution under a microscope equipped with a 20x objective. Lysed cells take up the dye and appear blue, whereas unlysed cells are impermeable to the dye and remain translucent. Continue adding 2-µl aliquots of 5% Nonidet P-40 and check cell lysis until >80% of the cells are lysed.

c. Recover the nuclei by centrifugation at 1300*g* (2500 rpm in a Sorvall H1000B rotor) for 1 minute in a benchtop centrifuge. Remove and discard the supernatant. Wash the pellet of nuclei twice in 1-ml of ice-cold nuclei wash buffer. Proceed to Step 2.

ISOLATION OF NUCLEI FROM TISSUE

a. Dissect and mince 10–15 g of tissue. Adjust the volume of minced tissue to 30 ml with ice-cold tissue homogenization buffer, and homogenize in a tight-fitting Dounce homogenizer.

b. To monitor lysis, mix 10 µl of the cell suspension with an equal volume of 0.4% Trypan Blue dye and examine the solution under a microscope equipped with a 20x objective. Lysed cells take up the dye and stain blue, whereas intact cells exclude dye and remain translucent. Continue to homogenize the tissue until >80–90% of the cells are broken.

c. Dilute the homogenate to 85 ml with ice-cold tissue homogenization buffer. Layer 27-ml aliquots over 10-ml cushions of ice-cold homogenization buffer in ultraclear or polyallomer swinging bucket centrifuge tubes. Centrifuge the tubes at 103,900*g* (24,000 rpm in a Beckman SW28 rotor) for 40 minutes at 4°C.

d. Decant the supernatant and allow the tubes to drain in an inverted position for 1–2 minutes. Place the tubes on ice. Resuspend each pellet in 2 ml of glycerol storage buffer by pipetting the mixture up and down.

(*Optional*) Use a razor blade to cut off the top two thirds of the tube and place the bottom one third containing the nuclei on ice before resuspending the pellets in glycerol storage buffer.

e. Mix 10 µl of resuspended nuclei with 990 µl of 0.5% SDS. Measure the OD_{260} in a UV spectrophotometer and dilute resuspended nuclei with glycerol storage buffer to a final concentration of 50 OD_{260}/ml. Divide the preparation of nuclei into 200-µl aliquots in 1.5-ml microfuge tubes, snap freeze the aliquots in liquid nitrogen, and store them at –70°C. Proceed to Step 2.

2. Radiolabel the nascent RNA transcripts in the isolated nuclei.

RADIOLABELING OF THE TRANSCRIPTS IN NUCLEI ISOLATED FROM CULTURED CELLS

a. Remove as much supernatant as possible from the last wash (Step 1c), and resuspend the nuclei in 50–100 µl of labeling buffer. Incubate the nuclei for 15–20 minutes at 30°C in a shaking water bath.

▲ **WARNING** Exercise extreme care after the radioactive UTP has been added to the solution. Wear gloves and goggles and be careful not to contaminate bench surfaces, etc., with this highly radioactive solution.

b. Pellet the nuclei by centrifugation at 800*g* (1960 rpm in a Sorvall H1000B rotor) for 5 minutes in a benchtop centrifuge, and carefully discard the supernatant as radioactive waste. Proceed to Step 3.

The incorporation of [^{32}P]UTP into RNA can be monitored by trichloroacetic acid (TCA) precipitation as described in Appendix 8. In a successful labeling reaction containing 100 µCi of radiolabeled UTP and 10 OD_{260} of nuclei, 80–90% of the ^{32}P will be incorporated into TCA-precipitable material.

RADIOLABELING OF THE TRANSCRIPTS IN NUCLEI ISOLATED FROM TISSUE

a. Transfer an appropriate number of aliquots of the nuclear preparation from –70°C to an ice bucket. When the aliquots have thawed, add 400 units of RNasin to each tube. Add 200 µl of 2x reaction buffer supplemented with nucleotides and dithiothreitol to each tube of nuclei. Add 100 µCi of [α-^{32}P]UTP.

▲ **WARNING** Exercise extreme care after the radioactive UTP has been added to the solution. Wear gloves and goggles and be careful not to contaminate bench surfaces, etc., with this highly radioactive solution.

b. Incubate the nuclei for 20 minutes in a 30°C shaking water bath. Recover the nuclei by centrifugation at 2000 rpm for 1–2 minutes. Carefully discard the supernatant as radioactive waste. Proceed to Step 3.

The incorporation of [^{32}P]UTP into RNA at this step can be monitored by TCA precipitation as described in Appendix 8. In a successful labeling reaction using 100 µCi of radiolabel and 10 OD_{260} of nuclei, 80–90% of the ^{32}P will be incorporated into TCA-precipitable material.

3. Resuspend the nuclear pellet in 1 ml of ice-cold HSB buffer, and add 10 µl of DNase solution. Pipette the nuclei up and down until they are resuspended and the viscosity of the solution is reduced (1–5 minutes). Add 2 ml of stop buffer.

DNase treatment serves to reduce the viscosity of the solution and to prevent the trapping of nascent radiolabeled RNA transcripts in genomic DNA. The viscosity never completely disappears and clumps of nuclei often remain.

4. (*Optional*) To increase the yield of radiolabeled RNA, add proteinase K after the DNase step. Following the addition of 2 ml of stop buffer, add proteinase K to a final concentration of 100 µg/ml. Incubate the solution for 30 minutes at 42°C. Proceed to Step 5.

For more extensive DNA removal and radiolabeled RNA purification protocols, please see Groudine et al. (1981).

5. Add 3 ml of phenol and incubate the mixture for 15 minutes at 65°C with vortexing every 5 minutes. Add 3 ml of chloroform:isoamyl alcohol, vortex, and separate the organic and aqueous phases by centrifugation at 1900*g* (3000 rpm in a Sorvall H1000B rotor). Extract the aqueous layer again with 3 ml of chloroform, centrifuge as before, and transfer the aqueous layer to a fresh tube.

6. Add 0.3 ml of 5 M LiCl and 2.5 volumes of ethanol, and mix well. Collect precipitated nucleic acids by centrifugation at 12,000*g* (10,000 rpm in a Sorvall SS-34 rotor) for 10 minutes.

7. Resuspend the pellet in 0.4 ml of H_2O and transfer it to a 1.5-ml microfuge tube. Add 40 µl of 5 M LiCl and 2.5 volumes of ethanol. Centrifuge the solution for 10 minutes at maximum speed in a microfuge.

8. Resuspend the pellet in 100 µl of H_2O and measure the cpm/µl in a liquid scintillation counter.

Hybridization of the RNA to Immobilized DNA

9. Linearize 10 µg of recombinant plasmid DNA containing the cDNA or gene of interest and 10 µg of empty plasmid vector using a restriction enzyme whose sites of cleavage are present in the vector sequences.

10. Recover the cleaved DNAs using standard ethanol precipitation, and resuspend each of the pellets separately in 20 µl of DNA denaturation solution. Boil the resuspended DNAs for 2 minutes, and then add 180 µl of 6x SSC to each tube.

11. Cut a piece of nylon or nitrocellulose membrane to the appropriate size for use in a dot- or slot-blotting apparatus. Wet the membrane in H_2O and then soak it for 5–10 minutes in 6x SSC. Clamp the wet membrane in the blotting apparatus, attach a vacuum line, and apply suction to the device (please see Chapter 7, Protocol 9).

12. Filter the denatured DNAs through separate slots and wash each filter with 200 µl of 6x SSC.

13. Dismantle the device, dry the membrane in the air, and fix the DNA to the membrane by baking or by exposure to UV light.

14. Place the membrane in prehybridization solution and incubate it for at least 16 hours at an appropriate temperature (e.g., 42°C for solvents containing 50% formamide).

15. Add the radiolabeled probe (2×10^6 to 4×10^6 cpm/ml of ^{32}P-labeled RNA from Step 8) directly to the prehybridization solution, and incubate the filter for a further 72 hours.

16. Wash the membrane at high stringency and expose it to X-ray film or a phosphorimager plate. Typical exposure times are 24–72 hours for X-ray film and 4–24 hours for a phosphorimager plate.

HYBRIDIZATION CONTROLS AND TROUBLESHOOTING

- The inclusion of α-amanitin <!> in the labeling step at 0.5 μg/ml can be used to demonstrate that an observed hybridization signal is due to transcription by RNA polymerase II (Marzluff and Huang 1984).
- Several hybridization controls should be included in a nuclear run-on experiment. As a negative control for spurious hybridization, isolate and analyze nuclear RNA from cells that do not express the gene of interest. Immobilize an empty plasmid vector on the nylon/nitrocellulose filter to act as a control for spurious hybridization. Prepare two positive hybridization controls, including a gene that is expressed in the cells but is known not to respond to the regulatory input (e.g., actin, glyceraldehyde 3-phosphate dehydrogenase, and cyclophilin), and a gene that is known to respond to the stimulus.
- The cDNA or gene of interest in the immobilized DNA should not contain repetitive DNA sequences and represent as much of the gene as possible. DNA fragments containing separate regions or exons of the gene can be used to assay for differences in the rate of elongation (Bentley and Groudine 1986) and/or to confirm a given hybridization result. It should also be kept in mind that, in rare instances, both strands of the DNA can be transcribed. For this reason, use a single-stranded DNA probe from one or more regions or exons as a control in at least one experiment.
- The overall sensitivity of the hybridization assay can be enhanced by trimming the excess membrane from the immobilized DNA (i.e., leaving just the DNA-containing slot or dot) and carrying out the hybridization in a test tube in a small volume under mineral oil in a water bath set at the appropriate temperature.
- In some cases, partial hydrolysis of nascent RNA transcripts will enhance hybridization. Resuspend the final RNA pellet from Step 8 in 100 μl of 10 mM Tris-Cl (pH 7.4), 10 mM EDTA, and 200 mM NaCl, and add 25 μl of 1 N NaOH. Incubate the solution on ice for 15 minutes and then neutralize the reaction by adding 25 μl of 1 N HCl. Add 500 μl of 1.2x Denhardt's solution and set up the hybridization reaction as described.
- If substantial background is encountered in these protocols, treat the washed filter with RNase T1 (10 units/ml) and RNase A (20 μg/ml) in 2x SSC for 1 hour at 37°C to reduce nonspecific binding of the probe to the membrane.

Reporter Assays: CAT, Luciferase, and β-galactosidase

REPORTER GENES OR MARKERS PROVIDE A CONVENIENT MEANS to identify and analyze the regulatory elements of genes. Standard recombinant methods are used to join the regulatory sequence of interest to a reporter gene or marker carried in an expression vector. The resulting recombinant is then introduced into an appropriate cell line, where its expression is detected by measurement of the reporter mRNA or the reporter protein, or, in the case of enzyme reporters, by assaying for the relevant catalytic activity. Whatever the method of detection, these reporters typically have an easily measured output that can be distinguished from the background of proteins in the host cell. Most of the detection methods in common use are sensitive, specific, quantitative, reproducible, and rapid to perform.

Reporter systems are used to measure transcriptional activity, in particular to study promoters and enhancers and their interactions with *cis*-acting elements and *trans*-acting proteins, as well as their responses to environmental changes. The fine structure of a regulatory region can be analyzed by a series of "promoter-bashing experiments" in which selected mutations are introduced into the sequence under study, and its consequent activity (or ability to express the reporter) is measured and compared to that of the wild-type or normal sequence.

REPORTER GENES USED IN ANALYSIS OF REGULATORY ELEMENTS

After Gorman et al. (1982) first described the use of chloramphenicol acetyltransferase (CAT) as a reporter, the CAT gene became widely adopted as a reporter for many of the standard lines of cultured mammalian cells. CAT remains in common use and fulfills many of the criteria required of a reporter (please see Table 17-1). Several different assays are available to measure CAT activity, using procedures and equipment that are available in most laboratories. Despite its virtues, CAT is not an ideal reporter in all circumstances. Other reporter systems have therefore been developed in an effort to increase the sensitivity of detection and to expand the range of cell lines that could be used as hosts (for reviews, please see Alam and Cook 1990; Bronstein et al. 1994; Groskreutz and Schenborn 1997; Naylor 1999).

Each of these newer reporter systems uses a different method of detection and each has different strengths and weaknesses.

- The firefly luciferase gene produces light from luciferin in the presence of ATP (de Wet et al. 1987; please see the information panel on **LUCIFERASE**). Measurements of luciferase activity therefore require a luminometer or liquid scintillation counter with single photon-counting

TABLE 17-1 Comparison of Commonly Used Reporter Genes

Reporter Gene[a]	Advantages	Disadvantages
CAT (bacterial)	no endogenous activity; automated ELISA available	narrow linear range; use of radioisotopes; stable
β-galactosidase (bacterial)	well-characterized and stable; simple colorimetric readouts; sensitive bio- or chemiluminescent assays available	endogenous activity (mammalian cells)
Luciferase (firefly)	high specific activity; no endogenous activity, broad dynamic range; convenient assays	requires substrate (luciferin) and presence of O_2 and ATP
Luciferase (bacterial)	good for measuring/analyzing prokaryotic gene transcription	less sensitive than firefly; not suitable for mammalian cells
Alkaline phosphatase (human placental)	secreted protein; inexpensive colorimetric and highly sensitive luminescent assays available	endogenous activity in some cells; interference with compounds being screened
GFP (jellyfish)	autofluorescent (no substrate needed); no endogenous activity; mutants with altered spectral qualities available	requires posttranslational modification; low sensitivity (no signal amplification)

[a]β-glucuronidase is frequently used as a reporter in plants (Jefferson 1987).
Reproduced, with permission, from Naylor (1999 ©Elsevier Science).

ability. For some experiments, luciferase is a better reporter than CAT. The assay for luciferase is more sensitive and is therefore preferred when a weak promoter is analyzed or when the line of cultured cells is transfected with low efficiency. Luciferase is also the reporter of choice when analyzing promoters whose activity is down-regulated in response to a signal. The half-life of luciferase in transfected cells is short (~3 hours) and the enzymatic activity declines rapidly as a result of down-regulation of the promoter. CAT, on the other hand, is very stable ($T_{0.5}$ >50 hours) and maintains its full enzymatic power long after the rate of transcription has been reduced (Thompson et al. 1991). Although it is possible to follow the disappearance of CAT using mRNA by primer extension or nuclease protection, these assays are far more laborious than those used to quantify luciferase activity.

- Growth hormone is secreted into the medium, where it is easily detected and accurately quantified by a commercially available radioimmunoassay. However, the rationale for using growth hormone as reporter is built on the assumption that the rate at which secreted protein accumulates in the medium parallels the rate at which the gene encoding the preprotein is transcribed in the nucleus. This assumption may seem reasonable, but it has not been proven in all circumstances. Secretion and transcriptional control lie at opposite ends of the continuum of events that constitute gene expression and are separated by a large number of steps, each of which may be subjected to control. Secretion may be a good surrogate for transcription in most cases, but there are situations in which it certainly is not, for example, in cell lines that have defects in the secretory pathway.

- Green fluorescent protein (GFP) and its engineered variants are the best nonenzymatic reporter systems in current use. GFP is unique among various light-emitting proteins in being autofluorescent, i.e., it requires no exogenous cofactors or independent substrates for activity. Moreover, as its presence is easily detected by measuring absorbance at the appropriate wavelength, the system provides a noninvasive means of monitoring reporter gene expression in both fixed and living cells. However, because the fluorescent signal is not amplified (even in some of the brighter mutants of GFP), detection requires that expression of GFP be driven by very strong promoters or other regulatory elements. The most spectacular applications are in

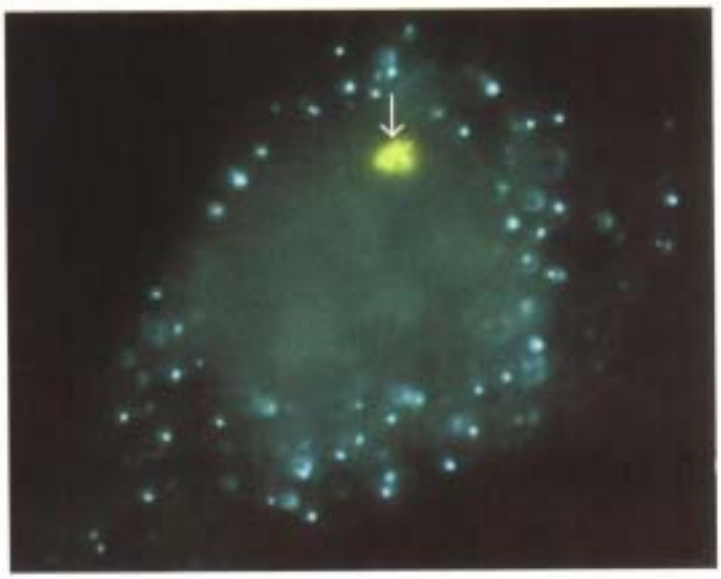

FIGURE 17-2 Localization of a Stably Integrated Transgene and Its Protein Product

A gene encoding a fusion protein composed of cyan fluorescent protein and a peroxisomal targeting signal was cloned downstream from a tetracycline-responsive element (TRE) controlling a minimal cytomegalovirus promoter. Lac operator sequences from the *E. coli lacZ* gene were located upstream of the TRE. The construct was used to transfect BHK cells, and a stable cell line was selected that expressed cyan fluorescent protein from integrated copies of the transgene. The chromosomal site of integration can be detected in live interphase cells by transient expression of a fusion protein consisting of yellow fluorescent protein and the *lac* repressor that binds operator sequences (please see arrow in the figure). The cyan fluorescent protein expressed from the transgene is visible in peroxisomes distributed throughout the cytoplasm of the cell. (Photo provided courtesy of Toshiro Tsukamoto [Himeji Institute of Technology, Japan] and David L. Spector [Cold Spring Harbor Laboratory].)

the utilization of GFP as a fusion partner to follow the transport, localization, and fate of a targeted protein (e.g., please see Figure 17-2). For further information on GFP, please see Tsien (1998) and the information panel on **GREEN FLUORESCENT PROTEIN** at the end of this chapter.

- Epitope tagging provides another method to monitor expression and localization of proteins. A well-characterized epitope tag expressed as part of a protein of interest confers immunoreactivity to a well-characterized antibody. Epitope tags can be used both for immunolocalization of the target protein and for quantitation by commercially available radioimmunoassays. For further information, please see the excellent review by Jarvik and Telmer (1998) and the information panel on **EPITOPE TAGGING**. Specific protocols for engineering fusion constructs using epitope tags and fluorescent proteins may be found in *Cells: A Laboratory Manual* (Spector et al. 1998; Chapters 71 and 78, respectively)

TRANSFECTION CONTROLS

When measuring the effect of promoters and enhancers on gene expression, it is essential to include an internal control that will distinguish differences in the level of transcription from differences in the efficiency of transfection or in the preparation of extracts. This control is best achieved by cotransfecting the cells with two plasmids: one plasmid that carries the construct under investigation and another plasmid that constitutively expresses an activity that can be assayed in the same cell extracts. *E. coli* β-galactosidase is a convenient enzyme for this purpose and methods to assay this enzyme in cell extracts are described in Protocol 7.

Protocol 5

Measurement of Chloramphenicol Acetyltransferase in Extracts of Mammalian Cells Using Thin-layer Chromatography

THE FIRST EXPERIMENTS TO MAP REGULATORY DNA SEQUENCES in a eukaryotic promoter used primer extension to detect transcripts of a viral thymidine kinase gene that had been injected into *Xenopus* oocytes (McKnight and Gavis 1980; McKnight and Kingsbury 1982). Although the prevailing viewpoint at the time was that eukaryotic genes were impossibly complex and quite beyond analysis by methods then available (Lewin 1974), McKnight showed that this was not the case and in so doing initiated the field of eukaryotic promoter analysis. Today, many hundreds of regulatory elements have been identified using variations on his methods, and a large number of nuclear proteins that interact with these sequences have been purified and their genes cloned.

As more and more laboratories began mapping eukaryotic promoters, it soon became apparent that a simpler and more rapid assay than primer extension was needed to measure promoter activity. Of the many so-called reporter genes that have been developed to meet this need, the bacterial enzyme chloramphenicol acetyltransferase (CAT) and the firefly enzyme luciferase (please see Protocol 6) have become the most popular.

CAT is encoded by a prokaryotic gene that confers resistance to the antibiotic chloramphenicol. The enzyme transfers an acetyl group from acetyl-coenzyme A (acetyl-CoA) to chloramphenicol and thereby inactivates the ability of the antibiotic to bind to and inhibit prokaryotic ribosomes (for further details, please see the information panel on **CHLORAMPHENICOL ACETYLTRANSFERASE**). Because there are no CAT genes in mammalian cells, and because the assay for CAT enzymatic activity is sensitive and reproducible, the prokaryotic CAT gene has become a popular reporter of eukaryotic promoter output. In a typical experiment, a fragment of eukaryotic DNA is placed upstream (5′) of the coding region of the CAT gene and the resulting plasmid is transfected into mammalian cells. After a period of time to allow expression of the transfected gene, CAT activity is measured using one of the assays described in this protocol. If the assay is set up correctly, there will be a linear relationship between the amount of CAT activity and the level of transcription of the transfected construct. By making mutations in the putative promoter DNA fragment and assaying the ability of the mutant constructs to direct the synthesis of CAT activity after transfection, it is possible to define regulatory sequences in the DNA.

Despite the quantitative nature of the CAT assay, it should always be kept in mind that transcription is not directly measured in the assay and that parameters such as the half-life of the CAT protein in a transfected cell can influence the results. This consideration becomes especially important when scoring for suppression of transcription. Another potential problem is that CAT activity may be generated from transcripts that are accurately initiated both at the promoter of interest and from transcripts initiated at ectopic sites in the vector (Langner et al. 1986). The level of such aberrant transcription may greatly inflate the estimates of the activity of the promoter under test. In some cases, the background caused by spurious transcription can be eliminated by placing a transcription termination signal upstream of the promoter of interest (Heard et al. 1987; Araki et al. 1988). To reduce the possibility of error, the conclusions obtained by analysis of promoters or enhancers linked to CAT (or any other reporter enzyme activity) must be confirmed by direct assay of the mRNAs encoded by one or more of the chimeric constructs. The accuracy with which transcripts are initiated from chimeric genes should also be checked by mapping the precise location of the 5′ terminus of the mRNA on its template DNA. Techniques to measure mRNA levels and to map the 5′ termini of mRNAs include primer extension, digestion of DNA-RNA hybrids with nuclease S1, and digestion of RNA-RNA hybrids with RNase A. Protocols for these types of experiments are detailed in Chapter 7.

In the current protocol, we outline three different assays that can be used to detect CAT enzyme activity expressed from pCAT3 reporter vectors transfected into mammalian cells (please see Figure 17-3): measuring CAT activity using thin-layer chromatography (main protocol), measuring CAT activity following extraction with organic solvents (first alternative protocol, p. 17.40), and measuring CAT activity following diffusion of products into scintillation fluid (second alternative protocol, p. 17.41).

CONTROLS

Controls to determine intrinsic CAT enzyme activity should include mock-transfected cells and cells transfected with the CAT vector lacking a promoter. A control that lacks any cell extract should also be included to measure the background contributed by the thin-layer chromatograms. As a positive control for CAT activity and transfection, use extracts from cells transfected with a construct equipped with a strong promoter (SV40 early or late region promoters, cytomegalovirus immediate early region, or Rous sarcoma virus long terminal repeat) linked to the CAT gene (e.g., please see Figure 17-3). Finally, results obtained with the CAT assay should be confirmed by direct measurements of RNA.

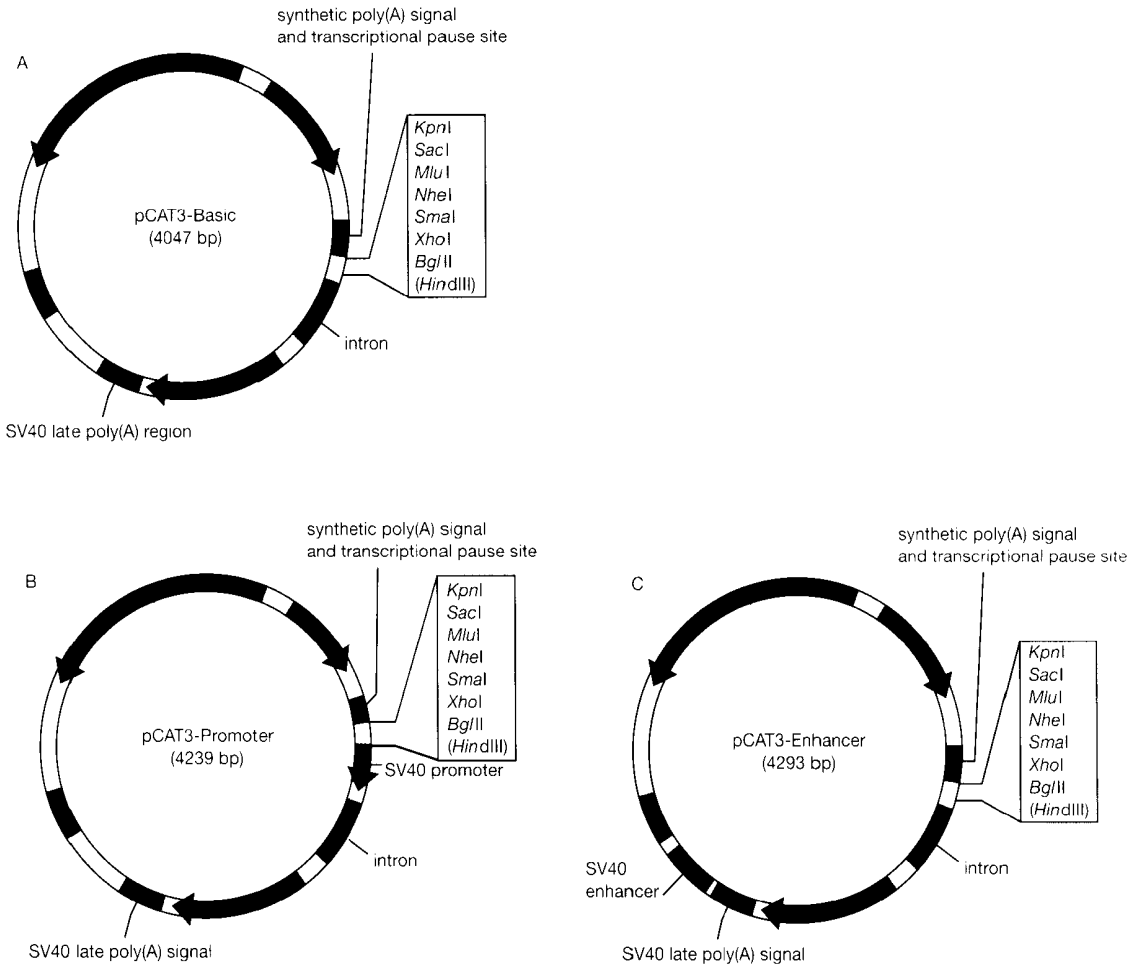

FIGURE 17-3 pCAT3 Vectors

Summarized here are the features of pCAT3 vectors that carry the coding sequence for CAT (Luckow and Schütz 1987). All vectors in the series contain (1) the origin of replication derived from filamentous phage (f1 ori), (2) an origin of plasmid replication in *E. coli* (ori), (3) an ampicillin resistance marker (Amp^R) for selection in prokaryotic cells, and (4) a poly(A) addition signal and a transcriptional pause site located 5′ of the CAT gene to reduce the background of readthrough transcription from upstream sequences. The arrows in the CAT gene and in Amp^R indicate the direction of transcription. The sequence of interest is inserted into the multiple cloning site (MCS). (*A*) The basic vector lacks eukaryotic promoter and enhancer sequences. The expression of CAT in this vector depends on the insertion and proper orientation of a functional promoter upstream of the intron and CAT gene. Putative enhancer elements can also be inserted upstream of the promoter or in the *Bam*HI or *Sal*I sites downstream from the CAT gene. (*B*) The promoter vector contains an SV40 promoter upstream of the intron and the CAT gene. DNA sequences carrying putative enhancer elements can be inserted either upstream or downstream from the promoter-CAT transcription unit. (*C*) The enhancer vector carries an SV40 enhancer located downstream from the CAT gene and poly(A) addition signal. The enhancer aids in identifying functional promoter elements because its presence often results in high levels of transcription of the CAT gene. (Modified, with permission, from Promega Corp.)

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

CAT reaction mixture 1

1 M Tris-Cl (pH 7.8)	50 µl
[^{14}C]chloramphenicol (60 mCi/mmole, diluted in H_2O to 0.1 mCi/ml) <!>	10 µl
acetyl-CoA (freshly prepared at a concentration of 3.5 mg/ml in H_2O)	20 µl

Prepare 80 µl of CAT reaction mixture 1 per 50 µl of cell lysate to be assayed. Assemble the reaction mixture immediately before use.

Acetyl-CoA is the *S*-acetylated form of coenzyme A. Two carbon units from fat and carbohydrate enter the citric acid cycle in this form. It is used as an acetylating cofactor in many biological reactions, as in this protocol, for acetylation of chloramphenicol by CAT.

Ethyl acetate <!>

Ethyl acetate ($CH_2COOCH_2CH_3$) is an organic solvent used in thin-layer chromatographic assays of CAT activity. Mix 1 part ethyl acetate with 19 parts chloroform to make a solvent that separates acetylated and nonacetylated forms of chloramphenicol on silica gel plates. Ethyl acetate is an extremely flammable (flash point = –4°C) and volatile ester with a scent of ripe fruit.

Lysis buffer

0.1 M Tris-Cl (pH 7.8)
0.5% (v/v) Triton X-100

Use if lysing the cells with detergent (please see Step 4).

The same lysis buffer can also be used to prepare cell extracts for measurements of β-galactosidase activity (please see Protocol 7).

▲ **IMPORTANT** Use a highly purified preparation of Triton X-100 in the cell lysis buffer. Lower-grade detergent samples can inhibit CAT enzyme activity. The detergent Nonidet P-40 at 0.125% (v/v) can be substituted for Triton X-100 in the lysis buffer.

Phosphate-buffered saline (PBS) without calcium and magnesium salts

Thin-layer chromatography (TLC) solvent

190 ml of chloroform <!>
10 ml of methanol <!>

Prepare 200 ml per TLC tank. Two TLC plates can be developed per tank.

Tris-Cl (1 M, pH 7.8)

Radioactive Compounds

Radioactive ink <!>

Use to mark adhesive dot labels as guides for orienting the autoradiogram with the TLC plate.

Special Equipment

Dry ice/ethanol bath <!>

Use these items if lysing the cells by freezing and thawing.

Marking pen with ethanol-insoluble ink

Rotary vacuum evaporator

For example, a Savant SpeedVac.

Rubber policeman

Thin-layer chromatography plates (e.g., Sybron SIL G/UV254, Brinkmann)

Thin-layer chromatography tank (27.5 x 27.5 x 7.5 cm)

This tank is available from scientific supply houses (e.g., Sigma-Aldrich Techware).

Water bath preset to 65°C

Cells and Tissues

Cultured mammalian cells transfected with pCAT vectors carrying the DNA of interest

The cells should be transfected (using one of the transfection protocols in Chapter 16) with a CAT reporter construct (e.g., the pCAT3 series) and an expression plasmid containing the β-galactosidase gene (pCMV-SPORT-β-gal; please see Figure 16-2 in Chapter 16) or another reporter gene suitable for normalizing the results of CAT assay. For details of the pCAT vector series, please see Figure 17-3.

METHOD

Preparation of Transfected Cell Pellets

1. Use gentle aspiration to remove the medium from transfected monolayers of cells growing in 90-mm tissue culture dishes. Wash the monolayers three times with 5 ml of PBS without calcium and magnesium salts.
2. Stand the dishes at an angle for 2–3 minutes to allow the last traces of PBS to drain to one side. Remove the last traces of PBS by aspiration. Add 1 ml of PBS to each plate, and use a rubber policeman to scrape the cells into microfuge tubes. Store the tubes in ice until all of the plates have been processed.
3. Recover the cells by centrifugation at maximum speed for 10 seconds at room temperature in a microfuge. Gently resuspend the cell pellets in 1 ml of ice-cold PBS, and again recover the cells by centrifugation. Remove the last traces of PBS from the cell pellets and from the walls of the tubes. Store the cell pellets at –20°C for future analysis or prepare cell extracts by either of the methods in Step 4.

   The PBS can be conveniently removed with a disposable pipette tip attached to a vacuum line. Use gentle suction, and touch the tip to the surface of the liquid. Keep the tip as far away from the cell pellet as possible while the fluid is withdrawn from the tube. The pipette tip can then be used to vacuum the walls of the tube to remove any adherent droplets of fluid.

Preparation of Cell Extracts

4. Lyse the cells either by repeated cycles of freezing and thawing or by incubating the cells in detergent-containing buffers. The latter is a quicker and easier method of cell lysis that permits CAT, β-galactosidase, and other marker gene assays to be adapted to a 96-well microtiter plate format (Protocol 6) (Bignon et al. 1993).

LYSIS OF CELLS BY REPEATED FREEZING AND THAWING

a. Resuspend the cell pellet from one 90-mm dish in 100 µl of 0.25 M Tris-Cl (pH 7.8). Vortex the suspension vigorously to break up clumps of cells.

b. Disrupt the cells by three cycles of freezing in a dry ice/ethanol bath and thawing at 37°C. Make sure that the tubes have been marked with ethanol-insoluble ink.

c. Centrifuge the suspension of disrupted cells at maximum speed for 5 minutes at 4°C in a microfuge. Transfer the supernatant to a fresh microfuge tube. Set aside 50 µl of this supernatant for the CAT assay, and store the remainder of the extract at –20°C.

LYSIS OF CELLS USING DETERGENT-CONTAINING BUFFERS

a. To lyse cells with detergent, resuspend the cell pellets from Step 3 in 500 µl of lysis buffer. Incubate the mixture for 15 minutes at 37°C.

Use 100 µl of this lysis buffer per cell pellet for extracts prepared from cells grown in 35-mm dishes.

b. Remove the cellular debris by centrifuging the tubes at maximum speed for 10 minutes in a microfuge. Recover the supernatant. Assay CAT activity using one of the methods described in this protocol. Snap freeze the remainder of the cleared lysates in liquid nitrogen and store them at –70°C.

Detection of CAT Activity Using Thin-layer Chromatography

5. Incubate a 50-µl aliquot of the cell extract for 10 minutes at 65°C to inactivate endogenous deacetylases. If the extract is cloudy or opaque at this stage, remove the particulate material by centrifugation at maximum speed for 2 minutes at 4°C in a microfuge.

6. Mix each of the samples to be assayed with 80 µl of CAT reaction mixture 1, and incubate the reactions at 37°C. The length of the incubation depends on the concentration of CAT in the cell extract, which in turn depends on the strength of the promoter and the cell type under investigation. In most cases, incubation for 30 minutes to 2 hours is sufficient.

   The reactions can be incubated for longer periods of time (up to 16 hours) when the expression of the CAT gene is low in the transfected cells. However, in this case, it is advisable to add an additional 10-µl aliquot of acetyl-CoA to each reaction after 2 hours of incubation.

7. Add 1 ml of ethyl acetate to each sample, and mix the solutions thoroughly by vortexing for three periods of 10 seconds. Centrifuge the mixtures at maximum speed for 5 minutes at room temperature in a microfuge.

   The acetylated forms of chloramphenicol partition into the organic (upper) phase; unacetylated chloramphenicol remains in the aqueous phase.

8. Use a pipette to transfer exactly 900 µl of the upper phase to a fresh tube, carefully avoiding the lower phase and the interface. Discard the tube containing the lower phase in the radioactive waste.

9. Evaporate the ethyl acetate under vacuum by placing the tubes in a rotary evaporator (e.g., Savant SpeedVac) for ~1 hour.

10. Add 25 µl of ethyl acetate to each tube and dissolve the reaction products by gentle vortexing.

11. Apply 10–15 µl of the dissolved reaction products to the origin of a 25-mm silica gel TLC plate. The origin on the plate can be marked with a soft-lead pencil. Apply 5 µl at a time, and evaporate the sample to dryness with a hair dryer after each application.

12. Prepare a TLC tank containing 200 ml of TLC solvent. Place the TLC plate in the tank, close the chamber, and allow the solvent front to move ~75% of the distance to the top of the plate.

    A number of different TLC plates and solvents can be used to separate acetylated forms of chloramphenicol. We routinely use chloroform:methanol (95:5) and Sybron SIL G/UV254 (Brinkmann) TLC plates. Touchstone (1992) provides a good introduction to TLC methods and troubleshooting.

13. Remove the TLC plate from the tank and allow it to dry at room temperature. Place adhesive dot labels marked with radioactive ink on the TLC plate to align the plate with the film, and

then expose the plate to X-ray film. Alternatively, enclose the plate in a phosphorimaging cassette. Store the cassette at room temperature for an appropriate period of time.

Do not cover the TLC plate with Saran Wrap, as this coverage will block the relatively weak radiation emitted by the ^{14}C isotope.

14. Develop the X-ray film and align it with the plate. Alternatively, expose the chromatogram to the imager plate of a phosphorimager device or subject the plate to scanning.

Typically, three radioactive spots are detected. The spot that has migrated the least distance from the origin consists of nonacetylated chloramphenicol that partitioned into ethyl acetate. The two faster-migrating spots are modified forms of chloramphenicol that have been acetylated at one or the other of two potential sites. Diacetylated chloramphenicol may be detected as a third, even faster migrating spot only when high concentrations of CAT or lengthy incubations with copious amounts of extract protein are used.

15. To quantitate CAT activity, cut the radioactive spots from the TLC plate and measure the amount of radioactivity they contain in a liquid scintillation counter (please see Appendix 9). Use another aliquot of the cell extract (from Step 3 above) to determine the concentration of protein in the extract, using a rapid colorimetric assay, such as the Bradford assay. Reduce the concentration of Triton X-100 to ≤0.1% by dilution before determining the concentration of protein to prevent interference with the assay. Express the CAT activity as pmoles of acetylated product formed per unit time per milligram of cell extract protein.

Thin-layer chromatography on silica gels followed by scraping and scintillation counting of the modified chloramphenicol products can become quite tedious when large numbers of samples are prepared. An alternate method for quantitating the amount of product in these cases is to use a phosphorimager to scan the TLC plates.

"Intrinsic" acetylation of chloramphenicol in the absence of cellular extracts can contribute to background. If this is a problem, try decreasing the concentration of chloramphenicol in the assays two- to fourfold (Heard et al. 1987).

ALTERNATIVE PROTOCOL: MEASUREMENT OF CAT BY EXTRACTION WITH ORGANIC SOLVENTS

In this procedure (Sleigh 1986), the acetylated CoA is radiolabeled, and transfer of ^{14}C-labeled acetate to unlabeled chloramphenicol is measured. The acetylated, radiolabeled forms of chloramphenicol are separated from unreacted acetyl-CoA by extraction with ethyl acetate. The acetylated chloramphenicol product partitions into the organic phase and the acetyl-CoA substrate remains in the aqueous phase.

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Additional Materials

CAT reaction mixture 2

8 mM chloramphenicol **<!>**	20 µl
0.25 M Tris-Cl (pH 7.8)	30 µl
[^{14}C]acetyl-CoA **<!>**	20 µl

The 8 mM solution of chloramphenicol is made by dissolving 2.57 mg of chloramphenicol in 1 ml of ethanol. The solution of [^{14}C]acetyl-CoA is prepared by dissolving [^{14}C]acetyl-CoA (58 Ci/mmole) in H_2O to a concentration of 50 mCi/ml. Dispense the solution into 20-µl aliquots and store them at –70°C. Immediately before setting up the reaction, dilute the [^{14}C]acetyl-CoA tenfold into a solution of unlabeled acetyl-CoA (0.5 mM). The concentrations of the reagents in the final reaction mixture are 2.3 mM chloramphenicol, 0.11 M Tris-Cl, and 129 mM (1 mCi/ml) [^{14}C]acetyl-CoA.

For each 30 µl of cell extract to be tested, 70 µl of CAT reaction mixture 2 is required.

Scintillation fluid (e.g., Insta-Gel, Packard)

Method

1. Prepare extracts of transfected cells as described in the main protocol, Steps 1–4. Set aside 30-µl aliquots of the extracts for the CAT assay.
2. Add 30 µl of each cell extract to 70 µl of CAT reaction mixture 2. Incubate the reactions for 10 minutes at 65°C to inactivate deacetylases and then for 1 hour at 37°C to allow the CAT enzyme to function.
3. Transfer the samples to an ice bath, and add 100 µl of ice-cold ethyl acetate. Mix the phases by vigorous vortexing. Centrifuge the mixtures at maximum speed for 3 minutes at room temperature in a microfuge.
4. Transfer 80 µl of the organic (upper) phase to a fresh tube. Add 100 µl of ice-cold ethyl acetate to the original tube (the aqueous phase). Vortex vigorously and centrifuge again as in Step 3. Transfer 100 µl of the organic phase to the tube containing 80 µl of ethyl acetate from the first extraction.

   Take great care not to transfer any of the aqueous phase, which contains radiolabeled substrate.

5. Mix the combined organic phases with 1 ml of scintillation fluid in a 1.5-ml plastic tube. Measure the radioactivity by liquid scintillation counting (please see Appendix 8). Determine the specific activity of the CAT after measuring the concentration of protein in the cell extracts using a rapid colorimetric assay such as the Bradford assay.

   The linear range of this assay is between 0.03 and 0.25 unit of enzyme per milliliter of incubation mixture (a unit of CAT activity is defined as the amount of enzyme that transfers 1 nmole of acetyl groups from acetyl-CoA to chloramphenicol in 1 minute at 37°C [pH 7.8]).

ALTERNATIVE PROTOCOL: MEASUREMENT OF CAT BY DIFFUSION OF REACTION PRODUCTS INTO SCINTILLATION FLUID

This improved version of the previous alternative protocol does not involve extraction of the acetylated chloramphenicol into ethyl acetate. Instead, the reaction mixture is overlaid with water-immiscible scintillation fluid. Acetylated forms of chloramphenicol produced by the activity of CAT in the aqueous phase diffuse rapidly into the scintillation fluid (Neumann et al. 1987), where they are trapped. Acetyl-CoA and nonacetylated chloramphenicol remain in the aqueous phase. Only the radioactivity in the scintillation fluid can be detected by liquid scintillation counting, and this can be measured at any stage during the enzymatic reaction. Because this technique is a continuous assay, rather than a single-endpoint assay, it yields semiquantitative kinetic data that can be analyzed by standard mathematical formulas.

In the original description of this method, high concentrations (100 μM) of unlabeled acetyl-CoA were used to ensure that sufficient substrate was present to satisfy the K_m of CAT. Large amounts (5 μCi of ^{3}H) of expensive radiolabeled acetyl-CoA were therefore required in each assay. However, adequate results can be obtained by omitting the unlabeled acetyl-CoA from the assay and reducing the amount of radioactive substrate to 0.1 μCi (Eastman 1987). Under these conditions, the reaction is linear with enzyme concentration as long as less than 0.0125 unit of CAT is present per assay (where 1 unit of CAT catalyzes the acetylation of 1 nmole of chloramphenicol in 1 minute at 37°C at pH 7.8). Commercial preparations of CAT are available (e.g., Sigma) that can be used both as positive controls and to standardize enzyme activity in crude extracts of transfected cells.

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Additional Materials

CAT reaction mixture 3

1 M Tris-Cl (pH 7.8)	25 μl
5 mM chloramphenicol **<!>**	50 μl
[^{3}H]acetyl-CoA (200 mCi/mmole) **<!>**	0.1 μCi
H_2O	to 200 μl

The 5 mM solution of chloramphenicol is made by dissolving 1.6 mg of chloramphenicol in 1 ml of ethanol. [^{3}H]acetyl-CoA can be purchased at the indicated specific activity (e.g., New England Nuclear) or diluted from higher specific activity stocks in H_2O. Store the radiolabeled acetyl-CoA at –70°C. [^{14}C]acetyl-CoA (0.1 μCi) can be substituted for the tritium-labeled compound. The concentrations of reagents in the final reaction mixture are 125 mM Tris-Cl, 1.25 mM chloramphenicol, and 0.35 mM acetyl-CoA.

For each 30 μl of cell extract to be tested, 200 μl of CAT reaction mixture 3 is required.

Glass scintillation vials (7 ml)

Water-immiscible scintillation fluid (e.g., Econofluor, New England Nuclear)

Method

1. Prepare extracts of transfected cells as described in the main protocol, Steps 1–4. Reserve 30-μl aliquots of the extracts for the CAT assay.
2. Mix 30 μl of each cell extract with 20 μl of 100 mM Tris-Cl (pH 7.8) in a 7-ml glass scintillation vial. Heat the mixtures for 15 minutes at 65°C to inactivate deacetylases in the extract. Transfer the vials to a water bath set at 37°C.
3. Add 200 μl of freshly prepared CAT reaction mixture 3. Use a pipette to carefully overlay the reaction mixtures with 5 ml of a water-immiscible scintillation fluid, and then incubate the mixtures at 37°C. Mixing of the two phases is not necessary. Measure the radioactivity in the scintillation fluid by liquid scintillation counting (please see Appendix 8). Calculate the specific activity of the CAT after measuring the concentration of protein in the cell extracts.

   The vials containing the reaction mixtures may be counted for 0.1 minute at selected time intervals (e.g., every 20 minutes) until the enzymatic reaction is complete, or they may be counted at a single endpoint determined on the basis of previous experiments.

Protocol 6

Assay for Luciferase in Extracts of Mammalian Cells

LUCIFERASE IS THE REPORTER GENE OF CHOICE in many laboratories: (1) The luciferase assay is more sensitive than assays for CAT or other commonly used reporter genes. The exceptionally high sensitivity of the luciferase assay allows analysis of weak promoters and use of smaller amounts of DNA and cells in transfection studies. (2) The assay does not require the use of radioactive materials. (3) The assay is linear over eight orders of magnitude, and small amounts of transfected cell lysate can therefore be assayed for enzyme activity and whole dish-to-dish comparisons are made easier. (4) The buffer used to lyse cells is compatible with other assays for marker genes such as CAT, other luciferase genes, and β-galactosidase, which simplifies the process of normalization, and in some cases, allows the assay of two marker genes in the same aliquot of cell lysate. (5) The luciferase assay can be carried out in 96-well plates to facilitate the analyses of large numbers of transfected cells (please see the panel on **ALTERNATIVE PROTOCOL: ASSAY FOR LUCIFERASE IN CELLS GROWING IN 96-WELL PLATES** at the end of this protocol).

Luminometers or standard scintillation counters can be used to detect light released by the action of the luciferase enzyme. Of these two, measurement with a scintillation counter is more sensitive (Hill et al. 1993) but requires more time. Many different types of luminometers are commercially available (for review, please see Stanley 1992). Although these devices are quite expensive ($20,000–30,000), the assays themselves are very quick, and it is thus usually possible for several laboratories to share one machine.

In this protocol, we describe methods for the measurement of luciferase expressed from vectors transfected into mammalian cells (please see Figure 17-4). Additional enzyme activities, such as those for CAT, β-galactosidase, and alkaline phosphatase, can also be directly measured in cell lysates prepared as described in this protocol. For a more complete description of luciferase, please see the information panel on **LUCIFERASE**.

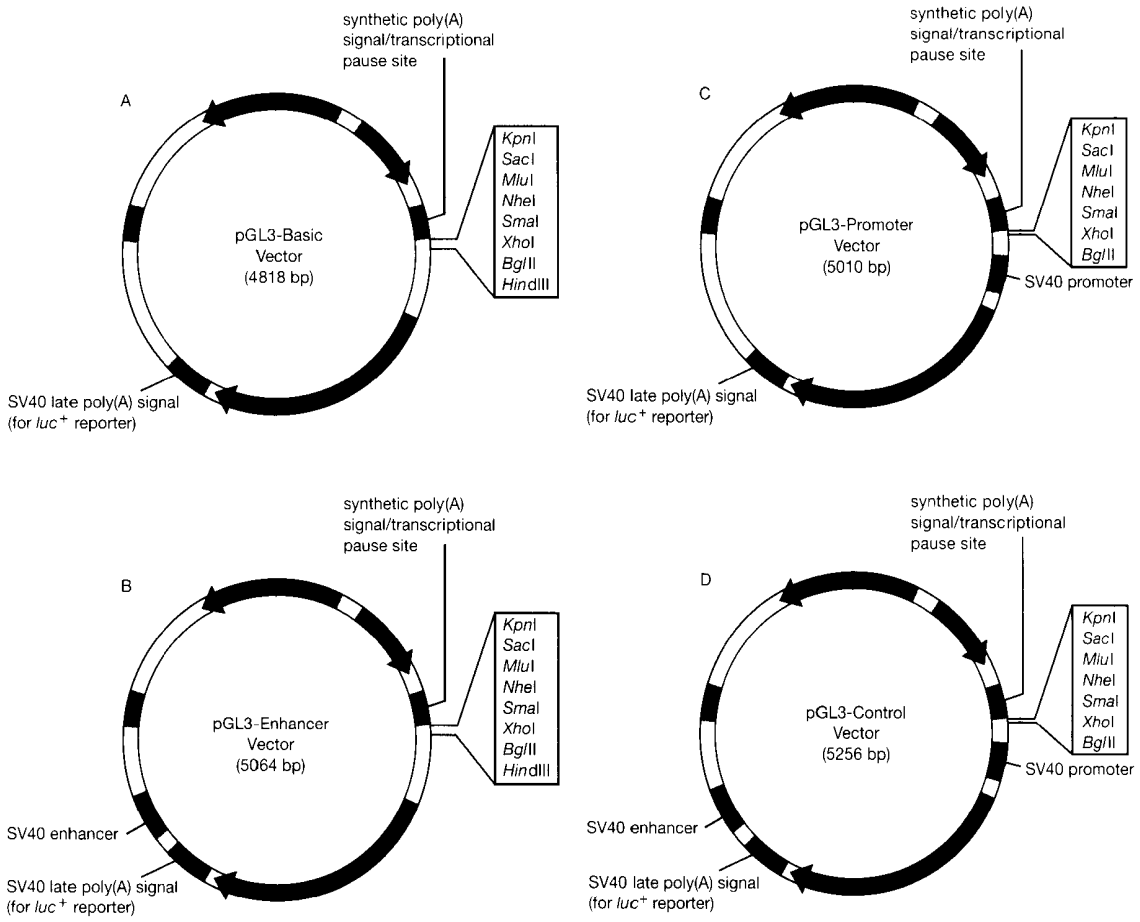

FIGURE 17-4 pGL3 vectors

Summarized here are the features of the pGL3 vectors that carry the coding sequence for a modified version of firefly luciferase (*luc*$^+$). All vectors in the series contain (1) the origin of replication derived from filamentous phage (f1 ori), (2) an origin of plasmid replication in *E. coli* (ori), (3) an ampicillin resistance marker (Amp^R) for selection in prokaryotic cells, and (4) a poly(A) addition signal and a transcriptional pause site located 5′ of the *luc*$^+$ gene to reduce the background of readthrough transcription from upstream sequences. The arrows in *luc*$^+$ and Amp^R indicate the directions of transcription. The sequence of interest is inserted into the multiple cloning site (MCS) at the 5′ end of *luc*$^+$. (*A*) The basic vector lacks eukaryotic promoter and enhancer sequences. The expression of luciferase in this vector depends on the insertion and proper orientation of a functional promoter upstream of the intron and *luc*$^+$ gene. Putative enhancer elements can also be inserted upstream of the promoter or in the *Bam*HI or *Sal*I sites downstream from the *luc*$^+$ gene. (*B*) The enhancer vector carries an SV40 enhancer located downstream from the *luc*$^+$ gene and poly(A) addition signal. The enhancer aids in identifying functional promoter elements, because its presence often results in high levels of transcription of the *luc*$^+$ gene. (*C*) The promoter vector contains an SV40 promoter upstream of the intron and the *luc*$^+$ gene. DNA sequences carrying putative enhancer elements can be inserted either upstream or downstream from the promoter-*luc*$^+$ transcription unit. (*D*) The control vector contains the SV40 promoter and enhancer sequences, resulting in strong expression of *luc*$^+$ in many mammalian cell lines. This vector may be used to monitor transfection efficiency and is a convenient standard for promoter and enhancer activities expressed by pGL3 recombinants. (Modified, with permission, from Promega Corp.)

MATERIALS

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Cell lysis buffer

25 mM glycylglycine (pH 7.8)
15 mM $MgSO_4$
4 mM EGTA
1% (v/v) Triton X-100

Just before use, add dithiothreitol from a 1 M stock solution to a final concentration of 1 mM. Approximately 1 ml of cell lysis buffer is needed per 100-mm dish of cells to be assayed.

Luciferase assay buffer

15 mM potassium phosphate (pH 7.8)
25 mM glycylglycine
15 mM $MgSO_4$
4 mM EGTA
2 mM ATP

Just before use, add dithiothreitol from a 1 M stock solution to a final concentration of 1 mM. Approximately 400 µl of luciferase enzyme assay buffer is needed per luminometer assay tube.

Luciferin solution

25 mM glycylglycine
15 mM $MgSO_4$
4 mM EGTA
0.2 mM luciferin

Just before use, add dithiothreitol from a 1 M stock solution to a final concentration of 2 mM. Approximately 200 µl of luciferin solution is needed per luminometer assay tube. The addition of 1–2 µM CoA to the luciferin solution will produce a more intense and sustained light emission (Wood 1991).

▲ **IMPORTANT** Luciferin is a generic term for substrates that generate light when acted upon by a luciferase enzyme. The most common luciferase gene in use is derived from the firefly and acts on a particular luciferin substrate. Other luciferase enzymes, such as those from the sea pansy (*Renilla reniformis*) or certain marine bacteria, use chemically different luciferin substrates. Make sure that the luciferin substrate used in the above buffer matches the luciferase gene incorporated into the expression plasmid.

Phosphate-buffered saline (PBS) without calcium and magnesium salts

Special Equipment

Luminometer and luminometer assay tubes
Rubber policeman

Cells and Tissues

Cultured mammalian cells transfected with the DNA of interest

The cells should be transfected (using one of the transfection protocols in Chapter 16) with a luciferase reporter construct (please see Figure 17-4) and an expression plasmid containing the β-galactosidase gene (pCMV-SPORT-β-gal; please see Figure 16-2 in Chapter 16) or another reporter gene suitable for normalizing the results of luciferase assay.

OPTIMIZING THE MEASUREMENT OF LUCIFERASE ENZYME ACTIVITY

- The importance of working in the linear range of the luciferase assay cannot be overemphasized. A twofold difference in signal between two enzyme preparations assayed in the nonlinear range can translate into a 100-fold difference when the same preparations are assayed in the linear range. For each transfected culture, it is important to establish that the signal obtained is proportional to the volume of lysate added to the assay.
- Lysis of cells by freezing and thawing results in the inactivation and inefficient recovery of luciferase (Brasier et al. 1989). For this reason, a buffer containing a nonionic detergent such as Triton X-100 is used to lyse the plasma membranes of transfected cells and to release cytoplasmic luciferase. At the concentrations of detergent used, the nuclear membrane remains intact and does not release chromatin into the cell lysate.
- The concentration of ATP required to obtain maximum luciferase activity varies depending on the cell type transfected. For some cells, such as HepG2 cells, the optimum concentration of ATP in the assay is 2 mM (Brasier et al. 1989), whereas in other cell lines such as mouse L cells, the optimum is 0.3 mM (Nguyen et al. 1988). The presence of excess ATP leads to a decrease in enzyme activity due to allosteric inhibition (DeLuca and McElroy 1984). For these reasons, it is a good idea to determine empirically the optimum ATP concentration for each cell line (or buffer) used in luciferase assays.
- The amount of luciferase expressed in a transfected cell from a given construct is a function of the strength of the promoter, as well as the kinetics of luciferase mRNA transport, translation, and enzyme turnover. The time at which luciferase expression is maximal following transfection can be as short as 16 hours or as long as 120 hours, depending on the cell line.

METHOD

1. Between 24 and 72 hours after transfection, wash the cells three times at room temperature with PBS without calcium and magnesium salts. Add and remove the PBS gently, because some mammalian cells (e.g., human embryonic kidney 293 cells) can be easily displaced from the dish by vigorous pipetting.

   Although 24–72 hours may be a typical period of time to allow maximal expression of the luciferase gene in transfected cells, please see the comments in the panel on **OPTIMIZING THE MEASUREMENT OF LUCIFERASE ENZYME ACTIVITY**.

2. Add 1 ml of ice-cold cell lysis buffer per 100-mm dish of transfected cells. Swirl the buffer gently and scrape the lysed cells from the dish using a rubber policeman. Transfer the cell lysate to a 1.5-ml microfuge tube.

3. Centrifuge the cell lysate at maximum speed for 5 minutes at 4°C in a microfuge. Carefully transfer the supernatant to a fresh 1.5-ml microfuge tube.

4. Determine the concentration of protein in the lysate using a rapid colorimetric assay, such as the Bradford assay. Reduce the concentration of Triton X-100 to ≤0.1% by dilution before determining the concentration of protein to prevent interference with the assay.

   The cell lysates may be stored at this step as small aliquots at –70°C. Although the luciferase is unstable when stored at 4°C or –20°C in this lysis buffer (Brasier et al. 1989), the enzyme can be safely stored at 4°C in lysis buffer containing 15% (v/v) glycerol and 1% (w/v) bovine serum albumin.

5. Tap the side of the tube containing the lysate to gently mix the contents. Add 5–200-µl aliquots of cell lysate to individual luminometer tubes containing 360 µl of luciferase assay buffer at room temperature. Place a tube in the luminometer.

   An alternative to using a luminometer to measure the luciferase enzyme activity is presented in the panel on **ALTERNATIVE PROTOCOL: USING A SCINTILLATION COUNTER TO MEASURE LUCIFERASE**.

6. To start the assay, inject 200 µl of luciferin solution into the luminometer tube and measure the light output for a period of 2–60 seconds at room temperature.

   The optimum time of light collection must be determined empirically and will depend on the type of cell transfected and the particular substrate and luciferase enzyme used.

7. Measure the relative light units generated in each tube and determine the linear range of the assay. Use the amount of cell lysate protein that produces a response in the middle of the linear range in subsequent assays. This amount will vary depending on the strength of the promoter being studied, and to a lesser extent, on the efficiency of transfection in individual experiments. Express luciferase activity as relative light units/mg of protein in the cell lysate.

ALTERNATIVE PROTOCOL: USING A SCINTILLATION COUNTER TO MEASURE LUCIFERASE

A scintillation counter can be used in place of a luminometer to detect light emitted by the action of luciferase on luciferin (Nguyen et al. 1988; Fulton and Van Ness 1993). A somewhat higher sensitivity is claimed for scintillation counting over luminometry (Hill et al. 1993); however, luciferase assays require more time when using a scintillation counter. Nguyen et al. (1988) reported that the intensity and kinetics of light emitted by luciferase in cell lysates were sensitive to pH and the particular buffer used in the lysate. If the luciferase assay buffer recommended in the protocol does not yield consistent enzyme activity measurements, then substitute 25 mM Tris-phosphate (pH 7.8) for the glycylglycine component of all the buffers.

Method

1. Prepare cell lysates from transfected cells as described in Steps 1–4 of the main protocol.
2. Transfer an aliquot of cell lysate in a 1.5-ml microfuge tube, add luciferase assay buffer followed by the luciferin solution, and quickly mix the ingredients by gently tapping or vortexing the tube. Within 10–15 seconds of mixing the reagents, place the tube in a scintillation counter and count for a 3-minute interval, using either a specialized channel for chemiluminescence or a broad channel to detect all low-energy emissions. It is important to standardize the time between reagent mixing and scintillation counting, as variations in this time can give rise to 2–3% fluctuations in luminescent intensity (Nguyen et al. 1988).

If the scintillation counter has a switch to turn off the coincidence circuit (i.e., a specialized channel for measuring chemiluminescence), and this circuit is turned off before counting of the luciferase-containing tube, then the counts per minute detected are directly proportional to the amount of luciferase enzyme present in the aliquot of cell lysate (minus any blank value obtained with mock-transfected cell lysate). If the coincidence circuit is not turned off, then the amount of luciferase enzyme is proportional to the square root of the counts per minute, i.e.,

$$\text{Amount of enzyme} = (\text{cpm in sample} - \text{cpm in blank})^{1/2}$$

The coincidence circuit in a scintillation counter links dual amplifiers (photomultipliers) that flank the counting chamber and record simultaneous signals (radioactive decay) emitted by the sample. A degradation event is only counted if it is detected by both amplifiers at the same time. This method of detection eliminates background noise resulting from stray radiation and heat. When measuring chemiluminescence, the chance that two light-emitting events will occur simultaneously is proportional to the chance of having two coincident events in two independent series of totally random events, a frequency that is described by the square of the luminescent intensity. Thus, by taking the square root of the observed intensity (cpm obtained when the coincidence circuit is on), the activity of luciferase in the sample is accurately obtained.

ALTERNATIVE PROTOCOL: ASSAY FOR LUCIFERASE IN CELLS GROWING IN 96-WELL PLATES

To facilitate high-throughput screening, transfected cells can be cultured in 96-well microtiter plates and screened in a luminometer capable of reading the assay directly from the plates. The following protocol is adapted from one supplied by Makoto Makishima and David Mangelsdorf (University of Texas Southwestern Medical Center, Dallas).

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Additional Materials

0.1 M ATP
50 mM CoA
10x Core buffer
  300 mM tricine (pH 7.8)
  80 mM magnesium acetate
  2 mM EDTA
10 mM luciferin
β-mercaptoethanol **<!>**
Phosphate-buffered saline (PBS) lacking calcium and magnesium salts
10% (v/v) Triton X-100

Method

1. Prepare the luciferase assay–lysis buffer as follows:

10x core buffer	2 ml
10% Triton X-100	2 ml
10 mM luciferin	1 ml
0.1 M ATP	300 µl
50 mM CoA	200 µl
β-mercaptoethanol	140 µl
H_2O	to 20 ml

   A 90-mm culture dish will provide enough cells to inoculate four 96-well plates. Each plate will require ~5 ml of luciferase assay–lysis buffer.

2. Wash the transfected cells three times with PBS, tapping the inverted plate gently onto paper towels between each wash.
3. Add 50 µl of luciferase assay–lysis buffer to each well of cells. Avoid making bubbles in the wells. Incubate the plates for 1 minute at room temperature.
4. Measure the light output from the reactions in a luminometer according to the manufacturer's instructions. The optimum time of light collection must be determined empirically and will depend on the type of cell transfected and the particular substrate and luciferase enzyme used.

Protocol 7

Assay for β-galactosidase in Extracts of Mammalian Cells

THE *E. COLI* β-GALACTOSIDASE GENE IS OFTEN USED AS AN INTERNAL REFERENCE in transfection studies (Hall et al. 1983). In a typical experiment, a test plasmid containing a eukaryotic gene promoter linked to CAT or luciferase is cotransfected into a mammalian cell line with a small amount of a plasmid that contains the β-galactosidase gene linked to a strong constitutive promoter. After a period of time to allow expression, enzyme activities arising from the expression of test and control plasmid are determined in cell lysates. By dividing the amount of CAT or luciferase activity by the β-galactosidase activity, a normalized expression value can be obtained (please see below). Constructs are available that carry the β-galactosidase gene downstream from promoters that express strongly in a wide variety of eukaryotic cell types (e.g., the SV40 early promoter, the Rous sarcoma virus long terminal repeat promoter, or the immediate early region promoter of cytomegalovirus; for a description of these plasmids, please see Figure 16-2 in the introduction to Chapter 16). Extracts of most types of cultured mammalian cells contain relatively low levels of endogenous β-galactosidase activity, and an increase in enzyme activity of up to 100-fold can usually be detected during the course of a transfection. With effort, β-galactosidase can also be used as an internal control in certain specialized cells (e.g., gut epithelial cells and human embryonic kidney 293 cells) that express high endogenous levels of β-galactosidase activity. Because endogenous β-galactosidase activity is usually more heat-labile than the bacterial enzyme, a heating step can be used to eliminate the endogenous β-galactosidase activity while preserving the bacterial activity expressed from the control plasmid (Young et al. 1993). In addition, most mammalian β-galactosidases are associated with the lysosome and therefore have an acidic pH optimum. The *E. coli* enzyme has a neutral to slightly alkaline pH optimum. The contribution of the mammalian enzyme can therefore be reduced by carrying out the β-galactosidase assay at pH 7.5. For further details, please see the information panel on **β-GALACTOSIDASE.**

Several different approaches are used to normalize CAT or other reporter enzyme activities to β-galactosidase activity. In one approach, the amount of protein in individual extracts prepared from a series of transfected cells is first measured, and CAT and β-galactosidase are then assayed separately using a standard amount of protein in each assay. Finally, the CAT activity is normalized to the β-galactosidase activity. In another method, the β-galactosidase activity in a constant volume of extract is first measured, and CAT assays are then carried out using amounts of extract containing the same amount of β-galactosidase activity. Alternatively, both enzymatic assays are carried out in a constant volume of extract, and the results are then normalized to a defined level of β-galactosidase activity (i.e., the amount of CAT activity is divided by the amount of β-galactosidase activ-

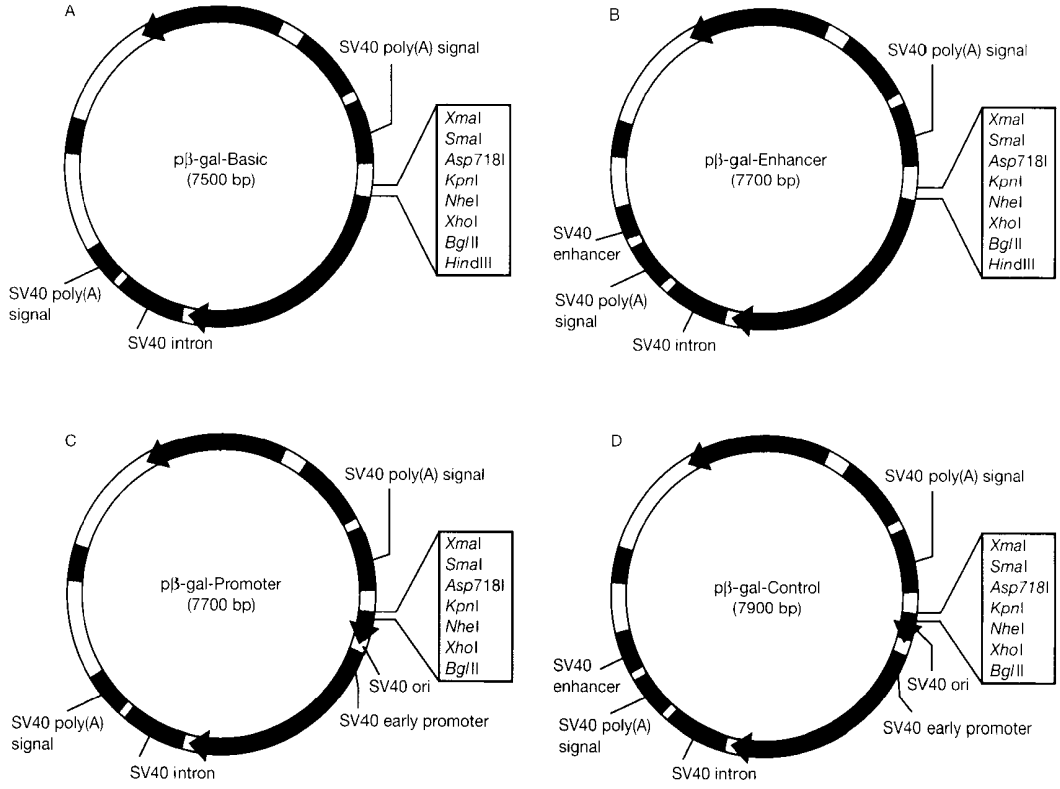

FIGURE 17-5 pβ-gal Vectors

Summarized here are the features of pβ-gal reporter vectors that carry the coding sequence for β-galactosidase. All vectors in the series contain (1) the origin of replication derived from filamentous phage (f1 ori), (2) an origin of plasmid replication in *E. coli* (ori), (3) the origin of replication for SV40 that allows replication in mammalian cells, (4) an ampicillin resistance marker (Amp^R) for selection in prokaryotic cells, and (5) a poly(A) addition signal located 5′ of *lacZ* to reduce the background of readthrough transcription from upstream sequences. The sequence of interest is cloned into the multiple cloning site (MCS) at the 5′ end of the *lacZ* gene. (*A*) pβ-gal-Basic lacks eukaryotic promoter and enhancer sequences. This vector may be used as a negative control or as a vehicle to characterize cloned promoters. (*B*) pβ-gal-Enhancer lacks the SV40 promoter, but contains the SV40 enhancer. This vector can be used to study cloned promoter sequences. (*C*) pβ-gal-Promoter lacks the SV40 enhancer, but contains the SV40 promoter. This vector can be used to study cloned enhancer sequences. (*D*) pβ-gal-Control contains the SV40 early promoter and enhancer. This vector can be used as a positive control or as a reference when comparing the activities of different promoter and enhancer elements. (Modified, with permission, from CLONTECH.)

ity). With some marker genes such as luciferase, the amounts of β-galactosidase and luciferase that are present in the same aliquot of cell lysate can be determined by using different luminescent substrates simultaneously.

This protocol describes the detection of β-galactosidase expressed from reporter vectors (please see Figure 17-5) transfected into mammalian cells. The assay described is both simple and rapid and can be carried out using a visible light spectrophotometer. Please note that several manufacturers sell kits that can be used to assay β-galactosidase in eukaryotic cell lysates. The average cost of a single reaction is typically ≤1 dollar. Many of these kits contain the same buffers listed here and adhere closely to the protocol. However, some kits gain a distinct advantage by containing a cell lysis buffer which allows multiple enzyme activities to be assayed, including β-galactosidase, CAT (Protocol 5), and luciferase (Protocol 6).

ONPG (*o*-nitrophenyl-β-D-galactopyranoside) is the most widely used substrate in assays for β-galactosidase in bacterial and eukaryotic cell lysates. ONPG is colorless but on hydrolysis yields *o*-nitrophenol that is yellow in alkaline solution (λ_{max} 420 nm at pH 10.2). When ONPG is in excess, the OD_{420} of the assay solution increases linearly as a function of time and enzyme concentration (Lederberg 1950; Hestrin et al. 1955; Pardee et al. 1959; Miller 1972, 1992). The reaction can be stopped by adding a concentrated solution of Na_2CO_3, which shifts the pH to ~11, inactivates β-galactosidase, and maximizes the absorbance of *o*-nitrophenol at 420 nm.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

100x Mg^{2+} solution

0.1 M $MgCl_2$

4.5 M β-mercaptoethanol **<!>**

Just before use, add an appropriate amount of β-mercaptoethanol from a 14.7 M stock.

Na_2CO_3 (1 M)

Dissolve 10.6 g of the anhydrous solid in 100 ml of H_2O.

1x ONPG

Dissolve ONPG at a concentration of 4 mg/ml in 0.1 M sodium phosphate (pH 7.5).

Sodium phosphate (0.1 M, pH 7.5)

Mix 41 ml of 0.2 M $Na_2HPO_4 \cdot 2H_2O$ (M_r = 178.05; 35.61 g/liter), 9 ml of 0.2 M $NaH_2PO_4 \cdot 2H_2O$ (M_r = 156.01; 31.21 g/liter), and 50 ml of H_2O.

Tris-Cl (1 M, pH 7.8)

Enzymes and Buffers

E. coli β-*galactosidase*

The enzyme is commercially available (e.g., Sigma).

Additional Reagents

Step 1 of this protocol requires the reagents listed in Protocol 5 of this chapter.

Cells and Tissues

Cultured mammalian cells transfected with the DNA of interest

Use one of the transfection protocols in Chapter 16 to transfect the cells with a plasmid containing a β-galactosidase reporter gene (e.g., the pβ-gal reporter series from CLONTECH; please see Figure 17-5).

β-GALACTOSIDASE SUBSTRATES

The assay relies on the ability of the *E. coli* β-galactosidase enzyme to hydrolyze ONPG to free *o*-nitrophenol and β-D-galactose (Lederberg 1950). The substrate *o*-nitrophenol is yellow in aqueous solutions and absorbs light of 420 nm wavelength. Since the invention of this assay by Joshua Lederberg, more sensitive substrates for the detection of β-galactosidase have been developed. These include 4-methylumbelliferyl β-D-galactoside (Sigma, catalog no. M1633), whose hydrolysis product 4-methylumbelliferone is detected by fluorometry (excitation wavelength = 364 nm, emission wavelength = 440 nm) and is blue in buffers with a basic pH (Roth 1969), and chlorophenol red β-D-galactopyranoside (Boehringer Mannheim), whose hydrolysis product is detected in a visible-light spectrophotometer at 570 nm wavelength (Eustice et al. 1991). An assay using 4-methylumbelliferyl-β-D-galactoside as a substrate is about tenfold more sensitive than one using ONPG, whereas an assay using chlorophenol red β-D-galactopyranoside is ~20 times more sensitive than one using ONPG. Finally, chemiluminescent substrates for β-galactosidase whose hydrolysis product can be detected in a luminometer or scintillation counter are sold by several companies (e.g., Lumi-Gal, Lumigen Corp., Detroit, Michigan; Galacto-Light, Tropix Corp., Bedford, Massachusetts). For a review of one of these dual-assay kits, please see Martin et al. (1996). Assays using chemiluminescent substrates are 20–1000-fold more sensitive than ONPG-based assays (Jain and Magrath 1991; Beale et al. 1992). For further details, please see Appendix 9.

METHOD

1. Prepare cell extracts from the transfected cells as described in Protocol 5, Steps 1–4. Set aside ~30 µl of the extract for the β-galactosidase assay. The exact amount of extract required will depend on the strength of the promoter driving the expression of the β-galactosidase gene, the efficiency of transfection, and the incubation time of the assay. If a heat treatment is to be used to inactivate endogenous β-galactosidases, incubate the cell lysates for 45–60 minutes at 50°C before assay. Luciferase activity is also inactivated by preheating; assay luciferase and β-galactosidase activities in separate aliquots of cell lysate if a preheating step has been used.
2. For each sample of transfected cell lysate to be assayed, mix:

100x Mg^{2+} solution	3 µl
1x ONPG	66 µl
cell extract	30 µl
0.1 M sodium phosphate (pH 7.5)	201 µl

   It is essential to include positive and negative controls. These assays check for the presence of endogenous inhibitors and β-galactosidase, respectively. All of the controls should contain 30 µl of cell extract from mock-transfected cells. In addition, the positive controls should include 1 µl of a commercial preparation of *E. coli* β-galactosidase (50 units/ml). The commercial enzyme preparation should be dissolved at a concentration of 3000 units/ml in 0.1 M sodium phosphate (pH 7.5). Just before use, transfer 1 µl of the stock solution of β-galactosidase into 60 µl of 0.1 M sodium phosphate (pH 7.5) to make a working stock of the enzyme containing 50 units/ml. One unit of *E. coli* β-galactosidase is defined as the amount of enzyme that will hydrolyze 1 µmole of ONPG substrate in 1 minute at 37°C.
3. Incubate the reactions for 30 minutes at 37°C or until a faint yellow color has developed. In most cell types, the background of endogenous β-galactosidase activity is very low, allowing incubation times as long as 4–6 hours to be used.
4. Stop the reactions by adding 500 µl of 1 M Na_2CO_3 to each tube. Read the optical density of the solutions at a wavelength of 420 nm in a spectrophotometer.

   The linear range of the assay is 0.2–0.8 OD_{420}. If the assay fails outside this range, repeat the experiment using less protein extract. The extract can be diluted in 0.25 M Tris-Cl (pH 7.8) to decrease the protein concentration.

Biochemists calculate the specific activity of the β-galactosidase enzyme and express this value as units of enzyme activity per milligram of cell protein, where 1 unit of *E. coli* β-galactosidase is defined as the amount of enzyme that will hydrolyze 1 µmole of ONPG substrate in 1 minute at 37°C. This value can then be used to normalize expression of the marker gene, whose specific activity has also been determined. Most molecular biologists simply divide the amount of CAT or luciferase activity by the amount of β-galactosidase activity present in a given volume to normalize for transfection efficiency, thus ignoring the calculation of specific activity.

Protocol 8

Tetracycline as Regulator of Inducible Gene Expression in Mammalian Cells

WHEN ESTABLISHED WITH DILIGENCE AND USED WITH CARE, tetracycline-responsive expression systems offer an elegant method to maintain control over the expression of genes transfected into eukaryotic cells. The systems discussed below have evolved over the years and have been used successfully to control gene expression in a wide variety of organisms, including cultured mammalian, amphibian, and plant cells (for review, please see Freundlieb et al. 1997), and *Saccharomyces cerevisiae* (Garí et al. 1997; Bellí et al. 1998); in transgenic organisms that include *Drosophila melanogaster* (Girard et al. 1998), plants (Weinmann et al. 1994; Zeidler et al. 1996), and mammals (Furth et al. 1994; Efrat et al. 1995; Ewald et al. 1996; Kistner et al. 1996; Redfern et al. 1999), and mammalian tissues into which genes have been directly injected (Fishman et al. 1994; Dhawan et al. 1995). For further general information on systems for inducible expression, please see, for example, Kost (1997), Saez et al. (1997), Shockett and Schatz (1997), and Rossi and Blau (1998).

TETRACYCLINE

The first of the tetracyclines — chlortetracycline — was discovered in 1948 as a naturally occurring antibiotic that was synthesized by *Streptomyces aureofaciens* and was active against a wide range of Gram-positive and -negative bacteria and protozoa. By 1980, ~1000 tetracycline derivatives had been isolated and/or synthesized, and the estimated global production of the drugs was

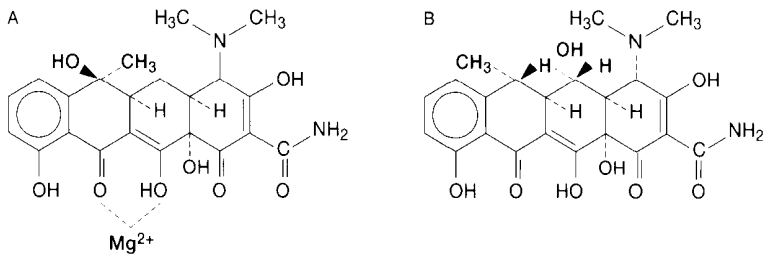

FIGURE 17-6 Structure of Tetracycline and Doxycycline

The carbon atoms in the tetracycline skeleton carry substitute groups in various tetracycline derivatives. Chemical bonds (*colored arrowheads*) appear above the plane of the figure; ionic bonds (*dashed lines*) appear below the plane of the figure. (*A*) Tetracycline-Mg^{2+}; (*B*) doxycycline.

in excess of 500 metric tons (for review, please see Chopra et al. 1992). All of these compounds share an identical four-ring carbocyclic skeleton that supports a variety of groups at carbons 5, 6, and 7 and binds Mg^{2+} through oxygen atoms attached to carbons 11 and 12 (Figure 17-6).

Entry of tetracycline into bacterial cells involves passive diffusion across the outer membrane through porin channels, which are composed of the OmpF protein. However, onward movement from the periplasmic space into the cytoplasm does not appear to involve a specific protein channel. Instead, tetracycline crosses the cytoplasmic membrane by facilitated diffusion in a process driven by pH or electropotential gradients. Tetracycline inhibits bacterial growth by binding to ribosomes ($K_a \sim 10^9\ M^{-1}$) and disrupting codon-anticodon interactions (for reviews, please see Tritton 1977; Gale et al. 1981; Chopra 1985; Chopra et al. 1992). Specifically, tetracycline prevents attachment of aminoacyl-tRNA to the acceptor site on the 30S ribosomal subunit. Tetracycline binds tightly, albeit reversibly, to a single site on the 30S subunit that is composed of residues from at least four proteins (S3, S7, S14, and S19) and residues from the 893–1054 region of 16S rRNA.

The chief mechanism by which *E. coli* becomes resistant to high concentrations of tetracycline involves multimeric antiporter proteins, known as Tet proteins, that are embedded in the bacterial inner membrane and, in exchange for a proton, catalyze the outward transport of tetracycline-Mg^{2+} complexes from the cytosol (Franklin 1967; McMurry et al. 1980; Kaneko et al. 1985; Hickman and Levy 1988; Yamaguchi et al. 1990; Thanassi et al. 1995). Of the several known classes of Tet antiporters, the TetA proteins encoded by transposon Tn*10* and the plasmid pBR322 are the most important in molecular cloning; 399 amino acids in length (Backman and Boyer 1983), they consist of two domains, each containing six transmembrane segments. The two domains are connected by a cytoplasmic loop of 30–40 amino acids rich in positively charged residues (for review, please see Chopra et al. 1992).

When TetA is present in high concentrations, cations are transported from the bacterial cell at such a rate that the membrane becomes depolarized and the viability of the cell is threatened (Eckert and Beck 1989). To prevent catastrophe, expression of TetA is tightly controlled by a helix-turn-helix repressor protein (TetR, 24 kD), the product of the *tetR* gene. In the absence of antibiotic, homodimers of the repressor bind tightly ($K_d = 10^{-11}$ M) to the major grooves of two 15-bp palindromic operator sequences (*tetO1,2*), thus preventing expression of the divergently transcribed genes *tetR* and *tetA* (Hillen et al. 1984; Heuer and Hillen 1988; Kleinschmidt et al. 1988; Hillen and Berens 1994; Hinrichs et al. 1994; Helbl et al. 1995; Orth et al. 2000). TetR is therefore a powerful negative regulator of transcription both of its own gene and of *tetA*.

Binding of tetracycline-Mg^{2+} to TetR ($K_a = 10^9\ M^{-1}$) induces a conformational change that reduces the affinity of the repressor for *tetO* by nine orders of magnitude (Kleinschmidt et al. 1988; Lederer et al. 1995). The differentials between binding constants ensure that transcription of *tetR* is suppressed in the absence of tetracycline and induced by concentrations of the drug that are too low to affect protein synthesis (please see Figure 17-7). Crystal structures are now available for free TetR (Orth et al. 1998), the complexes between TetR and tetracycline-Mg^{2+} (Hinrichs et al. 1994; Kisker et al. 1995), and the complexes between TetR and TetO (Figure 17-7) (Orth et al. 2000).

TetO AND TetR ARE USED TO CONTROL EXPRESSION OF GENES TRANSFECTED INTO EUKARYOTIC CELLS

Various forms of TetR and TetO are used to regulate expression of target genes transfected into eukaryotic cells. Because of all the components — repressor, operators, and effectors — are prokaryotic in origin, these systems have few if any significant effects on the expression of resident host genes.

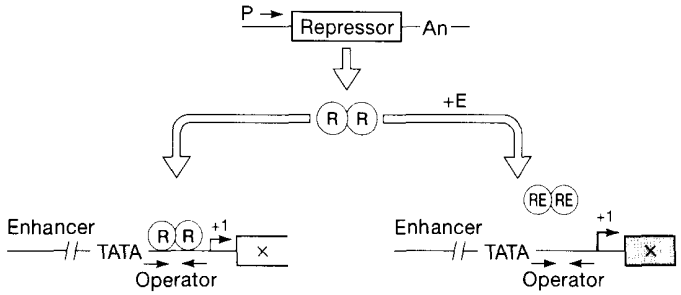

FIGURE 17-7 Schematic Representation of a Repression System

In the repression system, the repressor (R) is synthesized under the control of an appropriate promoter (P). When the effector (E), for example, tetracycline or doxycycline, is absent, the repressor binds one or several strategically placed operator sequences (dyad symmetries are indicated by small arrows) within a promoter/enhancer region and interferes with transcription initation (the TATA box and transcriptional start site [+1] of the promoter are indicated). In the presence of effector, repression is relieved (RE), thereby allowing transcription of the controlled gene (X). Reproduced, with permission, from Gossen et al. 1994 [©Elsevier Science].).

The Tet Repression System

In this system (initially described by Gossen and Bujard 1992), the initiation of transcription of a target gene is controlled by the Tet repressor, which is supplied in *trans*. A recombinant is constructed that contains several tandem copies of the *tetO* elements upstream of the transcriptional start site of the gene of interest and downstream from a minimal promoter. Expression from this promoter can be tightly controlled in eukaryotic cells that express Tet repressor. In the absence of tetracycline, the repressor binds to the *cis*-acting elements and interferes with initiation of transcription by RNA polymerase II (Heins et al. 1992). In the presence of tetracycline, repression is relieved, allowing the gene of interest to be transcribed. Tissue specificity is achieved by selection of an appropriate promoter for expression of the Tet repressor in the target cells.

The Tet repressor system has been used successfully in transgenic plants (Gossen and Bujard 1992; Furth et al. 1994; Wu and Chiang 1996), with the best results being achieved in tobacco (Gatz et al. 1991, 1992; for reviews, please see Gossen et al. 1993, 1994; Gatz 1995). However, efforts to establish a corresponding system in mammalian cells have been only partially successful at best, perhaps because repression of a strong promoter requires a concentration of repressor high enough to saturate the *tetO* elements. Such concentrations of Tet repressor are difficult to sustain in mammalian cells (Gossen et al. 1994).

The Tet *Trans*-activator System

Expression of genes transfected into eukaryotic cells can be controlled more efficiently by converting TetR to a transcriptional *trans*-activator. Fusing TetR to the carboxy-terminal acidic domain of the herpes simplex type-1 (HSV-1), VP16 protein creates a transcriptional activator (tTA) (Gossen and Bujard 1992; Weinmann et al. 1994; Gossen et al. 1995) that, in the absence of tetracycline, binds to tandemly arranged *tetO* sequences inserted into a minimal promoter and thereby induces transcription of a downstream target gene. However, doxycycline, a water-soluble analog of tetracycline, abolishes the ability of tTA to bind to *tetO* sequences and, in a dose-dependent fashion, destroys the *trans*-activating ability of the chimeric protein and restrains expression of the target gene. After withdrawal of the antibiotic, tTA activates transcription of the target gene. The gene product accumulates at a linear rate for several hours and may increase in concentration by >100,000-fold.

The dynamic range of the Tet system is much lower in transiently transfected cells than in stable cell lines carrying integrated copies of the target gene and its *trans*-activator (e.g., please see Freundlieb et al. 1999). To achieve differences of 1000-fold between the repressed and induced states, it is necessary to create stable cell lines containing integrated copies of the tTA gene and the target gene. This can be done in two ways:

- The target gene of interest is cloned into a "response" plasmid encoding a compound promoter that typically consists of seven tandemly arranged copies of TetO and the minimal immediate early promoter of cytomegalovirus. The gene encoding the *trans*-activating protein tTA is cloned into a separate "regulator" plasmid downstream from a suitable mammalian promoter. The two plasmids are then transfected into the mammalian cell of choice to create "double-stable" cell lines. Transfection is usually carried out in two stages. First, the regulator plasmid is used to generate stable cell lines that express tTA constitutively. These cells are then transfected with the response plasmid and further sublines are selected that express desired quantities of the target gene product only in the absence of tetracycline or doxycycline. In some cases, it is possible to reduce the labor of sequential transfection and screening by using cell lines in which integrated copies of the regulator plasmid have already been installed (e.g., please see Gossen and Bujard 1992; Wu and Chiang 1996). Several cell lines of this type are commercially available from CLONTECH.
- Alternatively, the *trans*-activator gene and the target gene can be cloned into a single plasmid. Because transfection of mammalian cells with both genes is carried out simultaneously, one round of tedious screening is eliminated. In addition, the variation in expression that may occur if the regulator and target genes are integrated at separate chromosomal sites may be lessened (Schultze et al. 1996).

Whether stable cell lines are established with one plasmid or two, full occupancy of the tandemly arranged *tetO* sequences is not required for maximal expression of the target gene. Between 6,000 and 10,000 molecules of tTA per cell are sufficient to increase the level of expression of integrated copies of response plasmids by a factor of 10^5. Larger quantities of tetracycline-dependent *trans*-activators may, in fact, be toxic (e.g., please see Howe et al. 1995; Shockett et al. 1995; Saez et al. 1997).

The CLONTECH Web Site contains a bibliography of several hundred papers (www.clontech.com/tet/Refs/index.html) that describe the successful use of the tetracycline activation systems in cultured cells and transgenic organisms. However, success is not guaranteed. The tTA system cannot be stably established in some cell lines, and, in others, the transcription of target genes placed under the control of TetO cannot be regulated by doxycycline (e.g., please see Ackland-Berglund and Leib 1995; Howe et al. 1995; Miller and Rizzino 1995). Integration of the target gene into an actively transcribed region of chromosomal DNA may lead to constitutively high levels of expression in the uninduced state. Ways to avoid these and other problems and to optimize the efficiency of the system are discussed by Gossen and Bujard (1995) and Yin et al. (1996). In addition, please see the panel on **TROUBLESHOOTING** at the end of this introduction.

The Tet Reversed Activator System

In the conventional Tet *trans*-activation system, low-to-moderate concentrations of doxycycline are constantly required to suppress transcription of the target gene, and induction after withdrawal of the antibiotic is slow and asynchronous. More efficient induction of expression of the target gene can be obtained with the Tet reversed system, which uses a mutant Tet repressor (rTetR) that differs from the wild-type protein at four amino acids (Gossen et al. 1995). When

fused to the VP16 activation domain, rTetR creates a "reverse" tTA (rtTA) that represses transcription in the absence of an effector, but activates transcription when doxycycline or anhydrotetracycline (Gossen and Bujard 1993) is supplied. Thus, genes placed under the control of rtTA may be kept in a repressed state until the inducer is introduced to the system. The rtTA system, which is available from commercial sources, is ~100 times more sensitive to doxycycline or anhydrotetracycline than to tetracycline.

The Autoregulatory Tet System

To increase the levels of expression of target genes and to suppress the toxic consequences of constitutive expression of tTA in mammalian cells, Shockett and co-workers (Shockett et al. 1995; Shockett and Schatz 1996) placed tTA under the control of *tetO* elements. Expression of tTA is therefore autoregulated in stably transfected cells and can be controlled by doxycycline. In the presence of the antibiotic, tTA is produced constitutively in small amounts from the minimal cytomegalovirus promoter but is unable to bind to *tetO* sequences upstream of tTA and the target gene. When the antibiotic is withdrawn from the system, tTA binds to both sets of *tetO* sequences and drives expression both of itself and the target gene.

When this system was used in stable lines of transfected 3T3 cells, expression of the recombination activating genes *RAG1* and *RAG2* was substantially higher and the proportion of transformed clones that could be induced was also increased (Shockett et al. 1995). Similarly, in transgenic mice expressing a luciferase reporter gene, the levels of expression were one to two orders of magnitude higher in the autoregulatory system than in the conventional *trans*-activation system.

Tet Systems with Reduced Basal Activity

High levels of basal transcription of the target gene may result from activation in the absence of bound *trans*-activators, from the inability of tetracycline or doxycycline to squelch *trans*-activation mediated by tTA, and/or from the integration of target genes at transcriptionally active chromosomal sites (Furth et al. 1994; Howe et al. 1995; Kistner et al. 1996). To repress basal transcription, tetracycline-controlled transcription silencers (tTS) have been constructed that suppress the activity of promoters responsive to rtTA. These silencers are chimeric proteins consisting of a modified Tet repressor (TetR) fused to repressor domains of, for example, the mammalian Kox1 or Kid proteins (Deutschle et al. 1995; Forster et al. 1999; Freundlieb et al. 1999). In the absence of doxycycline, homodimers of tTS bind to *tetO* sequences upstream of the target gene and suppress transcription. The silencers dissociate from *tetO* in the presence of doxycycline, allowing homodimers of rtTA to take their place and activate transcription of the target gene.

Success with this approach is possible because the affinity of rtTA for doxycycline is ~100-fold lower than that for tTS or tTA (Gossen et al. 1995). Low concentrations of doxycycline therefore allow tTS but not rtTA to bind to *tetO* sequences. Conversely, high concentrations of doxycycline allow rtTA to bind but prevent binding of tTS. When tTS is expressed in the same cell as rtTA, the *tetO* sites upstream of the target gene are occupied by tTS in the absence of doxycycline and transcription of the target gene is suppressed. In the presence of high concentrations of the antibiotic, the *tetO* sites are occupied by rtTA and the target gene is actively transcribed.

In this system, switching between suppression and activation might be compromised if tTS and rtTA were to form heterodimers that could still bind to *tetO*. This problem can be avoided by equipping tTS and rtTA with noncompatible dimerization domains, derived from different classes of TetR proteins (Rossi et al. 1998; Schnappinger et al. 1998; Baron et al. 1999; Forster et al. 1999).

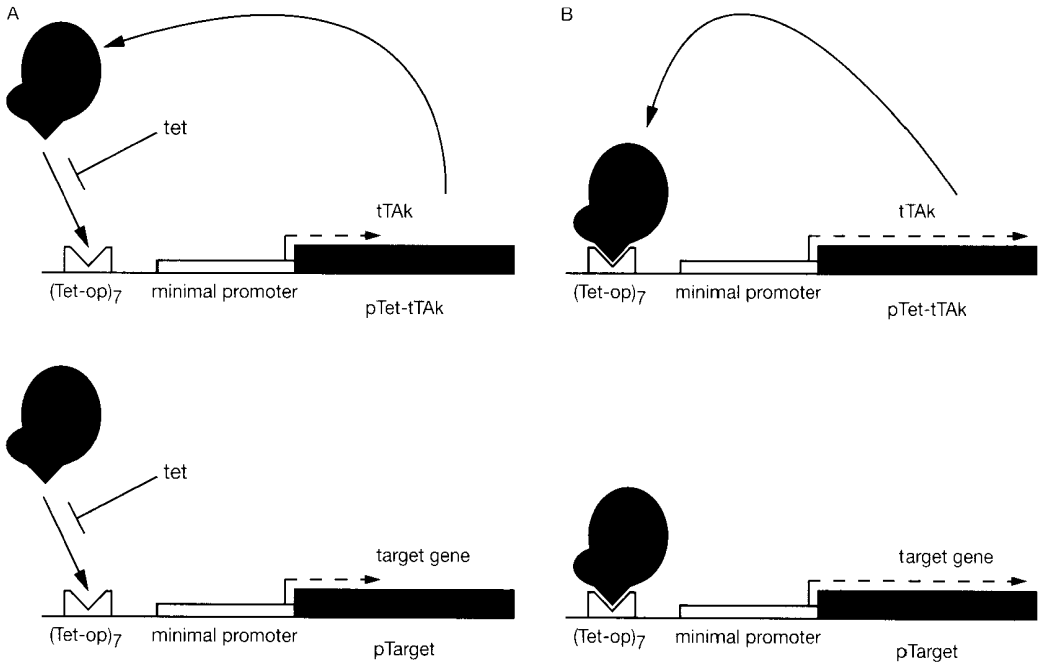

FIGURE 17-8 Autoregulatory Strategy for Inducible Gene Expression

Autoregulatory expression of tTA is accomplished in pTet-tTak by placing the tTAk gene under the control of *tetP* consisting of seven tandemly arranged copies of the *tet* operator sequence [(Tet-op)$_7$] upstream of the minimal hCMV promoter region which contains a TATA box and transcriptional start site. Expression of the target gene is also controlled by *tetP*. The tTA protein is shown as two adjoining ellipses that represent the two domains of the protein (for DNA binding and *trans*-activation). (*A*) In the presence of tetracycline (Tet), the basal activity of the minimal hCMV promoter results in very low levels of the tTA protein, and any tTA protein produced is blocked from binding to Tet-op. Both target gene and tTA expression are therefore maintained at low levels. (*B*) When tetracycline is removed, the small amounts of tTA present bind Tet-op, stimulating expression of the tTA gene. Higher levels of the tTA protein now stimulate higher levels of tTA and thus, target gene expression. (Modified, with permission, from Shockett et al. 1995 [©National Academy of Sciences, U.S.A.].)

The following protocol uses an autoregulatory system in which the transcriptional *trans*-activator (tTA) drives its own expression and that of a target gene in cultured cells. As discussed above, tTA is a fusion protein consisting of the tetracycline repressor of *E. coli* and the transcriptional activation domain of the VP16 protein of herpes simplex virus. In the absence of tetracycline, tTA binds to and activates genes preceded by a heptamerized version of the Tet operator sequences (*tetO*) plus a minimal cytomegalovirus promoter (here collectively referred to as TetP). Binding of tTA to TetP and subsequent gene activation are blocked in the presence of tetracycline (Figure 17-8). The plasmid pTet-Splice (Figure 17-9A) contains TetP upstream and SV40 splice and polyadenylation signals downstream from a multiple cloning site into which sequences encoding the open reading frame of a target gene are easily inserted. Autoregulatory tTA expression is driven from the plasmid pTet-tTAk (Figure 17-9B), in which the tTA open reading frame (including an optimal sequence for initiation of translation according to Kozak [1984]) has been inserted into pTet-Splice.

The following protocol is divided into three stages: stable transfection of fibroblasts with pTet-tTAk, stable transfection of inducible tTA-expressing NIH-3T3 cells, and analysis of the protein expression in transfected cells. Stably transfected cell lines expressing *trans*-activator and tar-

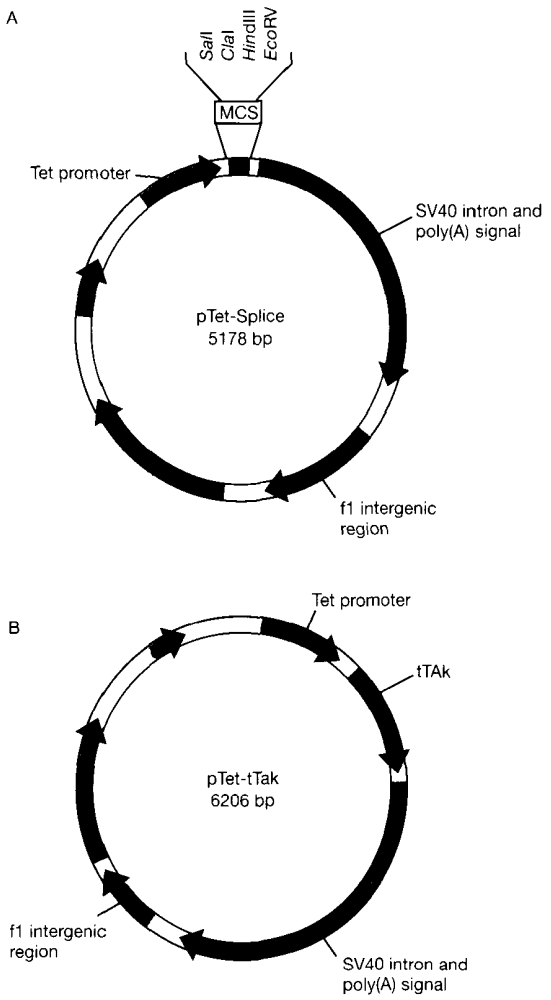

FIGURE 17-9 Tet-regulated Expression Vectors

Two plasmids are used to clone the target gene and place it under control of an inducible promoter. The two vectors are cotransfected into mammalian cells, and expression of the target gene is controlled by altering the amount of tetracycline in the culture medium. (*A*) The target gene is cloned into the multiple cloning site (MCS) of plasmid pTet-Splice. Its expression is controlled by the Tet promoter sequence. Proper processing of the transcript in mammalian cells is facilitated by the presence of the SV40 intron and polyadenylation signal. (*B*) pTet-tTAk contains the gene for the tetracycline *trans*-activator (tTA) under the control of the tetracycline operator (TetO) and the basal cytomegalovirus promoter. (Modified, with permission, from Life Technologies, Inc.)

get gene(s) are derived in two stages. In Stage 1, untransformed cells are cotransfected with pTet-tTAk and a plasmid encoding a selectable marker. Stable transformants exhibiting inducible tTA expression are selected. In Stage 2, these clones are cotransfected with plasmids encoding (1) a plasmid containing the target gene downstream from a minimal promoter and tandemly arranged *tetO* sequences target gene(s) and (2) a second selectable marker. In the examples presented here, the vector pSV2His is used to confer the first selectable marker, and pPGKPuro provides the second selectable marker. Other plasmids carrying selectable markers may be used, such as pTet-Splice-Neo, which confers neomycin resistance (Qiu and Stavnezer 1998). Alternatively, pTet-tTAk may be cotransfected with the expression plasmid and a plasmid containing a single selectable marker. The choice of approach depends on the feasibility of screening for the products of the target genes. Although the consecutive method is more systematic, the cotransfection

approach may be faster if a straightforward screening method for expression of the target gene is available. Stage 3 describes the analysis of expression in transfected cells as well as an alternative approach for transient transfection.

Stable clones expressing tTA (or tTA + target gene[s] if cotransfecting) may be obtained in ~12–14 days. Generally, an additional 2 weeks are required for expansion and further testing of candidate clones. Selection, expansion, and testing of doubly transformed clones that exhibit inducible expression of the target gene will require another 4–6 weeks of work. Alternatively, stable transformants expressing inducible tTA may be transiently transfected with an appropriate target gene construct. Although induction of expression may be less dramatic, expression of the target genes may be achieved within 48 hours. The following protocol was provided by Penny Shockett and David Schatz (Yale University School of Medicine, New Haven, Connecticut).

TROUBLESHOOTING

- The basal activity of the minimal cytomegalovirus promoter varies from one cell line to another and may be affected by DNA sequences in the response plasmid that act as enhancers or other modulators of transcription. Before constructing a double-stable cell line, carry out transient transfection experiments to compare the basal activity of the minimal promoter in one or more target cell lines with the basal activity in a "standard" cell line such as HeLa. Ideally, the basal activity of the response plasmid should be no greater in transfected target cells than in transfected HeLa cells.
- Careful selection of clones expressing tTA is essential as is the subsequent selection of "double-stable" cell lines in which expression of the gene of interest is adequately controlled. To obtain highly regulated gene expression, it may be necessary to select clones of cells where the Tet operator, together with its minimal promoter, is integrated into a transcriptionally "silent" region that nevertheless remains accessible to tTA (Gossen and Bujard 1995). Such integration events cannot be arranged to order but must be identified by trial and error. However, techniques have been described to screen populations of transfected cells for low basal expression and high inducibility using the tetracycline-regulated promoter (Kirchhoff et al. 1995).
- High levels of expression cannot be expected in stable cell lines that express tTA and are then transfected with a plasmid containing *tet* operator sequences and a target gene. The high concentrations of plasmid used for transfection may titrate all of the available tTA, thereby reducing the opportunity for binding of multiple repressors to tandem operator sequences (Gossen and Bujard 1995).
- In many cases, the level of target gene expression can be controlled by varying the concentration of effector. Doxycycline-HCl at a concentration of 1–20 ng/ml in culture medium is generally sufficient to inactivate tTA in most double-stable cell lines.

STAGE 1: Stable Transfection of Fibroblasts with pTet-tTAk

This stage of the protocol describes a method that can be used either to derive stable cell lines expressing inducible tTA alone or can be used to cotransfect cell lines simultaneously with both pTet-tTAk and the plasmid expressing the tetracycline-regulated target gene(s). In this protocol, the plasmids are introduced into NIH-3T3 cells using calcium-phosphate-mediated stable transfection. These protocols can be adapted for other cell types using the preferred methods of transfection and selection for those cells (for other transfection protocols, please see Chapter 16).

Cell lines that stably express both autoregulatory tTA and target genes have been derived by simultaneous transfection of all of the plasmids. This method may be faster than sequential transfection of the tetracycline-controlled plasmids, but it could require screening more clones than if stable lines with low basal and high induced levels of tTA are first derived, and subsequently transfected with plasmids encoding the target genes. Theoretically, for the derivation of these clones, any combination of selectable markers should work for consecutive cotransfection.

MATERIALS

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

$CaCl_2$ (2 M)

Sterilize the solution by filtration, and store the filtrate in 5-ml aliquots at –20°C.

Calf serum (10%)

Chloroquine (10 mg/ml)

Optional, please see Step 7.

Prepare the chloroquine in H_2O, sterilize the solution by filtration, and store the filtrate at –20°C. Chloroquine at 10 mg/ml is equivalent to 19 mM. Please see the information panel on **CHLOROQUINE DIPHOSPHATE** in Chapter 16.

Glycerol (15%) in HEPES-buffered saline

HEPES-buffered saline

Phosphate-buffered saline

Enzymes and Buffers

Appropriate restriction endonuclease(s)

Please see Step 2.

1x Trypsin-EDTA

0.05% trypsin

0.5 mM EDTA (pH 8.0)

Media

Dulbecco's modified Eagle's medium complete (DMEM complete)

DMEM
100 units/ml penicillin
100 µg/ml streptomycin
2 mM glutamine
10% bovine calf serum

DMEM complete containing 0.5 µg/ml tetracycline-HCl

Prepare a 10 mg/ml stock of tetracycline-HCl in 70% ethanol and store at –20°C. All DMEM complete media used in this protocol (with or without the selection reagents) that contain 0.5 µg/ml tetracycline-HCl may be stored protected from the light for ~1 month at 4°C.

Selection medium containing L-histidinol and 0.5 µg/ml tetracycline

histidine-free DMEM
100 units/ml penicillin
100 µg/ml streptomycin
2 mM glutamine
10% donor bovine calf serum
125, 250, or 500 µM L-histidinol (prepare a 125 mM stock and store it at –20°C)
0.5 µg/ml tetracycline-HCl (prepare a 10 mg/ml stock in 70% ethanol and store it at –20°C)

Histidine-free DMEM is available from Irvine Scientific, Santa Ana, California. Selection medium that contains 0.5 µg/ml tetracycline-HCl may be stored protected from the light for ~1 month at 4°C.

Special Equipment

Plastic cloning rings

Autoclave the cloning rings in an upright position in a thin layer of vacuum grease.

Polystyrene tubes (4 ml)

Tissue culture dishes (6 cm and 10 cm)

These protocols can be scaled down to require fewer cells by using smaller dishes or wells and reducing all components proportionately.

Additional Reagents

Step 23 requires the reagents listed in Chapter 7, Protocol 8, or Appendix 8.

Vectors and Bacterial Strains

pSV2-His

Purify all plasmids by equilibrium centrifugation in CsCl-ethidium bromide gradients (Chapter 1, Protocol 10) or by column chromatography (Chapter 1, Protocol 9).

For information on pSV2-His, please see Damke et al. (1995). The plasmids pTet-tTAk and pTet-Splice are available from Life Technologies. Other vectors carrying selectable markers are commercially available (e.g., pCI-neo from Promega or pTK-HYG from CLONTECH). If another vector is substituted for pSV2-His, then use the appropriate selection media for the selectable marker carried by that plasmid.

pTet-Splice carrying the target gene ORF(s)

Optional, please see Step 2.

pTet-tTAk

Cells and Tissues

Cultured mammalian cells

This protocol uses NIH-3T3 cells, but other cells would certainly work. Grow the cells in the appropriate medium.

METHOD

Culture and Transfection of Cells

1. Culture adherent cells in DMEM complete. The day before transfection, transfer the cells into DMEM complete containing 0.5 μg/ml tetracycline-HCl (tetracycline). Apply enough cells per 10-cm dish so that on the day of the transfection, the cells will be 33% confluent.

   ▲ **IMPORTANT** From this point on, maintain cells in the presence of 0.5 μg/ml tetracycline-HCl at 37°C, in an atmosphere of 5% CO_2, unless otherwise stated.

2. Linearize the plasmids at an appropriate restriction endonuclease site and adjust the DNA concentration of each plasmid to ≥0.5 mg/ml. Mix 10–20 μg of pTet-tTAk plasmid and 1–2 μg of pSV2-His (~10:1 molar ratio of Tet plasmid to the selectable marker plasmid) with 500 μl of HEPES-buffered saline in a clear 4-ml polystyrene tube.

   If the target gene is being cotransfected simultaneously, add a pTet-Splice recombinant carrying the target gene in an amount that is equimolar to pTet-tTAk.

   Prepare a control for mock transfection containing the HEPES-buffered saline and no DNA. All of the mock-transfected cells should die in histidine-free DMEM containing L-histidinol.

3. Add 32.5 μl of 2 M $CaCl_2$ to the DNA mixture. Immediately mix the solution by gentle vortexing. Store the solution at room temperature, mixing it from time to time. A cloudy precipitate should form over the course of 15–30 minutes.

   For additional details on transfecting cells using $CaPO_4$, please see Chapter 16, Protocols 2 and 3.

4. Aspirate all of the medium from the dishes of cells prepared in Step 1.

5. Mix the $CaCl_2$-DNA precipitate a few times by pipetting with a Pasteur pipette. Apply the mixture dropwise and distribute it evenly over the cell monolayers.

6. Incubate the cells in an atmosphere of 5% CO_2 for 30 minutes at 37°C, rocking the plate after 15 minutes to ensure even coverage of the DNA precipitate.

7. To each dish of cells, add 10 ml of DMEM complete containing tetracycline. Incubate the cells in an atmosphere of 5% CO_2 for 4–5 hours at 37°C.

   If the cells will tolerate it, chloroquine may be added at this time to a final concentration of 25 μM. The optimal incubation time for transfection may vary for different cell types.

8. Gently aspirate the medium from the cells. Avoid disruption of the precipitate that has settled onto the cells.

9. Subject the cells to a glycerol shock by adding 2.5 ml of 15% glycerol in HEPES-buffered saline warmed to 37°C. Store the cells for 2.5 minutes at room temperature. Add the glycerol dropwise to the culture.

   It is normal for cells to look somewhat ragged after glycerol shock. The use of chloroquine (Step 7) may further reduce cell integrity, but may improve transfection efficiency.

10. Aspirate the glycerol solution after *exactly* 2.5 minutes. Work quickly, because glycerol can be very toxic to cells.

    Exposure to the glycerol solution can be increased to 4–5 minutes to optimize the transfection efficiency for certain resilient cell types. As a general rule, cells should be shocked for the longest period of time that allows survival of ~50% of the cells.

11. Immediately, gently, and quickly wash the cells by adding 10 ml of DMEM complete containing tetracycline. Immediately remove the medium by aspiration and repeat the wash.

    ▲ **IMPORTANT** Because the cells tend to detach easily from the plate after glycerol chock, add all of the medium to a single spot on the plate.

12. Add 10 ml of DMEM complete containing tetracycline to the cells, and incubate the cultures overnight at 37°C.

13. Approximately 16–24 hours after transfection, aspirate the medium and replace it with 10 ml of DMEM complete containing tetracycline. Incubate the cultures for a total of 48 hours at 37°C after the transfection (i.e., the sum of the incubation times in Steps 12 and 13).

Selection and Cloning of Transfected Cells

14. Forty-eight hours after transfection, passage several dilutions of the cells into selection medium containing 125 μM L-histidinol and 0.5 μg/ml tetracycline-HCl. Cell densities should range from ~1 x 10^6 to 3 x 10^4 cells per 10-cm plate. Include several plates containing ~1 x 10^5 cells.

15. After incubating the cultures in selection medium for 4 days, feed them with a further 3–4 ml of selection medium containing 125 μM L-histidinol and 0.5 μg/ml tetracycline-HCl.

16. When colonies have formed (typically after ~10–12 days of selection), replace the medium with selection medium containing 250 μM L-histidinol and 0.5 μg/ml tetracycline-HCl.

    L-histidinol is normally toxic to cells. The concentration of L-histidinol in the selection medium is therefore raised only after the number of cells expressing pSV2-His at high levels reaches a critical mass.

17. When colonies are well-established (at day 12–15 of selection), delineate their borders by drawing a circle on the bottom of the culture dish around each colony. Aspirate the medium from the plate, and place a sterile plastic cloning ring on the plate to surround an individual clone. Repeat this process for each colony to be picked. Choose cells from plates on which individual colonies are well spaced and can be easily distinguished.

    ▲ **IMPORTANT** After stable transfection with pTet-tTAk, it is imperative that the cells be maintained in medium containing 0.5 μg/ml tetracycline to prevent any toxic effects of tTA expression and subsequent selection against clones expressing high levels of tTA.

18. Quickly wash the clones with ~100 μl of phosphate-buffered saline. To release the cells, add 2 drops of 1x trypsin-EDTA (~100 μl) and incubate for 30–60 seconds. Loosen the cells by pipetting up and down with a Pasteur pipette. Transfer each colony to one well of a 24-well tissue culture plate that contains 1 ml of selection medium containing 250 μM L-histidinol and tetracycline.

    Perform all subsequent passaging of cells by using a standard procedure, such as (i) a quick PBS wash, (ii) a 1–3-minute incubation with trypsin-EDTA (2 ml per confluent 10-cm plate) using selection medium containing tetracycline, or (iii) 10% calf serum (3 ml) to dilute/stop the activity of the trypsin.

19. When the cells in the wells have grown to 80% confluency, transfer them into 6-cm tissue culture dishes in selection medium containing 500 μM L-histidinol and tetracycline.

    NIH-3T3 cells become 80% confluent in ~4–7 days; however, the time required to reach 80% confluency varies from cell line to cell line and even from clone to clone.

20. Expand the cells (typically use a 1:5 to 1:10 dilution of the cells) in selection medium containing 500 μM L-histidinol and tetracycline.

Testing of Cells for Inducible Protein Expression

21. When the cell monolayers are again ~80% confluent, recover a portion of each clone of cells and store them in aliquots in liquid nitrogen. Passage the remainder of the cells until they have expanded sufficiently to allow testing for inducible expression of protein.

    When the frozen cells are later used, they should be revived and grown in histidine-free DMEM containing 500 μM L-histidinol and 0.5 μg/ml tetracycline-HCl.

22. If cells were cotransfected with both tTA and the target plasmids, then directly analyze the products of the target genes, as described in Stage 3. If cells were transfected with only the pTet-tTAk plasmid, then prepare the cells to be tested for inducible expression as follows:

    a. The night before induction, plate the cells in selection medium containing 500 μM L-histidinol and 0.5 μg/ml tetracycline at an appropriate density so that they will be subconfluent at the time of harvest.

    b. The next day, wash the cells three times with PBS, swirling the plates gently each time.

    c. After the third wash, immediately add selection medium containing 500 μM L-histidinol, but lacking tetracycline. Culture the cells in the presence or absence of tetracycline for 6–48 hours.

    > It is essential to include controls that are maintained in selection medium containing 500 μM L-histidinol and 0.5 μg/ml tetracycline.

23. Test the cells for inducible expression of tTA, by northern analysis or immunoblotting. Cell lines expressing tTA may then be transfected with the target plasmid(s) as described in Stage 2.

    In stably transfected NIH-3T3 cells, induced tTA and target gene expression is observed typically after 6 hours of induction and reaches a maximum 6 hours later.

STAGE 2: Stable Transfection of Inducible tTA-expressing NIH-3T3 Cells with Tetracycline-regulated Target Genes

This procedure describes the transfection with target gene(s) of cell lines already expressing inducible tTA (generated in Stage 1). Selection of pTet-tTAk and pSV2-His with L-histidinol is maintained and a plasmid encoding puromycin resistance (or another selectable marker) is cotransfected with plasmid(s) encoding the target gene(s). Cells carrying these plasmids are subsequently selected in both L-histidinol and puromycin.

MATERIALS

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Calf serum (10%)
HEPES-buffered saline
Phosphate-buffered saline

Enzymes and Buffers

Appropriate restriction endonuclease(s)
1x Trypsin-EDTA
0.05% trypsin
0.5 mM EDTA (pH 8.0)

Media

Selection medium containing 500 μM L-histidinol and 0.5 μg/ml tetracycline (with or without 3 μg/ml puromycin)
histidine-free DMEM
100 units/ml penicillin
100 μg/ml streptomycin
2 mM glutamine
10% bovine calf serum
500 μM L-histidinol (dilute in a 125 mM stock and store it at −20°C)
0.5 μg/ml tetracycline-HCl (prepare a 10 mg/ml stock in 70% ethanol and store it at −20°C)
Histidine-free DMEM is available from Irvine Scientific (Santa Ana, California). Selection medium that contains 0.5 μg/ml tetracycline-HCl may be stored protected from the light for ~1 month at 4°C.
Add puromycin to 3 μg/ml when appropriate.

Special Equipment

Plastic cloning rings
Autoclave the cloning rings in an upright position in vacuum grease.
Polystyrene tube (4 ml)
Tissue culture dishes (6 cm and 10 cm)
Tissue culture plates (24-well)

Additional Reagents

Step 3 of this stage requires the reagents listed in Stage 1 of this protocol.

Vectors and Bacterial Strains

pPGKPuro (or vector carrying another selectable marker)

Purify all plasmids by equilibrium centrifugation in CsCl-ethidium bromide gradients (Chapter 1, Protocol 10) or by column chromatography (Chapter 1, Protocol 9).

For information on selectable markers, please see Damke et al. (1995). The plasmids pTet-Splice and pUHC13-3 are available from Life Technologies. Other vectors carrying selectable markers are commercially available (e.g., pCI-neo from Promega and pTK-HYG or pPUR from CLONTECH). If another vector is substituted for pPGKPuro, then use the appropriate selection media for the selectable marker carried by that plasmid.

pTet-Splice carrying a reporter gene, (optional, e.g., pUHC13-3)

pTet-Splice carrying the target gene ORF(s)

Cells and Tisssues

Stable cell lines that inducibly express autoregulatory tTA (Stage 1)

METHOD

Culture and Transfection of Cells

1. Culture stable cell lines that inducibly express autoregulatory tTA (isolated in Stage 1) in complete selection medium containing 500 μM L-histidinol and 0.5 μg/ml tetracycline-HCl. The day before transfection, passage the cells into 10-cm tissue culture dishes containing complete selection medium. Transfer enough cells per dish so that on the day of the transfection, the cell monolayers will be 33% confluent.

   ▲ **IMPORTANT** From this point on, maintain the cells in the presence of 0.5 μg/ml tetracycline-HCl at 37°C, in an atmosphere of 5% CO_2 unless otherwise stated.

2. Linearize the plasmids to be used for transfection and adjust the DNA concentration of each to ≥0.5 mg/ml. Mix 10–20 μg of each target gene plasmid(s) and 1–2 μg of pPGKPuro (a 10:1 molar ratio of each tetracycline plasmid to selectable marker plasmid) with 500 μl of HEPES-buffered saline in a clear 4-ml polystyrene tube.

   Prepare a control for mock transfection containing HEPES-buffered saline and no DNA. All of the mock-transfected cells should die when incubated in a medium containing puromycin. Please see the note to Step 4.

3. Carry out Steps 3–13 from Stage 1.

   ▲ **IMPORTANT** Be sure to substitute the selection medium containing 500 μM L-histidinol and 0.5 μg/ml tetracycline-HCl in this transfection, whenever Stage 1 calls for DMEM complete containing tetracycline.

Selection and Cloning of Transfected Cells

4. Forty-eight hours after transfection, passage the cells into selection medium containing 500 μM L-histidinol, 3 μg/ml puromycin, and 0.5 μg/ml tetracycline at several dilutions ranging from ~1×10^6 to 3×10^4 cells per 10-cm plate. Include several plates containing ~1×10^5 cells.

   The lowest concentration of puromycin that kills all untransfected cells within a few days should be determined empirically before transfection and varies with the cell type. A concentration of

3 μg/ml puromycin is sufficient for selection of transfected NIH-3T3 cells. Most types of cells are killed efficiently in concentrations of puromycin ranging from 0.1 μg/ml to 10 μg/ml.

5. After incubating cultures in selection medium for 4 days, feed them with a further 3–4 ml of selection medium containing 500 μM L-histidinol, 3 μg/ml puromycin, and 0.5 μg/ml tetracycline.

6. When colonies are well-established (at day 12–14 of selection), delineate their borders by drawing a circle on the bottom of the culture dish around each colony. Aspirate the medium from the plate, and place a sterile plastic cloning ring on the plate to surround an individual clone. Repeat the procedure with each colony that is to be picked. Choose cells from plates on which individual colonies are well spaced and can be easily distinguished.

7. Quickly wash the clones with ~100 μl of phosphate-buffered saline. To release the cells, add 2 drops of 1x trypsin-EDTA (~100 μl) and incubate for 30–60 seconds. Loosen the cells by pipetting up and down with a Pasteur pipette. Transfer each colony to one well of a 24-well tissue culture plate that contains 1 ml of selection medium containing 500 μM L-histidinol, 3 μg/ml puromycin, and 0.5 μg/ml tetracycline.

   Carry out all subsequent passaging of cells by a standard procedure, such as (i) a quick PBS wash, and (ii) a 1–3-minute incubation with trypsin-EDTA (2 ml per confluent 10-cm plate) using 10% calf serum (3 ml) to dilute/stop the activity of the trypsin.

8. When cells in the wells have grown to 80% confluency, transfer them into 6-cm dishes that contain selection medium containing 500 μM L-histidinol, 3 μg/ml puromycin, and 0.5 μg/ml tetracycline.

   NIH-3T3 cells become 80% confluent in ~4–7 days; however, the time required to reach 80% confluency varies from cell line to cell line and even from clone to clone.

9. Expand the cells (typically use a 1:5 to 1:10 dilution of the cells) in selection medium containing 500 μM L-histidinol, 3 μg/ml puromycin, and 0.5 μg/ml tetracycline.

10. When cell monolayers are again ~80% confluent, recover a portion of each clone of the cells and store them in aliquots in liquid nitrogen. Passage the remainder of the cells until they have expanded sufficiently to allow testing for inducible expression of the target gene product(s) as described in Stage 3.

    When the frozen cells are later used, they should be revived and grown in selection medium containing 500 μM L-histidinol, 3 μg/ml puromycin, and 0.5 μg/ml tetracycline-HCl.

STAGE 3: Analysis of Protein Expression in Transfected Cells

Two strategies are presented for analyzing expression of the target protein(s) in transfected cells. In the main protocol, stably transfected cells (obtained in the first two stages of this protocol) are induced for expression of the target gene. After harvesting and lysis of the cells, the lysates are analyzed by SDS-polyacrylamide gel electrophoresis, and target proteins are detected by immunoblotting. An alternative protocol describes the transient transfection and induction of transiently transfected tetracycline-regulated plasmids.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Calf serum (10%)
Phosphate-buffered saline
1x Protein sample buffer

Antibodies

Antibodies appropriate for detecting the target proteins of interest by immunoblotting

Gels

Tris-glycine SDS-polyacrylamide gel <!>
Cast the gel with a concentration of acrylamide that is appropriate for observing the target protein(s). Please see Appendix 8.

Media

Selection medium containing 500 μM L-histidinol and 3 μg/ml puromycin (with or without 0.5 μg/ml tetracycline)
histidine-free DMEM
100 units/ml penicillin
100 μg/ml streptomycin
2 mM glutamine
10% bovine calf serum
500 μM L-histidinol (dilute in a 125 mM stock and store it at –20°C)
3 μg/ml puromycin
Histidine-free DMEM is available from Irvine Scientific (Santa Ana, California).
Add tetracycline to 0.5 μg/ml when appropriate (prepare a 10 mg/ml stock of tetracycline-HCl in 70% ethanol and store at –20°C). Selection medium that contains 0.5 μg/ml tetracycline-HCl may be stored protected from the light for ~1 month at 4°C.

Special Equipment

Boiling water bath
Polyvinylidene difluoride (PVDF) membrane

Additional Reagents

Step 13 of this protocol requires reagents and equipment for immunoblotting as listed in Appendix 8.

Cells and Tissues

Stable cell lines that inducibly express autoregulatory tTA and contain the plasmids harboring the target genes of interest

METHOD

Growth and Induction of Cells

1. The night before induction, plate the cells in selection medium containing 500 μM L-histidinol, 3 μg/ml puromycin, and 0.5 μg/ml tetracycline at an appropriate density so that they will be subconfluent at the time of harvest.
2. The next day, wash the cells three times with phosphate-buffered saline, swirling the plates gently each time.
3. After the third wash, immediately add selection medium containing 500 μM L-histidinol, 3 μg/ml puromycin, but lacking tetracycline. Culture the cells in the presence or absence of tetracycline for 6–48 hours.

   In stably transfected NIH-3T3 cells, induced tTA and target gene expression typically is observed by 6 hours and peaks at ~12 hours after induction.

> It is essential to include controls that are maintained in selection medium containing 500 μM L-histidinol, 3 μg/ml puromycin, and 0.5 μg/ml tetracycline.

Harvesting of the Cells

4. After the cells have grown for the appropriate length of time, harvest them quickly and place them in a tube in an ice bucket.

   If the cells are harvested using trypsin, wash the cells with cold phosphate-buffered saline lacking calcium and magnesium salts and stop the trypsin treatment with cold selection medium containing 10% calf serum (with or without tetracycline, as appropriate). Immediately transfer the tubes to an ice bucket.
5. For each clone and control, transfer 0.5×10^6 cells to a microfuge tube, and centrifuge all of the tubes at 3000 rpm (low to moderate speed) for 5 minutes at 4°C.
6. Wash the cell pellets by adding 1 ml of ice-cold phosphate-buffered saline. Pellet the cells as in Step 5, and gently aspirate the supernatant without disturbing the cell pellet.
7. Keep the cell pellets on ice and loosen them by gently and quickly running the tubes over the open holes of a microfuge rack before freezing the cell pellets at –70°C.

Preparation of Lysates

8. Resuspend each cell pellet in 30 μl of protein sample buffer by gently pipetting the cells and then vortexing the tubes.

   This step may also be carried out before freezing the cells.
9. Boil the cells in protein sample buffer for 10 minutes.
10. Recover the cell debris by centrifugation at maximum speed for 2 minutes in a microfuge.
11. Load 10 μl of cell lysate per lane of a Tris-glycine SDS-polyacrylamide gel.

    If the cell lysates are not loaded immediately onto a gel, they may be stored at –20°C or –70°C, but should be boiled again before loading them onto a gel.
12. Run the gel for the appropriate length of time (please see Appendix 8).
13. Electrotransfer the proteins from the SDS-polyacrylamide gel to a PVDF membrane, and probe the membrane with the appropriate antibodies (please see Appendix 8).

ALTERNATIVE PROTOCOL: TETRACYCLINE-REGULATED INDUCTION OF GENE EXPRESSION IN TRANSIENTLY TRANSFECTED CELLS USING THE AUTOREGULATORY tTA SYSTEM

Transient transfection of tetracycline-regulated plasmids is useful in several situations, for example, the initial testing of the autoregulatory system in a given cell line, and screening tTA-expressing cell lines for inducible expression of another Tet plasmid. When testing the autoregulatory tTA system, induction of tTA mRNA is generally a reliable indicator of induced tTA expression. Alternatively, the vector pUHC13-3 (Life Technologies), which encodes luciferase under tetracycline control, may be transiently transfected into cell lines that are capable (or are likely to be capable) of tTA expression (Damke et al. 1995). Transfected cells are then cultured for 12–48 hours in the presence and absence of tetracycline. Luciferase activity in cell lysates can be easily measured (using a kit available from Promega) and is normalized either to total protein, determined using a Bradford protein assay, or to a transfection control (Damke et al. 1995).

▲ **IMPORTANT** Be aware that the basal expression of tetracycline-controlled genes carried in transiently transfected plasmids is generally higher than the basal expression of similar genes in stably transformed cells. In addition, the high sensitivity of the luciferase assay may generate misplaced optimism about the efficiency of induced expression of tetracycline-regulated genes. As long as the results are interpreted with caution, transient transfection with plasmids such as pUHC13-3 offers a rapid method to screen many clones in a short period of time.

Additional Materials

Calf serum (10%)
Cells appropriate for transfection
Medium containing 0.5 μg/ml tetracycline-HCl appropriate for growing the cells to be transfected
Prepare a 10 mg/ml stock of tetracycline-HCl in 70% ethanol and store it at –20°C. All media used in this protocol (with or without the selection reagents) containing 0.5 μg/ml tetracycline-HCl may be stored protected from the light for ~1 month at 4°C.
pTet-tTAk
pTet-Splice carrying the target gene or pTet-Splice carrying a reporter marker
The plasmids pTet-tTAk and pTet-Splice are available from Life Technologies.
Phosphate-buffered saline (PBS)
Step 2 of this protocol requires the reagents listed in the appropriate transfection protocol in Chapter 16.
Step 8 requires the reagents listed in Chapter 6, Protocol 8; Chapter 7, Protocol 8; or Appendix 8.

Method

1. The night before the transfection, transfer the cells into the appropriate medium containing 0.5 μg/ml tetracycline-HCl.
2. Transfect semiconfluent cultures of cells using pTet-tTAk alone or in combination with a vector carrying the target sequence (pTet-Splice carrying the target gene or pTet-Splice carrying a reporter marker) using the preferred method of transfection for the cells under study (for a selection of transfection protocols, please see Chapter 16).
3. Wash the cells that will be induced three times with *medium lacking tetracycline*.

   Wash the cultures of cells that will remain uninduced with medium containing tetracycline.

4. Feed the cells with 10 ml of medium with or without tetracycline, as appropriate. Culture the cells for 12–48 hours.
5. After the cells have grown for the appropriate length of time, harvest them quickly and transfer them to a tube in an ice bucket.

   If the cells are harvested using trypsin, wash them with cold PBS and stop the trypsin treatment with cold medium containing 10% calf serum (with or without tetracycline, as appropriate). Immediately transfer the tubes to an ice bucket.

6. Wash the cell pellets by adding 1 ml of ice-cold PBS. Pellet the cells by centrifuging the tubes at 3000 rpm for 5 minutes at 4°C in a microfuge, and gently aspirate the supernatant without disturbing the cell pellet.
7. Keep the cell pellets on ice and loosen them by gently and quickly running the tubes over the open holes of a microfuge rack before freezing at –70°C or lysing the cells for analysis of inducible protein expression.
8. Analyze tTA or target gene expression (experimental or reporter) by immunoblotting, Southern or northern hybridization, or other appropriate assay.

   In cells that stably express tTA, transient target gene expression is generally observed within 12 hours. In cells transiently expressing tTA and a tetracycline-sensitive luciferase reporter (pUHC13-3), luciferase activity has been observed to increase by two orders of magnitude within 20 hours following induction.

Protocol 9

Ecdysone as Regulator of Inducible Gene Expression in Mammalian Cells

TRANSCRIPTION UNITS REGULATED BY STEROIDS OCCUR COMMONLY in a wide variety of eukaryotes. In *Drosophilia melanogaster*, for example, the molting hormone ecdysone is an inducer of metamorphosis. The degeneration of larval tissues and the appearance of adult structures during molting are triggered by the interaction of ecdysone, the nuclear ecdysone receptor, and *cis*-acting response elements (EcRE). The functional ecdysone receptor is a heterodimer composed of the ecdysone receptor (EcR) and the Ultraspiracle protein (USP), another member of the nuclear receptor family (Yao et al. 1992, 1993). In the presence of ecdysone, the two proteins EcR and USP interact and bind to the two inverted half-sites of ecdysone response elements, which are placed upstream of many of the genes involved in *Drosophila* morphogenesis (for further information and references, please see Russell 1996; Thummel 1997; White et al. 1997).

Responsiveness to ecdysone may be reconstituted in mammalian cells that have been cotransfected with EcR and USP. When these cells are exposed to ecdysone or to one its analogs, such as ponasterone A or muristerone A, transcription of an ecdysone-responsive reporter gene is induced (Christopherson et al. 1992; Yao et al. 1992). The sensitivity of the reconstituted system has been improved by creating a more potent receptor complex, in which (1) USP has been replaced with its mammalian homolog, the retinoid X receptor (RXR), (2) EcR has been truncated at the amino terminus and fused to the VP16 activation domain (Sadowski et al. 1988; Triezenberg et al. 1988a,b; Cress and Triezenberg 1991; No et al. 1996), and (3) the DNA-binding domain within EcR has been mutated at three amino acid residues, altering its binding specificity to mimic that of a glucocorticoid receptor (GR) (Umesono and Evans 1989). In transfected cells able to express both RXR and the modified EcR, the addition of ecdysone or one of its analogs results in the formation of functional heterodimers that bind to a set of hybrid response elements contained within an inducible expression vector (Figure 17-10).

The hybrid response elements consist of two different half sites, $^{5'}$AGGTCA$^{3'}$, which is bound by RXR, and $^{5'}$AGAACA$^{3'}$, which is recognized by the GR-binding domain of EcR. This hybrid response element is uniquely responsive to the hybrid receptor protein (No et al. 1996). Binding of the heterodimer to the response elements stimulates transcription from an adjacent minimal promoter of any gene that has been cloned into the inducible expression vector (Figure 17-11). Because mammalian cells are not normally responsive to ecdysone or its analogs and do not contain the ecdysone receptor, basal levels of transcription are very low or undetectable. Upon addition of the hormone, induction levels of >1000-fold have been reported (for reviews, please see Clackson 1997; Saez et al. 1997; Harvey and Caskey 1998).

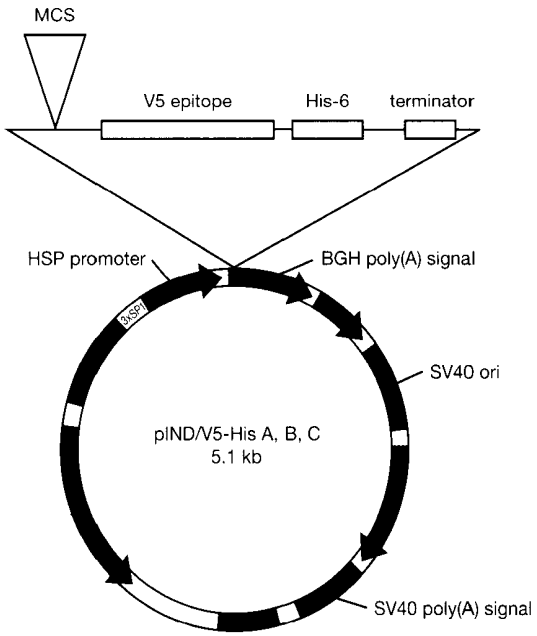

FIGURE 17-10 pIND(SP1)/V5-His A

The vector is used to clone a target gene and place its expression under control of the ecdysone-sensitive response elements. The main features of the vector are the ecdysone/glucocorticoid response elements (E/GRE, 5 copies); SP1 enhancer elements (SP1, 3 copies); *h*eat shock minimal *p*romoter (HSP); poly(A) addition signal from *b*ovine *g*rowth *h*ormone (BGH); and tags for convenient purification of the expressed protein (V5 epitope and polyhistidine [His6] tags). Other features include (1) the origin of replication derived from filamentous phage (f1 ori), (2) the colE1 origin of replication in *E. coli*, (3) an ampicillin resistance marker (Amp^R) for selection in prokaryotic cells, (4) the origin of replication for SV40 that allows replication in mammalian cells, and (5) a neomycin resistance marker for selection in mammalian cells (Neo^R). (Modified, with permission, from Invitrogen.)

The use of the ecdysone-inducible expression system for the selective production of proteins within transfected mammalian cells was first reported by No et al. (1996) and has since been used successfully to study the functions of numerous proteins, including the roles of Smad4 in colon cells (Calonge and Massagué 1999), the effect of missense mutations in the proapoptotic gene *BAX* (Gil et al. 1999), and the functions of the tumor suppressor PTEN phosphatase (Tamura et al. 1998). In addition, the system has been used to analyze the activity of "designer" zinc finger transcription factors (Kang and Kim 2000) and to develop a mechanism that modulates neuronal excitability by controlling the expression of transduced ion channels (Johns et al. 1999). The following protocol is adapted from the one that accompanies an Ecdysone-inducible Mammalian Expression System (available from Invitrogen). A similar system is available commercially from Stratagene.

MATERIALS

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Neomycin

Ponasterone A

An alternative ecdysone analog is muristerone A (Sigma).

Zeocin

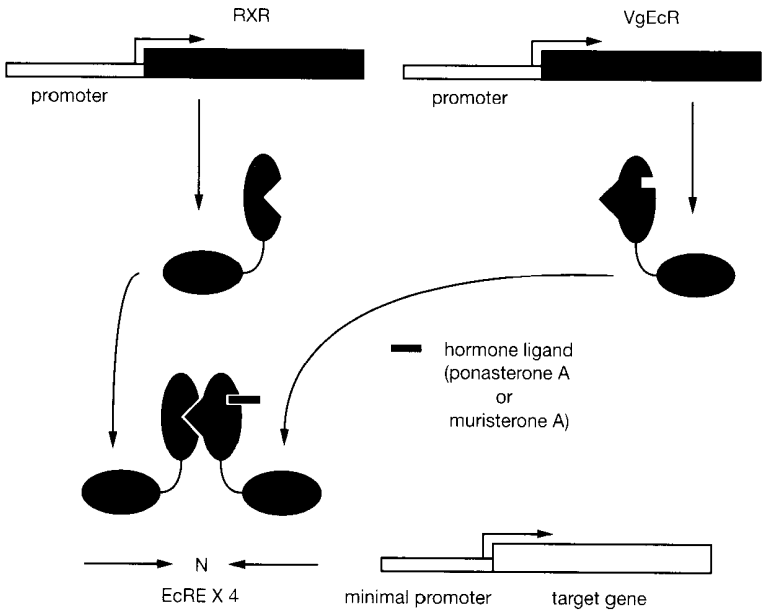

FIGURE 17-11 Schematic Diagram of Ecdysone-inducible Gene Expression System

A plasmid encoding the genes for the ecdysone receptor (EcR) and the retinoid X receptor (RXR) is used to express the two receptor proteins. A second plasmid is used to clone the target gene and place it under control of ecdysone-sensitive response element (EcRE) sequences that are positioned upstream of a minimal promoter (please see Figure 17-10). The two vectors are transfected into mammalian cells and expression of the target gene is controlled by addition of inducing hormone in the culture medium. In the presence of hormone (ponasterone A or muristerone A), EcR and RXR heterodimerize to form the functional ecdysone receptor that activates transcription of the target gene from the EcRE-containing promoter. Please see text for further details. (Modified, with permission, from No et al. 1996 [©National Academy of Sciences, U.S.A.].)

Media

Medium appropriate for growing the cells to be transfected

The medium must be variously supplemented with Zeocin, neomycin, and ponasterone A.

Additional Reagents

Steps 1, 2, and 6 of this protocol require the reagents listed in the appropriate transfection protocol in Chapter 16.

Step 4 of this protocol requires the reagents listed in Protocol 6 of this chapter.

Step 8 of this protocol requires the reagents listed in Chapter 6, Protocol 8; Chapter 7, Protocol 8; or Appendix 8.

Vectors and Bacterial Strains

An ecdysone-inducible expression plasmid (e.g., the pIND series; Invitrogen) carrying a luciferase reporter gene

An ecdysone-inducible plasmid harboring the gene of interest

pVgRXR (Invitrogen)

Cells and Tissues

Cultured mammalian cells

METHOD

1. Stably transfect cells with pVgRXR using the preferred method of transfection for the cells under study (for a selection of transfection protocols, please see Chapter 16).

   If pVgRXR is used, then use Zeocin to select for cells carrying the plasmid. For plasmid(s) other than pVgRXR, use the appropriate antibiotic to obtain colonies of stable integrants.

   > Perform a control mock transfection with no DNA added to the cells. All of the mock-transfected cells should die in the presence of Zeocin.

2. To choose clones capable of selectively inducing gene expression in the presence of ecdysone or one of its analogs, transiently transfect Zeocin-resistant colonies obtained in Step 1 with an ecdysone-inducible expression plasmid carrying a luciferase reporter gene (again, for a selection of transfection protocols, please see Chapter 16).

3. Twenty-four to ninety-six hours after transfection, induce the expression of luciferase by replacing the medium with fresh medium containing Zeocin, neomycin, and 5 μM ponasterone A. Incubate the cells for 20 hours at 37°C in a humidified incubator with an atmosphere of 5–7% CO_2.

   The amount of ponasterone A and the length of the induction period that will yield optimal induction of the reporter molecule will vary with different cell lines. To optimize, test a range of hormone concentrations, from 0.1–10 μM ponasterone A, and vary the period of induction from 16 to 72 hours.

   > It is essential to include control cultures that are not exposed to ponasterone A. Incubate these control cultures in medium containing only Zeocin and neomycin.

4. Assay for luciferase activity according to Protocol 6.

5. Use clones that exhibit the desired level of ecdysone-induced luciferase activity. Expand the cell culture in medium containing Zeocin and neomycin.

6. Stably transfect cells from Step 5 with an ecdysone-inducible plasmid harboring the gene of interest and a hygromycin resistance marker using the preferred method of transfection for the cells under study (for a selection of transfection protocols, please see Chapter 16).

   > Perform a control mock transfection with no DNA added to the cells. All of the mock-transfected cells should survive in the presence of Zeocin, but die in the presence of the second antibiotic (typically neomycin or hygromycin).

7. Expand the chosen colonies of cells that are resistant to both antibiotics, hygromycin and neomycin.

8. Analyze expression of the target gene by immunoblotting, northern hybridization, or other appropriate assay.

FOOTPRINTING DNA

Footprinting is used to identify the region in a segment of cloned DNA that is recognized by a sequence-specific DNA-binding protein such as a transcription factor. The technique involves probing the accessibility of each nucleotide in a defined sequence of DNA to reagents that cleave the phosphodiester backbone. These reagents include enzymes such as DNase I (Galas and Schmitz 1978; Schmitz and Galas 1979) and chemical nucleases such as hydroxyl radicals and copper-phenanthroline ions (for review, please see Sigman and Chen 1990; Sigman et al. 1993).

The key to success with DNA footprinting lies in establishing conditions for cleavage that generate reproducible differences when the same segment of DNA is reacted in the presence and absence of protein. The power of the method lies in the side-by-side visual comparison on sequencing gels of the cleavage products obtained with and without protein.

Commonly Used Cleavage Reagents

The two types of cleavage reagents used in DNA footprinting attack DNA in quite different ways. Enzymes such as DNase I use an in-line SN-2 mechanism to catalyze nucleophilic attack on the scissile phosphodiester bond. By contrast, chemical agents such as hydroxyl radicals and copper-phenanthroline ions are redox-active coordination complexes that oxidize the deoxyribose moiety of DNA (Sigman et al. 1979; Hertzberg and Dervan 1982).

DNase I

DNase I was the reagent originally used to develop DNA footprinting (Galas and Schmitz 1978; Schmitz and Galas 1979) and despite the subsequent discovery of elegant chemical methods to cleave DNA in a sequence-independent fashion, it remains by far the most popular way to localize specific interactions between proteins and DNA. It has been known for many years that pancreatic DNase I, in the presence of Mg^{2+}, introduces nicks into each strand of double-stranded DNA independently. However, whether this nicking occurs at random or displays sequence specificity remains a surprisingly murky topic, with conflicting data from several groups. On the one hand, biochemical analysis of the digestion products of bulk *E. coli* DNA shows only weak sequence specificity (Ehrlich et al. 1973; Bernardi et al. 1975). On the other hand, Scheffler et al. (1968) have shown that DNase I has a very marked preference for cleaving poly[d(A-T)]·poly[d(A-T)] to the 5′ side of T residues, a result that was confirmed with homopolymeric poly[d(A-T)] by Lomonossoff et al. (1981). However, this specificity may be due more to an unusual conformation of the DNA associated with the homopolymer, rather than to preference of the enzyme for particular sequences (Klug et al. 1979). Analysis of the crystal structure of complexes between DNase I and short double-stranded oligonucleotides shows that an exposed loop of the enzyme binds in the minor groove of B-DNA with both strands of the nucleic acid bending to make contact with the enzyme (Suck et al. 1984; Suck and Oefner 1986). Because regions of DNA containing several consecutive adenine or thymine residues are comparatively rigid and have a narrow minor groove, Suck et al. (1988) have suggested that A-T tracts in DNA might be relatively resistant to cleavage with DNase I.

In view of this confusion, it is prudent to check that DNase I displays no major bias in its pattern of cleavage of radiolabeled target DNA that has not been incubated with protein. Bias can be ascertained from pilot experiments set up to establish conditions for optimum cleavage of the radiolabeled target DNA by DNase I. The aim here is to cleave each DNA molecule once between the labeled end and the distal terminus of the binding site. The longer the distance between the labeled end and the binding site, the lower the amount of cleavage required. Pilot experiments are usually carried out using a range of concentrations of enzyme to find conditions under which the naked DNA is neither underreacted (much of the original fragment remains uncleaved and the bands forming the ladder are faint) or overreacted (little of the original fragment remains and the smaller fragments are overrepresented in the digest). As a rough guide, an amount of DNase should be used that cleaves only ~50% of the labeled molecules in the reaction. For variations on the protocol, please see Tullius et al. (1987), Hochschild (1991), Garabedian et al. (1993), and Lakin (1993). The goal is to establish conditions where partial cleavage of the relevant segment of naked DNA by DNase I yields a ladder of partial digestion products that differ in size from one another by one base. Ideally, there should be no gaps in the ladder and no dramatic differences in intensity from one band

to the next. In practice, however, it is usually impossible to achieve this level of impartiality, even with naked DNA.

A frequent finding associated with the use of DNase I in footprinting is the appearance of intense bands on the autoradiogram in samples incubated with a DNA-binding protein and the cleavage enzyme. These so-called hypersensitive sites, which reflect enhanced cleavage of the DNA by DNase, may arise as a consequence of conformational changes in double-stranded DNA induced by binding of protein or they may be due to protein-protein interactions between the nuclease and a protein bound to the DNA. The nature of the conformational changes is not well-understood, but it may be related to localized bends, kinks, base flipping (Klimasauskas et al. 1994), or single-stranded bulges (Kimball et al. 1995) in the DNA brought about by binding of protein. The hypersensitive sites typically flank a bona fide footprint.

When very short DNAs are used as substrates for DNase I, "end-effects" become apparent (Galas and Schmitz 1978; Lomonossoff et al. 1981). The probability that a particular phosphodiester bond will be cleaved increases as a function of its distance from the 5′ end of a DNA strand, at least as far as the eighth phosphodiester bond. It is therefore important to ensure that the footprinted region does not lie very close to the labeled 5′ end of the DNA fragment.

Usually, footprinting reactions are analyzed side by side with Maxam-Gilbert reactions on DNA sequencing gels (please see Chapter 12, Protocol 7). If the footprinted DNA fragment is labeled at its 5′ end, the autoradiographic bands obtained from the two sets of reactions do not line up because the radiolabeled products carry different groups at their 3′ ends. The base-specific chemical reactions cause the removal of a base and its sugar and generate a 3′-phosphorylated terminus on the labeled DNA strand. DNase I cleaves the phosphodiester bond and leaves a 3′-hydroxyl terminus on the labeled DNA strand. The electrophoretic mobility of the chemical cleavage reactions is therefore slightly greater than that of the fragment produced by digestion with DNase I. This problem is more severe when short DNA fragments are examined.

DNA fragments representing eukaryotic promoter sequences often contain multiple binding sites for one or more transcription factors. To define accurately the boundaries of individual footprints, it is best to carry out footprinting assays in which the 5′ end of the DNA fragment is radiolabeled in one experiment and the 3′ end of the DNA is radiolabeled in a second experiment. By comparing the protected regions of DNA obtained in the two experiments, subtleties in the boundaries can be detected, and a more accurate picture of the binding sites and their relationships to each other can be determined. Use of 3′-labeled fragments also eliminates the problem of electrophoretic migration differences between DNA standards generated by Maxam-Gilbert cleavage and the footprinted DNA, since in this case, all DNAs will have 3′-phosphorylated termini.

Hydroxyl Radicals

Hydroxyl radicals cleave DNA by abstracting a hydrogen atom from a deoxyribose moiety (Hertzberg and Dervan 1982; Price and Tullius 1992). These radicals are usually generated by reacting the EDTA complex of Fe(II) with H_2O_2 (Fenton 1894):

$$Fe(II) + H_2O_2 \rightarrow Fe(EDTA)^+ + {}^{\bullet}OH + {}^{-}OH$$

Fe(II) is regenerated from the Fe(III) product by including ascorbate in the reaction mixture. The hydroxyl radicals, which are diffusible and extremely short-lived, react with deoxyribose residues on the surface of the DNA. Cleavage therefore occurs in a manner that is largely independent of nucleotide sequence (Henner et al. 1982). In addition, because of their smaller size, the hydroxyl radicals can react more efficiently than DNase I with nucleotides on the periphery of the binding site. This access means that the region of tight contact between the protein ligand and its binding site can be defined with higher precision. The efficiency of cleavage of naked DNA can be improved if the Fe(II)-EDTA complex is linked to a DNA-binding ligand, for example, propylmethidium (Hertzberg and Dervan 1982; Tullius et al. 1987). However, in this case, cleavage of the backbone depends on intercalation of the methidium moiety into double-stranded DNA. When intercalation is prevented by binding of a protein, the resulting footprint is larger than that obtained with free Fe(II)-EDTA and is very similar to that produced by digestion with DNase I (Van Dyke and Dervan 1983; Tullius et al. 1987).

1,10-Penanthroline-Copper

The chemistry of this reaction is similar to that of Fe(II)-EDTA, except that the tetrahedral cuprous complex binds in the minor groove of DNA and positions the copper ion close to a deoxyribose residue.

Oxidation of the cuprous ion by hydrogen peroxide then generates a copper-oxo species that efficiently abstracts a hydrogen atom from the deoxyribose (Spassky and Sigman 1985; Sigman and Chen 1990). Unlike Fe(II)-EDTA, 1,10-phenanthroline-copper(I) cleaves naked DNA in a fashion that is greatly influenced by the nucleotide sequence. This effect is presumed to be a consequence of sequence-specific variation in structural features of the minor groove of DNA.

The footprints obtained with the λ repressor with 1,10-phenanthroline-copper(I) are very similar in size to those produced by cleavage with DNase I (Tullius et al. 1987). Apparently, the bound protein can suppress binding of the cuprous complex even on the side of the helix that is not in contact with the protein.

Other Reagents

Several additional chemical reagents cleave DNA and can be used to study DNA-protein interactions. Examples include rhodium complexes with 1,10-phenanthroline (Chow and Barton 1992), which cleave DNA in a light-dependent fashion and are insensitive to common ingredients in laboratory buffers such as divalent cations, EDTA, glycerol and reducing reagents (Sitlani et al. 1992), porphyrin derivatives (Ward et al. 1986), and uranyl salts such as uranyl acetate and uranyl nitrate (Nielsen et al. 1988; Gaynor et al. 1989). These chemical nucleases must be synthesized in the laboratory, and their use requires more than a passing knowledge of inorganic chemistry. For many of them, it is not yet clear whether they provide additional information over and above that obtained with 1,10-phenanthroline-copper or hydroxyl radicals in footprinting experiments. However, certain rhodium derivatives of 1,10-phenanthroline (Chow et al. 1992) and the uranyl salts (Gaynor et al. 1989) also cleave RNA and can thus be used to define RNA-protein interactions.

Selection of a Cleavage Reagent

The choice among DNA cleavage reagents is largely a matter of personal preference. DNase I is relatively bulky (450 x 400 x 350 nm; Suck et al. 1984) and might be expected to have difficulty in gaining access to nucleotides on the periphery of a binding site that are sterically shielded by a bound protein. This limitation may explain why footprinting with DNase I tends to give larger less-well-defined footprinting patterns, whereas hydroxyl radicals yield smaller focused footprints (Sawadogo and Roeder 1985; Tullius et al. 1987). DNase I maps the outer limits of the area of contact between DNA and protein, whereas hydroxyl radicals define an inner, tight core. Obviously, both pieces of information are valuable, and it is therefore worthwhile to carry out footprinting experiments with two different reagents. DNase I is a safe bet since it has gained wide acceptance and has been used successfully by large numbers of laboratories. However, chemical reagents, such as 1,10-phenanthroline-copper(I), are a better choice if cleavage (1) cannot be detected between every base pair when naked DNA containing the region of interest is partially degraded by DNase I (Galas and Schmitz 1978) and (2) if the target region is known or suspected of containing long runs of adenine or thymine residues.

Both DNase I (Papavassiliou 1993) and 1,10-phenanthroline-copper(I) (Kuwabara and Sigman 1987) can be used to cleave the DNA moiety of protein-DNA complexes within the matrix of a separating gel. This use allows footprinting to be coupled directly with a gel retardation assay. By contrast, hydroxyl radicals, which are preferred when accurate definition is required of the region of contact between the protein and DNA, are always used on protein-DNA complexes in free solution. DNase I can also be used to digest protein-DNA complexes in solution, followed by gel electrophoresis to separate protein-DNA complexes from free DNA. The DNA can then be extracted from the complexes, denatured, and analyzed on sequencing gels.

In Vivo DNA Footprinting

The 5′-flanking regions of many eukaryotic genes contain dozens of binding sites for different transcription factors. Although it is relatively straightforward to document the ability of proteins to bind to these sites using DNA footprinting assays and the cleavage reagents discussed above, it is far more difficult to determine which binding sites are used in vivo and which are a consequence of the use of high concentrations of naked DNA and enriched preparations of nuclear proteins. These questions may be answered by performing in vivo footprinting experiments in which the ability of proteins to bind to the regulatory regions of the target gene is determined in an expressing cell. The earliest experiments of this nature were carried out by George Church and Walter Gilbert, who used chemical cleavage reagents to examine methylation patterns in the 5′-flanking regions of murine immunoglobulin heavy-chain genes (Church and Gilbert 1984). To

detect the very weak signals emanating from the single-copy target gene and their differential methylation required heroic measures that involved the generation of very high specific activity probes, separation of cleaved genomic DNA by electrophoresis through sequencing gels, followed by electrophoretic transfer of the DNA to nylon filters, and Southern analysis to detect methylation-sensitive variations in the cleavage products derived from the immunoglobulin genes.

Few laboratories could match the technical wizardry required to perform these reactions and their application to in vivo footprinting. The method might have suffered an ignoble death of neglect had not Barbara Wold and colleagues used PCR specifically to amplify in-vivo-footprinted DNA fragments (Mueller and Wold 1989; Pfeifer et al. 1989). In this adaptation, which they called ligation-mediated PCR, the genomic DNA of living cells is first challenged with a DNA cleavage reagent such as dimethylsulfate, and the fragmented DNA is purified by extraction with phenol:chloroform and ethanol precipitation. A round of primer extension on the treated DNA defines the cleavage endpoints and produces blunt-ended fragments to which linkers of a defined sequence are added by ligation. A PCR is next carried out using a primer that is complementary to the added linker sequence and a second primer that lies downstream from the suspected DNA footprint. In the absence of protein binding, a ladder of products is amplified that can be visualized after separation by gel electrophoresis. Each DNA fragment in the ladder represents a distinct cleavage point along the target gene. However, if a protein was bound to a site that lies between the two amplification primers, DNA fragments whose endpoints are within the binding site will be underrepresented due to protection of the DNA from the cleavage reagent. These will have a reduced intensity on the gel when compared to DNAs generated in the absence of protein binding.

Detailed protocols for ligation-mediated PCR are now available (Zaret 1997), and in general, these methods are quite reproducible in most molecular biology laboratories. The method has been used to demonstrate the in vivo binding of tissue-specific transcription factors (Mueller and Wold 1989), to map methylation sites in inactive genes (Pfeifer et al. 1989), and in combination with other enzymatic, chemical cleavage, and cross-linking reagents to define protein-DNA interactions and the presence of unusual DNA conformations in transcribed genes (Zaret 1997). By varying the conditions in which the cells of interest are cultured, or the times at which cells are harvested from an organism, it is possible to paint a detailed picture of the footprints left by the dynamic associations of various transcription factors with the regulatory regions of a target gene.

GEL RETARDATION ASSAYS

Electrophoresis of protein-DNA complexes through nondenaturing acrylamide or agarose gels is the simplest and most widely used of several physical assays to detect specific interactions between DNA-binding proteins and their target sequences. The gel retardation assay typically involves the addition of protein to defined end-labeled fragments of double-stranded DNA, separation of protein-DNA complexes from naked DNA by electrophoresis, and visualization of the DNA by autoradiography. Binding of protein almost always reduces the electrophoretic mobility of the target DNA, resulting in discrete bands that correspond to individual protein-DNA complexes.

Gel retardation was introduced by Dahlberg et al. (1969) and Shaup et al. (1970) as a technique to assay interactions between ribosomal proteins and ribosomal RNA. The method in common use today, however, is a direct descendant of studies in the early 1980s of the equilibria and kinetics of association of purified prokaryotic regulatory proteins with their target DNA sequences (Fried and Crothers 1981, 1983, 1984a,b; Garner and Revzin 1981; Hendrickson 1985; Hendrickson and Schleif 1985). Certainly, at that time, it was not recognized that the technique could be used to detect sequence-specific DNA-binding proteins in complex mixtures, such as crude lysates of mammalian cells. This advance came only after unlabeled carrier DNA (see below) was shown to suppress nonspecific binding of proteins to the radiolabeled target DNA (Strauss and Varshavsky 1984; Carthew et al. 1985; Singh et al. 1986). Since then, the technique has been extended to analyze complexes formed between proteins and unusual conformations of DNA, including Holliday junctions (Parsons et al. 1990; Dunderdale et al. 1991), mismatched base pairs (Jiricny et al. 1988), and Z-DNA (Nordheim and Meese 1988; for review, please see Lane et al. 1992). However, the chief use of

the assay remains by far the detection and analysis of complexes formed between *trans*-acting proteins and *cis*-acting DNA sequences that control gene expression in both eukaryotes and prokaryotes. Among the advantages of the gel retardation assay for these purposes are the following.

- ***Speed, high sensitivity, and discrimination.*** Femptomole quantities of sequence-specific binding proteins can be detected by their effect on the mobility of a radiolabeled target DNA even when other DNA-binding proteins are present, as, for example, in a crude cell extract. The gel retardation assay can be completed within a few hours and is therefore ideal for monitoring the purification of *trans*-acting transcription factors and other sequence-specific binding proteins.
- ***Target sequences for a particular DNA-binding protein can be identified in a mixed population of DNA fragments.***
- ***Complexes between DNA-binding proteins and their target sequences can often be resolved*** into several components that reflect alternative stoichiometries, interactions between several different proteins, or multiple proteins competing for the same site.
- ***The method can easily be adapted for quantitative determination*** of association rate constants, dissociation rate constants, cooperativity, abundance, and specificity.

Many of these points are discussed in greater detail below.

Mechanism of Gel Retardation

That protein-DNA complexes migrate as discrete bands in gels was unanticipated since the half-life of many complexes is manyfold shorter than the time required to run a gel. Two theories have been proposed to explain why protein-DNA complexes are kinetically more stable in gels than in free solution. The first theory suggests that the gel directly affects the dissociation constant of protein-DNA complexes. Although this idea was supported by early experimental data (Fried and Crothers 1981), subsequent analyses have failed to confirm gel-mediated stabilization of protein-DNA complexes. Instead, it seems that the gel acts as a dehydrated cage that prevents diffusion of dissociated components. This caging effect maintains high local concentrations of the components and effectively drives the equilibrium of the bimolecular reassociation reaction to the right. A robust theoretical underpinning for this argument has been provided by Cann (1989) whose calculations show that the optimal range of concentrations of DNA in standard gel retardation assays is 1×10^{-8} to 5×10^{-8} M over a range of binding constants from 10^9 to 10^{13} M^{-1}, with the optimal ratio of binding protein to DNA varying from 0.5 for strong interactions to 10 or more for weak interactions.

Measuring Dissociation Constants of Protein-DNA Complexes by Gel Retardation

To measure the value of K_d, the dissociation constant for a protein-DNA complex, a series of binding reactions are set up using a wide range (four to six orders of magnitude) of protein concentrations. The aim is to find the concentration required to bind half of the DNA. The data are generally plotted as a fraction of the free DNA (usually estimated from densitometry of gel bands) versus $\log_{10}$ concentration of protein in the binding reaction. The equilibrium constant can then be estimated from the resulting sigmoid curve provided (1) the ratio of protein to available binding sites at the midpoint of the reaction ($= K_d$) is >10 (Carey 1988, 1991), (2) virtually all of the DNA in the reaction can be driven into complex by a vast excess of protein, and (3) the experimental data fit a theoretical binding curve calculated from an equation describing binding between independent and equivalent sites. For noncooperative interactions, an increase of 1.81 $\log_{10}$ units in protein concentration is required to increase the fraction of DNA appearing in complex from 10% to 90%. Deviation from this value indicates that binding is cooperative or is occurring at multiple sites. Values <1.8 $\log_{10}$ units indicate positive cooperativity during the binding reaction: Values >1.8 $\log_{10}$ units indicate negative cooperativity (Carey 1991).

Mobility of Protein-DNA Complexes

Three major factors affect the rate of migration of protein-DNA complexes through gels. These are the mass of the protein-DNA complexes, their overall charge, and the conformation of the DNA within them. As a general rule, the mobility of the complex is related to the size of the free protein (Carey 1988). Thus, the mobilities of the retarded bands typically decrease as a monotonic function of protein mass (e.g., please see

Hope and Struhl 1985; Bétermier et al. 1989). If, however, the bound protein is highly acidic and carries a strong negative charge, the mobility of the complex may not be appreciably different from that of naked DNA. This problem can be solved by carrying out electrophoresis at low pH (Carey 1988).

A more radical deviation in mobility occurs when binding of protein induces bending of the DNA fragment. The mobility of the "bent" complex is then lower (sometimes by a considerable amount) than might be predicted simply from the mass of the bound protein. The greater the angle of induced bend, the greater the reduction in mobility (Koo and Crothers 1988). Furthermore, the closer the location of the bend to the middle of the molecule, the slower its migration. This position effect has been used to map the location of protein-induced bends in DNAs (e.g., please see Wu and Crothers 1984; Kim et al. 1989). In general, conformation-induced effects are (1) magnified when DNA complexes are analyzed by electrophoresis at low temperatures in the presence of Mg^{2+} (Diekmann 1987) and in gels with small pore sizes (Marini et al. 1983) and (2) reduced in the presence of DNA-binding ligands such as distamycin (Wu and Crothers 1984).

Practical Matters

In addition to the theoretical matters discussed above, the practical advice that follows may be useful to the first-time user of gel retardation assays.

- ***Gel matrices.*** 5% polyacrylamide gels are used to analyze complexes formed with DNA fragments >200 nucleotides in length; 10% polyacrylamide gels are generally used for shorter DNAs. Agarose gels are not used unless the mass of the binding protein(s) or the DNA is very large (>1 kb). Because of their large pore sizes, agarose gels cannot detect protein-induced bending of DNAs.
- ***Electrophoresis buffers.*** Most protein-DNA complexes are stable and carry a slight negative charge at neutral pH, and thus 0.5x TBE is the standard buffer of choice. However, in the small minority of cases where the protein component of the complex carries a strong negative or positive charge, it may be necessary to use acid (e.g., TAE at pH 6.0) or alkaline buffers (e.g., 50 mM Tris-glycine at pH 9.2).
- ***Addition of carrier DNAs.*** Unlabeled carrier DNA is generally added to the binding mixture to eliminate nonspecific binding of proteins present in cell extracts to the radiolabeled target DNA. The aim is to add just sufficient carrier to absorb all of the proteins that bind nonspecifically to DNA without affecting the kinetics of formation or the stability of specific complexes involving the target DNA. The amount of carrier required in a particular circumstance must be determined empirically, but this task is rarely onerous because the range of acceptable carrier concentrations is usually quite broad. If too much carrier is used, none of the target DNA will form complexes: if too little carrier is used, all of the probe will bind nonspecifically to proteins in the extract and will thereby be prevented from entering the gel.

E. coli DNA was the first carrier DNA to be used as a nonspecific competitor in gel retardation assays (Strauss and Varshavsky 1984), and this was followed by eukaryotic chromosomal DNAs of high complexity (e.g., calf thymus and human DNA). However, the possibility that these DNAs might contain specific binding sites for the proteins under study quickly led to their replacement by synthetic alternating copolymers such as poly(dA-dT)·poly(dA-dT) or poly(dI-dC)·poly(dI-dC) or by the polysulfated carbohydrate heparin (Carthew et al. 1985; Singh et al. 1986).

- ***Cofactors.*** Certain transcription factors, particularly those of prokaryotic origin, require the presence of a specific cofactor for optimum binding. The CAP protein, for example, depends on cAMP for binding (Fried and Crothers 1983), whereas the tryptophan repressor TrpR requires tryptophan for efficient binding (Carey 1988).
- ***Extracts.*** Mammalian DNA-binding proteins are usually detectable in concentrated lysates of whole cells or in extracts of nuclear preparations. The methods to prepare these extracts have long since been optimized (e.g, please see Dignam et al. 1983; Chodosh et al. 1986; Kadonaga and Tjian 1986; Singh et al. 1986) and there is little point in trying anything new and fancy, at least during the initial phases of characterization of a new DNA-binding protein.
- ***Size of bound proteins.*** The size of a protein in a protein-DNA complex can be measured by cross-linking with UV irradiation and then resolving the complexes by SDS-polyacrylamide gel electrophoresis. In many cases, the presence of a previously characterized DNA-binding protein can be confirmed by immunological analysis. An antibody that binds specifically to a particular DNA-binding protein can either prevent formation of a specific protein-DNA complex or further retard ("supershift") the electrophoretic mobility of the complex (Kristie and Roizman 1986).

BACULOVIRUSES AND BACULOVIRUS EXPRESSION SYSTEMS

Baculoviruses cause a "melting" disease of lepidopteran larvae (e.g., silkworms) that has been studied by microbiologists since the nineteenth century. In the 1940s, Dr. G. Bergold discovered that many rod-shaped virus particles ("baculo" means rod) were embedded within the polyhedral crystals (~2 μm in diameter) known to be the disease agent of melting disease (Bergold 1947). Furthermore, these rod-shaped virus particles could be released from the polyhedra by treatment with alkaline solutions such as those found in the midgut of the insect host.

Research during the 1950s and 1960s was aimed at understanding viral pathogenesis, primarily by electron microscopic analysis (Harrap and Robertson 1968; Tanada and Leutenegger 1968, 1970; Harrap 1970; Summers 1971; Stoltz and Summers 1972). Our current view of how baculoviruses cause disease emerged from these studies. The crystals studied by Bergold are the occluded form of a subset of baculoviruses known as nuclear polyhedrosis viruses (NPVs). The crystals (also known as polyhedral inclusion bodies or PIBs) are ingested by the insect and solubilized in the insect midgut, the primary site of infection. The midgut cells and other cells within the insect produce PIBs as well as a second form of the virus, the budded virus (BV) that is responsible for systemic infection of the host and is the infectious form in cell culture. By the late 1960s and early 1970s, insect cell lines were established that could support budded virus replication as well as the production of occluded virus (Grace 1962; Goodwin et al. 1970; Hink 1970, 1972).

In 1975, the first baculovirus was registered as a pesticide for use on cotton by the Environmental Protection Agency in the United States (Ignoffo 1973, 1981). For several years, the cotton bollworm virus was commercially marketed as a substitute for the increasingly ineffectual organophosphate pesticides. But, in the late 1970s, the pyrethroid-based chemicals were registered and marketed, eliminating the market for the more expensive virus pesticides. During the 1980s, the U.S. Forest Service developed other baculovirus pesticides, including NPVs of the gypsy moth and the tussock moth, which are still used today for pest control in public forests (Martignoni 1984). Industrial interest, however, faded until the advent of technology to genetically improve baculoviruses as pesticides (McCutchen et al. 1991; O'Reilly and Miller 1991; Stewart et al. 1991; Tomalski and Miller 1991, 1992), coupled with increased resistance of pests to pyrethroids.

The registration of baculoviruses as pesticides had positive effect on both baculovirus research and biotechnology. The application of these viruses on millions of acres of agricultural and forest land highlighted the need to know more about how these viruses caused disease and the nature of their host-range limitation (Summers et al. 1975). Increased research led to a more sophisticated understanding of the viruses and eventually to the development of baculoviruses as expression vectors.

Baculoviruses constitute an immense family of viruses, the Baculoviridae, which includes >500 known members ubiquitously distributed in terrestrial and marine ecosystems (Martignoni and Iwai 1986). Each baculovirus infects a limited number of arthropod species and some cause lethal epizootics. Those viruses causing diseases of pest species (e.g., Armyworms) or beneficial insects (e.g., silkworms or shrimp) have received more attention because of their potential use as pesticides or their potential to cause devastating diseases of commercially valuable arthropods.

The baculovirus most commonly used as a gene expression vector, *Autographa californica* nuclear polyhedrosis (AcNPV or AcMNPV), for example, also has considerable potential as an insect pest control agent against certain agricultural pest moth species (e.g., the cabbage looper *Trichoplusia ni* and the fall armyworm *Spodoptera frugiperda*). AcMNPV was isolated from alfalfa loopers (*A. californica*) in the early 1970s (Vail et al. 1971). Because it had potential as a pesticide and could be readily propagated in several established cell lines, it was adopted for molecular genetic analysis (Lee and Miller 1978, 1979; Smith and Summers 1978, 1979; Brown et al. 1979; Carstens et al. 1979; Miller and Dawes 1979; Miller 1981). The *Bombyx mori* nuclear polyhedrosis virus (BmNPV) is also used as a gene expression vector (Maeda 1989), primarily for expression in insect larvae because of the large size of the silkworm larvae.

Baculoviruses have large (~80–200 kbp) circular DNA genomes (Summers and Anderson 1972, 1973), several of which (including AcMNPV 133,894 bp; Ayres et al. 1994) have been completely sequenced. The AcMNPV genome contains at least 154 open reading frames, most of which have been assigned at least a rudimentary function.

Approximately 20 genes appear to encode viral structural proteins (Rohrmann 1992; Kool and Vlak 1993), whereas a similar number have been assigned roles in gene regulation (Todd et al. 1994). A number

of genes appear to have been acquired from the host at some point in evolution; for example, baculovirus genes encoding proteins with significant sequence identity to host proteins include superoxide dismutase, ubiquitin, protein kinases, protein phosphatase, proliferating cell nuclear antigen, ω-conotoxin-like protein, and chitinase (Kool and Vlak 1993; Ayres et al. 1994). The virus interacts extensively with cellular processes and actively blocks apoptosis (Clem et al. 1991; Clem and Miller 1993; Crook et al. 1993; Birnbaum et al. 1994), an antiviral defense mechanism (Clem and Miller 1993). The virus controls its host at the organismal level as well as at the molecular and cellular levels. For example, the virus contains a gene encoding a UDP-glucose transferase that acts specifically on ecdysone, the major molting hormone of insects, thus allowing the virus to block molting and pupation of its host (O'Reilly and Miller 1989).

Regulation of baculovirus gene expression appears thus far to be controlled primarily at the level of transcription. AcMNPV genes are transcribed in three basic phases: early, late, and very late phases. Early phase genes appear to be transcribed by host RNA polymerase II (Grula et al. 1981; Huh and Weaver 1990a,b; Hoopes and Rohrmann 1991; Glocker et al. 1993), but early gene transcription is additionally modulated by the products of at least three early viral genes, *ie-1*, *ie-2*, and *pe-38* (Guarino and Summers 1986; Carson et al. 1988; Kovacs et al. 1991; Lu and Carstens 1993). Transcription of the late and very late genes involves a virus-induced α-amanitin-resistant RNA polymerase (Grula et al. 1981; Huh and Weaver 1990a,b; Yang et al. 1991). The latter appears to be encoded at least in part by the virus (Passarelli et al. 1994).

Late and very late gene transcription is dependent on DNA replication (Gordon and Carstens 1984; Rice and Miller 1986; Lu and Carstens 1991; Lu and Miller 1994). Although the viral DNA replication origins have not been defined, eight regions known as "homologous regions" (hrs) are dispersed in the viral genome and appear to act as origins of DNA replication for plasmids in transient expression assays (Pearson et al. 1992; Kool et al. 1993a,b); the homologous regions also have enhancer-like function for early gene expression (Guarino and Summers 1986). Origin-specific plasmid DNA replication can be *trans*-activated by the addition of ten viral genes, including the three genes involved in early gene regulation (Kool et al. 1994; Lu and Miller 1994).

Optimal expression from a late reporter gene in transient expression assays requires these ten genes and eight additional genes, all of which influence the steady-state levels of reporter gene expression (Lu and Miller 1994; Todd et al. 1994). Two of these genes encode proteins with motifs conserved in the largest and second largest subunits of eukaryotic and prokaryotic RNA polymerases, suggesting a direct role in transcription (Lu and Miller 1994; Passarelli et al. 1994). Only one factor specifically affecting very large late gene expression has been identified thus far, and this factor is related by sequence motifs to the λ integrase family (McLachlin and Miller 1994).

Although the early viral promoters are largely reminiscent of RNA polymerase II promoters, late and very late promoters of baculoviruses are unusual and appear to lack "upstream-activating" sequences (for review, please see O'Reilly et al. 1992). Both late and very late promoters contain an essential sequence, TAAG, at the transcriptional start site. This sequence is probably sufficient to serve as a "late promoter" for the new RNA polymerase, although the context of the TAAG sequence, especially the 5 or 6 bp immediately upstream and downstream from the TAAG, influences the expression level (Morris and Miller 1994). For the very late polyhedrin promoter, the 50 bp between the TAAG and the translational start codon of the polyhedrin open reading frame are required for the massive transcriptional activation observed during the very late phase of infection (Ooi et al. 1989). These 50 bp including the TAAG sequence are sufficient, in the context of the viral genome, to drive high levels of polyhedrin or heterologous gene expression during the very late phase of infection. Mutations within this 50-bp region influence steady-state levels of mRNA by affecting transcriptional initiation rather than mRNA turnover rates (Ooi et al. 1989). The choice of promoters used for heterologous gene expression is thus a crucial determinant of when and how much gene expression occurs. However, the context of the translational initiation codon and additional 5′ leader and 3′ trailer can also exert some effect.

Since polyhedrin promoter-driven expression initiates ~20 hours after infection and cell lysis does not occur until 72–94 hours postinfection, the very late phase encompasses ~30–50 hours of intense gene expression. Very high levels of polyhedrin mRNA are produced during this time, and polyhedrin constitutes ~25% of the total protein of the infected cell by the time of lysis. Similar levels of expression have been observed for several stable proteins encoded by foreign genes placed under the control of the polyhedrin promoter in baculovirus vectors. Usually, however, foreign proteins are expressed at a somewhat lower level, typically between 1% and 10% of total cellular protein.

Baculovirus Vectors

Until recently, recombinant baculoviruses were produced by cotransfecting stable lines of cultured insect cells with linearized baculovirus DNA and a transfer plasmid carrying the foreign gene behind a strong viral promoter (usually the polyhedrin promoter). Once inside the cell, homologous recombination between the plasmid and the viral genome generated a recombinant that carries the foreign gene in place of the endogenous polyhedrin gene (Smith et al. 1983; Maeda et al. 1984; Pennock et al. 1984; for more complete descriptions of the method, please see King and Possee 1992; O'Reilly et al. 1992; Luckow 1993; Miller 1993).

The linearized baculovirus DNA used for transfection is obtained by digesting the genome of an AcMNPV vector with restriction enzymes that remove a reporter gene (*lacZ* or GFP) and part of an essential baculovirus gene. The resulting linear DNA is noninfectious and cannot generate viable progeny viruses unless it recombines with the transfer plasmid (Kitts et al. 1990; Kitts and Possee 1993). The recombinant viruses can be recognized because they generate plaques in monolayers of insect cells that are either colorless (*lacZ*) or nonfluorescent (GFP).

Many different transfer plasmids have been developed for a variety of applications. For example, plasmid vectors are available for expression of proteins as fusions to glutathione *S*-transferase (GST) or as His-6-tagged fusions. Other plasmids allow for the simultaneous expression of two or more (up to four so far) different genes. A variety of promoters that drive expression at different stages in the virus infection process have also been developed; promoters that drive expression earlier than the polyhedrin promoter are often not as strong but provide for a longer period of expression, while the cell is more capable of posttranslationally modifying the gene product.

More recently, methods have been developed to ligate foreign genes directly into baculovirus vectors. Ernst et al. (1994) created a baculovirus that could be linearized at a unique *Sce*I site and could be used to propagate and express foreign genes equipped with *Sce*I termini. The usefulness of this method was greatly increased when Lu and Miller (1996) developed a more versatile vector system that could accept DNAs with *Eco*RI termini. As a consequence of these advances, baculovirus expression systems have assembled a tremendous record of success: More than 800 different gene products have been expressed to levels that are sufficient for biochemical and structural analyses of the purified proteins. Whereas baculovirus vectors were once used when all else failed, they are now often the first systems to be tried for expression of a newly isolated eukaryotic gene.

Drawbacks of Baculovirus Expression Systems

The major advantage of baculovirus vectors is their capacity to produce very high levels of biologically active proteins. An additional benefit accrues if the foreign protein is equipped with a signal sequence. In this case, the protein can be translationally modified by N-linked glycosylation at consensus Asn-X-Ser/Thr sequences and secreted from the infected cells. Authentic co- and posttranslational processing of eukaryotic secreted proteins is generally essential for their full biological activity. Finally, by comparison to mammalian cells, lines of cultured insect cells are relatively easy to grow, inexpensive to maintain, and can be produced in large numbers.

Nevertheless, baculovirus expression systems have certain disadvantages. High-level expression of proteins is discontinuous and short lived: Cultured insect cells must be grown, infected, and harvested before lysis, usually within 1 week of infection with recombinant viruses. To overcome these problems, stable plasmid-based expression systems have been developed (for review, please see McCarroll and King 1997). The results obtained so far with stably transformed lines of insect cells are encouraging in that a few proteins have been expressed at relatively high levels. However, other proteins are expressed at much lower levels in stably transformed cell lines than in the conventional system of acutely infected cells. The reasons for this variability are unknown. Insect cells do not generally provide "complex" N-glycosylation such as addition of galactose and sialic acid residues. Instead, they trim the core oligosaccharide to $Man_{3-5}GlcNac_2$, with some fucose addition on GlcNac. Although this type of N-glycosylation is usually sufficient to provide biologically active mammalian products, the lack of terminal complex glycosylation may result in subtle differences in, for example. solubility, stability, and immune response. In addition, because of the very high levels of expression that the baculovirus system can achieve, the posttranslational machinery of the cell often does not keep pace with expression, and protein modification may not be efficient (Jarvis et al. 1990). Finally, be warned that some genes just do not express well in the baculovirus expression system; in this respect, baculovirus systems are no different from other eukaryotic and prokaryotic expression systems.

Commercially Available Baculovirus Expression Systems

The best way to obtain the clones, vectors, and cell lines that are components of baculovirus expression systems is simply to buy a kit. Invitrogen and CLONTECH both sell comprehensive sets of reagents that are supplied with straightforward instructions and clearly written technical material. The manipulations are simple, the success rate is very high, and the kits are reasonably inexpensive. So go for it!

GREEN FLUORESCENT PROTEIN

The bioluminescent jellyfish *Aequorea victoria* (illustrated on the cover of this book) emits a characteristic green fluorescence, visible as a ring of light around the edge of the umbrella (Harvey 1952). This is due to the activity of two proteins: the calcium-binding photoprotein aequorin, and its companion, the green fluorescent protein (GFP). In the last 10 years, GFP has become one of the most interesting proteins in biochemistry and molecular biology. In addition to providing a tool to understand and manipulate the relationship between protein structure and spectroscopic function, GFP has been used with increasing success as a marker for gene expression and intracellular processes in organisms ranging from bacteria to transgenic mice.

GFP, discovered by Shimomura et al. (1962), is a 238-residue polypeptide (M_r = 26,888) encoded by three exons spread over 2.6 kb of the *A. victoria* genome (Prasher et al. 1992). The protein is stable to a wide variety of harsh conditions including heat, extreme pH, and chemical denturants (Ward and Bokman 1982) and continues to emit fluorescence after fixation in formaldehyde (Chalfie et al. 1994). However, the fluorescence is rapidly quenched under reducing conditions (Inouye and Tsuji 1994).

The emission spectrum of GFP peaks at 508 nm (Johnson et al. 1962), a wavelength close to that of living *Aequorea* tissue, but distinct from the chemiluminescence of pure aequorin, which is blue and peaks near 470 nm. With the initial purification and crystallization of GFP, it was discovered that calcium-activated aequorin could efficiently transfer its luminescent energy to GFP when the two were coadsorbed onto a cationic support (Morise et al. 1974). Green light is produced when energy is transferred by a Föster-type mechanism from Ca^{2+}-activated aequorin to GFP. Blue light emitted by activated aequorin is captured by a hexapeptide chromophore (beginning at residue 64 of GFP) that contains a cyclic structure (4-[*p*-hydroxybenzylidene] imidazolidin-5-one) attached to the peptide backbone through the 1- and 2-positions of the ring (Shimomura 1979). Interestingly, this structure appears to be conserved among fluorescent proteins, even those from nonbioluminescent organisms (Matz et al. 1999).

Structure and Function

The resolution of the crystal structure of GFP provided an explanation for many of its observed physical properties (Ormo et al. 1996; Yang et al. 1996). The protein consists of a β-barrel structure composed of 11 strands (β sheets) that encapsulate a central α-helix. The chromophore, formed by the cyclization of residues Ser-65, Tyr-66, and Gly-67, is contained within a short helical structure, which is itself buried inside the tightly woven 11-stranded β-barrel (Ormo et al. 1996; Yang et al. 1996; Brejc et al. 1997). The insulation of the chromophore inside the β "can" confers many of the physical properties of GFP, including resistance to urea, detergents, proteolytic attack, thermal denaturation, and, in some cases, to formaldehyde fixation. The secondary and tertiary structures of GFP suggest a mechanism for the function of the protein. Of recent note, the resolution of the crystal structure of the aequorin from *Aequorea aequorea*, reported by Head et al. (2000), has provided further details of the mechanism of the bioluminescent reaction for that calcium-sensitive photoprotein.

The GFP chromophore does not require special biosynthetic pathways that are specific to Cnidaria. Instead, it can be formed in a wide range of cells that normally do not produce light. GFP undergoes an autocatalytic, intramolecular reaction to create the chromofluor in a posttranslational formation that occurs with a time constant of nearly 4 hours in the native protein (Heim et al. 1994; Inouye and Tsuji 1994). This reaction involves cyclization and oxidization of the trimer Ser-65, dehydro-Tyr-66, and'Gly-67 (Heim et al. 1994). The isolated chromophore, the intact GFP protein, and synthetic chromophores all dis-

play very similar spectral characteristics: They absorb light maximally at ~390 nm with a smaller peak of absorbance at ~480 nm (Morise et al. 1974; Ward et al. 1980; Cody et al. 1993). However, only the intact GFP emits green light (with a peak at 509 nm and a shoulder at 540 nm) (Morise et al. 1974). Because the ratio of the two absorption peaks is sensitive to such factors as pH, temperature, and ionic strength (Ward and Bokman 1982), it has been suggested that the chromophore may exist in two different forms. Recent structural studies demonstrate that the two peaks of absorbance, ~390 nm and ~480 nm, represent two forms of the chromophore, having protonated and deprotonated tyrosyl hydroxyl groups, respectively (Brejc et al. 1997; Palm et al. 1997). Molecular dynamic studies of the wild-type and mutant versions of the protein, such as GFP-S65T and GFP-F64L/65T (EGFP), provide an explanation of how these conformational and chemical changes within the chromophore affect its function (Haupts et al. 1998).

GFP as Reporter

The demonstration that GFP maintained its ability to fluoresce in organisms other than *Aequoria* (Chalfie et al. 1994) suggested that no other agents such as antibodies, cofactors, or enzyme substrates are necessary for its activity. These initial findings opened the way for GFP to be used as a marker in *Caenorhabditis elegans* (Chalfie et al. 1994), bacteria and yeasts (Flach et al. 1994; Nabeshima et al. 1995; Yeh et al. 1995; Niedenthal et al. 1996), *Drosophila* (Wang and Hazelrigg 1994; Barthmaier and Fyrberg 1995); zebrafish (Amsterdam et al. 1995), plants (Chiu et al. 1996), and cultured mammalian cells (Marshall et al. 1995; Misteli et al. 1997). There are now several reports that GFP may be used effectively as a reporter in transgenic mice (Ikawa et al. 1995; Chiocchetti et al. 1997; Okabe et al. 1997; Zhuo et al. 1997).

These early remarkable successes suggested that many potential difficulties in the heterologous expression of the jellyfish protein were not insurmountable. Despite these demonstrations, however, wild-type GFP suffered from several limitations that may have impact on experimental design.

- The posttranslational modifications required to form the chromophore and the inaccessibility of the chromophore in the depths of the β "can" result in a lag (>1 hour) between synthesis of GFP and its ability to emit fluorescence. This delay may complicate studies of gene expression where an immediate readout is desired.
- Efficient expression in higher eukaryotes and plants may require optimization of the coding sequence of GFP.
- No definitive prediction can be made about whether a particular fusion protein involving GFP will generate a functional and fluorescent protein. To avoid problems, a variety of fusion constructs should be generated and characterized.
- Overexpression of protein in cells may cause problems in general. It is thought, for example, that expression of GFP to high levels in yeast can lead to mislocalization of the protein within the cells. It is unclear, however, whether this effect is due to the overabundance or the nature of the protein.
- It may be difficult to detect GFP-specific fluorescence over background autofluorescence, although, in some cases, this may be overcome using confocal microscopy. To record a good signal, the correct equipment, careful choice of filters, and a thorough knowledge of microscopy may be necessary.
- GFP exhibits significant spectral changes in response to protein concentration, ionic strength, and pH. It is therefore important to assay GFP under standard conditions.

The heterologous expression of *Aequorea* GFP in different organisms therefore originally met with only limited success. For example, the presence of cryptic splice sites in the original clone resulted in the deletion of portions of the coding region in some organisms such as plants, the translation initiation site was not optimal for expression in many foreign hosts (Kozak 1987), and some of the codons were infrequently used. The entire cDNA sequence encoding GFP has now been mutagenized or synthesized in several different ways by various groups to alter some or all of these features, and the signal produced by the reporter has been increased considerably (Haseloff and Amos 1995; Reichel et al. 1996; Zolotkin et al. 1996; Haseloff et al. 1997). In addition, the problem of a relatively low level of transcription has been addressed by the insertion of strong constitutive promoters from viruses such as cytomegalovirus (CMV), SV40, or the human immunodeficiency virus (HIV) long terminal repeat upstream of the GFP-coding region (Gervaix et al. 1997), which results in significant levels of expression.

In attempts to overcome some of the limitations of detection of GFP, extensive structure-driven, site-directed mutagenesis studies have been carried out. As a result of these studies, an increasingly long list of

variants has been described, each having altered fluorescence excitation and/or emission spectra (for a summary of these, please see Figure 17-12) (Crameri et al. 1996; Heim and Tsien 1996; Cormack et al. 1997). In many of these cases, the altered properties provide significant advantages over wild-type GFP for many applications. For example, mutation of Tyr-66 has significant impact on GFP because the fluorescent properties of the chromophore largely derive from the π electron-conjugated framework of this amino acid. Amino acid substitutions at position 66 result in alteration of excitation/emission wavelengths, in some cases, generating proteins that fluoresce yellow, blue, and cyan. However, mutation of Tyr-66 can also reduce fluorescent output to 20% of the wild-type protein. By contrast, mutants at the adjacent position Thr-65, such as S65T (Heim et al. 1995) or S65G, S72A (Cormack et al. 1996), display an excitation peak that is four-

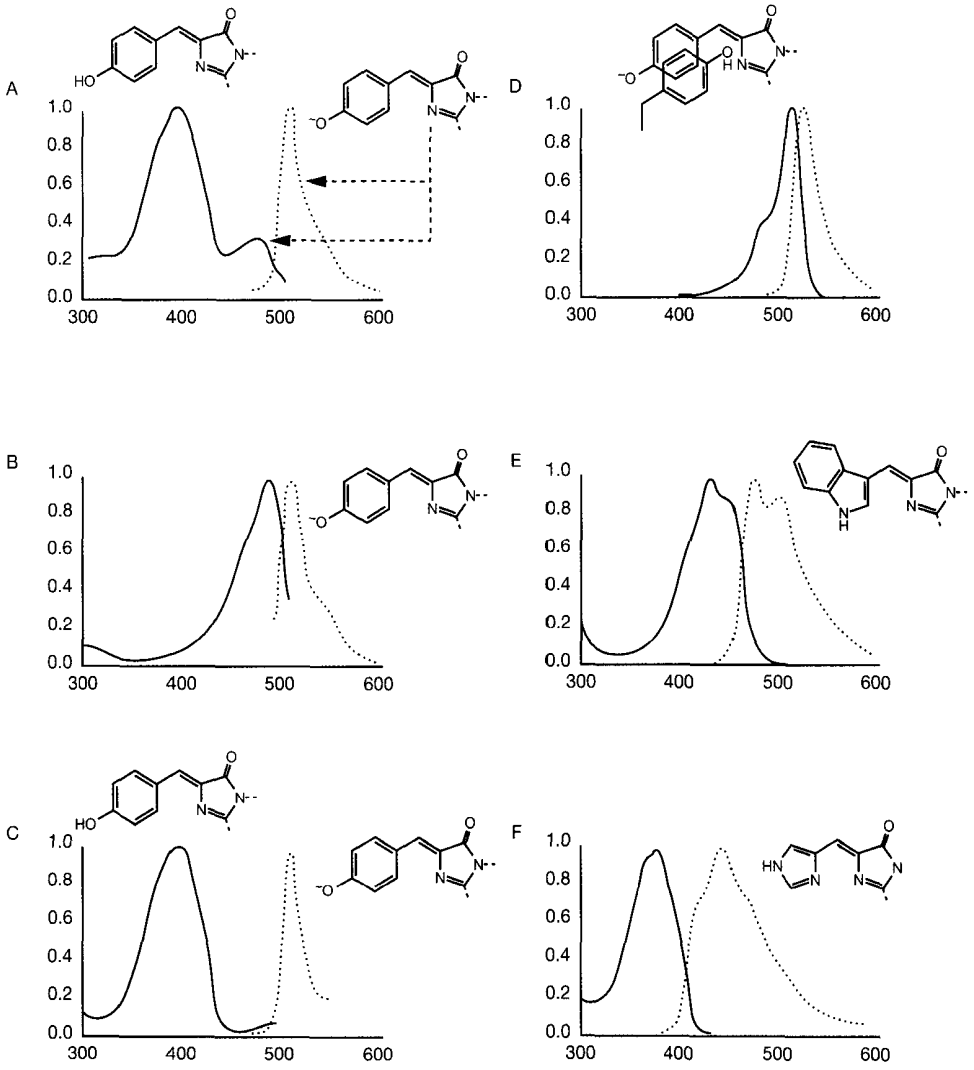

FIGURE 17-12 Fluorescence Excitation and Emission Spectra for GFP Variants

The fluorescence excitation and emission spectra are represented as solid and dashed lines, respectively, for typical members of the six major classes of GFP mutants, together with the chromophore structures believed to be responsible for the spectra. Spectra have been normalized to a maximum amplitude of 1. When only one structure is drawn, both excitation and and emission spectra arise from the same state of chromophore protonation. The actual GFPs depicted are wild type (Class I) (*A*); Emerald (Class II) (*B*); H9-40 (Class III) (*C*); Topaz (Class IV; yellow fluorescent protein) (*D*); W1B (Class V; cyan fluorescent protein) (*E*); P-4-3 (Class VI; blue fluorescent protein) (*F*). (Adapted, with permission, from Tsien 1998 [©Annual Reviews].)

to sixfold greater than that of wild-type GFP. In some mutants, the oxidation step required to generate the fluorophore occurs more rapidly in the mutant protein than in the wild-type protein. Figure 17-12 illustrates the fluorescent excitation and emission spectra for several GFP mutants.

GFP as Fusion Tag

GFP markers are most commonly used either as a tag to track the levels and localization of the fusion partner or as an indicator to detect environmental changes or protein interactions. In tagging applications, the use of recombinant techniques as well as mutagenesis has resulted in the production of several vectors that optimize expression of the fusion product. Such vectors typically employ a "brightened" form of the fluorescent protein whose codon usage has been optimized for expression in a particular cell line (e.g., please see Zolotkin et al. 1996), and the expression of such constructs is typically driven by strong promoters such as that from cytomegalovirus. Figure 17-13 describes the pd2EGFP vector series that offer many of these features.

Various recombinant strategies may be used to fuse the GFP tag to the amino terminus or carboxyl terminus of the target protein (for an excellent discussion of creating fusion constructs, please see Hughes 1998). In cases where the addition of the tag to the end a protein is not well-tolerated, it may be possible to insert the GFP tag within the coding sequence of the target protein. This placement will, in some cases, allow proper folding of the tag and produce a functional chromophore (e.g., please see Siegel and Isacoff 1997). These constructs may be introduced into the cell or organism using standard methods for transient or stable expression (please see Chapter 16). The fate of the constructs (e.g., their transport or expression) is then followed using conventional fluorescence microscopy. Because detection does not require permeabilization or fixation of cells, there is little probability of introducing artifacts. Moreover, expressed GFP-fusion proteins are rarely toxic to cells, although fusion partners localized to the cell nucleus may induce more damaging side effects than those found in the cytoskeleton, for example (T. Misteli and D. Spector, unpubl.).

Among the most successful tagging applications has been the use of GFP to monitor the dynamic localization and fate of fused proteins in living cells and organisms. Since the initial report that described tracking ribonucleoprotein (RNP) particles during *Drosophila* oogenesis (Wang and Hazelrigg 1994), GFP has been targeted to and expressed successfully in nearly every major organelle of the cell. Among the wide range of reports in the literature are studies dealing with visualizing the dynamic properties of organelles such as the Golgi (Cole et al. 1996; Presley et al. 1997), observing events in the cytoskeleton (Olson et al. 1995) and along secretory pathways (Wacker et al. 1997), and following the events of protein trafficking (Lee et al. 1996) and cytokinesis (Finger et al. 1998). Of particular note are studies that use a set of GFP variants to track different proteins simultaneously within the cell (Misteli and Spector 1997; Tsien and Miyawaki 1998). Recently, fluorescent proteins having significant homology with GFP have been isolated from the nonbioluminescent species of *Anthozoa* (Matz et al. 1999). Among these, a red fluorescent protein was shown to exhibit a maximum emission spectrum at 583 nm, "red-shifted" well outside the range of other GFP variants. As is depicted in Figure 17-12, the large shifts in the mutant GFPs are in the excitation, rather than in the emission wavelengths. The red fluorescent protein can be easily detected using either the standard epifluorescent microscope or typical confocal microscope, and therefore promises to be of great use in double- or triple-labeling studies.

The combination of random and directed mutagenesis studies have produced altered chromophore structures that enable GFP to serve as indicators of environmental changes in the cell or of interactions between or among proteins (for a more complete description of these studies and their possibilities, please see the review on biochemical imaging by Tsien and Miyawaki 1998). These studies of resonance energy transfer are based on systems for detecting the transfer of energy between two molecules, serving as donor and acceptor, on different proteins. Because the probability of energy transfer between two molecules diminishes as the sixth power of the distance between them, this strategy provides an exquisitely sensitive measure of the distance and interaction between the molecules. The use of GFP variants in energy transfer experiments can facilitate, for example, the detection of conformational changes in a protein associated with the binding of calcium to calmodulin (Miyawaki et al. 1997), as well as the depolarization of ion channels (Siegel and Isacoff 1997). Recently, GFP applications using fluorescence resonance energy transfer (FRET) have been used to detect and measure protein activation and interactions (Day 1998; Mahajan et al. 1998, 1999; Wouters and Bastiaens 1999). For a detailed discussion of the use of FRET to detect protein interactions, please see Chapter 18, Protocol 7. A variation of this approach, known as bioluminescent resonance

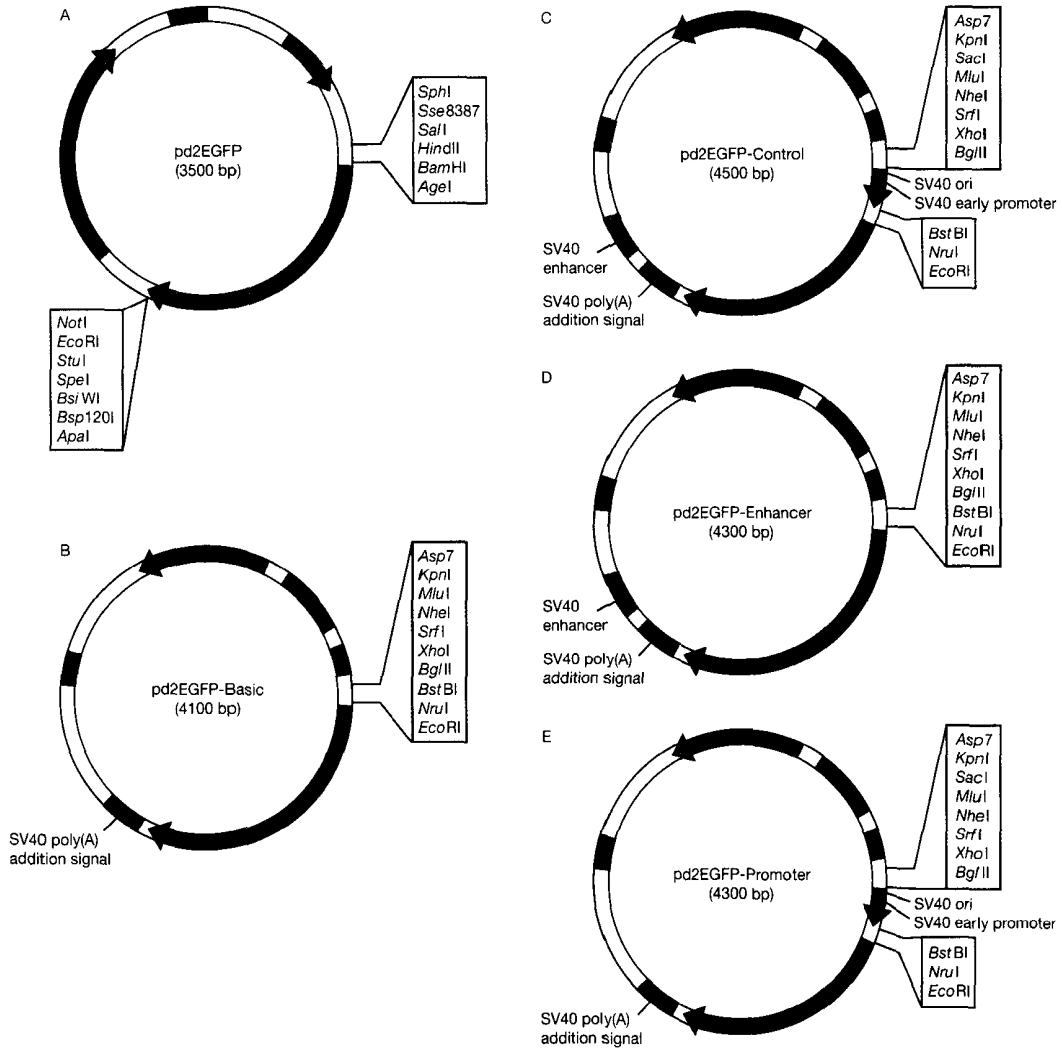

FIGURE 17-13 pd2EGFP Vectors

Summarized here are the features of the pdEGFP reporter vectors. All vectors in the series carry the coding sequence for a destabilized variant of the enhanced GFP (dEGFP). EGFP has a single, red-shifted excitation peak and fluoresces ~35 times more intensely than does GFP. The codon usage of EGFP is optimized for human coding preferences. The destabilized variant has a half-life of ~2 hours in mammalian cells, by contrast to EGFP, which has a half-life of ~24 hours. Because of its rapid turnover, d2EGFP is useful as a reporter for measuring the kinetics of transient mRNA transcription from a regulated promoter. All vectors in the series carry (1) an origin of plasmid replication in *E. coli* (pUC ori), (2) an ampicillin resistance marker (Amp^R) for selection in prokaryotic cells, and (3) a multiple cloning site (MCS) at the 5′ end of the EGFP sequence for insertion of the sequence under study. (*A*) pd2EGFP is intended primarily as a source of the d2EGFP-coding sequence. The coding region can be amplified by PCR or excised using the flanking restriction sites in the MCS. (*B*) The basic vector lacks eukaryotic promoter and enhancer sequences, allowing maximum flexibility in cloning regulatory sequences. The expression of EGFP depends on the insertion and proper orientation of a functional promoter upstream of the intron and EGFP gene. (*C*) The enhancer vector lacks the SV40 promoter, but contains the SV40 enhancer. This vector can be used to study promoter sequences cloned into the MCS. (*D*) The promoter vector lacks the SV40 enhancer, but contains the SV40 early promoter. This vector can be used to study enhancer sequences cloned into the MCS. (*E*) The control vector contains the SV40 early promoter and SV40 enhancer. This vector can be used as a positive control or as a reference when comparing the activities of promoter and enhancer elements. (Modified, with permission, from CLONTECH.)

energy transfer (BRET), relies on the use of a natural bioluminescent pathway to transfer energy to GFP (Angers et al. 2000). In this case, either the enzyme luciferase from the sea pansy *Renilla reniformis* or the photoprotein aequorin from *A. victoria* serves as energy donor by catalyzing the oxidation of coelenterazine. Luciferase and aequorin normally emit blue light; therefore, a detectable shift in emission toward a longer wavelength characteristic of a green or yellow fluorescent protein acceptor molecule signals that the transfer of energy has occurred.

Clearly, the possibilities for using fluorescent tags to probe the mysteries of the cell seem to be limitless. The use of natural and engineered GFP variants having distinctive spectral properties will facilitate the tracking of many proteins through the cell simultaneously, as well as the detection of their physiological activities and interactions. Live cell imaging in developing organisms is likely to resolve many questions of cell migration during development and differentiation.

Resources for Using GFP

Further information on use of wild-type and mutant forms of GFP as markers for gene expression in a wide variety of species can be found in the many reviews of the protein that have appeared in recent years (e.g., please see Leffel et al. 1997; Tsien 1998; Haseloff et al. 1999; Ikawa et al. 1999; Naylor 1999). These reviews are obligatory reading for those investigators who want to use GFP as a reporter in their particular experimental organism or cell type.

An extensive range of GFP variants (natural as well as mutant), vectors, and antibodies is now commercially available. CLONTECH has perhaps the most comprehensive set of vectors; GFP antibodies are available from many companies, including Chemicon Intl., Panvera, CLONTECH, and Alexis Corp. For the Web Sites of many of these companies as well as addressess for other resources that provide information relevant to studies using GFP, please see Table 17-2.

EPITOPE TAGGING

Epitope Tagging: An Overview

Fusion proteins consist of the amino acid residues of interest covalently attached at their amino or carboxyl termini to a set of carrier sequences. When the carrier sequences contain a useful antigenic determinant, the fusion protein is said to be tagged with an epitope. Epitope tagging is a powerful technique to characterize proteins of interest without purification. Another major advantage of epitope tagging is that well-characterized and highly specific antibodies can be used to study proteins of interest without the long laborious routines and uncertainties for production and characterization of antibodies. Epitope tagging has become a routine practice in the yeasts *Saccharomyces cerevisiae* and *Schizosaccharomyces pombe* (Bahler et al. 1998; Longtine et al. 1998). A tag can be fused to the carboxyl terminus of a protein at its endogenous locus using existing PCR modules without cloning and disrupting its endogenous promoter. In mammalian cells, this approach is not feasible at the present time. In most cases, the fusion protein is expressed under the control of a heterologous promoter (Sells and Chernoff 1995; Chubet and Brizzard 1996; Georgiev et al. 1996; Hosfield and Lu 1998), which typically results in abnormal expression of the gene of interest. Therefore, epitope tagging cannot be used, for example, to study regulation of a cell-cycle-regulated gene.

One assumption here is that addition of an epitope tag does not affect the function, intracellular transport, modification, or location of the target protein. Several studies have suggested that most proteins can accept a tag at one terminus or other regions without severe loss of their functions (Prasad and Goff 1989; Anand et al. 1993; Ross-Macdonald et al. 1997). However, whether this holds true must be tested whenever possible. In yeast, where the excavation of chromosomal genes is a routine matter, it is often possible to erase any doubts immediately by testing the ability of the epitope-tagged protein to complement a null allele. In mammalian cells, these matters must be taken on faith, and any results obtained should remain open to question until they have been confirmed by other means. In cases where a sensitive functional assay is available in vitro, it is sometimes possible to synthesize enough of the tagged protein in cell-free systems to confirm that it has retained full activity.

Epitope Tagging: Practical Considerations

Table 17-3 presents a sample of the epitopes that have been used for tagging. Because most of these epitopes are derived from a hormone or an oncogene, there is a finite but small chance of immunological cross-reaction with cellular material. In most cases, a single monoclonal antibody specific for the epitope can be used for immunostaining, immunoblotting, immunoprecipitation, and immunopurification.

The number of well-characterized epitopes is growing rapidly, and many commercial companies now sell kits that contain the materials and instructions to construct and test epitope-tagged fusion proteins of various sorts. However, before deciding to use an epitope-tagging strategy, it is best to work out the cost of the necessary reagents. This is especially important if the goal is to use the epitope for large-scale affinity purification of the fusion protein. Some of the companies charge such outrageous prices for monoclonal antibodies that the ongoing cost of the system quickly becomes prohibitive for many laboratories.

Another important consideration is to determine whether the selected epitope has been used in the literature for a purpose similar to that of its intended application. Even though epitope tagging may vary from protein to protein, the fact that similar approaches have been exploited with a particular tag increases the likelihood of its success and may provide some ideas and some detailed information on how to utilize this epitope, which may not exist in most general protocols.

It is very important to choose a tag whose cognate antibody will not cross-react with a protein in the host cells used for expression of the epitope-tagged protein and to choose a tagging site on the target protein that will not interfere with the function of any topogenic sequences (e.g., hydrophobic signal sequences) or trafficking signals (e.g., nuclear transport signals or endoplasmic reticulum retention sequences). Whenever possible, however, the epitope tags should be added to the amino or the carboxyl terminus of the target protein, where they are most likely to be accessible to antibody and least likely to interfere with the function of the target protein.

When an epitope tag is used for immunopurification, it is best to choose a tag that may be removed from the target protein. Removal is sometimes necessary to restore protein function, to increase solubility,

or to decrease antigenicity. Although success is not guaranteed, removal may be accomplished by incorporating a protease cleavage site in the peptide linker between the epitope tag and the target protein (for details, please see the introduction to Chapter 15). However, enzymatic removal is often inefficient (because the cleavage site is inaccessible) and sometimes destructive (because the cleaving protease is not absolutely specific or because of contamination with nonspecific proteases) (Nagai and Thøgersen 1987; Dykes et al. 1988).

Epitope Tagging: Applications

Since the introduction of epitope tagging by Munro and Pelham (1984), it has been used to address several experimental problems, including the detection, localization, and purification of expressed proteins. The protein of interest can be detected with immunological reagents directed against the epitope and purified by affinity chromotography in the absence of a functional assay (Field et al. 1988). In addition, because the tagged protein can be differentiated unambiguously from related cellular proteins (Davis and Fink 1990), its size and location can be ascertained by western blotting and immunofluorescence (Munro and Pelham 1986, 1987; Geli et al. 1988; Pelham et al. 1988; Swanson et al. 1991), its pattern of biosynthesis and post-translational modification can be followed by pulse-labeling and immunoprecipitation, and its interactions with other proteins can be probed by coimmunoprecipitation (Kolodziej and Young 1989; Squinto et al. 1990). Finally, with the development of sensitive mass spectrometry for peptide sequencing, epitope tagging has been used increasingly for purification of protein complexes and identification of components in the protein complexes (Ogryzko et al. 1998; Shao et al. 1999). Although it is not possible to provide a comprehensive list of the relevant literature, below are some recent major applications of epitope tagging.

- ***Gene expression and localization.*** Epitope tagging has been used to study gene expression in various organisms using western blotting. If it is difficult to detect the expression of a fusion protein using a single epitope, due to a low expression level and instability of the protein, sensitivity can be increased by adding multiple epitopes (Nakajima and Yaoita 1997). Once a fusion protein is expressed, its localization can be detected by immunofluorescence. This technique is very useful to study localizations of isoforms of a gene family that share highly significant sequence identity, where specific antibodies to different isoforms are always difficult to generate (Scherer et al. 1995; Toyota et al. 1998). Epitope tagging can also be used for mapping regions of a protein that are responsible for targeting the protein to specific locations (Xu et al. 1998).
- ***Interactions.*** By using coimmunoprecipitation and detection by western blotting, epitope tagging has been used widely to study protein-protein interactions in vitro and in vivo (Chinnaiyan et al. 1995; Hsu et al. 1996) (for details, please see Chapter 18, Protocols 2, 3, and 4). In cases where no antibodies are available for either of the two potentially interacting proteins, different tags may be attached to each of the two proteins. The antibody that recognizes one epitope is then used for immunoprecipitation, whereas the antibody against the other epitope is used for detection of the immunoprecipitated proteins. In this case, it is always wise to perform the reciprocal coimmunoprecipitation experiment to determine whether the interaction is specific. Morover, it is important to recognize that because candidate proteins identified by immunoprecipitation may not interact directly with the bait protein, it is advisable to use other means to confirm whether a direct interaction exists.
- ***Purification of protein complexes.*** In many cases, a biological function is carried out by a protein complex instead of a single protein. Therefore, it is essential to identify and purify all of the components of a protein complex. In organisms such as yeast where genetic approaches exist to identify all of the components performing the same function, it is still necessary to purify protein complexes to study their biochemical functions. Epitope tagging has provided a way to purify protein complexes by immunoaffinity chromatography and immunoprecipitation (Chiang and Roeder 1993; Ogryzko et al. 1998; Shao et al. 1999). Now that the complete genomic sequences of several organisms are available (e.g., the yeast *S. cerevisiae, C. elegans*, and *Drosophila*), and with the significant reduction in the amounts of materials required for peptide sequencing by mass spectrometry (Dukan et al. 1998; Huang et al. 2000), the use of immunoprecipitation to identify components in protein complexes is likely to become one of the major techniques in proteomics.

TABLE 17-3 Epitope Tagging

Origin of Tag	Description of Epitope	Source of Antibodies	References
Substance P	QFFGLM The sequence of this hexapeptide corresponds to the carboxy-terminal half of substance P.	MAb NCI/34 to substance P recognizes only the carboxy-terminal pentapeptide of substance P (Cuello et al. 1979). However, this antibody can be used for western blotting or immunofluorescence only after carboxyl groups in the target protein have been converted to amides with soluble carbodiimide and NH_4Cl (Munro and Pelham 1984).	Cuello et al. (1979); Munro and Pelham (1984); Albers and Fuchs (1987)
Human c-Myc protein	EQKLISEEDL	MAb 9E10 (Evan et al. 1985) was raised against a synthetic peptide comprising residues 409–439 of human c-*myc*. The epitope recognized by MAb 9E10 was identified by progressive deletion of residues 409–439 of c-*myc* (Munro and Pelham 1986).	Evan et al. (1985); Munro and Pelham (1986, 1987); Pelham et al. (1988); Squinto et al. (1990); Adamson et al. (1992); Sells and Chernoff (1995)
Anonymous open reading frame	KAEDESS The translational stop codon at the end of the *HGPRT* gene was mutated to allow extended translation to the next in-frame stop codon. The resulting protein, which is enzymatically active, carries a unique negatively charged heptapeptide at its carboxyl terminus.	Polyclonal antibodies were raised against a synthetic peptide and affinity-purified.	Yee et al. (1987)
Colicin A protein	178 amino-terminal amino acids of colicin A protein.	MAb 1c11 recognizes an epitope located in the first 70 amino acids of colicin A protein (Cavard et al. 1986).	Cavard et al. (1986)
Influenza virus hemagglutinin	YPYDVPDYA	MAbs were originally raised against a synthetic peptide corresponding to amino acids 75–110 of the hemagglutinin protein of the H3 subtype of influenza virus (Niman et al. 1983). MAbs 12CA5 and 3F10 are now available commercially from Berkeley Antibody Co. (Babco), which recognize the complete antigenic determinant (YPYDVPDYA) of the immunizing 36-residue peptide (Wilson et al. 1984). This nonapeptide can be used to release fusion proteins from the MAb.	Niman et al. (1983); Wilson et al. (1984); Field et al. (1988); Swanson et al. (1991); West et al. (1992); Marck et al. (1993); Sells and Chernoff (1995)
SV40 T antigen	85 amino-terminal amino acids of SV40 large T antigen.	MAb Pab 419 (L19 in Harlow et al. 1981).	Harlow et al. (1981); Sugano et al. (1992)
FLAG sequence	DYKDDDDK FLAG was designed as a hydrophilic, immunogenic purification tag that could be removed from the target protein by proteolytic cleavage (Hopp et al. 1988). The five carboxy-terminal amino acids of the FLAG epitope are adapted from the site cleaved by enterokinase in its natural substrate bovine	MAb 4E11 (Hopp et al. 1988; Prickett et al. 1989), which is specific for the FLAG sequence, can be used for immunoblotting, immunoprecipitation, and immunoaffinity purification. Binding of proteins tagged with the FLAG epitope to this antibody is calcium-dependent and reversible with chelating agents such as EGTA or at low pH.	Davie and Neurath (1955); Hopp et al. (1988); Knott et al. (1988); Prickett et al. (1989)

	trypsinogen. Digestion with enterokinase, which cleaves after the lysine residue in the sequence VDDDDK (Davie and Neurath 1955), should remove an amino-terminal FLAG sequence after immunopurification of a tagged protein.		
Vesicular stomatitis virus (VSV) G protein	YTDIEMNRLGK 11 amino acids from the carboxyl terminus of VSV G protein (Kreis 1986).	Polyclonal and monoclonal antibodies were raised against a synthetic peptide containing the 15 carboxy-terminal amino acids (497–511) of VSV G protein (Kreis 1986). Affinity-purified polyclonal antibodies recognize epitopes distributed along the entire 15-residue peptide, whereas the MAb PD54 reacted only with the carboxy-terminal pentapeptide. Both types of antibodies recognize proteins tagged with the 11-residue epitope, although the polyclonal antibody reacts more strongly (Soldati and Perriard 1991).	Kreis (1986); Soldati and Perriard (1991)
T7-Tag	MASMTGGQQMG	MAb T7 • Tag (sold by Novagen).	Lutz-Freyermuth et al. (1990); Tsai et al. (1992)
AU epitopes	DTYRYI (AU1) and TDFYLK (AU5)	MAbs AU1 and AU5 were developed against papillomavirus major capsid protein.	Lim et al. (1990)
His-6 epitope	HHHHHH	MAbs 6-His, 6xHis, and HIS-11 are commercially available.	
HPOL	HPOL	Mab1051c recognizes a peptide from the thumb region of the herpes simplex virus type-1 DNA polymerase (HPOL).	Schreiner et al. (1999)
Btag	QYPALT	Two MAbs (D11 and F10) developed against the major core protein, VP7, of bluetongue virus were tested to recognize the BTag epitope at any regions of recombinant proteins.	Wang et al. (1996)
3B3	QRQYGDVFKGD	MAb 3B3 was raised against ORF gE of a varicella zoster virus and tested to react with the 3B3 epitope placed in other proteins.	Hatfield et al. (1997)
Glu-Glu	EYMPME or EFMPME	Synthetic peptide EEEEYMPME from polyomavirus medium T antigen was used to produce MAb Glu-Glu. This antibody has been used for affinity purification.	Grussenmeyer et al. (1985)
IRS	RYIRS	MAb IRS1 recognizes fusion proteins containing the epitope at the carboxyl terminus of the proteins only.	Liang et al. (1996); Luo et al. (1996)

CHLORAMPHENICOL ACETYLTRANSFERASE

Acetyl-coenzyme:chloramphenicol acetyltransferase (acetyl-CoA:CAT; EC 2.3.1.28) has become widely used as a reporter molecule for the indirect assay of transcriptional regulatory elements in transfected mammalian cells. The enzyme covalently modifies chloramphenicol by transferring an acetyl group from acetyl-CoA to the primary hydroxyl residue (C3) of chloramphenicol (please see Figure 17-14).

The product of this reaction, 3-acetyl chloramphenicol, undergoes a nonenzymatic rearrangement in which the acetyl group is transferred to the C1 residue, forming 1-acetyl chloramphenicol. This rearrangement reopens the primary hydroxyl on C3 to a second cycle of acetylation that gives rise to the diacetylated product 1,3-diacetyl chloramphenicol.

The CAT gene is responsible for resistance to chloramphenicol in strains of bacteria that are resistant to the antibiotic. After mono- or diacetylation, chloramphenicol cannot bind to the peptidyl transferase center of prokaryotic ribosomes, the exclusive target for the antibiotic's action. In field strains of Enterobacteria and other Gram-negative bacteria, the CAT gene is constitutively expressed and is usually carried on plasmids that confer multiple drug resistance. In staphylococci, CAT activity is almost invariably encoded by small (<5 kb) plasmids that carry no other resistance markers. Amino acid sequences of several variants of CAT from both Gram-positive and Gram-negative bacteria are highly homologous. All known variants are trimers consisting of identical subunits of M_r = 25,000. The type I variant, which is encoded by a 1102-bp segment of transposon Tn9, is in wide use as a reporter gene. However, most kinetic and structural analyses are carried out with the type III variant, which yields crystals suitable for X-ray analysis. The trimeric structure is stabilized by a β-pleated sheet that extends from one subunit to the next (Leslie et al. 1988). The two substrates (chloramphenicol and acetyl-CoA) approach the active site through tunnels located on opposite sides of the molecule. The active site, which is located at the subunit interface, contains a histidine residue, which is postulated to act as a general base catalyst in the acetylation reaction (Leslie et al. 1988; Shaw et al. 1988).

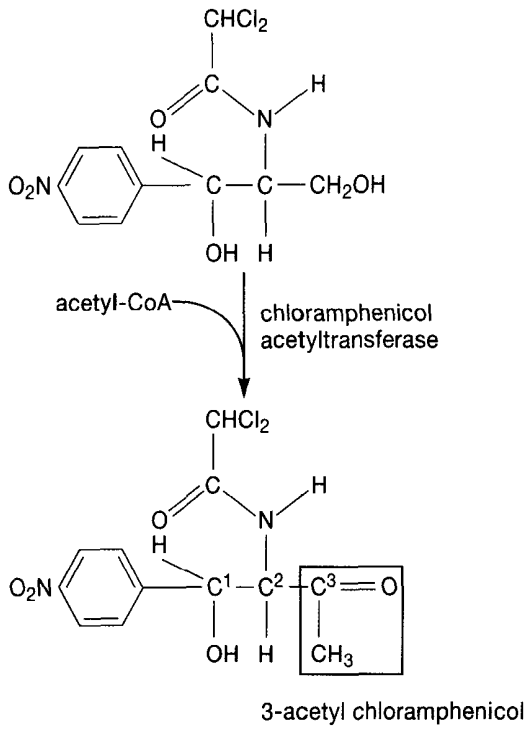

FIGURE 17-14 Reaction Catalyzed by CAT

Expression of CAT in Mammalian Cells

Virtually all transfection experiments with CAT have been carried out with constructs derived from the plasmid pSV2CAT, which contains the SV40 promoter/enhancer, 29 bp of untranslated sequence, the CAT-coding sequence, and 8 bp of DNA 3′ to the UAA stop codon (Gorman 1985). pSV2CAT cannot confer chloramphenicol resistance upon bacteria because the CAT gene is not linked to a prokaryotic promoter. To assay putative promoters in mammalian cells, a derivative of pSV2CAT has been constructed (pSVOCAT) (Gorman et al. 1982) that allows the promoter region of SV40 to be replaced by the promoter under test.

The CAT gene fulfills many of the criteria required of an ideal reporter gene in mammalian cells. Because CAT is a prokaryotic enzyme, there are no endogenous or competing activities in mammalian cells and the enzyme is quite stable. However, some of the assays used to measure CAT activity in lysates of transfected cells are expensive and time-consuming, and unless great care is taken, they may be inaccurate. Many of the older assays are variations on the methods of Shaw (1975) and Gorman et al. (1982) in which extracts prepared from transfected cells are incubated with ^{14}C-labeled chloramphenicol. The acetylated products are separated from the unmodified drug by thin-layer chromatography and quantitated by autoradiography or by scraping the spots from the thin-layer plates and counting them by scintillation spectroscopy. CAT activity is then calculated as the percentage of chloramphenicol converted to mono- and diacetylated products. However, all of these older methods are labor-intensive, semiquantitative, and of limited sensitivity ($\sim 10^{-2}$ units of CAT activity). (One international unit of CAT is defined as the amount of enzyme that catalyzes the production of 1 μmole of product per minute. This is approximately equivalent to 1.5×10^{11} molecules of enzyme.)

The insensitivity of the assay is in part due to the presence of enzymes in extracts of transfected cells that hydrolyze acetyl-CoA. The sensitivity and reproducibility of the assay are greatly improved if the extracts are adjusted to 10 mM EDTA and then heated to 60°C for 10 minutes (Sleigh 1986; Crabb and Dixon 1987) before assay. Newer assays that circumvent the use of thin-layer chromatography include the acetylation of unlabeled chloramphenicol with ^{14}C-labeled acetyl-CoA. At the end of the reaction, the mixture is extracted with ethyl acetate. The mono- and diacetylated forms of chloramphenicol partition into the organic phase, whereas the acetyl-CoA remains in the aqueous phase. The amount of chloramphenicol converted to the acetylated form can then be measured in a liquid scintillation counter. Subsequent variations on this assay include:

- Extraction of reaction products into liquid scintillation fluor (e.g., please see Eastman 1987; Neumann et al. 1987; Nielsen et al. 1989).
- Enzymatic butyration of radiolabeled chloramphenicol (Seed and Sheen 1988).
- Use of fluorescent substrates for CAT that display bright fluorescence when excited at the appropriate wavelength (Young et al. 1991).

Because of the peculiar chemistry of the CAT reaction, however, none of these assays are truly quantitative. As discussed above, the monoacetylated reaction product, 3-acetyl chloramphenicol, is converted by a nonenzymatic rearrangement to 1-acetyl chloramphenicol. This remains tightly bound to CAT and is then acetylated relatively slowly to 1,3-diacetyl chloramphenicol. Assays that measure the yield of mono- and/or diacetylated products therefore cannot be quantitative. This problem is exacerbated when the concentration of substrate in the assay is significantly lower than the K_m of CAT for chloramphenicol, which is variously reported to be between 7.5 and 60 μM (e.g., please see Sankaran 1992 and references therein). CAT assays can, however, be made truly quantitative by two methods:

- Use as substrate 1-deoxy chloramphenicol (Murray et al. 1991). This substrate, in which the residue on the C1 atom is replaced by a proton, generates a single acetylated product (3-acetyl, 1-deoxy chloramphenicol), thereby simplifying measurement of enzymatic activity. Radioactive 1-deoxy chloramphenicol is available from Amersham.
- Measure the initial kinetics of the enzymatic reaction, instead of the radioactivity accumulated after a set length of time. This will ensure that the reaction has not been performed under conditions where substrate is limiting (Desbois et al. 1992).

It is preferable to express CAT activity as the amount of product formed per milligram cell extract per unit time (i.e., as a specific activity, not simply as a percent conversion figure).

LUCIFERASE

It is luciferase activity that makes fireflies glow as they dance through the summer night air. While providing children with countless hours of twilight fun, luciferase also aids molecular biologists interested in mammalian gene transcription. With few exceptions, such as the gut of the firefly beetle and some marine organisms, luciferase enzyme activity is not found in eukaryotic cells, and thus it serves as an excellent reporter gene in promoter analysis studies. Most luciferase marker genes currently in use for promoter analysis are derived from the *luc* gene of the firefly (*Photinus pyralis*) (de Wet et al. 1985, 1987; Bronstein et al. 1994). The utility of the firefly luciferase gene was recognized by de Wet et al. (1987) who isolated the gene and expressed it as an active enzyme in mammalian cells. These authors took advantage of many years of research into the biochemistry of chemiluminescence and bioluminescence to develop a rapid and sensitive assay for luciferase activity expressed from transfected DNAs. Since this initial report, many modifications have been made to the luciferase assay including the development of modified luciferase genes with higher levels of expression, the use of different assay reagents that change the kinetics of light release, the use of small molecules that stabilize the luciferase enzyme, and the isolation and expression of luciferase genes from several different organisms (de Wet et al. 1987; Bronstein et al. 1994; Himes and Shannon 2000). The enzyme has a characteristic behavior with respect to substrate specificity, light release kinetics, allosteric modulation, and intracellular stability. Luciferase, in the presence of Mg^{2+}, catalyzes the reaction:

$$\text{ATP} + \text{luciferin} + O_2 \rightarrow \text{AMP} + \text{oxyluciferin} + PP_i + \text{light (560 nm)}$$

The luciferase enzyme encoded by the firefly cDNA contains a peptide sequence at its carboxyl terminus that targets the protein to the peroxisome compartment of the cell. The peroxisome is a subcellular organelle surrounded by a lipid bilayer that contains a variety of enzymes participating in oxidative metabolism and other aspects of intermediary metabolism. Early studies showed that overexpression of luciferase from some promoter constructs overloaded the capacity of the peroxisome to import the enzyme, leading to a constipated and sick cell. To eliminate this and other problems relating to the expression of an insect enzyme in mammalian cell lines, several alterations have been made to the original firefly luciferase cDNA, including the removal of the peroxisomal targeting sequence, the elimination of sequences predicted to give rise to RNA secondary structure, the inclusion of an optimum translational initiation sequence (a Kozak sequence), the swapping of prevalent insect codons for their mammalian counterparts, the inclusion of polyadenylation sequences upstream and downstream from the luciferase cDNA, and the removal of restriction enzyme sites within the cDNA. An example of a commercially available vector containing a highly modified luciferase cDNA is the pGL series available from Promega (please see Figure 17-4).

Other luciferase genes have been isolated from diverse marine and bacterial organisms and some of these are beginning to be used in molecular biological assays. An example is the luciferase/luciferin enzyme system from the sea pansy (*Renilla reniformis*), which utilizes a substrate different from that of firefly luciferase and which has different biochemical properties. Together, the firefly and sea pansy luciferase enzymes constitute a dual reporter assay system that is available from Promega and that allows measurement of both enzymes in the same test tube (Dual-Luciferase Reporter Assay System). The advantage of this and other dual reporter assay systems (e.g., Dual-Light by Tropix, Inc., Bedford, Massachusetts) is that both the test gene construct (linked to the firefly luciferase) and a transfection/standardization control (a constitutive eukaryotic promoter linked to the sea pansy luciferase or β-galactosidase genes) can be assayed in a single aliquot of cell lysate by the same biochemical method (light emission). It is likely that other luciferase/substrate combinations will be developed in the future that will expedite the use of this system for transcription studies. Keep in mind that the optimum assay components may differ for the luciferase enzymes of different species.

β-GALACTOSIDASE

E. coli β-galactosidase (M_r = 465,412; EC 3.2.1.23) is a tetramer of four identical polypeptide subunits, each consisting of 1023 amino acids. This polypeptide is encoded by the first gene (*lacZ*) of the *lac* operon. Fowler and Zabin (1978) determined the amino acid sequence of β-galactosidase and Kalnins et al. (1983) reported the nucleotide sequence of the *lacZ* gene 8 years later (GenBank accession number = V00296). X-ray diffraction analysis of crystals of β-galactosidase show that the tetramer displays 222-point symmetry (Jacobson et al. 1994). The individual polypeptide chains fold into five sequential domains, with an extended segment of ~50 amino acid residues at the amino terminus. This segment corresponds to the α-peptide, discussed in more detail later. β-galactosidase, whose synthesis is induced by lactose and certain other galactosides, catalyzes two enzymatic reactions:

- Hydrolysis of β-D-galactopyranosides. The enzyme is essential for the hydrolysis in *E. coli* of the disaccharide lactose (1,4-*O*-β-D-galactopyranosyl-D-glucose) into glucose and galactose.
- A transgalactosidation reaction in which lactose is converted to allolactose (1,6-O-β-D-galactopyranosyl-D-glucose), the true inducer of the *lac* operon (Müller-Hill et al. 1964; Jobe and Bourgeois 1972).

β-galactosidase also interacts with a series of synthetic analogs of lactose in which glucose has been replaced by other moieties. As described in more detail below, these include:

- The chromogenic substrates *o*-nitrophenyl-β-D-galactoside (ONPG) and 5-bromo-4-chloro-3-indolyl-β-D-galactoside (X-gal), and the fluorogenic substrate 4-methylumbelliferyl-β-D-galactoside (MUG).
- Inhibitors such as *p*-aminophenyl-β-D-thio-galactoside (TPEG), which is used for affinity purification of *lacZ* fusion proteins (Germino et al. 1983; Ullmann 1984).

β-galactosidase is tolerant of deletions and substitutions of amino acids at its amino and carboxyl termini. Up to 26 amino acids can be removed from the amino terminus and replaced with several hundred or more residues of a variety of other proteins without affecting enzymatic activity (Brickman et al. 1979; Fowler and Zabin 1983). The two carboxy-terminal amino acids are dispensable and can be replaced by other coding regions to generate active chimeric β-galactosidases (Rüther and Müller-Hill 1983).

β-galactosidase has one other extremely useful peculiarity: the amino and carboxyl domains of the enzyme need not be carried on the same molecule to generate β-galactosidase activity. Instead, two inactive fragments of the polypeptide chain, one lacking the amino-terminal region (the α-acceptor) and the other the carboxy-terminal region (the α-donor), are able to associate both in vivo and in vitro to form a tetrameric active enzyme (Ullmann et al. 1967; Ullmann and Perrin 1970). This unusual form of complementation, called α-complementation, is widely used in molecular cloning to monitor insertion of foreign DNA sequences into vectors encoding the amino-terminal (α-donor) fragment of β-galactosidase (for more details, please see the information panel on α-**COMPLEMENTATION** in Chapter 1).

Quantitative Assays

Hydrolysis of ONPG

β-galactosidase activity in bacterial cultures is usually assayed spectrophotometrically. Because the enzyme cleaves β-galactosidic linkages (please see Figure 17-15), it will hydrolyze the synthetic chromogenic substrate ONPG, generating *o*-nitrophenol, which is yellow in aqueous solution. The course of the reaction can therefore be followed by monitoring absorbance at 420 nm (Lederberg 1950).

The assay is carried out using bacterial cells that have been permeabilized with toluene or chloroform and suspended in a buffer containing high concentrations of β-mercaptoethanol (Miller 1972). After incubation with ONPG for set periods of time, the reaction is terminated with Na_2CO_3 and the OD_{420} is measured. Because the absorbance at 420 nm is a combination of absorbance by *o*-nitrophenol and light scattering by bacterial debris, it is essential to centrifuge the reaction mixtures briefly (60 seconds in a

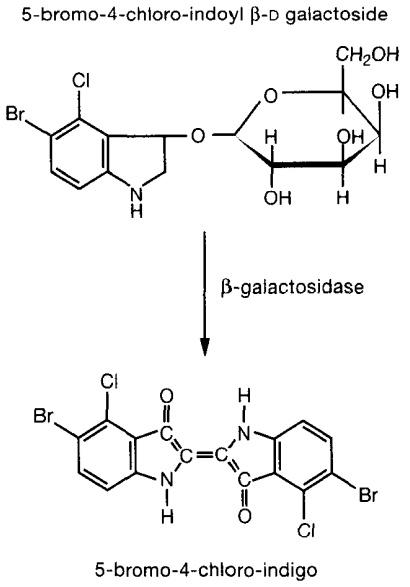

FIGURE 17-15 Reaction Catalyzed by β-galactosidase

microfuge) before measuring the OD_{420} of the supernatant. β-galactosidase activity of the bacterial culture is expressed in Miller units:

$$\text{Units of β-galactosidase} = F(1000 \times OD_{420}, t \times v \times OD_{600})$$

where OD_{420} is the absorbance at 420 nm of the reaction mixture; OD_{600} is the absorbance at 600 nm of the bacterial culture just before the enzyme activity is assayed; t is the time of the reaction in minutes; and v is volume of the culture (ml) used in the assay. Miller units are proportional to the increase in *o*-nitrophenol per minute per bacterium; 1 ml of a fully induced wild-type culture of *E. coli* contains ~1000 units of β-galactosidase activity, whereas an uninduced culture contains <1 unit.

E. coli β-galactosidase can also be expressed in mammalian cells (e.g., please see Hall et al. 1983). A slightly modified version of the Miller assay can be used to measure the activity of the bacterial enzyme expressed in cultured vertebrate cells (Norton and Coffin 1985) and yeasts (Rose and Botstein 1983; Sledziewski et al. 1990).

Hydrolysis of MUG

β-galactosidase will hydrolyze the synthetic fluorogenic substrate MUG (available from Sigma), generating 4-methylumbelliferone, which emits an intense bluish fluorescence in alkaline solution. The course of the reaction can therefore be followed fluorometrically by exciting at 364 nm and recording the light emitted at 440 nm (Roth 1969; Youngman 1987).

The fluorometric assay is ~10 times more sensitive than the spectrophotometric assay, but of course, it requires an expensive fluorometer. The fluorometric assay is useful only under special circumstances, for example, to quantitate the activity of a weakly expressed gene that has been fused to *lacZ*. The older spectrophotometric assay is perfectly adequate for almost all routine assays of β-galactosidase activity in bacterial, mammalian, and yeast cultures.

Histochemical Stains

β-galactosidase in many ways is an ideal histochemical marker. It is a stable enzyme and its expression in cultured mammalian cells, yeasts, *Drosophila*, or transgenic mammals does not appear to be either deleterious or advantageous to the host. In addition, a sensitive chromogenic assay is available (see below) that generates a nondiffusible, brightly colored product. Finally, in all but a few specialized eukaryotic cells, hydrolysis of β-galactosidic linkages is catalyzed by lysosomal enzymes that are active only under acid conditions. Because these enzymes are inactive at the neutral pH used to assay for *lacZ*, background staining is negligible.

Substituted indolyl dyes were first used in the 1950s for histochemical localization of nonspecific esterases (for review, please see Burstone 1962). These dyes work because the enzymatically released indolyl is oxidized rapidly to an insoluble indigo that can be seen readily at the sites of enzyme activity. In the early 1960s, the "indigogenic principle," as it was known, was applied successfully to the histochemical localization of mammalian glucosidase through the use of 5-bromo-3-indolyl-β-D-glucopyranoside (Pearson et al. 1961). This work was extended to β-galactosidase (Pearson et al. 1963) when a new series of dihalageno-indolyl compounds were synthesized by J. Horwitz and his co-workers at the Detroit Institute of Cancer Research (Horwitz et al. 1964). Among these compounds was X-gal, which is hydrolyzed by β-galactosidase to 5-bromo-4-chloro-indigo.

In 1967, Julian Davies, working at the Pasteur Institute, was trying to develop nondestructive histochemical stains that would allow him to distinguish between *lac*$^+$ and *lac*$^-$ colonies. This goal required finding a specific chromogenic substrate that would be hydrolyzed by β-galactosidase to highly colored products that were both nondiffusible and nontoxic. Davies was pleased to find that phenyl-β-galactosides produced a satisfactory color reaction, but he was less gratified by their conversion into toxic nitrophenols that efficiently killed the very cells he was trying to identify. Understandably, Davies, who is voluble and Welsh, found this situation a little frustrating. He expressed his Cymric indignation to Mel Cohn, a visitor to the laboratory, who fortunately remembered reading the brief paper by Horwitz and his colleagues describing the use of dihalageno-indolyl compounds as histological stains for β-galactosidase (Horwitz et al. 1964). Davies' next problem was to persuade the people at the Pasteur Institute to buy some X-gal. In those days, X-gal was not available commercially and custom synthesis cost 1000 dollars per gram. After much discussion, X-gal was ordered, synthesized, and delivered. In addition to being sensitive and nontoxic, X-gal turned out to be an extremely beautiful histochemical reagent that has generated gorgeous pictures of β-galactosidase expression in flora and fauna of all types.

In their original paper, Pearson et al. (1963) mentioned that the level of β-galactosidase activity in brain was low. This was hard for the people at the Pasteur Institute to understand, since in their mind, there was clearly a connection between β-galactosidase and intellect. When Jacques Monod first saw the brilliant blue color of induced bacterial colonies, he commented that this was proof that *E. coli* was the most intelligent organism in the world.

In eukaryotic organisms, the histochemical reaction for β-galactosidase is carried out on cryosections (Goring et al. 1987), on cultured cells and tissue sections fixed with buffered aldehyde (Sanes et al. 1986) or unbuffered formaldehyde (Login et al. 1987), or on sections fixed with glutaraldehyde in a microwave oven (Murti and Schimenti 1991). Since β-galactosidase is a cytosolic enzyme, staining is sometimes difficult to see in eukaryotic cells such as lymphocytes that contain very little cytoplasm. This problem can be eliminated by using a modified form of β-galactosidase (Bonnerot et al. 1987) that carries an amino-terminal nuclear transport signal (PKKKRKV) derived from SV40 large T antigen. The modified enzyme migrates to a perinuclear location and accumulates near nuclear pores. The resulting concentration of histochemical staining improves the sensitivity of detection of β-galactosidase and allows the enzyme to be precisely localized in complex tissues.

TABLE 17-4 Heterologous Expression of β-galactosidase

ORGANISM	ORIGINAL REFERENCE
Bacteria	Davies and Jacob (1968)
Yeast	Guarente and Ptashne (1981)
Drosophila	Lis et al. (1983)
Mammalian cells in culture	Hall et al. (1983)
Transgenic mice	Goring et al. (1987). *lacZ* had previously been used as a reporter in a recombinant retrovirus that had been injected into mouse embryos (Sanes et al. 1986).

Chapter 18

Protein Interaction Technologies

Erica A. Golemis, Peter D. Adams, Philippe I.H. Bastiaens, Margret B. Einarson, Robert J. Fisher, Alisa G. Harpur, Maxine V. Medaglia, Michael Ohh, Ilya Serebriiskii

THE PRIMARY GOAL OF THIS MANUAL HAS BEEN THE DESCRIPTION OF METHODS to identify and manipulate nucleic acids. In Chapters 15, 16, and 17, the focus broadened to address the proteins encoded by nucleic acids of interest and detailed means to express these proteins in bacteria and a variety of eukaryotic host organisms. This chapter provides an introduction to a number of current methodologies that are used to begin to understand the interactions of proteins.

Different biological subdisciplines ask distinct questions about protein-protein interactions. Broadly defined, much of the current effort directed at the study of proteins can be divided into four subcategories:

- ***Biochemical and structural studies*** of protein interactions with other proteins or small ligands.
- ***Mechanistic studies*** that delve into the networks of protein interaction that mediate signal transduction, the cell cycle, and gene expression.
- ***Genetic studies,*** in which evidence bearing on protein interactions is initially inferred from patterns of genetic interference or epistasis.
- ***Cell biological studies,*** which are frequently focused on localization and colocalization of proteins in dynamically reorganizing cells.

Within these biological contexts, many discrete questions may be posed about the interactions of any one protein. For example, does the protein function alone, as part of a small complex (e.g., dimerically), or as part of a large assembly? Would the protein be likely to associate with high affinity with a single partner molecule or would any interactions involve multiple lower-affinity contacts across a broader surface? Does the protein utilize a canonical and separable domain for interaction with a defined motif on a partner protein? If so, how is specificity for partner proteins conferred and how are nonspecific interactions with other proteins containing similar motifs suppressed? Is the protein subject to transient interactions, such as might occur between particular kinases or other modifying enzymes and substrates? Do modifications such as phosphorylation and glycosylation affect interactions of the protein and other partner molecules? Do protein interactions regulate the catalytic function or substrate specificity of proteins with enzymatic activity? Do mutations that affect protein interactions, whether naturally occurring or experimentally induced, have clear measurable biological effects? Can therapeutic agents be developed that specifically modulate protein-protein interactions? Do two proteins of predicted common function colocalize in such a way as to enable direct interactions? Does the affinity of a protein-protein interaction measured in vitro reflect the strength of the interaction in vivo? If a protein interacts simultaneously with multiple partners, are the interactions competitive, additive, or synergistic? How does one begin to identify such arrays of partners?

These and other questions devolve into several discrete classes of inquiry. In one class, the goal is to identify every possible interacting set of proteins for the protein of interest. In this case, physiological significance is temporarily downplayed in an effort to cast a broad net. In the second class, where interacting proteins of interest have been defined, the goal is to establish physiological significance by detailing the biological function and impact of their interactions. In this case, it is essential to study the interaction under conditions that correspond as closely as possible to the endogenous situation. In the third class, an interaction has been identified, and validated as physiological, and is reasonably well understood. Here, the goal is to devise high-throughput methodologies to identify agents that modulate the interaction in desirable ways. No single technique is optimal to address all of the questions or classes of interest; however, by com-

bining experimental approaches, it is possible to make considerable progress. The techniques presented here bear on all three described classes.

A complete review of the origins and nature of methods to analyze and characterize protein interactions is beyond the scope of this chapter. An excellent list of references has been compiled by Phizicky and Fields (1995), along with an extensive discussion of parameters that can be crucial in choosing a specific technique to detect particular protein interactions. In addition, space does not allow presentation of all available interaction techniques. Thus, for example, traditional biochemical copurification methodologies have been omitted. One more recently developed approach, omitted here but worth considering for some applications, is the use of mass spectrometry. This technique has been used with recent striking success in large-scale biochemical applications, identifying constituents of large complexes composed of multiple proteins that associate to perform a specific function or group of functions. For useful introductions to this method, please see Kuster and Mann (1998), Rigaut et al. (1999), and Yates (2000). Another field with direct relevance to protein interactions is that of molecular modeling, which combines information about protein domains, patterns of evolutionary conservation, and structural coordination to predict interaction patterns. For discussions of modeling approaches, please see Aitken (1999), Enright et al. (1999), and Marcotte et al. (1999).

This chapter focuses on a number of basic techniques that have gained wide acceptance and are amenable to use by individual investigators focused on the study of specific proteins.

- Bacterially expressed glutathione *S*-transferase (GST)-fused proteins are used to perform direct measure of protein-protein interactions and for affinity purification. Far western analysis (Blackwood and Eisenman 1991; Kaelin et al. 1992), in which a labeled protein probe is used to probe for interactions with defined or library-encoded proteins immobilized on a membrane, is an offshoot of conventional western analyses. The GST pulldown (Kaelin et al. 1991) is a related technique in which either (1) a single defined in-vitro-expressed protein, (2) an unknown protein present in a pool of proteins in a cell lysate, or (3) an unknown protein expressed from a pool of in-vitro-translated cDNAs is collected by its interaction with a fusion protein composed of the target protein linked to a GST moiety. The complex is then isolated through the binding of the GST moiety to glutathione-coupled beads, followed by purification. This technique can also be used to derive semiquantitative estimates of the affinity of protein-protein interactions.

- In phage display (Smith 1985), a library of proteins (Bass et al. 1990) or peptides (Cwirla et al. 1990; Scott and Smith 1990) is expressed as fusions to a surface-displayed coat protein of a filamentous phage such as M13. Proteins expressed in this manner can be probed using strategies similar to those utilized for screening conventional bacterial expression libraries with antibodies or GST-fused probes. The life cycle and culturing properties of the filamentous bacteriophage facilitate the generation of libraries of particularly high complexity (up to 10^{10} individual constituents), thereby maximizing chances of finding a novel interaction or discovering mutations that perturb a predefined interaction in a meaningful way. For the theory and practice of affinity selection techniques used with phage display-based systems, please see Barbas et al. (2001) and the information panel on **FILAMENTOUS PHAGE DISPLAY** at the end of this chapter.

- Two-hybrid systems (Fields and Song 1989; Chien et al. 1991; Durfee et al. 1993; Gyuris et al. 1993; Vojtek et al. 1993) also mimic natural systems. These systems utilize the genetic power of the yeast *Saccharomyces cerevisiae* as host for analysis of protein-protein interactions. The two-hybrid system (Fields and Song 1989) artificially mimics the natural process of transcription, building on observations that transcriptional activators can be separated into discrete regions

corresponding to DNA-binding domains and transcriptional activation domains (Brent and Ptashne 1985; Hope and Struhl 1986). In the standard two-hybrid approach, the association of an activation domain with a DNA-binding domain is rendered dependent on a bridging function provided by two interacting proteins, fused respectively to the DNA-binding domain and the activation domain; productive interaction leads to transcriptional activation of reporters whose products can be easily scored on the basis of colorimetric tests or the ability of the novel *trans*-activator to transcribe a yeast gene essential for growth of the organism. The ease of manipulation and genetic power of yeast allow assessment of a large number of interactions at low cost, and with the potential for high throughput, as exemplified in recent genomic applications (e.g., please see Fromont-Racine et al. 1997; Uetz et al. 2000; Walhout et al. 2000).

- Immunological studies have long used naturally generated antibodies as tools to probe diverse cellular functions (Harlow and Lane 1988). Coimmunoprecipitation — the detection of a protein by immunoprecipitation with an antibody directed against a partner molecule — has been used for at least two decades (e.g., please see Moon and Lazarides 1983) and provides a direct method of establishing protein association in either in vitro or in vivo situations. In parallel, antibodies have been developed as tools to localize specific proteins in the context of cellular ultrastructure. Initial analysis of the cellular cytoskeleton with antibodies to actin (Lazarides and Weber 1974) developed into the current set of colocalization strategies to assign proteins with suspected common function to overlapping compartments (e.g., please see Weber et al. 1982). More recent refinements include fluorescence resonance energy transfer (FRET), in which the transfer of energy from an excited donor fluorophore carried by one protein is transferred to an acceptor fluorophore carried by another protein. Association between the two proteins results in a quantifiable change in the ratio of intensity of the two labeled protein probes, which is a dynamic measure of their proximity within a living or fixed cell (Adams et al. 1991). One advantage of FRET is that proteins can be made fluorescent in a variety of ways, either by reaction with labeled antibody, or direct coupling of dye, or by synthesis as a fusion protein with a form of green fluorescent protein (GFP).
- Finally, biochemical approaches designed to allow rapid measurement of binding constants and other physical parameters associated with protein-protein or protein-peptide interactions led to the development of surface plasmon resonance (for early descriptions of the technique, please see Place et al. [1985] and Jonsson et al. [1991]). In this approach, one protein to be analyzed is secured to a flat sensor chip in a flow chamber, after which a solution containing a prospective interacting partner is passed over the first protein in a continuous flow. Light is directed at a defined angle across the chip, and the resonance angle of reflected light is measured; the establishment of a protein-protein interaction causes a change in this angle. By calculating such changes over time, equilibrium binding constants and on and off rates can be readily estimated. Its speed and high sensitivity make this technique extremely attractive for many forms of analyses.

The two-hybrid and GST-fusion-based screening approaches described in Protocols 1, 2, and 3 are all suitable in applications that cast a broad net. For studies addressing physiological validation and exploration of interactions, coimmunoprecipitation of endogenous proteins (Protocol 4) and FRET (Protocol 5) are clearly preferred. For the rapid analysis of previously defined interactions, two-hybrid and GST pulldown assays have found some significant use; surface plasmon resonance (Protocol 6) obviously has much potential power.

It is important to note that the intrinsic nature of particular proteins dictates, to some extent, which techniques can be gainfully used for analysis of protein-protein interactions. For

example, if an interaction is likely to be mediated by posttranslational modifications that occur only in eukaryotes, phage display is not likely to be useful. If a protein interacts simultaneously with multiple partners in a complex fashion, yeast two-hybrid assays may not be of great value. As a basic caveat, many of the techniques described here do not prove whether an observed interaction is direct or indirect, i.e., whether it is mediated by additional proteins present in a pooled lysate or expressed in yeast. If the goal is to establish direct interactions, a method using pure proteins eventually must be used. Anticipating these kinds of potential problems in advance can save much time and effort that otherwise may be invested in an inappropriate assay system.

Beauty is a harmonious relation between something in our nature and the quality of the object which delights us.

Blaise Pascal (1623–1662)

Two-hybrid and Other Two-component Systems

Erica A. Golemis and Ilya Serebriiskii
Fox Chase Cancer Center, Philadelphia, Pennsylvania 19111

Most PROTEINS CONSIST OF MULTIPLE DOMAINS of partially or completely separable function. Significantly, these multiple domains in many cases do not need to be physically attached by covalent bonds; instead, activities of the intact protein can be reproduced by bringing individual domains into intimate contact. This basic property has been exploited in screening systems to measure the affinity of protein-protein interactions in vivo and to identify novel protein-protein interactions. Protein interactions so exploited have spanned a range of biological functions, including α-complementation (Ullmann et al. 1967), ubiquitin-mediated targeting for protein degradation (Johnsson and Varshavsky 1994), reconstitution of repressor function (Hu et al. 1990), and generation of a transcriptional activator by combining DNA-binding domains with transcriptional activation domain functions (Fields and Song 1989). This last approach has developed into the two-hybrid system (Figure 18-1) and has become a standard and powerful tool for protein analysis. As the system matured, it has spun off a series of second-generation-related technologies that promise to greatly expand its utility.

TWO-HYBRID SYSTEMS

Starting Point

Two-hybrid systems were initially designed to identify and estimate the affinity of interactions between pairs of single proteins (Fields and Song 1989). However, because two-hybrid systems consist of a substantial number of components (plasmids for bait, prey, and reporter, as well as integrated reporters), it was initially uncertain whether they could accurately distinguish interactions of physiological relevance from lower-affinity interactions of questionable relevance. After several years of use by the scientific community, and after controlled tests of measured interaction affinity (Estojak et al. 1995), it became apparent that for the majority of bait proteins (>75%), a two-hybrid approach could be effectively used both to screen expression libraries for novel interacting proteins and to study interactions between known partners. Given this demonstrated effectiveness of the basic two-hybrid systems (Chien et al. 1991; Durfee et al. 1993; Gyuris et al. 1993; Vojtek et al. 1993) at solving a two-body problem, interest turned to the possibility of extending two-hybrid system capabilities to address more complex interactions involving greater numbers of system components.

Modified Baits

Initially, all two-hybrid systems used the yeast *S. cerevisiae* as a host cell. This proved to be a limitation in some studies of bait proteins from higher organisms, when posttranslational modifi-

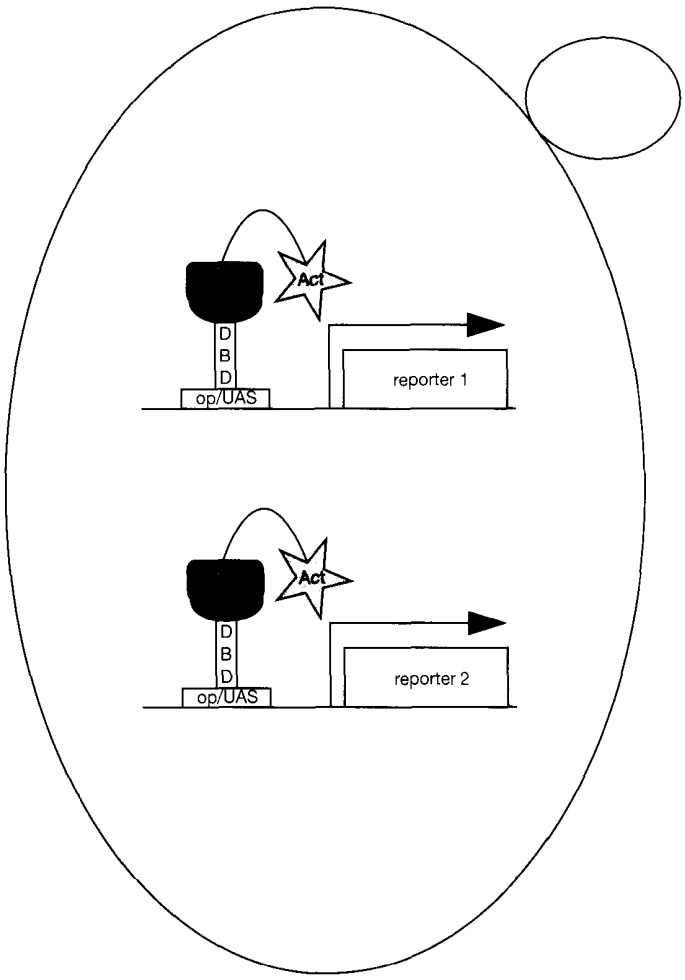

FIGURE 18-1 The Two-hybrid System

Diagram of the basic two-hybrid system to detect interactions between two proteins in a yeast cell. As shown, a DNA-binding domain (DBD)-fused bait protein of interest interacts with an activation domain (Act)-fused to a partner protein (Prey), either known or selected from a cDNA library. The interacting pair binds a specific sequence motif (op, operator, or UAS, upstream activating sequence, depending on whether LexA or GAL4 is used as a DBD), activating transcription of two separate reporter genes.

cations required to enable certain protein-protein interactions were not possible because of the absence of the appropriate modifying enzymes in yeast. The problem was especially severe in the case of baits relevant to higher eukaryotic signal transduction, given the prevalence of site-specific phosphorylation by tyrosine kinases as a means of regulating protein-protein interactions.

To solve the problem, Osborne et al. (1995, 1996) set up a two-hybrid screen in a strain of yeast that had been engineered to express the mammalian tyrosine kinase Lck. This enabled them to successfully screen a library for proteins that could bind specifically to a bait, derived from an IgE receptor, that carried phosphorylated tyrosine residues. Other groups have since had similar successes expressing other kinases of mammalian origin, and this approach has become generally useful (Figure 18-2). One potential drawback to this type of approach arises if the overexpressed modifying enzyme is deleterious in yeast: For example, constitutive expression of Src is generally toxic, probably due to the broad specificity of its phospho-kinase activity. In general, this approach is most success-

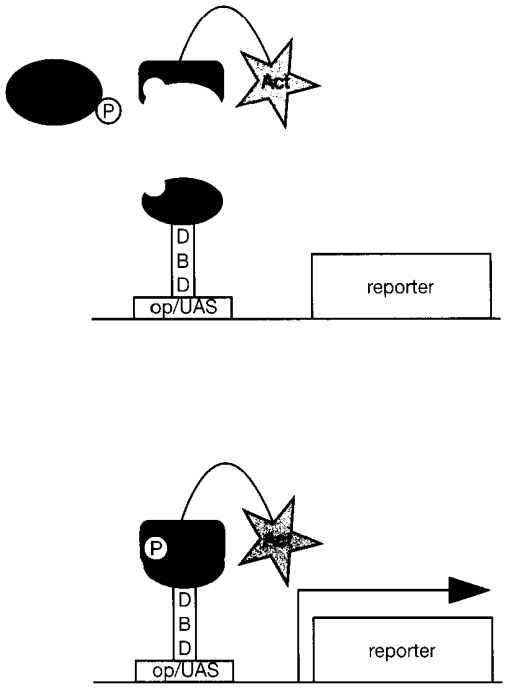

FIGURE 18-2 Modified Bait

A prey is unable to interact with a bait in the absence of posttranslational modification of the bait. A coexpressed kinase phosphorylates the bait protein, creating a binding interface for the prey.

ful either when working with a kinase or other posttranslational modifier of circumscribed substrate specificity or when placing the modifier under control of an inducible or repressible promoter.

Peptides

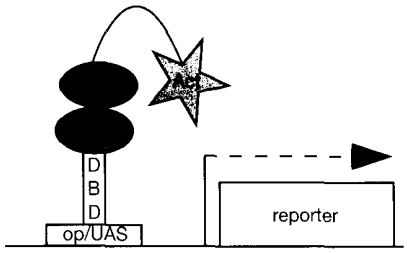
Extending the capacity of a two-hybrid system to interactions between proteins and very small (<16 residue) peptides was of considerable interest for several reasons. One anticipated benefit was the ability to identify minimal sets of conserved sequences required for interaction with a bait. A second benefit was the identification of small peptides that could regulate the activity of a bait protein, either by competitive binding and blocking of an interaction between a protein and its normal partner or by interfering with the protein's intrinsic catalytic activity.

In two independent demonstrations, small specific interacting peptides were successfully selected from a library: M. Yang et al. (1995) used a retinoblastoma (Rb) bait to isolate multiple peptides containing the canonical LxCxE Rb-interacting motif, whereas Colas et al. (1996) isolated Cdk2-interacting peptides (termed aptamers), some of which proved to inhibit Cdk2 kinase activity. The peptide libraries used in the two studies were significantly different in design, with the peptides in one case fused to the carboxyl terminus of the GAL4 activation domain (M. Yang et al. 1995), and in the second case, constrained on both ends within a loop on the surface of the cytoplasmic protein thioredoxin (Colas et al. 1996). The fact that both approaches worked well implies considerable flexibility in peptide-protein recognition. Peptide aptamers can not only be identified from genetic screens, but also be used as baits in further screens for interacting proteins, thus helping to elucidate complex genetic networks, such as the yeast mating pheromone response pathway (Geyer et al. 1999; Norman et al. 1999).

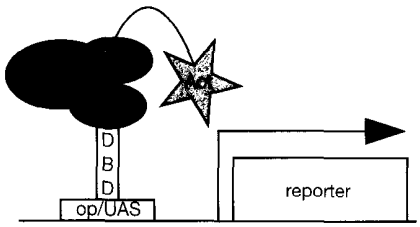
In a related application, Stagljar et al. (1996) described a rapid method to identify small interaction-specifying sequences within larger proteins. In this approach, cDNA encoding a known interacting protein was sheared by sonication and cloned into a prey vector using the shotgun technique. The resulting targeted library was cotransformed with the bait of interest, and direct selection was made for fragments capable of conferring interaction (Stagljar et al. 1996). The low-tech, cost-effective quality of such an approach makes it a useful addition to studies of protein function.

Ternary Complexes

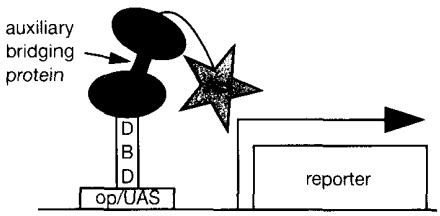
A single protein may be strongly bound to a multiprotein complex by interacting simultaneously and at low affinity with several different components of the complex. Some bait proteins that normally exist in a multisubunit complex may therefore interact with individual partners with affinity inadequate to be detected by the two-hybrid system. Coexpression of the bait with a previously defined partner protein might provide an interface that supports stronger interactions, allowing the identification of additional complex members (Figure 18-3). A number of groups



weak interaction: minimal reporter activation



strong ternary interaction: strong reporter activation



strong interaction mediated by a bridge: strong reporter activation

FIGURE 18-3 Ternary Complexes

A bait and prey, while part of the same higher-order complex, either form transient contacts or do not directly interact, resulting in little or no activation of reporter genes (*top*). Coexpression of a third partner (Auxiliary) known to associate with the bait and to be a component of the complex may stabilize previously weak interactions between bait and prey (*middle*) or act as a bridge to recruit prey to bait (*bottom*).

have demonstrated that coexpression of an "auxiliary bait" is sufficient to strengthen such ternary interactions (Tomashek et al. 1996; Zhang and Lautar 1996; Tirode et al. 1997). This straightforward approach has been used successfully to identify caspase substrates (Kamada et al. 1998; Van Criekinge et al. 1998) and to analyze a four-subunit protein complex (Pause et al. 1999).

The ternary "partner" in a three-component interaction need not necessarily be a protein, but instead may be a hormone or a drug. Chiu et al. (1994) first described the use of an FKBP12 bait in conjunction with rapamycin to identify the RAPT1 protein from a library, subsequently demonstrating that the interaction was dependent on the presence of rapamycin. In a separate study, Lee et al. (1995) were able to identify proteins that interacted with the thyroid hormone receptor in the presence or absence of thyroid hormone. The primary constraint on this use of the two-hybrid system is the permeability of yeast to the ternary small molecule of choice.

Bait and Hook

Further applications of two-hybrid systems that promise to be particularly powerful are strategies to study protein-RNA or protein-drug interactions. In these strategies, a standardized "hook" is used to display an RNA molecule or a drug to the incoming prey, forming a nonprotein bridge to the reporter gene (Figure 18-4).

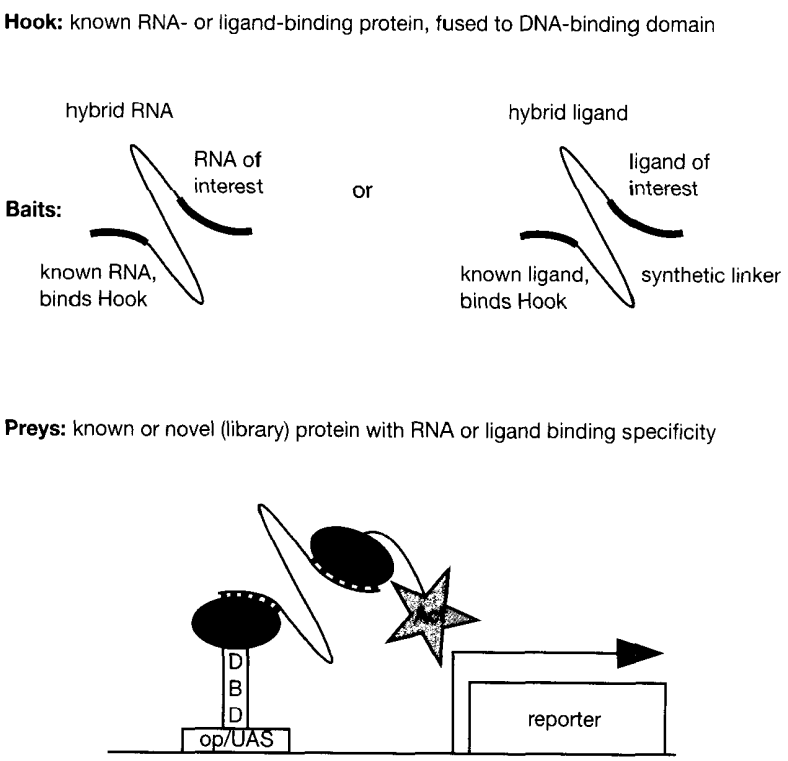


FIGURE 18-4 Bait and Hook

In this strategy, the DNA-binding domain (DBD) is fused to a defined protein with the capacity to bind either RNA or a chemical ligand. This fusion construct, termed "Hook," is coexpressed with a hybrid RNA (Bait) containing the RNA-binding site for the Hook and a novel probe sequence or, alternatively, yeast containing the Hook are grown in the presence of a chemically synthesized molecule (Bait) that fuses the Hook ligand and the actual probe sequence. The prey constitutes an activation-domain-fused protein as in other two-hybrid manifestations; in this case, the protein has the property of binding the probe RNA or chemical ligand.

In one example used to identify RNA-interacting molecules, a DNA-binding domain was fused to the coat protein of the MS2 phage, which is known to bind a consensus RNA stem-loop. The RNase P (polymerase III) promoter was then used to express high levels of a synthetic RNA comprising the MS2 target stem-loop and the actual RNA target of interaction, the iron response element (IRE). When the prey, consisting of the iron regulatory protein fused to an activation domain, was bound to the IRE sequence, it was able to activate expression efficiently of the bait-responsive reporter (SenGupta et al. 1996). This system is commercially available from Invitrogen. A similar system has also been built around a DNA-binding domain, a bait derived from the human immunodeficiency virus (HIV) Rev protein, and a Rev response element (RRE) fused to RNA (Putz et al. 1996). Both systems have been used to screen libraries and have identified specific RNA-interacting molecules (e.g., please see Putz et al. 1996; Wang et al. 1996; Park et al. 1999b; SenGupta et al. 1999). A major problem with the technique is a relatively high background of false positives due to nonspecific RNA-interacting proteins (Park et al. 1999a).

To detect interactions between proteins and chemical ligands, the hook was constructed as a fusion between a DNA-binding domain and the hormone-binding domain of the glucocorticoid receptor. To generate a bait, dexamethasone (the glucocorticoid receptor ligand) was conjugated to the compound of interest, FK506. Using this hook-bait combination, it was possible to analyze interactions between FK506 and its binding partner, FKBP12. This system appears to be genetically robust, as it was used to isolate FKBP12 from a cDNA library in a blind screen and to discriminate FKBP12 mutants with high and low affinity for FK506 (Licitra and Liu 1996). A similar strategy could be adapted to the study of multiple drugs of pharmacological interest, although a potential limitation is the poor permeability of yeast to some classes of compounds.

Reverse Two-hybrid

The original two-hybrid systems relied on transcriptional activation of selectable markers to score protein-protein interaction. In a reciprocal approach, two-hybrid activation of counterselectable markers was used to develop an assay for loss of protein-protein interactions (Figure 18-5). In the first description of this approach, Vidal et al. (1996a,b) described a rapid screen for mutations that disrupted the ability of the transcription factor E2F1 to associate with its partner DP1. In the absence of interaction between the two partner proteins, transcription of the *URA3* reporter gene was abolished, thereby preserving the viability of yeasts grown in the presence of 5-FOA, a metabolite toxic to the uracil pathway. Application of a secondary positive selection eliminated mutations that resulted in complete loss of translation of the E2F1 bait. This system has been used successfully with other pairs of interacting proteins (Yasugi et al. 1997). In addition to its use in mutational hunts, this type of reverse selection may theoretically be used to screen drugs or peptide ligands that disrupt protein-protein interactions. A first elegant example has been published by Huang and Schreiber (1997). Similar results can be achieved with a "split-hybrid" system (Shih et al. 1996). Upon interaction, expression of the tetracycline repressor (TetR) is induced, which binds to and represses transcription from a TetR-operator-controlled *HIS3* gene. Disruption of the original protein interaction results in elimination of TetR transcription, which in turn restores *HIS3* synthesis and allows cells to grow in the absence of histidine. This approach was used to identify mutants of the cAMP response element-binding protein (CREB) that no longer associate with CREB-binding protein (Shih et al. 1996).

Dual Bait

The original two-hybrid systems register the interaction of single bait–single prey combinations through activation of two bait-responsive reporter genes. If the complexity of the system is

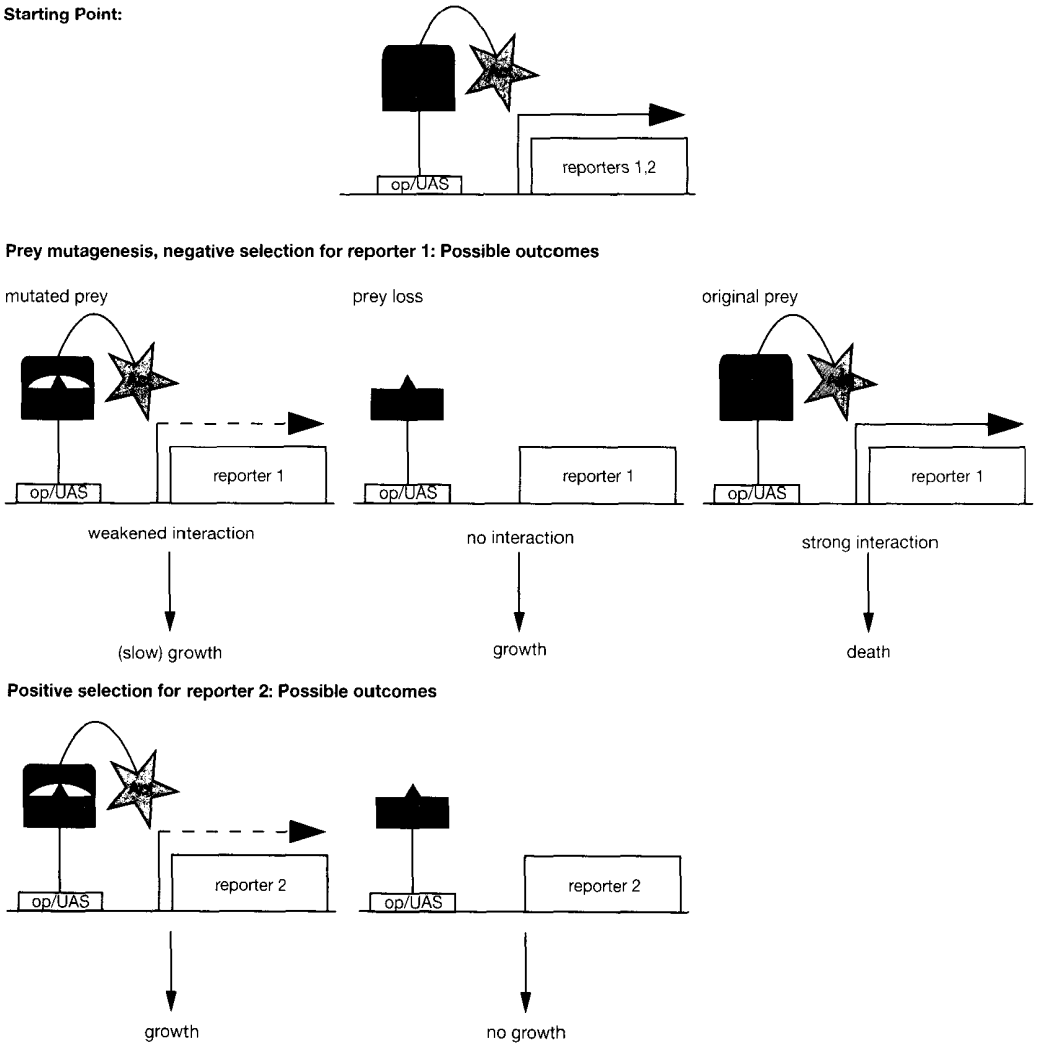

FIGURE 18-5 Reverse Two-hybrid

As shown, mutations that weaken the interaction between bait and prey are selected in two steps. As a starting point, a bait-prey interaction is constructed using two reporters (one of which is counterselectable) whose normal expression is dependent on an interaction event. Following mutagenesis of the prey construct, a first counterselection is applied; yeast in which the interaction has been reduced, or the prey has been lost, continue to grow, whereas yeast with nonmutated (original) preys continue to activate reporter strongly, and are killed. At a second positive selection stage, only yeast containing a prey capable of interacting with the bait survive.

increased so that yeast expresses a single prey and two independent baits, each targeted to distinct reporter genes, several novel applications become possible (Figure 18-6). In one scenario, it is possible to screen in a single step for mutations (or for coexpressed proteins, or pharmaceutical agents) that selectively alter the interaction between a prey and one of two distinct partners. For genomic applications (see below), dual baits facilitate the assignment of protein interaction patterns. In library screens, the presence of two independent baits with distinct reporter readouts would allow the performance of two separate interactor screens from a single library

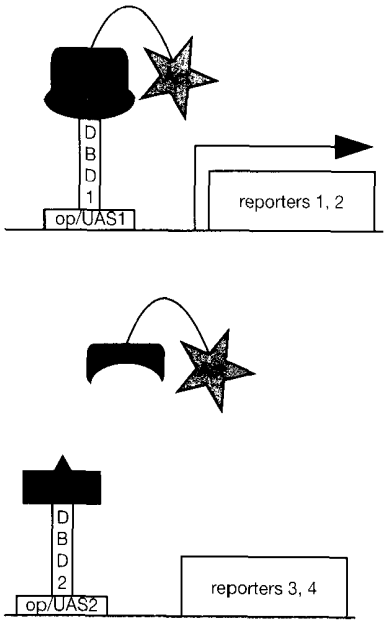

FIGURE 18-6 Dual Bait

This method discriminates between the interactions of a single prey with two different baits. The first DNA-binding domain fusion protein (DBD1-Bait) drives the expression of reporters 1 and 2 through op/UAS1. A second separate DNA-binding domain fused to a distinct bait (DBD2-Bait*) directs expression of reporters 3 and 4 through op/UAS2. This reagent set can be used to select preys that interact with the DBD1-Bait but not DBD2-Bait* from a library. Alternatively, if a prey interacts with both DBD1-Bait and DBD2-Bait*, it can be used to select for mutations or molecules that selectively disrupt the interaction with one of the two baits.

transformation; furthermore, each screen could be used as a control to eliminate false positives from the other screen.

One limitation slowing the development of successful dual bait strategies has been the difficulty in devising combinations of markers and reporters to drive expression of all required components in yeast. Initial versions of dual bait approaches have solved the problem by utilizing single reporters, rather than the normal double reporters for each of the two baits (Jiang and Carlson 1996; Inouye et al. 1997; Xu et al. 1997). A slightly improved version using a double reporter for one bait, and a single reporter for the second bait, was described by Grossel et al. (1999). A fully developed incarnation of this approach retains two separate reporter systems for each of two independent baits and has been able to distinguish clearly specific interactions by a number of criteria (Serebriiskii et al. 1999). This version may prove to be particularly useful for screening of high-complexity libraries where high specificity and suppression of false positives are mandatory. Dual-bait reagents have been used to identify mutations in Pak1 kinase that selectively reduce the affinity of the kinase for either of two partners, the Cdc42 or Rac GTPases (M. Reeder and J. Chernoff, pers. comm.). These techniques may also be useful when combined with approaches such as those described by Marykwas and Passmore (1995) to characterize specific mutant alleles responsible for disrupting protein-protein interactions.

STREAMLINING THE BASIC TECHNIQUE: MISCELLANEA

A number of investigators have generated modified reagents or protocols designed to improve the functioning of the "basic" two-hybrid system; some of these reagents may also find use in more recently developed systems (see above) or in genomic applications described below. Improved vectors with extended polylinkers and/or altered reading frames (James et al. 1996; Roder et al. 1996) should facilitate construction of activation domain (AD) and DNA-binding domain (DBD) fusions. Both AD and DBD can now be fused to proteins of interest at either the amino- or carboxy-terminal end (Beranger et al. 1997; Brown and MacGillivray 1997) to minimize the risk of sterically blocking domains involved in protein interactions. New vectors conditionally expressing auxiliary baits facilitate three-hybrid analysis (Tirode et al. 1997; Fuller et al. 1998), whereas integrating, low-copy, or conditionally expressing vectors yield more robust results in traditional two-hybrid analysis (e.g., please see Durfee et al. 1999). New reporter genes that have the potential to be more sensitive and/or more reliable and convenient are being introduced: yeast α-galactosidase (MEL1) (Aho et al. 1997), *Escherichia coli* β-glucuronidase (Hirt 1991; Serebriiskii et al. 1999), and GFP (Mancini et al. 1997; Cormack et al. 1998; Mayer et al. 1999). The use of suitable antibiotic resistance genes (e.g., Zeomycin resistance, Zeo^R, and others) as selectable plasmid markers in yeast (Huang and Schreiber 1997) increases the number of plasmids that can be simultaneously expressed in a single yeast, facilitating the set-up of three-hybrid or reverse two-hybrid experiments. Other vector sets containing alternate antibiotic resistance genes (Watson et al. 1996; Bannasch and Schwab 1999) reduce the number of steps required in recovering positive library plasmids to *E. coli* after a screen.

Beyond vectors, a number of related techniques have the potential to speed two-hybrid analysis, including (1) the use of agarose overlays to score activation of *lacZ* and β-glucuronidase reporter genes (Duttweiler 1996), (2) polymerase chain reaction (PCR) screening of putative positive clones (Kaiser et al. 1994; Klebanow and Weil 1999), and (3) wider use of robotic microtiter-plate-based replica techniques (Buckholz et al. 1999).

Reagents from the two workhorse two-hybrid systems, derived separately from GAL4 and LexA, have long been described as incompatible because of the overlapping use of selective markers. However, a recent report suggests that reagents sometimes can be combined, reducing the need to reclone baits/preys when working with different sets of clones (Dagher and Filhol-Cochet 1997). In addition, increased use of Zeo^R and other antibiotic markers (Huang and Schreiber 1997) may facilitate exchange of libraries between the GAL4 and LexA- or cI-based systems.

A recombination-based technique to (re)construct two-hybrid plasmids rapidly in yeast was developed by Petermann et al. (1998). This technique does not require plasmid isolation and intermediate hosts, and it can be used to facilitate interaction mating and/or retesting of interactions by retransformation. Using this approach, PCR-amplified library inserts, obtained from primary positive transformants, can be rapidly converted into plasmids; alternatively, this approach can be used to construct entire two-hybrid libraries (Hua et al. 1998; Fusco et al. 1999) or to generate full-length cDNA molecules from yeast two-hybrid clones and RACE (rapid amplification of cDNA ends) products (Hemenway et al. 1999).

Considerable effort has gone into solving the problem of false positives in two-hybrid screens. Parameters affecting isolation of false positives in two-hybrid screens have been studied, and some new approaches to their detection have been developed (Serebriiskii et al. 2000). A host strain that contains three reporter genes under the control of different GAL4-inducible promoters allows elimination of virtually all false positives specific to the promoter element in the GAL4 system (James et al. 1996); and, as discussed earlier, two-bait systems should help in rapid detec-

tion and elimination of false positives at an early stage in library screens (e.g., please see Serebriiskii et al. 1999). A database of false positives available on the World Wide Web will help to validate cDNAs obtained from screens (http://www.fccc.edu/research/labs/golemis/InteractionTrapInWork.html). This and other sites on the Internet provide a wealth of information on setting up and analyzing results of two-hybrid analysis; descriptions of the available vectors, libraries, maps, and sequences; protocols and references; full texts of important articles on two-hybrid systems; and even information on upcoming two-hybrid courses (if the investigator should become overwhelmed by the options and reagents available).

SOLUTIONS FOR ACTIVATING BAITS: "SWAPPED" TWO-HYBRID AND RNA POLYMERASE-III-BASED TWO-HYBRID SYSTEMS

One of the major limitations of the two-hybrid system is that the bait protein (traditionally fused to DBD) should not be self-activating for transcription. The first system to overcome this limitation was the so-called "swapped system" (Du et al. 1996) in which a gene encoding a protein of interest was fused to an activation domain and screened against a library of DBD-fused proteins. In this initial work, the majority of isolated clones were self-activating DBD fusions, a problem that can be alleviated by prescreening as discussed in the information panel on **GENOMICS AND THE INTERACTION TRAP**.

A more radical solution is provided by a two-hybrid system based on RNA polymerase III. The promoter of the essential *SNR6* gene is responsive to polymerase III; reporter genes have been developed in which a binding site for GAL4 is incorporated within the context of the *SNR6* promoter. This system detects the interaction between a GAL4-fused bait and a τ138-fused prey protein; upon interaction, τ138 recruits the remaining components of the TFIIIC factor, enabling the polymerase III machinery to transcribe the yeast essential gene *SNR6*. There are no known transcriptional activators of polymerase III, and polymerase II *trans*-activators do not regulate polymerase-III-mediated transcription in yeast. In fact, as demonstrated, strong transcriptional activators such as GAL4 or VP16 fused to GAL4 DBD were quite incapable of activating transcription of the UAS(G)-*SNR6* gene (Marsolier et al. 1997; Marsolier and Sentenac 1999). Additional modifications have allowed the development of one- and three-hybrid approaches based on this system.

SUMMARY

The number of potential uses for two-hybrid-derived systems has expanded at a breathtaking pace during the last several years. Perhaps because the basic system reagents — yeast and plasmids — are inexpensive and relatively easy to manipulate, a great many investigators have felt free to extend the limits of the technology. The resulting demonstration of innovation and creativity has led to the generation of a great number of basic tools that can now be recombined for use in ever more sophisticated screens (e.g., please see Liberles et al. 1997). If the next few years match the pace of the preceding years, it may be that screening a genome's worth of coding information will not be as daunting a task as it now seems (please see the information panel on **INTERACTION TRAP AND RELATED TECHNOLOGIES** at the end of this chapter).

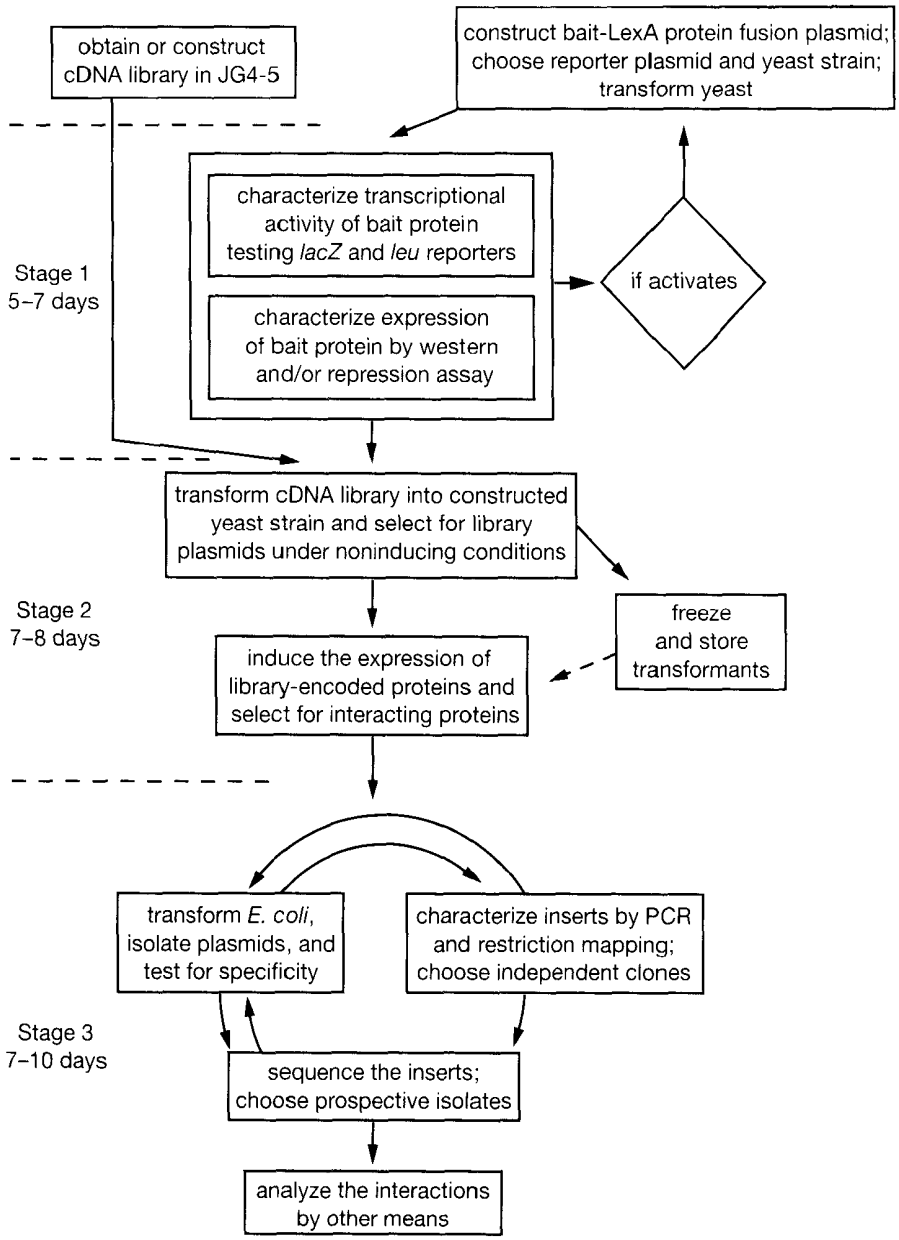

FIGURE 18-7 Flowchart: Two-hybrid System

Flowchart, controls, and library screen. See text for details. (Redrawn from Spector et al. 1998.)

The following protocol for the execution of an interaction trap/two-hybrid screen is divided into three stages: Characterization of a Bait-LexA Fusion Protein, Selecting an Interactor, and Second Confirmation of Positive Interactions. In Stage 1, characterization of a novel bait is described, with attention to controls to increase the likelihood that the bait will function effectively. In Stage 2, transformation of a cDNA library and selection of positive interactors are detailed. In Stage 3, a series of first-order and subsequent control experiments are outlined to establish the biological significance of an interacting protein. A flowchart illustrating the order and approximate time necessary to perform various stages is shown in Figure 18-7.

STAGE 1: Characterization of a Bait-LexA Fusion Protein

An interactor hunt begins with the generation of a construct that expresses the protein of interest fused to the bacterial protein LexA (a pBait). This construct is cotransformed with a *lexAop-lacZ* reporter plasmid into a yeast strain containing a chromosomally integrated *lexAop-LEU2* reporter gene. The pBait is analyzed in control experiments to establish whether it can be used in a two-hybrid screen. These controls determine whether the bait is expressed as a stable nuclear protein of the correct predicted size that does not independently activate transcription of the *lexA* operator-based reporter genes to any significant degree. Depending on the result of these controls, the bait may be used directly to screen a library under conditions established during validation of the bait. Alternatively, different combinations of reporter strains/plasmids can be used, or the bait can be modified according to provided guidelines. Tables 18-1 and 18-2 describe the features and various functions of the plasmids used in construction and testing of the plasmid carrying the gene encoding the bait fusion protein. The structures of the LexA fusion and activation domain fusion vectors are shown in Figure 18-8.

In choosing how to construct a bait, it is important to remember that the assay depends on the ability of the bait to enter the nucleus and requires the bait to be a transcriptional *non*-activator. Therefore, if the chosen protein has obvious sequences that confer attachment to membranes, or sequences that are transcriptional activation domains, these should be removed. Although some investigators have attempted to use two-hybrid systems to find associating partners for proteins that are normally extracellular, this is an unproven strategy and should be regarded as a high-risk venture.

The following methods utilize basic yeast media and transformation procedures. It is good practice to move expeditiously through the characterization steps described below. If plasmids are retained for extended periods of time in yeast maintained on Parafilm-wrapped selective plates at 4°C, the expression levels of proteins will gradually drop. After 2 weeks or so, results may become somewhat variable. If delays are foreseen, the best options are either to repeat transformations with bait protein and the *lexAop-lacZ* reporter before moving on to library screening or to store at –70°C a stock of yeast transformed with bait and reporter constructs that can be thawed immediately before library screening.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

2x SDS gel-loading buffer

100 mm Tris-Cl (pH 6.8)
200 mM dithiothreitol
4% SDS (electrophoresis grade)
0.2% bromophenol blue
20% glycerol

SDS gel-loading buffer lacking dithiothreitol can be stored at room temperature. Add dithiothreitol from a 1 M stock just before the buffer is used.

Gels

SDS-polyacrylamide gel <!>

Please see Appendix 8 for preparation of SDS-polyacrylamide gels used in the separation of proteins.

Nucleic Acids and Oligonucleotides

Target DNA encoding the protein of interest (bait)

Antibodies

Monoclonal antibody to LexA (CLONTECH) or Polyclonal antibody to LexA (Invitrogen) or Specific antibody to the fusion domain of the target protein (if available)

Media

Please see Appendix 2 for components of yeast media.

CM selective medium

Use Table 18-3 to estimate the amount of media required and Table 18-4 to prepare the necessary selective media.

Yeast nitrogen base without amino acids (YNB) is sold either with or without ammonium sulfate. Table 18-4 assumes that the YNB contains ammonium sulfate. If the bottle of yeast nitrogen base instructs that 1.7 g/liter be added to make media, then it *does not* contain ammonium sulfate and 5 g of ammonium sulfate per liter of media should be added.

Yeast selective X-gal medium

i. Prepare the base medium in 900 ml of H_2O, according to Table 18-4. Autoclave the base medium and cool it to 55°C.
ii. In a separate bottle, autoclave 7 g of sodium phosphate (dibasic) and 3 g of sodium phosphate (monobasic) in 100 ml of distilled H_2O.
iii. Mix the two autoclaved solutions together, and add 0.8 ml of 100 mg/ml X-gal (in *N,N*-dimethylformamide <!>). Pour the plates.

YPD medium

20 g of peptone
10 g of yeast extract
20 g of glucose
20 g of agar (if for plates)

Add 1 liter of distilled H_2O and autoclave the medium for 20 minutes. Before pouring plates, cool the autoclaved medium to 55°C.

Special Equipment

Dry ice/ethanol bath <!>

Please see Step 13.

Flat-edged toothpicks, sterilized

To sterilize, transfer standard toothpicks to a 250-ml beaker, cover the beaker with aluminum foil, and autoclave under standard dry conditions.

Heat block or Thermocycler preset to 100°C, or Boiling water bath

Additional Reagents

Step 1 of this protocol requires the reagents for subcloning listed in Chapter 1, Protocol 17.

Step 2 of this protocol requires the reagents for transformation of yeast listed in Spector et al. (1998, Chapter 21).

Step 17 of this protocol requires the reagents for immunoblotting listed in Appendix 8.

Vectors and Yeast Strains

S. cerevisiae *strains for selection and propagation of vectors (please see Table 18-6)*

Vectors carrying LexA (please see Table 18-1) and activation domain fusion sequences (please see Table 18-2) and LacZ reporter plasmids (please see Table 18-5)

TABLE 18-1 LexA Fusion Plasmids

Plasmid	Selection in Yeast	Selection in *E. coli*	Comment/Description	Contact/ Sources[a,b,c]
pMW101	HIS3	Cm^R	Basic plasmid to clone bait as fusion with LexA; expression is driven by the ADH1 promoter.	Serebriiskii and Golemis
pMW103	HIS3	Km^R	Basic plasmid to clone bait as fusion with LexA; expression is driven by the ADH1 promoter.	Serebriiskii and Golemis
pEG202	HIS3	Ap^R	Basic plasmid to clone bait as fusion with LexA; expression is driven by the ADH1 promoter.	OriGene CLONTECH MoBiTec Display
pJK202	HIS3	Ap^R	A derivative of pEG202. The incorporation of nuclear localization sequences between LexA and polylinker enhances the ability of the bait fusion protein to translocate to nucleus.	OriGene
pNLexA	HIS3	Ap^R	Polylinker is upstream of LexA; allows fusion of LexA to carboxyl terminus of bait, leaving amino-terminal residues of bait unblocked.	OriGene
pGilda	HIS3	Ap^R	GAL1 promoter replaces ADH promoter in the pEG202 backbone; should be used if continuous presence of the the bait is toxic to yeast.	OriGene CLONTECH
pEG202I	HIS3	Ap^R	A derivative of pEG202, which can be integrated into yeast *HIS3* gene after digestion with *Kpn*I; ensures lower levels of bait expression.	Serebriiskii and Golemis
pRFHM1 (control)	HIS3	Ap^R	Homeodomain of *bicoid* cloned into pEG202 backbone; the resulting nonactivating fusion is recommended as a negative control for activation and interaction assays, and as a positive control for repression assays.	OriGene
pSH17-4 (control)	HIS3	Ap^R	GAL4 activation domain cloned into pEG202 backbone; recommended as a positive control for transcriptional activation.	OriGene
pHybLex/Zeo	Zeo^R	Zeo^R	Bait cloning vector, compatible with IT and all other two-hybrid systems. Minimal ADH1 promoter expresses LexA followed by extended polylinker.	Invitrogen
pCGLex/p2GLex	Zeo^R	Zeo^R	Gal-inducible bait vector, compatible with IT and all other two-hybrid systems. GAL1 promoter expresses LexA followed by extended polylinker; both high- and low-copy number versions available.	Huang and Schreiber (1997)

[b]Credits: Interaction Trap (IT) reagents represent the work of many contributors: The original basic reagents were developed in the Brent laboratory (Department of Molecular Biology, MGH, Boston). Plasmids with altered antibiotic resistance markers (all pMW plasmids) were constructed at Glaxo (Research Triangle Park). Plasmids and strains for specialized applications have been developed by E. Golemis (Fox Chase Cancer Center, Philadelphia: pEG202, EG48, EG191); J. Gyuris (Mitotix, Cambridge: pJG4-5); J. Kamens (BASF, Worcester: pJK101, pJK202); cumulative efforts of I. York (Dana-Farber Cancer Center, Boston) and M. Sainz and S. Nottwehr (University of Oregon: pNLexA); D.A. Shaywitz (MIT Center for Cancer Research, Cambridge: pGilda); R. Buckholz (Glaxo, Research Triangle Park: pEG202I, pJG4-5I); S. Hanes (Wadsworth Institute, Albany: pSH18-34, pSH17-4); R. Brent (Department of Molecular Biology, MGH, Boston: pRB1840); R. Finley (Wayne State University, Detroit: pRFHM1, RFY206); A.B. Vojtek and S.M. Hollenberg (Fred Hutchinson Cancer Research Center, Seattle, Washington).

[c] Earlier versions of screening protocols utilized LexA fusion and reporter plasmids incorporating genes for resistance to ampicillin (Amp^R) for plasmid maintenance in bacteria (pEG202, pSH18-34; Golemis et al. 1995). These versions have been superseded by comparable plasmids incorporating resistance to kanamycin (Km^R) (Watson et al. 1996) or chloramphenicol (Cm^R) (Watson et al. 1996). The use of these markers facilitates the purification of library plasmids in later steps by eliminating the need for passage through KC8 bacteria. Features of the basic vectors used in the two-hybrid system are illustrated in Figure 18-8.

TABLE 18-2 Activation Domain Fusion Plasmids

Plasmid	Selection in Yeast	Selection in *E. coli*	Comment/Description	Contact/ Sources[a,b,c]
pJG4-5	TRP1	Ap^R	Library construction plasmid; GAL1 promoter provides efficient expression of a gene fused to a cassette consisting of nuclear localization sequence, transcriptional activation domain, and HA epitope tag.	OriGene CLONTECH MoBiTec Display
pJG4-5I	TRP1	Ap^R	A derivative of pJG4-5 that can be integrated into yeast *TRP1* gene after digestion with *Bsu*36I; designed to study interactions that occur physiologically at low protein concentrations (in combination with pEE2021).	Serebriiskii and Golemis
pYESTrp	TRP1	Ap^R	GAL1 promoter expresses nuclear localization domain, transcriptional activation domain, V5 epitope tag, multiple cloning sites; contains f1 ori and T7 promoter/flanking site; used to express cDNA libraries.	Invitrogen

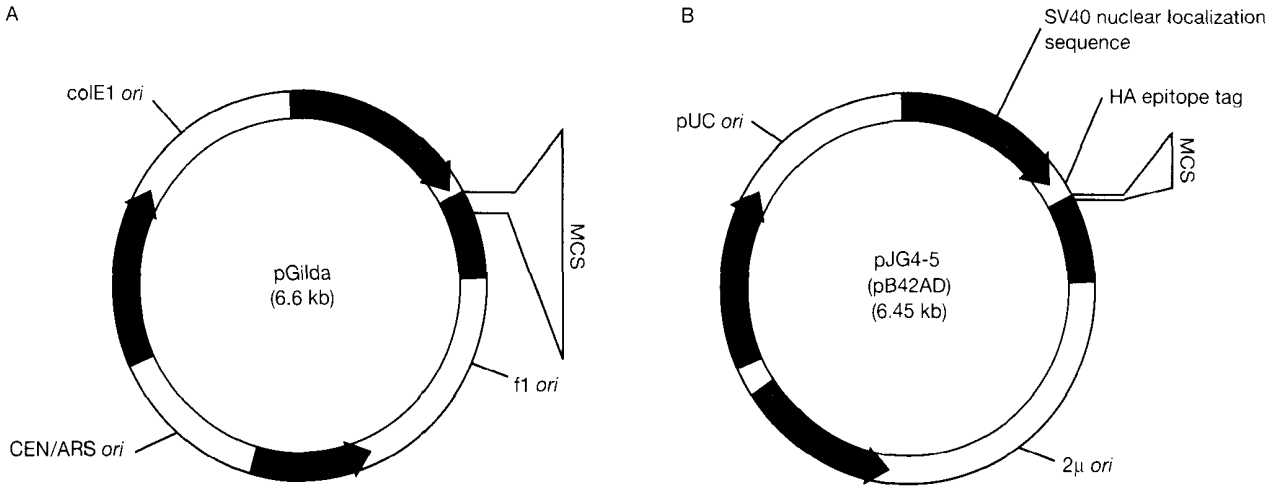

FIGURE 18-8 Two-hybrid Basic Vectors

(*A*) LexA fusion vector pGilda. The vector is used (as an example of a bait vector) to express bait proteins as fusions to the DNA-binding domain (DBD) of LexA under the control of the GAL1 inducible promoter (pGAL1). Plasmids contain the *HIS3* selectable marker, the 2-μm origin of replication to allow propagation in yeast, an antibiotic resistance gene, and the colE1 origin of replication to allow propagation in *E. coli*. Invitrogen has recently developed an Interaction-Trap system in which both the *HIS3* marker and antibiotic resistance markers have been replaced with the Zeocin resistance gene, which can be selected in both yeast and bacteria. As this vector backbone is combined with specialized LexA-fusion cassettes, it is likely to facilitate two-hybrid screening. (*B*) pJG4-5 (pB42AD). The vector is used to express inserts as fusion proteins to the SV40 nuclear localization sequence, the 88-residue activator B42, and the hemagglutinin (HA) epitope tag. Expression of the fusion protein is under control of the GAL1 inducible promoter (pGAL1). Details of polylinkers and vector sequences can be found at www.fccc.edu/research/labs/golemis/InteractionTrapInWork.html. (Adapted, with permission, from CLONTECH.)

TABLE 18-3 Yeast CM Selective Media Required for Two-hybrid Analysis

MEDIA	STAGE 1	STAGE 2	STAGE 3
CM Selective Media (ml)			
CM Glu –W			(100)
CM Glu –[UH]		(100)	400
CM Gal –[UHW]		100	
CM Selective Agar Plates (number)			
CM Glu –U	2		
CM Glu –[UH]		8–10	(3)
CM Glu –[UHL]	1		
CM Glu –[UHW]		4 + 30L*	6–12
CM Glu –[UHWL]			1–6
CM Gal –U	3–4		
CM Gal –[UHL]	3–4		
CM Gal –[UHW]			2–12
CM Gal –[UHWL]		20–24	2–12
CM Gal Xgal –U	(1)		
CM Glu Xgal –U	(1)		
CM Gal Xgal –[UHW]			(2–6)
CM Glu Xgal –[UHW]			(2–6)

Complete minimal (CM) is a medium that contains all necessary supplements. To test the growth requirement(s) of a particular strain, prepare a series of selective media for which each expected auxotrophy is supplemented, except the one of interest. In drop out or selective media, a particular ingredient is lacking or "dropped out" (e.g., –[UH] is lacking uracil and histidine).

Values are approximate minimum number of plates or volume of liquid medium required to complete each of the outlined protocols, assuming characterization and library screening with a single bait. Values in parentheses reflect plates that may or may not be required, based on the particular assay alternative chosen. (L*) Large plates are used in library screening (please see text); all other plates are 10-cm in diameter. Because the results of library screening are variable, the number of plates required in Stage 3 may be greater or less than the average values given.

TABLE 18-4 Yeast CM Selective Media for Two-hybrid Analysis

INGREDIENTS	CM(GLU) -U-H MEDIUM	CM(GLU) -U AGAR	CM(GLU) -U-H AGAR	CM(GLU) -U-H-L AGAR	CM(GLU, X-GAL)-U AGAR[a]	CM(GAL) -U-H-L AGAR	CM(GAL, X-GAL)-U-H-L AGAR[a]
YNB	6.7 g	6.7 g	6.7 g	6.7 g	6.7 g	6.7 g	6.7 g
Glucose	20 g	20 g	20 g	20 g	20 g		
Galactose						20 g	20 g
Dropout mix	2 g	2 g	2 g	2 g	2 g	2 g	2 g
Leucine	15 ml	15 ml	15 ml		15 ml		
Tryptophan	10 ml	10 ml	10 ml	10 ml	10 ml	10 ml	10 ml
Histidine		5 ml			5 ml		
Agar		20 g	20 g	20 g	20 g	20 g	20 g

To prepare liquid or agar medium, mix the ingredients in a final volume of 1 liter of H_2O. Autoclave for 20 minutes. Cool the agar medium to 55°C before pouring plates: Leucine stock = 4 mg/ml; Tryptophan stock = 4 mg/ml; Histidine stock = 4 mg/ml.

[a]For media containing X-gal, prepare the appropriate base medium in 900 ml of H_2O, and use it in the recipe for yeast selective X-gal medium.

TABLE 18-5 Reporter Plasmids

Plasmid	Selection in Yeast	Selection in *E. coli*	No. of Operators	Comment/Description	Contact/ Sources[a,b,c]
pMW112	URA3	Km^R	8	Transcription of the *lacZ* gene is directed by LexA operators: The most sensitive indicator plasmids for transcriptional activation have eight operators, intermediate reporters have two operators, and the most stringent reporters have one operator.	Serebriiskii and Golemis

[a,b,c]Please see Table 18-1.

METHOD

Construction of a Bait-LexA Fusion Protein

1. Clone the target DNA encoding the protein to be used as bait into the polylinker of a LexA fusion vector (e.g., pMW101 or pMW103) to synthesize an in-frame fusion to LexA. Ensure that a translational stop sequence is present at the carboxyl terminus of the desired bait sequence. The resulting plasmid is referred to as pBait.

2. Set up a series of transformations of the EGY48 *lexAop-LEU2* selection strain of yeast using the following combinations of LexA fusion and *lexAop-lacZ* reporter plasmids:

   a. pBait + pMW112 (test for activation)

   b. pSH17-4 + pMW112 (positive control for activation)

   c. pRFHM1 + pMW112 (negative control for activation)

   d. pBait + pJK101 (test for repression/DNA binding)

   e. pRFHM1 + pJK101 (positive control for repression)

   f. pJK101 alone (negative control for repression)

   For a description of the function of each of the plasmids, please see Tables 18-1 and 18-2.

3. Plate each transformation mixture on selective dropout plates: CM(Glu)-Ura-His (for plasmid combinations **a–e**) or CM(Glu)-Ura (for plasmid combination **f**), as appropriate. Incubate the plates for 2–3 days at 30°C to select for transformed yeast colonies that contain the plasmids.

   If colonies are not apparent within 3–4 days, or if only a very small number (<20) of colonies are obtained, transformation should be repeated.

4. Make a master plate of transformants, from which specific colonies can be assayed for the phenotype of activation of *lacZ* and *LEU2* reporters as described in Steps 5–9.

Characterization of Activation and Repression Activity: Assay for X-gal and Leu2 Phenotype

Steps 5–9 are used to test the bait-LexA fusion protein for transcriptional activity and to demonstrate that the fusion of the bait does not affect LexA DNA-binding activity (for an illustration of the repression assay, please see Figure 18-9). Several independent colonies are assayed for each combination of plasmids transformed in Step 2. This is important because, for some bait constructs, the level of protein expression varies among independent colonies, as does the apparent ability to activate transcription of the two reporters. Instead of performing Steps 5–8, a test for activation by the chloroform overlay assay is given in the alternative protocol at the end of Stage 1.

5. From each transformation **a–f** (from Step 2), use sterile, standard flat-edged toothpicks to pick ~8 colonies. Touch a clean toothpick to the colony to pick up cells, and restreak them as a 1-cm-long streak in a grid on a fresh CM(Glu)-Ura-His or CM(Glu)-Ura plate. As many as 60–80 streaks can generally be grown on a single plate. Incubate the plates overnight at 30°C.

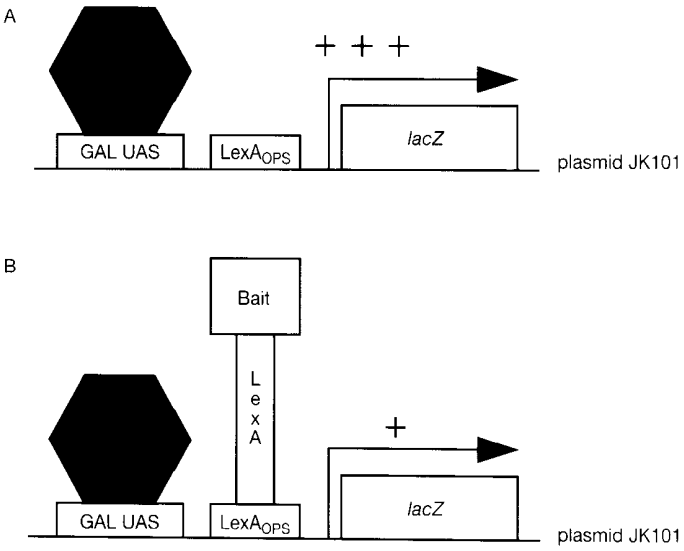

FIGURE 18-9 Repression Assay for DNA-binding (Brent and Ptashne 1984)

Plasmid JK101 contains the upstream-activating sequence (UAS) from the GAL1 gene followed by LexA operators upstream of the *lacZ*-coding sequence. (*A*) On medium containing galactose, the product of the yeast GAL4 gene accumulates and binds to the GAL upstream-activating sequence (GAL_{UAS}). (*B*) LexA-fused proteins enter the nucleus and bind the *lexA* operator sequences (Lex_{OPS}), thereby blocking activation from the GAL_{UAS} and repressing β-galactosidase activity three- to fivefold. Note that on glucose X-gal medium, yeast containing JK101 appear as white colonies because GAL_{UAS} transcription is repressed. (Redrawn from Spector et al. 1998.)

6. On the second day, restreak from the two master plates to each of the following:

Transformations ***a–f****:* Streak onto CM(Glu, X-gal)-Ura and onto CM(Gal, X-gal)-Ura

Transformations ***a–c****:* Streak onto CM(Glu)-Ura-His-Leu and onto CM(Gal)-Ura-His-Leu

Only uracil is dropped out (histidine is present) from the X-gal plates, to allow side-by-side comparison of the JK101 plasmid-only transformation (**f**) with (**d,e**). Lack of selection for the LexA-fused plasmid does not notably affect transcriptional activation over the period of this assay.

In general, it is helpful to make a relatively thick streak of yeast (i.e., cells should be visible by eye) on X-gal plates, but a relatively thin streak (i.e., cells barely visible by eye, but detectable by low-power dissecting scope) on –Leu plates. Yeast do not grow as well at neutral pH (buffered to 7.0 to optimize β-galactosidase activity) as they do on normal media (pH ~5.0–5.5). Hence, it is easier to determine a blue-white phenotype if sufficient cells are initially plated so that fewer cell divisions are required. Conversely, if yeast are plated too densely on –Leu plates, sufficient cross-feeding will occur between cells and some growth will occur even in the absence of activation of the reporter, obscuring a true positive result.

Two LexA fusion plasmids (pRFHM1 and pSH17-4) are used as positive and negative controls for assaying transcriptional activation by newly created LexA bait proteins. pMW102 itself (or the related plasmid pEG202) is not a good negative control because the peptide encoded by the uninterrupted polylinker sequence functions as a weak transcriptional activator.

pMW112 (and related plasmid pSH18-34) is one of the most sensitive *lacZ* reporters available and will detect any potential ability to activate *lacZ* transcription. However, for some baits, the *LEU2* reporter in yeast strain EGY48 is even more sensitive than the pSH18-34 reporter, so it is possible that a bait protein that gives little or no signal in a β-galactosidase assay would nevertheless permit some level of growth on –Leu medium. If the streak of cells derived by transformation with positive control plasmids (pSH17-4 and pMW112) does not turn deep blue on X-gal plates within 1–2 days, there may be a problem with the plates.

TABLE 18-7 Expected Results for a "Well-behaved" Bait

	Plasmids to Transform		Anticipated Results		
			X-gal Plates		Growth
Assay	Reporter	LexA Fusion	Glu	Gal	Leu-Gal
Activation					
test	pMW112	pBait	white/ light blue	white/ light blue	(no)
negative control	pMW112	pRFHM1	white	white	no
positive control	pMW112	pSH17-4	blue	blue	yes
Repression					
test	pJK101	pBait	(white)	(lighter blue)	
negative control	pJK101	–	white	blue	do NOT test
positive control	pJK101	pRFHM1	white	lighter blue	

See text for details.

7. Incubate the plates for up to 4 days at 30°C.
8. Assay for repression and activation activities:
   a. For repression, observe the X-gal phenotype at ~12–24 hours after streaking.
   b. For activation, observe the X-gal phenotype between 18 and 72 hours after streaking.
   c. Observe the Leu2 phenotype between 48 and 96 hours. The expected results for a well-behaved bait are given in Table 18-7 and are summarized below.
      - Optimally, at 12–24 hours after streaking to CM(Gal, X-gal)-Ura, the **d** + **e** transformants should be discernibly lighter in color than **f**.
      - At 48 hours after streaking to CM(Glu, X-gal)-Ura, **b** transformants should be bright blue, **c** should be white, and **a** should be white or very light blue.
      - At 48 hours after streaking, **b** transformants should be as well grown on CM(Glu)-Ura-His-Leu or CM(Gal)-Ura-His-Leu as on a CM(Glu)-Ura-His master plate, whereas **a** and **c** should show no growth.
      - Ideally, **a** transformants will still display no apparent growth at 96 hours after streaking.
9. Select the appropriate candidate colonies, based on the results of the repression and activation assays.

In an optimal experiment, colonies assayed from each transformation **a–f** would all possess equivalent phenotypes in activation and repression assays. For a small number of baits, this is not the case. Typically, some colonies are white on X-gal and do not grow on –Leu medium, whereas the remaining colonies display some degree of blueness and growth. *Do not* select the white, nongrowing colonies as the starting point in a library screen; generally, these colonies possess these phenotypes because they are synthesizing little or no bait protein (as determined by western blot, Step 17). Although the reasons for this are not clear, it appears to be a bait-specific phenomenon and may be linked to some degree of toxicity of continued expression of particular proteins in yeast. It will be necessary to adjust the sensitivity of the assay to allow work with blue/growing colonies (see below). For a small percentage of baits, the repression assay does not work, although the bait protein is clearly made at high levels. In these cases, it is generally reasonable to proceed with the library screen.

Detection of Bait Protein Expression

10. On the master plate, mark the colonies that are to be assayed for protein expression. Use the colony that has been shown to express bait appropriately as the founder to grow a culture for transformation of a library (in Stage 2).

11. Analyze at least two primary transformants for each novel bait construct. Include two transformants as positive controls for protein expression (e.g., pRFHMI).

    a. Use a sterile toothpick to pick colonies from the CM(Glu)-Ura-His master plate into CM(Glu)-Ura-His liquid medium.

       If gloves are worn, the toothpick can be dropped into the culture tube and left there without fear of contamination.

    b. Grow the cultures overnight on a roller drum or other shaker at 30°C.

    c. In the morning, dilute the saturated cultures into fresh tubes containing 3–5 ml of CM(Glu)-Ura-His, with a starting density of OD_{600} of ~0.15. Incubate the cultures for 4–6 hours at 30°C until the optical density has doubled approximately twice (OD_{600} ~0.45–0.7).

12. Transfer 1.5 ml of each culture to a microfuge tube, and centrifuge the cells at maximum speed for 3–5 minutes in a microfuge. The volume of the visible pellet should be 2–5 µl. Carefully decant or aspirate the supernatant.

    Some (although not all) LexA fusion proteins exhibit sharp decreases in detectable levels of protein with the onset of stationary phase of growth. Thus, it is not desirable to allow the cultures to proceed to saturation in the hopes of increasing the yield of protein to assay.

    It may be helpful to freeze duplicate samples at this stage if more than one round of assay is anticipated.

13. Add 50 µl of 2× SDS gel-loading buffer to the tube, and vortex the tube rapidly to resuspend the pellet. Immediately place the tube either on dry ice or in a dry ice/ethanol bath.

    Samples may be either used for immediate assay or frozen at –70°C, where they will remain stable for at least 4–6 months.

14. Transfer the samples from the dry ice or –70°C directly to 100°C and boil them for 5 minutes.

    A PCR machine set to 100°C is most convenient, although a water bath or heat block can also be used.

15. Chill the samples on ice and centrifuge them at maximum speed for 5–30 seconds in a microfuge to pellet large cell debris. Load 20–50 µl into each lane of a SDS-polyacrylamide gel.

16. Run the gel and analyze the products to determine whether bait protein of the expected size is expressed at reasonable levels.

17. To anticipate and forestall potential problems, analyze the lysates of yeast containing LexA-fused baits by immunoblotting (please see the note to this step).

    Immunoblotting may be performed as described in Appendix 8. LexA fusions can be visualized using antibody to the fusion domain, if available, or alternatively, using antibody to LexA.

    An important step in the characterization of a bait protein is direct assay of whether the bait is detectably expressed and whether the bait is of the correct size. In most cases, both of the above will be true. However, some proteins (especially where the fusion domain is ~60–80 kD or larger) will either be synthesized at very low levels or be posttranslationally clipped by yeast proteases. Either of these two outcomes can lead to problems in library screens. Proteins expressed at low levels, and apparently inactive in transcriptional activation assays, can be up-regulated to much higher levels under leucine selection and then suddenly demonstrate a high background of transcriptional activation. Where proteins are proteolytically clipped, screens may be performed inadvertently with LexA fused only to the amino-terminal end of the larger intended bait.

TROUBLESHOOTING AND MODIFICATIONS OF BAITS

Some basic bait problems can be identified and corrected before screening:

- ***The bait activates transcription.*** This problem can be addressed by constructing a series of truncations of the protein in an attempt to eliminate the activation domain. If the bait activates transcription very strongly, i.e., as efficiently as the positive control, this step will probably be necessary.

  If the bait activates moderately, the simplest approach is to redo the control experiments using less-stringent reporter plasmids and strains (please see Table 18-5), to determine if activation is reduced to an acceptable level. Alternatively, the protein can be truncated, as for a strong activator. Finally, it is possible to use an integrating form of bait vector (see Table 18-1), which will result in a stable reduction of protein levels.

  If the bait is a weak activator, one option is to use less-stringent reporter plasmids; alternatively, the investigator may choose to proceed with the tested reagents, accepting the risk that a background of false positives may be identified. In general, it is a good idea to use the most sensitive screening conditions possible; in some cases, use of very stringent interaction strains eliminates detection of biologically relevant interactions (Estojak et al. 1995).

- ***The bait plasmid produces an inappropriate level or size of protein.*** If the protein is poorly expressed or is very large, it may be subdivided into two or three overlapping constructs, each of which can be tested independently. Alternatively, the vector pJK202 incorporates a nuclear localization sequence, which increases the concentration of the bait in the nucleus, where it is useful; this approach may make the best of a situation where a protein cannot readily be expressed at higher levels.

- ***Very few transformants containing the bait plasmid express the bait protein, or yeasts expressing the bait protein grow noticeably more poorly than control yeast in the absence of any selection.*** These results would suggest that the bait protein is somewhat toxic to the yeast. Because toxicity can cause difficulties in library screening, it may be desirable to reclone the protein of interest into pGilda, which allows inducible expression of the protein from the GAL1 promoter, thus limiting time of expression of the protein to actual selection. Note, however, that tests with a pGilda construct should be performed on medium containing galactose as a carbon source.

ALTERNATIVE PROTOCOL: ASSAY OF β-GALACTOSIDASE ACTIVITY BY CHLOROFORM OVERLAY

For each combination of plasmids transformed in Step 2, a series of independent colonies are tested for activation using the chloroform overlay assay (adapted from Duttweiler 1996). Although somewhat laborious, this technique is generally more sensitive than the standard X-gal plate assay described in Steps 5–8 above. The following sequence is to be performed in place of Steps 5–8 of the main protocol.

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Additional Materials

Chloroform **<!>**
1% low-melting agarose in 100 mM $KHPO_4$ (pH 7.0), melted and cooled to 60°C
20 mg/ml X-gal
Yeast selective agar plates (please see Table 18-4 for recipes)
CM(Glu)-Ura-His
CM(Glu)-Ura
CM(Gal)-Ura (use the analogous recipe containing glucose, but substitute 20 g of galactose)
CM(Gal)-Ura-His-Leu
Microtiter plate (96-well)
Multichannel pipettor or Inoculating manifold/frogger (e.g., Dankar Scientific)

Method

1. Deliver 25–30 µl of sterile H_2O into 48 wells of a 96-well microtiter plate.
2. For each set of transformations a–f from Step 2 of the main protocol, use a sterile toothpick to transfer and disperse eight colonies, individually, into wells containing sterile H_2O (one half of the 96-well microtiter plate).
3. Use a multichannel pipettor or an inoculating manifold/frogger to plate an approximately equal volume (~3 µl) of each yeast suspension onto the following plates:

CM(Glu)-Ura-His	2 plates
CM(Glu)-Ura	1 plate
CM(Gal)-Ura	1 plate
CM(Gal)-Ura-His-Leu	1 plate

4. Using the second half of the microtiter plate, make a 1:10 dilution of yeast suspension into sterile H_2O for use in the activation assay. Plate the dilution on additional CM(Gal)-Ura-His and CM(Gal)-Ura-His-Leu plates. Incubate the cultures overnight at 30°C (-Ura-His or -Ura plates) before assaying for β-galactosidase activity, or for 3–4 days (-Leu plates) to monitor for growth.
5. Add chloroform to the transformants.
   a. Select one CM(Gal)-Ura plate and one CM(Glu)-Ura-His plate containing yeast transformants.
   b. Gently overlay each plate with chloroform (~5 ml). Pipette the chloroform slowly in from the side so as not to smear any colonies.
   c. Leave the colonies completely covered with chloroform for 5 minutes. Aspirate the chloroform.
6. Briefly rinse the plates with 5 ml of chloroform and let the plates dry for 5 minutes in a chemical fume hood.
7. For each plate, take ~7 ml of 1% agarose in 100 mM $KHPO_4$ (pH 7.0), melted and cooled to ~60°C, and add X-gal to 0.25 mg/ml. Overlay the plate with the agarose, making sure that all yeast spots are completely covered.

   Plates will become chilled during evaporation of chloroform, so it may be difficult to spread <7 ml of top agarose. Work quickly!

8. Incubate the plates at 30°C and monitor them for color changes. It is generally useful to check the plates after 20 minutes, and again after 1–3 hours.

   For the activation assay, strong activators such as the LexA-GAL4 control (pSH17-4) will produce a blue color in 5–10 minutes, and a bait protein (LexA fusion protein) that does so is likely to be unsuitable for use in an interactor hunt. Weak activators will produce a blue color in 1–6 hours (compare with the negative control pRFHM1) and may or may not be suitable (for typical results, please see Figure 18-10).

   The repression assay should be monitored within 1–2 hours if using overlay assay/filters, as the high basal LacZ activity will make differential activation of JK101 impossible to see after longer incubation. A good result (i.e., true repression) will generally reflect a two- to threefold reduction in the degree of blue color detected for JK101 + bait versus JK101 alone on plates containing galactose. Use of X-gal plates, with inspection at 12–24 hours after streaking, is generally somewhat easier.

9. Return to the main protocol and continue with Stage 1, Step 9.

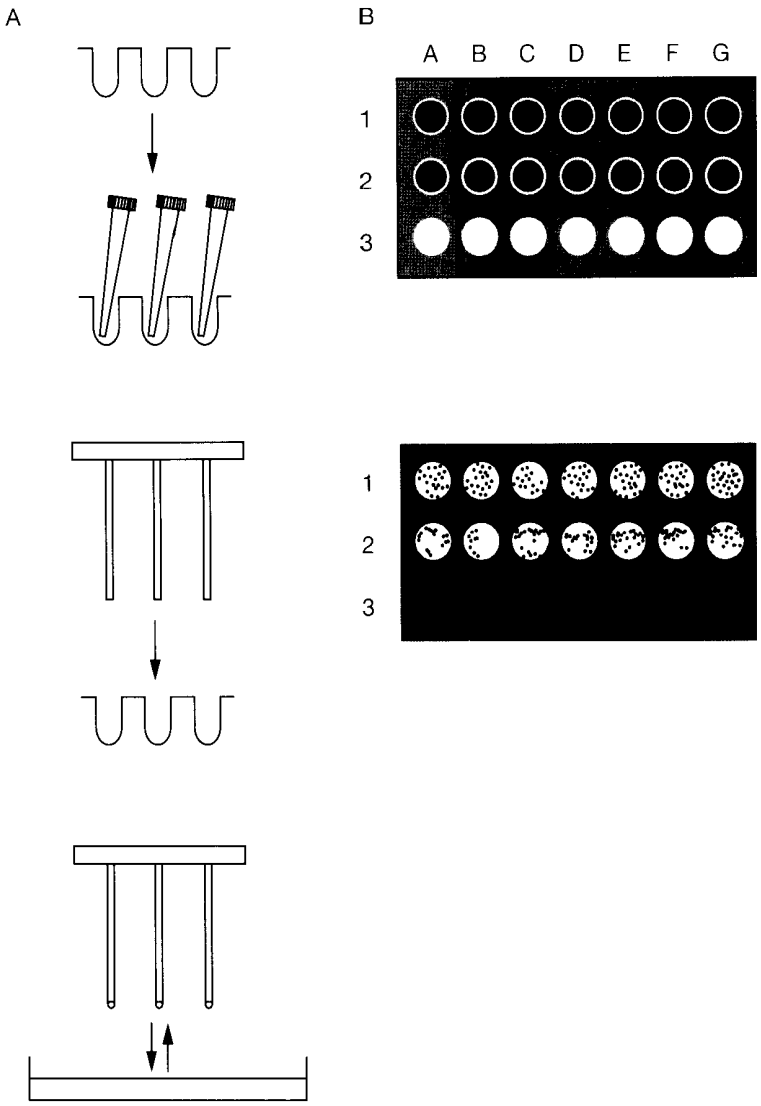

FIGURE 18-10 Replica Technique/Gridding Yeast

(*A*) Replica technique. Yeast colonies (1–2-mm diameter) picked from transformation plates are resuspended in 25–30 µl of sterile distilled H_2O in wells of a 96-well microtiter plate using sterile toothpicks, plastic pipette tips, or a frogger. When all yeast colonies are resuspended, print replicas onto the appropriate plates. When making prints on a plate, place the frogger on the surface of the solidified medium, tilt it slightly using a circular motion, and then lift the frogger. Make sure that the drops left on the surface are of approximately the same size. Let the liquid absorb to the agar before putting the plates upside down in the incubator. In subsequent transfer between master plates, invert the frogger on the lab bench, and then place the master plate upside down on the spokes, making sure that a proper alignment of the spokes and the colonies is made. (*B*) Typical results. Patches obtained after printing the yeast suspension on CM(Gal/X-gal)-Ura (*top*) and CM(Gal)-Ura-His-Trp-Leu (*bottom*) plates. Seven independent transformants are shown for each LexA fusion. (1A-1G) EGY48 with pMW112 plus strongly activating LexA fusion; (2A-2G) EGY48 with pMW112 plus moderately activating LexA fusion; (3A-3G) EGY48 with pMW112 plus nonactivating LexA fusion. (Redrawn from Spector et al. 1998.)

STAGE 2: Selecting an Interactor

Screening for interactors generally involves two sequential first platings of yeast. In a first round, yeast strains containing pBait and the *lexAop-lacZ* reporter are plated to select for the library plasmid. Libraries are generally cloned in the vector pJG4-5 (Figure 18-8) or a related plasmid that expresses cDNAs as a cassette with activation domain and other moieties under the control of the inducible GAL1 promoter: The first plating is performed under noninducing conditions, on CM(Glu)-Ura-His-Trp. In the second round, expression of library-encoded proteins is induced with galactose, and yeast that contain interacting proteins are selected by plating on CM(Gal/Raff)-Ura-His-Trp-Leu dropout plates. Finally, library plasmids encoding cDNAs that appear positive on selective media are purified by passage through bacteria, and subsequently retransformed into yeast cells to test the specificity of interaction with the pBait, as described in Stage 3 of this protocol.

A two-step selection is thought to be advantageous for a number of reasons. Most important, many biologically interesting cDNA-encoded proteins have been found to be toxic when constitutively expressed in yeast, and hence might be selected against in an initial mass plating on inducing medium. Additionally, immediately after simultaneous transformation and Gal induction, some interacting proteins may not be expressed at adequate levels to associate effectively with a LexA-fused partner and support growth on medium lacking leucine.

On rare occasions, baits that pass initial controls give rise to large numbers of "positives" during an actual screen. On analysis, these positives appear to arise by de novo acquisition by the bait of the ability to activate transcription. The mechanism by which this occurs is currently unknown. To avoid wasting time and reagents, some investigators test new baits by performing scaled-down screens (only 5–10 plates of transformants) and assessing initial results before proceeding to a full screen: If the background is unacceptably high, the investigator can switch to lower-sensitivity reporter strains and/or plasmids.

A list of available libraries that are compatible with the interaction trap is provided at www.fccc.edu/research/labs/golemis/librarysources/. In addition, other libraries prepared by CLONTECH, OriGene, and Invitrogen are commercially available. The following protocols are designed for saturation screening of a cDNA library derived from a genome of mammalian complexity. Fewer plates are required for screens with libraries derived from organisms with less complex genomes.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Dimethylsulfoxide (DMSO) **<!>**

Ethanol

Optional, please see Step 9.

Sterile glycerol solution for freezing transformants

65% sterile glycerol
0.1 M $MgSO_4$
25 mM Tris-HCl (pH 8.0)

TE (pH 7.5) (sterile)
TE (pH 7.5) containing 0.1 M lithium acetate
TE (pH 7.5) containing 40% PEG 4000 and 0.1 M lithium acetate (sterile)

Nucleic Acids and Oligonucleotides

Carrier DNA

Sheared salmon sperm DNA is typically used as carrier. It is extremely important that this DNA be of very high quality; use of a poor-quality preparation can drop transformation frequencies one to two orders of magnitude. For a simple procedure for generating high-quality salmon sperm DNA, please see Schiestl and Gietz (1989) and Chapter 6, Protocol 10; alternatively, a number of companies sell such preparations commercially.

Library to be screened for interaction

Interaction trap libraries are available commercially from, for example, CLONTECH (MatchMaker System), Invitrogen, OriGene, Display, MoBiTech (for a comprehensive listing of libraries from various species and tissue sources, please see www.fccc.edu/research/labs/golemis/lib sources.html).

Media

Please see Appendix 2 for components of yeast media.

CM selective medium

Use Table 18-3 to estimate the amount of media required and Table 18-8 to prepare the necessary selective media.

Yeast nitrogen base without amino acids (YNB) is sold either with or without ammonium sulfate. Table 18-8 assumes that the YNB contains ammonium sulfate. If the bottle of yeast nitrogen base instructs that 1.7 g/liter be added to make media, then it *does not* contain ammonium sulfate and 5 g of ammonium sulfate per liter of media should be added.

Yeast selective X-gal medium

i. Prepare the base medium in 900 ml of H_2O, according to Table 18-8. Autoclave the base medium and cool it to 55°C.
ii. In a separate bottle, autoclave 7 g of sodium phosphate (dibasic) and 3 g of sodium phosphate (monobasic) in 100 ml of distilled H_2O.
iii. Mix the two autoclaved solutions together, and add 0.8 ml of 100 mg/ml X-gal (in *N,N*-dimethyl formamide **<!>**). Pour the plates.

Centrifuges and Rotors

Sorvall GSA rotor or equivalent
Sorvall RT6000 centrifuge and H1000B rotor or equivalent

Special Equipment

Culture plates (24 x 24 cm) for selective media (see Table 18-3)

These plates are quite expensive, but they can be reused many times (see Step 9).

Falcon tubes (50 ml, sterile)
Glass beads (0.45-mm diameter, sterile; Sigma)

Optional, please see Step 9.

Heat block preset to 42°C
Microtiter plate (96-well)

Optional, please see Step 21.

Multichannel pipettor or Inoculating manifold/frogger (e.g., Dankar Scientific)

Optional, please see Step 21.

A frogger for the transfer of multiple colonies can be purchased or easily homemade; it is important that all of the spokes have a flat surface and that the spoke ends are level. The frogger can be sterilized by autoclaving or by flaming in alcohol.

Vectors and Bacterial or Yeast strains

S. cerevisiae *candidate strains carrying vectors expressing the bait and* lexAop-lacZ *reporter (from Stage 1)*

TABLE 18-8 Yeast CM Selective Media for Two-hybrid Analysis

Ingredients	CM (Glu) -U-H Medium	CM (Glu) -U-H-T Agar	CM (Glu) -U-H-T-L Agar	CM (Glu, X-gal) -U-H-T Agar[a]	CM (Gal) -U-H-T Agar	CM (Gal, raff) -U-H-T Medium	CM (Gal, raff) -U-H-T-L Agar	CM (Gal,raff,X-gal) -U-H-T Agar[a]
YNB	6.7 g	6.7 g	6.7 g	6.7 g	6.7 g	6.7 g	6.7 g	6.7 g
Glucose	20 g	20 g	20 g	20 g				
Galactose					20 g	20 g	20 g	20 g
Raffinose						10 g	10 g	10 g
Dropout mix	2 g	2 g	2 g	2 g	2 g	2 g	2 g	2 g
Leucine	15 ml	15 ml		15 ml	15 ml	15 ml		15 ml
Tryptophan	10 ml							
Agar		20 g	20 g	20 g	20 g		20 g	20 g

To prepare medium or agar, mix the ingredients together in a final volume of 1 liter of H_2O. Autoclave for 20 minutes. Cool the agar medium to 50°C before pouring plates: Leucine stock = 4 mg/ml; Tryptophan stock = 4 mg/ml; Histidine stock = 4 mg/ml.

[a]For media containing X-gal, prepare the appropriate base medium in 900 ml of H_2O, and use it in the recipe for yeast selective X-gal medium.

METHOD

Transforming the Library

1. Select a yeast colony, expressing the bait and *lexAop-lacZ* reporter, that was shown in Stage 1 to be optimal in the initial control experiments. From this colony, grow a 20-ml culture in CM(Glu)-Ura-His liquid dropout medium overnight at 30°C on a roller drum.

   ▲ **IMPORTANT** The bait and *lexAop-lacZ* reporter plasmids should have been transformed into the yeast <7–10 days before retransformation with the library. It is important to maintain sterile conditions throughout.

2. Dilute the 20-ml overnight culture into 300 ml of CM(Glu)-Ura-His liquid dropout medium such that the diluted culture has an OD_{600} of ~0.10–0.15. Incubate the culture at 30°C on an orbital shaker until the culture has gone through 1.5 doublings, to reach an OD_{600} of ~0.50.

3. Transfer the culture to sterile 250-ml centrifuge bottles, and centrifuge them at 1000–1500*g* (2500–3000 rpm in a Sorvall GSA rotor) for 5 minutes at room temperature. Remove the supernatant and add 30 ml of sterile H_2O to the pellet. Resuspend the pellet by gently rapping the bottle against a countertop. Transfer the slurry to a sterile 50-ml Falcon tube.

4. Centrifuge the cells at 1000–1500*g* (2500–3000 rpm in a Sorvall GSA rotor) for 5 minutes. Pour off the H_2O and resuspend the yeast cells in 1.5 ml of TE (pH 7.5) containing 0.1 M lithium acetate.

5. Add 1 µg of library DNA and 50 µg of freshly denatured carrier DNA to each of 30 sterile 1.5-ml microfuge tubes. Immediately add 50 µl of the yeast suspension (from Step 4) to each of the 30 tubes.

   A good transformation should yield ~10^5 transformants/µg of library DNA. The use of small volumes of DNA (optimally, <10 µl/transformation tube) generally enhances transformation efficiency.

   Transformation of yeast in multiple small aliquots in parallel helps reduce the likelihood of contamination, and it frequently results in significantly better transformation efficiency than that obtained by using larger volumes in a smaller number of tubes. Do not use an excess of transforming library DNA per aliquot of competent yeast cells, or each competent cell may take up multiple library plasmids, complicating subsequent analysis.

6. To each tube of the cell suspensions, add 300 µl of sterile TE (pH 7.5) containing 40% PEG 4000 and 0.1 M lithium acetate. Mix by gently inverting the tubes a number of times (do not vortex). Incubate the tubes for 30–60 minutes at 30°C.

7. To each tube, add 40 µl of DMSO, and mix the suspensions by inversion. Place the tubes in a heating block for 10 minutes at 42°C.

8. Plate the transformation mixtures as follows:

FOR 28 OF THE TUBES TO BE USED SOLELY TO GENERATE TRANSFORMANTS

a. Pipette the contents of each tube onto 24 x 24-cm CM(Glu)-Ura-His-Trp dropout plates.

b. Spread the cells evenly and incubate the plates at 30°C until colonies appear.

24 x 24-cm plates will each require 250–300 ml of medium, and should be allowed to dry at room temperature for 1–2 days after pouring, before being used. To reduce the chance of contamination, flame the surface of plates after pouring. Some investigators take the additional step of placing the open plates and inverted lids under UV light in a standard tissue culture hood for ~10 minutes.

FOR THE 2 REMAINING TUBES TO BE USED TO ASSESS TRANSFORMATION EFFICIENCY

a. Pipette 350 µl from each tube to 24 x 24-cm CM(Glu)-Ura-His-Trp dropout plates.

b. Spread the cells evenly and incubate the plates at 30°C until colonies appear.

c. Pipette the remaining 40 µl from each tube to make a series (at least 3) of 1:10 dilutions in sterile TE (pH 7.5) or H_2O.

d. Plate 100 µl of each dilution on 100-mm CM(Glu)-Ura-His-Trp dropout plates, and incubate the plates at 30°C until colonies appear.

Analysis of the dilution series will provide an estimation of the number of transformants obtained. Occasionally, the number of predicted transformant colonies arising on the 100-mm indicator plates differs significantly from the number on the 24 x 24-cm plates, particularly if the plates are from different batches. A good transformation should yield 20,000–40,000 colonies/large plate.

Harvesting and Pooling of Primary Transformants

Steps 9–14 generate a frozen stock representative of the complete set of primary transformants, which can be used in subsequent selection. In this process, a homogenized slurry is prepared from the pool of primary transformants (~10^6 cells), from which aliquots can be used to plate on to selective medium. This technique substitutes for more conventional methods of transferring yeast (e.g., replica plating), which transfer such large numbers of cells that some degree of growth is observed on selective plates, resulting in spurious background. If visible molds or other contaminants are observed on the plates, use a sterile razor blade to carefully excise them and the surrounding region before harvesting library transformants.

In Step 9, the first technique (by agitation) is faster to perform, and allows induction of the library and screening on selective plates to be carried out on the same day, and it also minimizes the time the plates are open, thus avoiding contamination from airborne molds and bacteria. About one third of the yeast slurry will be left on the plates; however, normally no more than 2% of the collected slurry is used, so it is important to ensure that colonies are washed from the plates with approximately equal efficiency. The second technique (by scraping) in Step 9 is more eco-

nomical of reagents and may be easier to use on plates from which molds and contaminants have been excised.

9. Harvest the library using one of the following methods.

TO HARVEST THE LIBRARY BY AGITATION

a. Pour 10 ml of sterile H_2O and approximately 30 sterile glass beads on each of five 24 x 24-cm plates containing transformants.

b. Stack the five plates on top of one another, and, holding the plates tightly, shake the stack until all the colonies are resuspended (1–2 minutes).

c. Use a sterile pipette to collect 5 ml of yeast slurry from each plate (tilt the plate). Pool the slurry into sterile 50-ml conical tubes.

d. Proceed to the next five plates and repeat Steps a–c. Continue harvesting yeast cells from all 30 plates, resulting in a total volume of 150 ml of liquid contained in three 50-ml tubes.

The same glass beads can be transferred to the fresh plates or new ones may be used. More than five plates can be washed off simultaneously, as many as can be held in the hands and shaken.

The plates can be reused many times. After cells have been harvested, remove the remaining agar, wash the plates, wipe with alcohol, expose to UV for 10 minutes, and store until needed.

TO HARVEST THE LIBRARY BY SCRAPING

a. Wearing gloves, place the 30 24 x 24-cm plates containing transformants at 4°C to harden the agar (generally, 2 hours to overnight is acceptable).

b. Sterilize a glass microscope slide by immersing it in ethanol and flaming; use this slide to scrape yeast cells gently from the transformation plates into 50-ml conical tubes. Reflame or use a fresh slide at intervals (every 5–10 plates).

Cells from all 30 plates can generally be pooled into one or two sterile 50-ml conical tubes.

The plates can be reused many times. After cells have been harvested, remove the remaining agar, wash the plates, wipe with alcohol, expose to UV for 10 minutes, and store until needed.

10. If necessary, fill each conical tube containing yeast to the 40–45-ml mark with sterile TE (pH 7.5) or H_2O, and vortex or invert the tubes to suspend cells.

11. Centrifuge the tubes in a benchtop centrifuge at 1000–1500*g* (2200–2700 rpm using a Sorvall H1000B rotor) for 5 minutes at room temperature, and discard the supernatant.

12. Repeat Steps 10 and 11.

After the second wash, the total volume of the cell pellet derived from 1.5 x 10^6 transformants should be 25 ml of cells.

13. Resuspend the packed cell pellet in 1 volume of sterile glycerol solution. Combine the contents of the different Falcon tubes and mix thoroughly.

14. Transfer 1-ml aliquots into a series of sterile microfuge tubes, and freeze at –70°C (cells remain stable for at least 1 year).

If proceeding directly to plating on selective medium (which requires 5 hours to complete), leave one aliquot unfrozen and carry out the next sequence of steps. Assume that the viability of the unfrozen culture is 100%. In general, for yeast frozen for <1 year, the expected viability will be >90%. If there is any cause for concern (i.e., particularly if no colonies are obtained following plating of the frozen aliquots on selective medium), measure the viability of the frozen cells by performing a series of limiting dilutions on CM(Glu)-Trp-His-Ura.

Screening for Interacting Proteins

Aliquots of the transformed library are plated on –Leu selective media to test for the inability to promote *LEU2* transcription. Not all cells containing interacting proteins plate at 100% efficiency on –Leu selective medium (Estojak et al. 1995). To maximize the chance of detecting interaction, each primary colony obtained from the library transformation should be represented on the selection plate by three to ten viable yeast cells. For example, if 5×10^5 colonies had been initially obtained, between 1.5×10^6 and 5×10^6 cells would be plated on two to five plates. Although this practice may result in redundant isolations of the same cDNA, it helps to ensure that all primary transformants are represented by at least one cell on the selective plate; in fact, reisolation of an identical cDNA among a relatively small set of "positives" can be taken as one sign of a specific protein-protein interaction.

15. Thaw one aliquot of library-transformed yeast (from Step 14), and dilute 1:10 with CM(Gal-Raff)-Ura-His-Trp dropout medium. Incubate the yeast with shaking for 4 hours at 30°C to induce transcription from the GAL1 promoter on the library.

16. Plate 10^6 cells (or 50 µl of a culture at $OD_{600} = 1.0$) on each of an appropriate number of 100-mm CM(Gal/Raff)-Ura-His-Trp-Leu dropout plates.

▲ **IMPORTANT** The value of 10^6 cells per plate is the highest plating density that generally can be effectively used. Plating at higher densities (e.g., 3×10^6) can result in cross-feeding between yeast cells, resulting in high background growth.

17. Incubate the plates for 5 days at 30°C.

Depending on the individual bait used, good candidates for positive interactors will generally produce colonies within 5 days, with the most of colonies appearing at 2–4 days.

18. Observe the plates for growth and mark colonies as they appear.

A good strategy (especially if a large number of colonies appear to be growing) is to observe the plates on a daily basis, but not necessarily to pick colonies immediately. Instead, on the first day that the colonies are visible by eye, mark their location on the plate with a dot of a given color from a lab marker (e.g., day 3 = red). Each day, mark nascent colonies with distinctive colors (day 4 = blue, etc).

19. At day 5, create a master plate (CM[Glu]-Ura-His-Trp) on which colonies are grouped by day of appearance.

If many apparent positives appear, it may be necessary to create separate plates with colonies obtained on day 2, on day 3, and on day 4. To generate a negative control for subsequent steps, pick at random 3–5 colonies from the plates used to determine viability (please see note to Step 14), and streak them in parallel on the master plates to be tested. If using a manifold/frogger for subsequent assay steps (see Step 21), make sure that the streaks are gridded in such a way that colonies will correspond to the spokes on a frogger (please see Figure 18-10).

20. Incubate the plates at 30°C until patches/colonies form.

TROUBLESHOOTING

- Colonies arising more than 1 week after plating are not likely to represent bona fide positives. In tests of master plates, true interactors tend to come up in a window of time specific for a given bait, with false positives clustering at a different time point; hence, grouping the colonies as they grow by their date of appearance facilitates the decision of which clones to analyze first. If using a replica technique, it is worthwhile making an extra master plate containing glucose (please see note to Step 19).
- Contamination that has occurred at an earlier step (i.e., during plate scraping) is generally manifest by the rapid growth (24 hours or less) of many (>500) colonies per plate. If contamination can be confirmed to be bacterial, one option is to prepare new selective plates that contain 15 µg/ml tetracycline, and repeat the library induction and plating.

First Confirmation of Positive Interactions: Test for β-galactosidase Activity and for Leu Requirement

Steps 21 and 22 test for galactose-inducible transcriptional activation of both the *lexAop-LEU2* and *lexAop-lacZ* reporters. Simultaneous activation of both reporters in a galactose-specific manner generally indicates that the transcriptional phenotype is due to expression of library-encoded proteins, rather than mutation of the yeast host. A master plate containing glucose and leucine is used as a source for test colonies.

21. Assay for transcription activation.

The assays can be performed by either restreaking colonies with a toothpick or utilizing a manifold/frogger, which is particularly useful when analyzing a large number of positive colonies (for details on the use of a frogger, please see Figure 18-10).

TO ASSAY BY DIRECT STREAKING

a. On each of the four following plates, use a flat-edged toothpick to replicate the grid from the master plate. Use the same toothpick to streak an individual colony across the four plates. Try to get a thick streak of yeast on plates containing X-gal, and a thin streak of yeast on plates lacking leucine.

CM(Glu/Xgal)-Ura-His-Trp	1 plate
CM(Gal/Raff/Xgal)-Ura-His-Trp	1 plate
CM(Glu)-Ura-His-Trp-Leu	1 plate
CM(Gal/Raf)-Ura-His-Trp-Leu	1 plate

b. Incubate the plates for 3–4 days at 30°C.

X-gal plates will yield results within 48 hours, with the strongest interactions appearing as early as 18 hours. Differential growth on leucine will generally be apparent between 48 and 72 hours.

TO ASSAY USING A MANIFOLD/FROGGER

a. Deliver 25–30 µl of sterile H_2O into 48 wells of a 96-well microtiter plate.

b. Use a frogger to transfer patches simultaneously from a pregridded master plate to the wells of a microtiter plate. Agitate the plate gently.

c. Use the frogger to transfer yeast from the microtiter plate to each of the following plates. This approach allows approximately equal quantities of cells to be transferred to each plate.

CM(Glu)-Ura-His-Trp	2 plates
CM(Gal)-Ura-His-Trp	1 plate
CM(Glu)-Ura-His-Trp-Leu	1 plate
CM(Gal/Raff)-Ura-His-Trp-Leu	1 plate

d. Incubate the plates for 3–4 days at 30°C. After 1 day of incubation, use one CM(Glu)-Ura-His-Trp plate and one CM(Gal)-Ura-His-Trp plate to assay for activation of the *lacZ* reporter, using the chloroform overlay assay (please see the panel on **ALTERNATIVE PROTOCOL: ASSAY OF β-GALACTOSIDASE ACTIVITY BY CHLOROFORM OVERLAY** at the end of Stage 1).

e. Continue to monitor growth: Differential growth on leucine will generally be apparent between 48 and 72 hours on the –Leu plates. The second CM(Glu)-Ura-His-Trp plate can be taken as a fresh master plate.

22. Interpret the results. Colonies and the library plasmids they contain are designated as first-round positives if:

- X-Gal analysis indicates blue color following culture on CM(Gal)-Ura-His-Trp plates.
- X-Gal analysis indicates white, or only faintly blue, following culture on CM(Glu)-Ura-His-Trp plates.
- Colonies grow well on CM(Gal/Raff)-Ura-His-Trp-Leu plates.
- Colonies grow poorly or not at all on CM(Glu)-Ura-His-Trp-Leu plates.

TROUBLESHOOTING/ANALYSIS

In very rare cases, if an interaction occurs with high affinity, and both proteins are stable in yeast, a weak enhancement of growth and X-gal activity will occur on glucose as well as galactose medium. This occurs because low levels of transcription from the GAL1 promoter on glucose medium allow accumulation of sufficient levels of strongly interacting, stable activation domain fusions for an interaction to be detected.

In some cases, strong activation of one of the two *lexAop* reporters will be observed, whereas only poor activation will be observed of the other. Some bait-interactor combinations preferentially activate *lacZ* versus *LEU2*, or vice versa (Estojak et al. 1995). In general, the confidence level for such system-specific interactors is substantially lower than for interactors that strongly activate both reporters. This is particularly the case when strong growth is observed on medium lacking leucine, and virtually no blue color is observed with X-gal. Whether these isolates are pursued is the decision of the investigator.

If *no* positives are obtained for a given bait, there are several points to consider: (1) The library source is inappropriate or an insufficient number of colonies have been screened; (2) the bait does not interact with any single partner protein with sufficient affinity to be detected (Estojak et al. 1995); and (3) the bait is not in a native conformation, either because of a truncation or because of steric interactions with the fusion domain, or it is not interacting well with the *lexA* operator since some moiety on the fusion protein is sequestering the protein (Golemis and Brent 1992). It is sometimes possible to modify the bait and screening conditions in order to obtain interactors; however, some baits simply do not generate interactors. It is left to the discretion of the investigator as to how much effort to apply in such instances.

STAGE 3: Second Confirmation of Positive Interactions

The number of positives obtained in an interactor hunt depends on the individual bait and the suitability of the library. Anywhere from zero to several hundred positive interactors might be identified; advanced predictions are generally difficult. If a reasonably small number (1–30) of interactors are obtained, the steps detailed below can be followed essentially as written. In cases where a very large number of interactors are obtained, it may or may not be desirable to work up all of them at once. An alternative strategy is to "warehouse" most of the positives, and work up 24–48 of the faster-growing clones, which frequently contain the strongest interactors. These clones can be screened for specificity of interaction and grouped by restriction digest analysis and/or sequenced to determine whether they are all unique cDNAs or whether they are repeated isolates of a limited number of cDNAs. In the former case (especially if the isolated cDNAs do not make sense biologically in the context of the bait), it is sometimes advisable to reconfigure the initial screen conditions and try again, using a less-sensitive combination of strain and plasmid. Obtaining many different interactors can be a sign of a low-affinity nonspecific interaction. The approach taken depends on the goals and resources of the investigator.

Plasmids isolated from yeast must be transformed into a strain of bacteria suitable for manipulations such as sequencing. Standard laboratory strains such as DH5α work well. If using the plasmids recommended above (pMW112, pMW102, etc.), which contain drug resistance markers different from those of JG4-5, the only step required is to transform *E. coli* DH5α by elec-

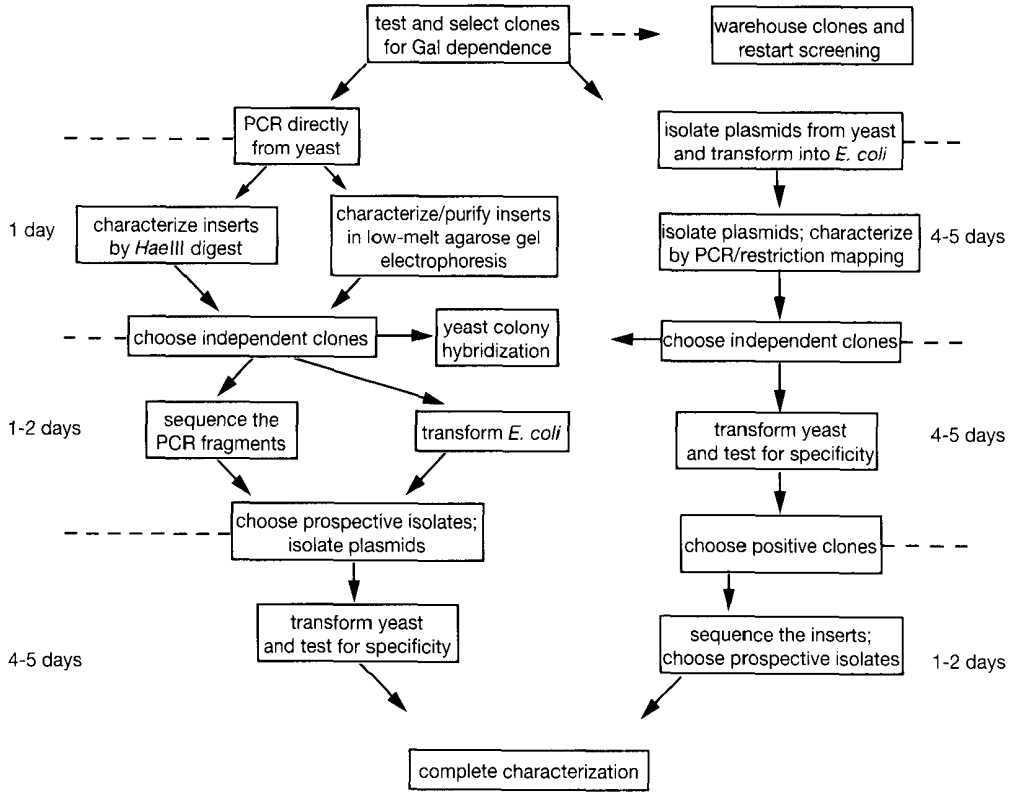

FIGURE 18-11 Library Screening Flow Chart

See text for details. (Redrawn from Spector et al. 1998.)

troporation with isolated plasmid DNA, and plate the tranformants onto medium containing ampicillin. Only bacteria that have taken up a library plasmid will grow. Transformation by electroporation is important: In general, chemical transformation methods work poorly with DNA isolated from yeast.

Two methods for working up positives are described in Figure 18-11. The right-hand sequence of steps is more traditional and has been successfully used in many laboratories: The method emphasizes thorough characterization of specificity of bait-library protein interaction before sequencing. The panel on **ALTERNATIVE PROTOCOL: RAPID SCREEN FOR INTERACTION TRAP POSITIVES** at the end of this protocol relies on an "upside down" approach and is recommended when both PCR and automated sequencing are readily available and affordable. Under the latter conditions, the protocol is 2–3 days faster and minimizes the number of isolates that must be tested for specificity (thus reducing numbers of both *E. coli* and yeast transformations). A final series of specificity tests are described that may be used to verify the interaction-dependent phenotype.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Ammonium acetate (7.5 M)

Chloroform **<!>**

Ethanol

Isopropanol

Lysis solution

Zymolyase 100T dissolved to 2–5 mg/ml in rescue buffer

or

β-glucuronidase 100,000 units/ml (Sigma) 1:50 in rescue buffer

Prepare fresh solution for each use.

Phenol (equilibrated to pH 8.0) **<!>**

Rescue buffer

50 mM Tris-HCl (pH 7.5)

10 mM EDTA

0.3% β-mercaptoethanol **<!>**

Prepare fresh solution for each use.

SDS (10% w/v)

STES lysis solution

100 mM NaCl

10 mM Tris-HCl (pH 8.0)

1 mM EDTA

0.1% (w/v) SDS

TE (pH 8.0)

Enzymes and Buffers

Restriction endonucleases EcoRI, XhoI, HaeIII

Gels

Agarose gel

Please see Step 5.

TABLE 18-9 Yeast CM Selective Media for Two-hybrid Analysis

Ingredients	CM (Glu) -T Medium	CM (Glu) -U-H Agar	CM (Glu) -U-H-T Agar	CM (Glu) -U-H-T-L Agar	CM (Glu, X-gal) -U-H-T Agar[a]	CM(Gal, Raff, X-gal) -U-H-T Agar[a]	CM (Gal,Raff) -U-H-T-L Agar
YNB	6.7 g	6.7 g	6.7 g	6.7 g	6.7 g	6.7 g	6.7 g
Glucose	20 g	20 g	20 g	20 g	20 g		
Galactose						20 g	20 g
Raffinose						10 g	10 g
Dropout mix	2 g	2 g	2 g	2 g	2 g	2 g	2 g
Leucine	15 ml	15 ml	15 ml		15 ml	15 ml	
Tryptophan		10 ml					
Histidine	5 ml						
Uracil	5 ml						
Agar		20 g	20 g	20 g	20 g	20 g	20 g

[a]For media containing X-gal, prepare the appropriate base medium in 900 ml of H_2O, and use it in the recipe for yeast selective X-gal medium.

To prepare medium or agar, mix the ingredients together in a final volume of 1 liter of H_2O. Autoclave for 20 minutes. Cool the medium to 50°C before pouring plates: Leucine stock = 4 mg/ml; Tryptophan stock = 4 mg/ml; Histidine stock = 4 mg/ml; Uracil stock = 4 mg/ml.

Media

Please see Appendix 2 for components of yeast media.

CM selective medium

Use Table 18-3 to estimate the amount of media required and Table 18-9 to prepare the necessary selective media.

Yeast nitrogen base without amino acids (YNB) is sold either with or without ammonium sulfate. Table 18-9 assumes that the YNB contains ammonium sulfate. If the bottle of yeast nitrogen base instructs that 1.7 g/liter be added to make media, then it *does not* contain ammonium sulfate and 5 g of ammonium sulfate per liter of media should be added.

LB agar plates containing 50 μg/ml ampicillin

Minimal (-trp) medium for bacteria

Prepare the following autoclaved stocks:

i. 20% (w/v) magnesium sulfate
ii. 4 mg/ml uracil
iii. 4 mg/ml histidine
iv. 4 mg/ml leucine
v. 20% (w/v) glucose

Prepare the following filter-sterilized solutions:

vi. 50 mg/ml ampicillin
vii. 1% thiamine hydrochloride

Autoclave the following two solutions separately:

viii. 15 g of agar in 800 ml of distilled H_2O
ix. 10.5 g of potassium phosphate (dibasic)
4.5 g of potassium phosphate (monobasic)
1 g of ammonium sulfate
0.5 g of sodium citrate
160 ml of distilled H_2O

Cool Solutions **viii** and **ix** to 50°C, and mix them together. Quickly add 1 ml of Solution **i**, 10 ml of Solution **ii**, 10 ml of Solution **iii**, 10 ml of Solution **iv**, 10 ml of Solution **v**, 1 ml of Solution **vi**, and 0.5 ml of Solution **vii**. Mix the final solution well and pour the plates immediately.

Yeast selective X-gal medium

i. Prepare the base medium in 900 ml of H_2O, according to Table 18-9. Autoclave the base medium and cool it to 55°C.

ii. In a separate bottle, autoclave 7 g of sodium phosphate (dibasic) and 3 g of sodium phosphate (monobasic) in 100 ml of distilled H_2O.

iii. Mix the two autoclaved solutions together, and add 0.8 ml of 100 mg/ml X-gal (in *N,N*-dimethylformamide **<!>**). Pour the plates.

Centrifuges and Rotors

Sorvall RT6000 centrifuge, H1000B MPC and H6000A MPC rotors (for centrifuging microtiter plates)

Special Equipment

Glass beads (0.45-mm diameter, sterile; Sigma)

Microtiter plate (24-well or 96-well [optional])

Repeating pipettor

Optional, please see Step 1.

Additional Reagents

Step 2 of this protocol requires the reagents for electroporation listed in Chapter 1, Protocol 26.

Steps 3 and 4 of this protocol require the reagents for the preparation of miniprep DNA from plasmids listed in Chapter 1, Protocol 1.

Step 10 of this protocol requires the reagents for sequencing of yeast DNA listed in Chapter 4, Protocol 13.

Vectors and Bacterial and Yeast Strains

E. coli *DH5α* or E. coli *KC8* (pyrF leuB600 trpC hisB463; *CLONTECH), competent for electroporation*

Please see Chapter 1, Protocol 26.

Nonspecific bait plasmid

Please see the note to Step 6.

pMW112, pRFHM-1

pBait (from Stage 1)

Yeast colonies with the appropriate phenotype growing on a CM(Glu)-Ura-His-Trp master plate (identified in Stage 2, Step 21)

Yeast strain EGY48

METHOD

Isolation of Positive Plasmids

Two approaches are given for the isolation of discrete library plasmids. For the isolation of a small number of colonies, cells are lysed in SDS. For the isolation of a large number of colonies, cells are lysed in Zymolyase.

1. Prepare cell lysates from positive colonies.

FOR ISOLATION OF A SMALL NUMBER OF COLONIES

Generally, this approach is most useful when working with ~24–36 positives or less, although some investigators prefer to use this approach to work up the entire set of positives initially obtained, even if such positives number in the hundreds. In this case, it is usually more effective to utilize the alternative protocol at the end of this protocol as a means to distinguish unique from commonly occurring positive clones.

a. Starting from the CM(Glu)-Ura-His-Trp master plate (Stage 2, Step 21), pick colonies that display the appropriate phenotype on selective plates into 5 ml of –Trp glucose medium. Grow the cultures overnight at 30°C.

Omitting the -Ura-His selection in this situation encourages loss of nonlibrary plasmids and facilitates isolation of the desired library plasmid.

b. Centrifuge 1 ml of each culture at maximum speed for 1 minute at room temperature in a microfuge. Resuspend the pellets in 200 µl of STES lysis solution, and add 100 µl of 0.45-mm-diameter sterile glass beads. Vortex the tubes vigorously for 1 minute.

c. Add 200 µl of equilibrated phenol to each tube, and vortex the tubes vigorously for another minute.

d. Centrifuge the emulsions at maximum speed for 2 minutes at room temperature in a microfuge, and transfer each aqueous phase to a fresh microfuge tube.

e. Add 200 µl of equilibrated phenol and 100 µl of chloroform to each aqueous phase, and vortex for 30 seconds. Centrifuge the emulsions at maximum speed for 2 minutes at room temperature in a microfuge, and transfer each aqueous phase to a fresh tube.

f. Add two volumes (400 µl) of ethanol to each aqueous phase, mix by inversion, and chill the tubes for 20 minutes at –20°C. Recover the nucleic acid by centrifugation at maximum speed for 15 minutes at 4°C in a microfuge.

g. Pour off the supernatants. Wash the pellets with ice-cold 70% ethanol, and dry the pellets briefly under vacuum. Resuspend each pellet in 5–10 µl of TE (pH 8.0). Proceed to Step 2.

FOR ISOLATION OF A LARGE NUMBER OF COLONIES

The following procedure for preparing DNA in batches was developed by Steve Kron (University of Chicago) as a scale-up of a protocol originally developed by Manuel Claros (Laboratoire Génétique Moléculaire, Paris). A refrigerated centrifuge with plate holders is required, and a repeating pipettor is helpful.

a. Transfer 2 ml of 2x CM(Glu)-Trp medium into each well of a 24-well microtiter plate. Use a toothpick to pick a putative positive colony from a master plate into each well (Stage 2, Step 21). Grow the cultures overnight at 30°C with shaking.

> The use of 2x minimal medium maximizes the yield of yeast. Four plates can generally be handled conveniently and spun simultaneously in a centrifuge.

b. Centrifuge the plate(s) in a centrifuge with microplate holders at 1500*g* (3000 rpm in a Sorvall H1000B MPC rotor) for 5 minutes at 4°C. Shake off the supernatant with a snap of the wrist and return the plate to an upright position. Swirl or lightly vortex the plate to resuspend each cell pellet in the remaining liquid. Add 1 ml of H_2O to each well and swirl the plate gently.

> Cell pellets can most easily be resuspended in residual liquid before adding new solutions. Addition of liquid can be accomplished using a repeating pipettor.

c. Centrifuge as in Step b, shake off the supernatant, resuspend the cells in residual supernatant, and add 1 ml of rescue buffer.

d. Centrifuge as in Step b, shake off the supernatant, and resuspend the cells in the small volume of liquid remaining in the plate. To each well, add 25 µl of lysis solution. Swirl or vortex the plate. Incubate the plate (with the cover on) on a rotary shaker for ~1 hour at 37°C.

> The lysis solution need not be completely dissolved before use. By 1 hour, lysis should be obvious as yeast cells coagulate into a white precipitate. The susceptibility of yeast strains to lytic enzymes varies. If lysis occurs rapidly, then use less lytic enzyme. If the lysis step is allowed to proceed too far, too much of the partially dissolved cell wall may contaminate the final material. Lysis can be judged by examining cells in a phase microscope. Living cells are white with a dark halo, and dead cells are uniformly gray. Lysis leads to the release of granular cell contents into the medium. Once cells are mostly gray and many are disrupted, it can be assumed that much of the plasmid has been released.

e. Add 25 µl of 10% SDS to each well. Disperse the precipitates completely by swirling the plates. Allow the plates to rest on the bench for 1 minute at room temperature. After 1 minute, the wells should contain a clear, somewhat viscous solution.

f. To each well, add 100 µl of 7.5 M ammonium acetate. Swirl the plates gently, and then store them for 15 minutes at –70°C or at –20°C until the lysates are frozen.

Addition of acetate should result in the formation of a massive white precipitate of cell debris and SDS. The freezing step appears to improve removal of inhibitors of *E. coli* transformation.

g. Remove the plates from the freezer. Once they begin to thaw, centrifuge the plates at 3000*g* (3800 rpm in a Sorvall H6000A MPC rotor) for 15 minutes at 4°C. Transfer 100–150 µl of the resulting clear supernatants to fresh 24-well plates.

▲ **IMPORTANT** In general, some contamination of the supernatants with pelleted material cannot be avoided. However, it is better to sacrifice yield in order to maintain purity.

h. To each well, add ~0.7 volume of isopropanol. Mix the solutions by swirling and allow the nucleic acids to precipitate for 2 minutes at room temperature. Centrifuge as in Step g. Shake off the supernatants with a snap of the wrist.

A cloudy fine precipitate should form immediately after isopropanol is added.

i. To each well, add 1 ml of cold 70% ethanol. Swirl the plates, and then centrifuge them at 3000*g* (3800 rpm in a Sorvall H6000A MPC rotor) for 5 minutes at 4°C. Shake off the supernatant with a snap of the wrist, invert the plates, and blot them well onto paper towels. Allow the plates to dry in the air.

j. To each well, add 100 µl of TE (pH 8.0). Swirl the plates and allow them to rest on the bench for several minutes, until the pellets appear fully dissolved. Transfer the preparations to microfuge tubes or the wells of a 96-well plate for storage at –20°C. Proceed to Step 2.

1–5 µl of each of the resulting preparations can be used to transform competent *E. coli* by electroporation. If insufficient numbers of colonies are obtained, reprecipitate the DNAs and dissolve them in 20 µl rather than 100 µl of TE, to concentrate the DNA stock.

Transformation into *E. coli*

If the bait is cloned in one of the specialized LexA-fusion plasmids (Table 18-1) that carries an ampicillin resistance marker, a proportion of the *E. coli* DH5α transformants will not contain the library plasmid. One option to resolve this problem is to analyze multiple transformants from each DNA preparation. Alternatively, it is possible to passage plasmids through a strain of *E. coli* possessing a *trpC* mutation, and select for a library plasmid by the ability of the yeast *TRP1* gene to complement the *E. coli trpC* mutation.

2. Introduce 1–5 µl of each preparation of plasmid DNA into competent *E. coli* DH5α or into strain KC8 (*pyrF leuB600 trpC hisB463*) by electroporation. Plate the bacteria on LB agar containing 50 µg/ml of ampicillin, and incubate the plates overnight at 37°C.

3. If plasmid DNA was transformed into DH5α, proceed to Step 4. If plasmid DNA was transformed into KC8:

a. Use restreaking or replica plating to transfer colonies from LB/ampicillin plates to minimal (–*trp*) medium for bacteria. Incubate the bacteria overnight at 37°C.

Colonies that grow under these conditions contain the pJG4-5 library plasmid, as the *TRP1* gene carried by this plasmid efficiently complements the bacterial *trpC9830* mutation.

The initial plating of transformation mixtures on LB/ampicillin plates is less stressful than directly plating on to bacterial minimal medium and maximizes the number of colonies obtained.

b. Prepare miniprep DNA from an isolated colony and use the DNA to transform DH5α cells as described in Step 2.

Minipreparations of KC8 DNA can be used for restriction digests, PCR, and retransformation of yeast. It is, however, advisable to use the KC8 miniprep DNA to transform a more amenable *E. coli* strain, such as DH5α, before sequencing is attempted. DNA prepared from KC8 is generally unsuitable for dideoxy or automated sequencing even after extensive purification.

4. Prepare miniprep DNA from DH5α cells carrying the library plasmid.

▲ **IMPORTANT** In general, it is a good idea to prepare DNA from two or three separate bacterial colonies generated from each original positive interactor. By contrast to bacteria, yeast can tolerate multiple 2μ plasmids with identical selective markers. If a single yeast cell contains two or three distinct library plasmids, only one of which encodes an interacting protein, the relevant cDNA clone can be lost at the stage of plasmid isolation. Again, in general, this is *not* a major problem; on average, perhaps 10% of yeast cells will contain two or more library plasmids.

5. Confirm by restriction endonuclease digestion that the duplicate samples prepared for each positive contain identical inserts, and/or determine whether a small number of cDNAs have been isolated repeatedly.

Digestion of library plasmids with *Eco*RI + *Xho*I will release cDNA inserts, whereas digestion with *Eco*RI + *Xho*I + *Hae*III will "fingerprint" the inserts. Independent isolation of only a few cDNAs is generally a good indication that the clones have biological relevance. Do not despair if the cDNA clones are not identical. In cases where only a small number of total positive colonies have grown, or in cases where the interactor cDNA was poorly represented in the library, true interactors have been obtained as single positive clones.

▲ **IMPORTANT** Some investigators sequence DNAs at this stage. A lot of money can be wasted on sequencing nonspecific interactors: It is strongly recommended that the transformation into yeast and specificity tests, as described below, be completed before sequencing.

Second Confirmation of Positive Interactions: Repeated Phenotype and Specificity Tests

The final test of the specificity of interacting proteins is the retransformation of library plasmids from *E. coli* into "virgin" *lexAop-LEU2/lexAop-lacZ*/pBait-containing strains. The aim is to verify that interaction-dependent phenotypes are still observed and are specific to the starting pBait. This test will eliminate false positives, including mutations in the initially transformed EGY48 yeast that favor growth or transcriptional activation on galactose medium; library-encoded cDNAs that interact with the LexA DNA-binding domain; and library-encoded proteins that are "sticky" and interact with multiple pBaits in a promiscuous manner.

6. Transform yeast strain EGY48 with the following sets of plasmids, and select colonies on CM(Glu)-Ura-His plates.

   a. pMW112 and pBait

   b. pMW112 and pRFHM-1

   c. pMW112 and a nonspecific bait

If the pBait initially used in the screen was able to activate transcription, even slightly, we strongly recommend that a nonspecific control bait that can also weakly activate transcription be included as a control. In general, baits that activate transcription poorly are difficult to distinguish from the background of false positives. Some false positives interact generically with weakly activating LexA-fused proteins.

7. After 2–3 days, transformed yeast from Step 6 should be available. Use electroporation to introduce library plasmids prepared from *E. coli* KC8 or DH5α into individual transformants **a**–**c**. Plate each transformation mixture on CM(Glu)-Ura-His-Trp dropout plates and incubate the plates at 30°C until colonies grow (2–3 days).

▲ **IMPORTANT** As a negative control, also electroporate examples of transformants **a**–**c** with the pJG4-5 library vector.

8. Create a CM(Glu)-Ura-His-Trp master dropout plate for each library plasmid being tested. It is generally helpful to streak tranformants **a**–**c** for each library plasmid in close proximity on the plate to facilitate detection of nonspecific interactions.

▲ **IMPORTANT** Each plate should also contain the **a**–**c** series transformed with the pJG4-5 negative control.

9. Test for β-galactosidase activity and for leucine auxotrophy, exactly as described in Stage 2, Step 21.

10. Analyze the results of these specificity tests and sequence the positive isolates (please see Chapter 4, Protocol 13).

- True "positive" cDNAs should render yeast blue on CM(Gal, Raff)-Ura-His-Trp plates but not on CM(Glu, X-gal)-Ura-His-Trp plates, and permit growth on CM(Gal, Raff)-Ura-His-Trp-Leu dropout plates, but not CM(Glu)-Ura-His-Trp-Leu dropout plates, specifically with the original pBait but not **b** or **c**. These positive cDNAs are ready to be sequenced (if they have not been already) using primer FP1 (please see the panel on **ALTERNATIVE PROTOCOL: RAPID SCREEN FOR INTERACTION TRAP POSITIVES** on the following page). Those cDNAs that also encode proteins that interact with either **b** or **c** should be discarded.
- It is possible to quantify roughly the relative affinity of interactions using numbers generated by β-galactosidase assays. Whether this is desirable is left to the discretion of the individual investigator.
- As an additional control, a database of common false positives has been compiled and made available on the World Wide Web, at

  http://www.fccc.edu/research/labs/golemis/InteractionTrapInWork.html

  Particularly for cDNAs isolated only once, or for cDNAs that do not appear to make biological sense in the context of the starting bait, it may be helpful to consult the database to make sure that the clone has not been reported to be a problem by other groups.

SUBSEQUENT CHARACTERIZATION

If all has gone well in the previous steps, the experiment will have generated a small set of sequenced cDNAs, encoding proteins that interact specifically with their starting bait. What next? In some cases, the subsequent characterization steps are obvious, with the isolated cDNA making clear biological sense in the context of a particular starting bait. However, in general, this is the point at which the bulk of the work really begins, with the obtained interactor either corresponding to a cDNA without a defined biological activity immediately relevant to the starting bait or corresponding to a novel sequence. There are many ways to approach the analysis of such novel interactors, and a complete discussion would go far beyond the scope of this chapter. For investigators not experienced in the characterization of novel proteins, the following questions cover a few issues that might be particularly helpful in getting started.

- ***Is the cDNA full-length?*** Many times, isolated interactors correspond to the carboxy-terminal end of incomplete cDNAs. Thus, some first steps would involve using a cDNA probe in northern analysis to establish transcript size. If the isolated cDNA is truncated, scanning sequence databases (those containing expressed sequence tags are useful) and subsequent screening of conventional cDNA libraries (Chapter 11, Protocol 2) or RACE (Chapter 8, Protocols 9 and 10) are used to obtain full-length clones.
- ***Is the cDNA expressed in an appropriate cell type and/or tissue location to conceivably interact with the Bait protein?*** For mammals, probing of a multitissue northern blot (many are commercially available from CLONTECH and other sources) will address this point.
- ***Does the full-length bait associate with the full-length interactor? Do the bait and interactor associate in another assay system different from the two-hybrid system?*** Ideally, investigators would like to coimmunoprecipitate the endogenous bait and interactor from their host organism. For mammals, an intermediate step while the antibody is forthcoming is to synthesize an epitope-tagged version of the interactor, transfect it into cells normally expressing the bait, and coimmunoprecipitate with this combination.
- ***Intracellularly, are bait and interactor expressed in overlapping or identical compartments?*** Cell fractionation and/or immunofluorescence performed with antibody either to a native or tagged interactor may be used to address these points (for details on these methods, please refer to Spector et al. [1998, Chapters 71 and 98]).
- ***Above all, do bait and interactors affect each other's biological activity?*** Some further assays may ultimately be useful in yeast, for example, mapping the domain of interaction using a series of truncated bait proteins. First and foremost, the main goal is to establish biological relevance of the interaction in the organism of origin.

ALTERNATIVE PROTOCOL: RAPID SCREEN FOR INTERACTION TRAP POSITIVES

This protocol is an alternative approach to screening for positive library plasmids. A major strength of this approach is that it will identify redundant clones before plasmid isolation and bacterial transformation, which in some cases greatly reduces the amount of work required. However, accurate records should be maintained detailing how many of each class of cDNAs are obtained. If there is any doubt whether a particular cDNA is part of a set or is unique, investigators should err on the side of caution. This rapid screening method is most advantageous when the number of selected colonies exceeds 23.

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Additional Materials

2% Agarose gel
β-glucuronidase lysis solution
50 mM Tris-HCl (pH 7.5)
10 mM EDTA
0.3% (v/v) β-mercaptoethanol (prepare fresh) <!>
1:50 β-glucuronidase type HP-2, crude solution from *H. pomatia* (Sigma)
Glass beads (150–212 μm diameter; Sigma)
0.7% Low-melting-temperature agarose gel
Oligonucleotides primers (20 mM in TE [pH 8.0])

Forward primer (FP1)	5′-CTG AGT GCA GAT GCC TCC
Reverse primer (FP2)	5′-CTG GCA AGG TAG ACA AGC CG

Microtiter plate (96-well)
Reagents for analyzing yeast colonies by PCR (Chapter 4, Protocol 13)
Reagents for purifying DNA fragments from low-melting-temperature agarose (Chapter 5, Protocol 6 or 7)
Restriction endonuclease HaeIII
Thermocycler
Thin-walled microfuge tubes (0.5-ml, sterile)

Method

1. Add 25 μl of β-glucuronidase lysis solution into the individual wells of a 96-well microtiter plate.
2. Starting from the CM(Glu)-Ura-His-Trp master plate (Stage 2, Step 21), transfer and resuspend individual positive candidate yeast colonies in each of the wells containing β-glucuronidase solution. Use tape to seal the wells, and incubate the plate on a horizontal shaker for 1.5–3.5 hours at 37°C.

   ▲ **IMPORTANT** Transfer approximately the volume of one middle-sized yeast colony (2–3-μl packed pellet); do *not* take more, or the quality of the isolated DNA will suffer. The master plate does not need to be absolutely fresh: Plates stored for 5 days at 4°C have been used successfully. If appropriate, a multicolony replicator/frogger can be used.
3. Remove the tape and add ~25 μl of glass beads (150–212 μm) to each well, and seal the wells again. Attach the microtiter plate to a vortex with a flat top surface (e.g., using rubber bands) and mix vigorously for 5 minutes.
4. Add 100 μl of sterile distilled H_2O to each well. Transfer 0.8–2 μl from each well to a fresh microfuge tube to be used as a template for each PCR. Reseal the plate with tape, and keep the remainder of the lysate frozen at –20°C.

5. In a series of sterile 0.5-ml thin-walled microfuge tubes (equal to the number of colonies to be analyzed), mix in the following order:

10x colony PCR buffer	2 µl
25 mM $MgCl_2$	1.2 µl
10 mM dNTPs	0.4 µl
oligonucleotide primers (FP1 and FP2)	10 pmoles of each
Taq polymerase	5 units (0.2 µl)
H_2O	to 20 µl

6. Add 0.8–2 µl of template (from Step 4) to each PCR tube.

7. Transfer the PCR tubes to the thermocycler, programmed as follows, and start the program.

Cycle Number	Denaturation	Annealing	Polymerization
1	2 min at 94°C		
2–32	45 sec at 94°C	45 sec at 56°C	45 sec at 72°C

Modified versions of this protocol with extended elongation times have also been found to work; the variant given above has amplified fragments of as much as 1.8 kb in reasonable quantity.

8. Analyze the PCR products:

   a. Remove 10 µl of the PCR products into fresh microfuge tubes, and perform a restriction digest with *Hae*III in a total volume of 20 µl.

   b. Load the digestion products onto a 2% agarose gel, and run the DNAs a sufficient distance to resolve the digestion products in the 200–1000 bp size range.

      Analysis by electrophoresis will generally yield distinctive and unambiguous groups of inserts, indicating whether multiple isolates of a small number of cDNAs have been obtained.

9. In parallel with the *Hae*III digestion, run the remainder of each PCR (~10 µl) on a 0.7% low-melting-temperature agarose gel. Confirm that groups of inserts predicted on the basis of the *Hae*III digest appear to be compatible with groups predicted by analysis of the nondigested PCR products.

   ▲ **IMPORTANT** Sometimes a single yeast colony contains two or more different library plasmids. This will be immediately revealed by PCR, so following bacterial transformation, check several independent clones to reduce the possibility of losing the "real" interactor.

10. Purify fragments from the low-melting-temperature agarose gel (Chapter 5, Protocol 6 or 7).

    In cases where a very large number of isolates of a small number of cDNAs have been obtained, the investigator may choose to sequence the PCR product directly. Only the forward primer, FP1, works well in sequencing of PCR fragments; the reverse primer only works in sequencing from purified plasmids. In general, the TA-rich nature of the ADH terminator sequences downstream from the polylinker in the pJG4-5 vector makes it difficult to design high-quality primers in this region.

11. Transform *E. coli* (either DH5α or KC8) with DNA from selected positives, using electroporation as described in the main protocol (Steps 2–5). Use 2–4 µl of the β-glucuronidase-treated frozen yeast (Step 4) as the source of DNA.

12. Proceed with the second confirmation of positive interactions, as outlined in the main protocol, commencing with Step 6.

Protocol 2

Detection of Protein-Protein Interactions Using Far Western with GST Fusion Proteins

Margret B. Einarson
Fox Chase Cancer Center, Philadelphia, Pennsylvania 19111

GST FUSION PROTEINS HAVE BEEN USED IN THOUSANDS OF PROJECTS since their introduction as components of recombinant proteins expressed in bacteria (Smith and Johnson 1988). They are now routinely used to generate antibodies to study protein-protein interactions and to analyze biochemical reactions. Protocols 2 and 3 describe the use of GST fusion proteins as probes for the identification of protein-protein interactions, although other systems are available for the production of recombinant proteins (for detailed discussions, please see Chapter 15). The techniques used are fundamentally similar to analogous techniques developed for detection of proteins by antibodies. For example, in western blots, an antibody is used to detect a candidate protein bound to a membrane. In a far western blot, the antibody has been replaced by a recombinant GST fusion protein produced in and purified from bacteria. The interaction of this probe protein and a target protein on the membrane can be detected by GST pulldown, which relies on the ability of glutathione agarose beads to precipitate GST fusion proteins that have previously bound to specific partner proteins in solution. GST pulldowns can be initiated prior to the availability of antibodies to the protein of interest, or when antibodies have been found to interfere with protein-protein interactions. It should be noted that these methods characterize in vitro interactions, which should subsequently be substantiated in vivo by independent means such as coimmunoprecipitation (Protocol 4). Although Protocols 2 and 3 yield results that are qualitative, GST fusion proteins also can be used in highly quantitative and sophisticated assays (e.g., please see Posern et al. 1998; McDonald et al. 1999).

Far western analysis was originally developed to screen expression libraries with a ^{32}P-labeled GST fusion protein (Blackwood and Eisenman 1991; Kaelin et al. 1992). The schema of a typical far western experiment is depicted in Figure 18-12. The probe protein is first synthesized and purified from bacteria (please see Chapter 15, Protocol 5). In the figure, the probe protein is a GST fusion containing the GST moiety followed by a protease cleavage site and a target site for a known protein kinase in-frame with the protein of interest. The purified fusion protein bound to glutathione beads is radiolabeled with ^{32}P using a commercially available protein kinase. The fusion protein is washed to remove unincorporated nucleotide, and the radiolabeled protein is cleaved with a protease (e.g., Factor X or thrombin) or eluted with glutathione to release the radiolabeled protein probe. The sample to be probed is prepared either by resolving the target proteins on an SDS-polyacrylamide gel and transferring the proteins to a membrane (e.g., please see Posern et al. 1998; Grgurevich et al. 1999; Hunter et al. 1999) or by plating a protein expression

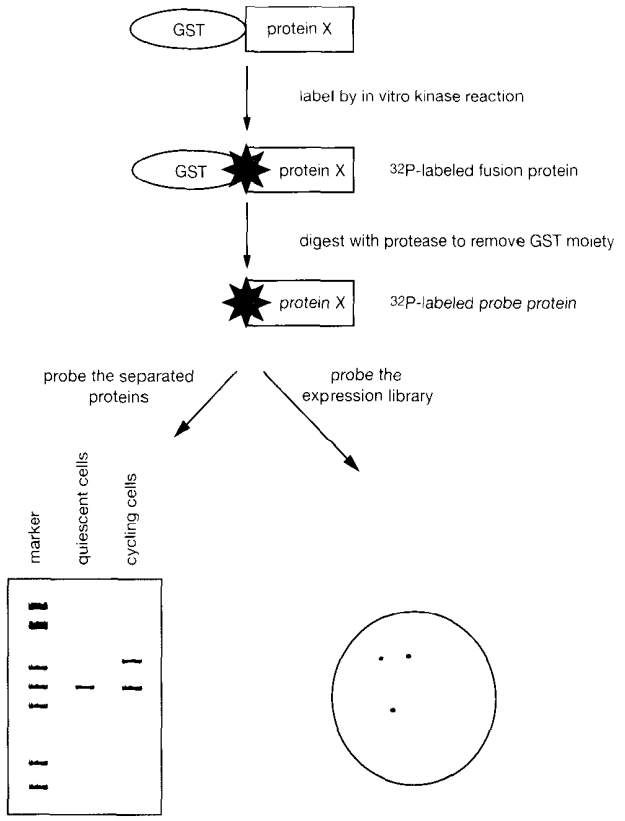

FIGURE 18-12 Outline of a Far Western

The purified recombinant GST-fusion protein is radiolabeled at a kinase consensus site contained in the fusion portion of the protein. The ^{32}P-labeled probe protein is separated from the GST moiety by protease digestion. The labeled protein can be used to probe membranes generated either by transfer of proteins separated by SDS-polyacrylamide gel electrophoresis (*left*) or plating an expression library (*right*). Variations on this procedure are described in the text.

library and transferring the proteins to a membrane (Macgregor et al. 1990; Blackwood and Eisenman 1991; Kaelin et al. 1991; Blanar and Rutter 1992; Ayer et al. 1993; Einarson and Chao 1995). The membrane is washed and blocked before addition of the radioactive protein probe. After incubation with the probe protein, the membrane is washed and subjected to autoradiography. Radiolabeling the fusion protein is rapid and easy, and generally has little impact on the subsequent activity of the protein, because the phosphorylation site is in the fusion portion of the protein. A variety of protein kinase sites have been integrated into fusion protein vectors (Blanar and Rutter 1992; Kaelin et al. 1992; Ron and Dressler 1992) to allow for ^{32}P labeling of recombinant proteins expressed in bacteria. The most commonly used kinases are protein kinase A, cAMP-dependent protein kinase, and enterokinase. An early variation on this technique utilized endogenous phosphorylation sites in the protein of interest for ^{32}P phosphorylation (Skolnick et al. 1991; Ayer et al. 1993). An alternative method of radiolabeling the probe without the need to generate a fusion protein is to label it with ^{35}S in an in vitro transcription/translation reaction (Lee et al. 1991).

Two other methods are commonly used to detect interactions between GST fusions and target proteins: Anti-GST antibodies can be used to locate unlabeled fusions proteins on far western

blots. Alternatively, biotinylated GST can be detected histochemically by streptavidin-conjugated enzymes. Biotinylation of proteins is now relatively easy due to the availability of kits (Amersham Pharmacia Biotech). However, biotinylation may have an impact on the ability of the probe protein to associate with other proteins. The use of commercially available anti-GST antibodies is a good option for detecting interactions on membranes of cell lysates. The latter two methods have the advantage of being nonradioactive. However, if a library screen is planned, the cost of the anti-GST antibody and detection reagents may be excessive.

The design of the fusion protein depends on the chosen detection method and on the type of screen that is planned. One issue to consider is using cleaved versus full-length GST fusion proteins. The GST moiety is known to dimerize and can generate background. Most fusion vectors contain cleavage sites to separate the GST portion from the protein of interest. Note, however, that if the fusion protein is cleaved, the interaction with the target protein can no longer be detected with anti-GST antibodies. To choose which cleavage site to use, it is important to scan the protein and ensure that it does not contain the recognition site of the protease. A second issue to consider is what region of the probe protein ought to be incorporated into the GST fusion protein. For a library screen, including as much of the probe protein as possible increases the number of interactions detected. On the other hand, if the probe protein contains known interaction domains and these are being tested to confirm predicted interactions, then a fusion protein containing only these motifs would be preferred.

Perhaps the most important consideration in planning a far western experiment is the ability to synthesize the fusion protein without undue degradation and insolubility. If the fusion protein is excessively degraded during purification, the probe protein will be a mixture of degradation products. Variable results may be obtained from preparations of the different fusion proteins. It is therefore important to monitor the status of the fusion protein during and after purification and, if the protein has been stored, before use. Two controls that will help to confirm the specificity of the protein-protein interactions are (1) to probe with a mutated version of the fusion protein that interrupts the interaction and (2) to probe the membrane with labeled GST.

A final decision is whether to probe the membrane with or without a cycle of denaturation/renaturation, which is designed to allow misfolded proteins to refold into their native conformations. In general, proteins transferred to a membrane from an SDS-polyacrylamide gel do not require denaturation and renaturation. However, many investigators who probe filters housing imprints of an expression library find denaturation/renaturation to be an essential step. Thus, if probing an SDS-polyacrylamide gel yields no protein-protein interactions, incorporating a denaturation/renaturation procedure may yield positive results (for details, please see the panel on **ADDITIONAL PROTOCOL: REFOLDING OF MEMBRANE-BOUND PROTEINS** at the end of this protocol).

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Basic buffer

20 mM HEPES (pH 7.5)
50 mM KCl
10 mM $MgCl_2$
1 mM dithiothreitol
0.1% Nonidet P-40

Blocking buffer
5% nonfat dry milk in basic buffer.
Interaction buffer
1% nonfat dry milk in basic buffer.
2x PK buffer
100 mM KPO_4
20 mM $MgCl_2$
10 mM NaF <!>
9 mM dithiothreitol
Reduced glutathione (20 mM) in 50 mM Tris-Cl (pH 8.0)
Optional, please see Step 3.
Wash buffer 1
Phosphate-buffered saline containing 0.2% Triton X-100.
Wash buffer 2
Phosphate-buffered saline containing 0.2% Triton X-100 and 100 mM KCl.

Enzymes and Buffers

Protease
Optional, please see Step 3.
Protein kinase A
Prepare fresh at each use according to the manufacturer's instructions.

Radioactive Compounds

[γ-^{32}P]ATP (6000 Ci/mmole) <!>

Special Equipment

Membranes or filters that will bind proteins to be screened
Please see Step 5.
Sephadex G-50 spun column
Optional, please see Step 4.

Additional Reagents

Step 3 of this protocol requires reagents for cleavage of the fusion protein from its carrier or the fusion protein attached to glutathione-agarose beads in Chapter 15, Protocol 5.
Step 5 of this protocol requires either a polyacrylamide gel containing the proteins to be probed (please see Appendix 8) or plates containing a cDNA expression library (please see Chapter 14, Protocol 2), and reagents for immunoblotting described in Appendix 8.
A negative control of GST alone or a nonspecific protein should be loaded onto the SDS-polyacrylamide gel with the target proteins. If the protein of interest is a member of a conserved family, the interaction of the protein of interest can be compared to other proteins from the same family.

Vectors and Bacterial Strains

GST fusion protein bound to glutathione-agarose beads
This protocol is for proteins containing a protein kinase A phosphorylation site in the fusion protein (Ron and Dressler 1992). Also available is a vector that contains a cAMP-dependent protein kinase recognition sequence (Amersham Pharmacia Biotech). If using an unlabeled GST fusion protein, please see the panel on **ALTERNATIVE PROTOCOL: DETECTION OF PROTEIN-PROTEIN INTERACTIONS WITH ANTI-GST ANTIBODIES** at the end of this protocol.

METHOD

Preparation of the Radiolabeled Protein Probe

1. Prepare the following reaction mixture in a microfuge tube:

[γ-^{32}P]ATP (6000 Ci/mmole)	5 µl
protein kinase A	1 unit/µl
GST fusion protein on glutathione-agarose beads	1–3 µg
2x PK buffer	12.5 µl
H_2O	to 25 µl

Incubate the reaction mixture for 30 minutes at 37°C.

The fusion protein may be cleaved with a protease before the labeling reaction. In this case, substitute the cleaved protein for the protein bound to glutathione-agarose beads in the labeling reaction, incubate for 30 minutes at 37°C, and proceed to Step 4.

If the GST moiety is retained on the fusion protein, the experiment must be replicated with GST alone (bound to glutathione-agarose beads) as a negative control. In the case of a library screen where this would be impractical, it is important to test positive plaques for their ability to bind GST alone. This control is usually carried out after quaternary purification, before clone characterization.

2. After the labeling reaction is complete, wash the beads by adding 200 µl of 1x PK buffer to the tube, and centrifuge the tube at maximum speed for 1 minute in a microfuge. Discard the supernatant containing the free radiolabeled nucleotide in an appropriate manner. Repeat the wash one more time.

3. Either cleave the labeled protein with a protease or elute the labeled GST fusion protein from the beads with 20 mM reduced glutathione in 50 mM Tris (pH 8.0) (please see Chapter 15, Protocol 5). Store the radiolabeled protein probe in an ice bucket and use it on the same day it is made.

4. If the labeled protein was cleaved from the GST moiety before the labeling reaction (please see the note to Step 1), then load the radiolabeled protein onto a Sephadex G-50 column equilibrated with 1x PK buffer to remove the free radiolabeled nucleotide. Once the probe protein is separated from the free nucleotide, it is ready for use. Store the radiolabeled protein probe in an ice bucket and use it on the same day it is made.

Probing the Membranes

5. Prepare the membrane to be probed by transferring proteins to the membrane according to standard techniques.

Proteins transferred from an SDS-polyacrylamide gel (Appendix 8) can generally be probed directly. If proteins are transferred from a cDNA expression library, it may be necessary to carry out the **ADDITIONAL PROTOCOL: REFOLDING OF MEMBRANE-BOUND PROTEINS** before proceeding to Step 6.

6. Cover the membrane completely with basic buffer and wash it for 10 minutes at 4°C with gentle agitation.

7. Discard the basic buffer. Cover the membrane completely with blocking buffer and incubate it with gentle agitation for 4 hours to overnight at 4°C.

8. Prepare a solution of labeled protein by adding 1–3 µg of the stock probe (from either Step 3 or 4) to enough interaction buffer to make a final concentration of 1–5 nM. Transfer the membrane to a dish containing the diluted probe. Make sure that the probe solution contacts the entire surface of the membrane evenly. Incubate the membrane for 4–5 hours at 4°C with gentle agitation.

9. Discard the radioactive probe solution in an appropriate manner. Cover the membrane completely with Wash buffer 1, and incubate the membrane for 10 minutes at 4°C with gentle agitation. Repeat the wash three more times.
10. Cover the membrane completely with Wash buffer 2, and wash the membrane for 10 minutes at 4°C with gentle agitation. Repeat this once.
11. Wrap the membrane carefully in plastic wrap and expose it to X-ray film.

INTERPRETATION OF THE RESULTS AND TROUBLESHOOTING THE EXPERIMENT

- The failure to detect any protein interactions could be a correct result. However, if there is supporting evidence that this is not the predicted result, try the **ADDITIONAL PROTOCOL: REFOLDING OF MEMBRANE-BOUND PROTEINS** and then probe the membrane again with the radiolabeled protein.
- The presence of an excessive number of signals can result from a number of causes. Degraded or impure probe protein is one possibility. Check the integrity of the probe on an SDS-polyacrylamide gel. GST homodimerization can be another source of background. In this case, try cleaving the GST moiety from the fusion protein. If this is not practical, add an excess of unlabeled GST before blocking the membrane or during incubation of the probe (this approach cannot be used if anti-GST antibodies are being used to detect the interaction). The incubation time can be shortened to reduce possible nonspecific interactions. Alternatively, if the probe is in excess, carry out the experiment using several different probe concentrations to determine the optimal concentration.
- The best control for establishing specificity of the observed protein interactions is to generate a probe protein with a mutation in the interaction domain. Demonstrating loss of interaction in an experiment performed with the mutant probe compared to a parallel experiment run with the wild-type probe is convincing evidence that the interaction(s) is relevant.

ADDITIONAL PROTOCOL: REFOLDING OF MEMBRANE-BOUND PROTEINS

In some instances, the proteins on the membrane are unable to interact with the probe protein, possibly due to improper folding during expression or transfer. Denaturation and slow renaturation of the proteins may be necessary. This is accomplished by washing the membrane in a denaturation buffer that is diluted serially to allow for slow renaturation during subsequent washing. Start with a stock solution of 6 M guanidinium hydrochloride prepared in basic buffer and dilute it serially as the membrane is washed.

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Additional Materials

Denaturation buffer

Prepare 6 M guanidine hydrochloride <!> in basic buffer (for recipe of basic buffer, please see the main protocol).

Method

1. After protein transfer, wash the membrane twice, each time in 50 ml of denaturation buffer for 10 minutes at 4°C with gentle agitation.

   The exact volume of buffer to use in this and subsequent steps depends on the size and number of membranes under study. Use enough buffer to cover the membrane(s) completely.

2. Remove the denaturation buffer from the container and retain 25 ml of it. Add 25 ml of basic buffer to the 25 ml of denaturation buffer to make a total volume of 50 ml. This is the first 1:1 dilution of the denaturation buffer. Return the diluted denaturation buffer to the container and wash the blot for 10 minutes at 4°C with gentle agitation.
3. Repeat this dilution and wash cycle (Step 2) four more times. The final wash therefore contains 187 mM guanidinium hydrochloride.
4. Return to the main protocol and proceed with Step 6.

ALTERNATIVE PROTOCOL: DETECTION OF PROTEIN-PROTEIN INTERACTIONS WITH ANTI-GST ANTIBODIES

A nonradioactive version of the far western uses an unlabeled GST fusion protein. Commercially available anti-GST sera are then used to detect protein-protein interactions. The use of this approach when screening a cDNA expression library is substantially more expensive (due to the cost of the antibody and detection reagents) than radiolabeling the proteins. In addition, care must be taken to control for nonspecific interactions between the GST moiety and the membrane-bound proteins.

Additional Materials

Anti-GST antibody

This antibody is available commercially from Amersham Pharmacia Biotech, Santa Cruz Biotech, Upstate Biotechnology, and Convance/Babco.

Incubation buffer

10% (w/v) nonfat dry milk
1x phosphate-buffered saline
0.3% (v/v) Tween-20

Secondary antibody

The secondary antibody should be an anti-IgG directed against the species used to prepare the anti-GST serum (e.g., use anti-goat IgG if the anti-GST antibody was obtained from goat serum). In addition, the secondary antibody should be part of a detection system that will permit the protein-protein interactions of interest to be visualized. For example, the secondary antibody could be conjugated to an enzyme such as horseradish peroxidase, which can be used in a chemiluminescent detection system. For additional details, please see Appendix 9.

Wash buffer

1x phosphate-buffered saline
0.3% (v/v) Tween-20

Method

1. Begin the main protocol at Step 2 and proceed through Step 10.
2. Incubate the membrane with anti-GST antibodies according to the manufacturer's recommendations.
3. Remove the anti-GST antibody solution. Rinse the membrane twice, each time with 25 ml of wash buffer to remove residual unbound antibody.
4. Wash the membrane twice, each time with 20–30 ml of wash buffer for 10 minutes at room temperature with gentle mixing.
5. Dilute the secondary antibody with incubation buffer according to the manufacturer's recommendations.
6. Pour the antibody-buffer mixture into the container with the membrane. Incubate the membrane for 1 hour at room temperature with gentle mixing.
7. Discard the antibody solution. Rinse the membrane twice, each time with 25 ml of wash buffer to remove the majority of unbound antibody.
8. Wash the membrane twice, each time with 20–30 ml of wash buffer for 10 minutes at room temperature with gentle mixing.
9. Develop the blot with the appropriate substrate for the conjugated secondary antibody.

Protocol 3

Detection of Protein-Protein Interactions Using the GST Fusion Protein Pulldown Technique

Margret B. Einarson
Fox Chase Cancer Center, Philadelphia, Pennsylvania 19111

THE GST FUSION PROTEIN PULLDOWN TECHNIQUE (KAELIN ET AL. 1991) uses the affinity of GST for glutathione-coupled beads to purify interacting proteins from a solution of noninteracting proteins. The schema of a GST pulldown experiment is depicted in Figure 18-13. The GST fusion probe protein is expressed and purified from bacteria (please see Chapter 15, Protocol 5). In parallel, a cell lysate (which can be ^{35}S-labeled or unlabeled) is prepared. The GST fusion protein probe and the cell lysate are mixed in the presence of glutathione-agarose beads and incubated to allow protein associations to occur. The GST fusion probe protein and any associated molecules are collected by centrifugation and the complexes are washed. The complexes can be eluted from the beads with excess free glutathione or boiled directly in SDS-PAGE gel-loading buffer. The proteins are resolved by SDS-polyacrylamide gel electrophoresis and processed for further analysis by western blotting, autoradiography, or protein staining. The GST pulldown technique is especially useful for probing protein interactions in solution that might go undetected in a membrane-based assay.

Two general uses of the GST pulldown experiment are to identify novel interactions between a fusion (or probe) protein and unknown (or target) proteins (Kaelin et al. 1991; Orlinick and Chao 1996) and to confirm suspected interactions between the probe protein and a known protein (e.g., please see Posern et al. 1998; Grgurevich et al. 1999; Hunter et al. 1999; Sun et al. 1999). These two experiments are designed and executed differently.

When attempting to identify novel interactions between a probe and unknown proteins, it is possible that the unknown proteins will be in limiting concentrations. To identify a novel interaction, the unknown protein must be present in sufficient quantities to allow the interaction to be visualized with the chosen method of detection. Radiolabeled cell lysates are the most frequently used source of protein for experiments of this type. Some important questions to ask before choosing the source of test proteins are: Is the probe protein normally expressed in that particular cell or tissue? If not, the physiologically relevant target proteins may not be present either. Is the goal to compare different types of cell populations (e.g., quiescent cells versus cycling cells or growth-factor-treated cells versus untreated cells)? Contemplating such variables at an early stage can mean the difference between success and failure.

If a predicted interaction between the probe protein and another protein is being tested, the experimental design is more straightforward. A wide variety of protein sources can be used to identify and map the interaction. The method used to detect the interaction is determined by the

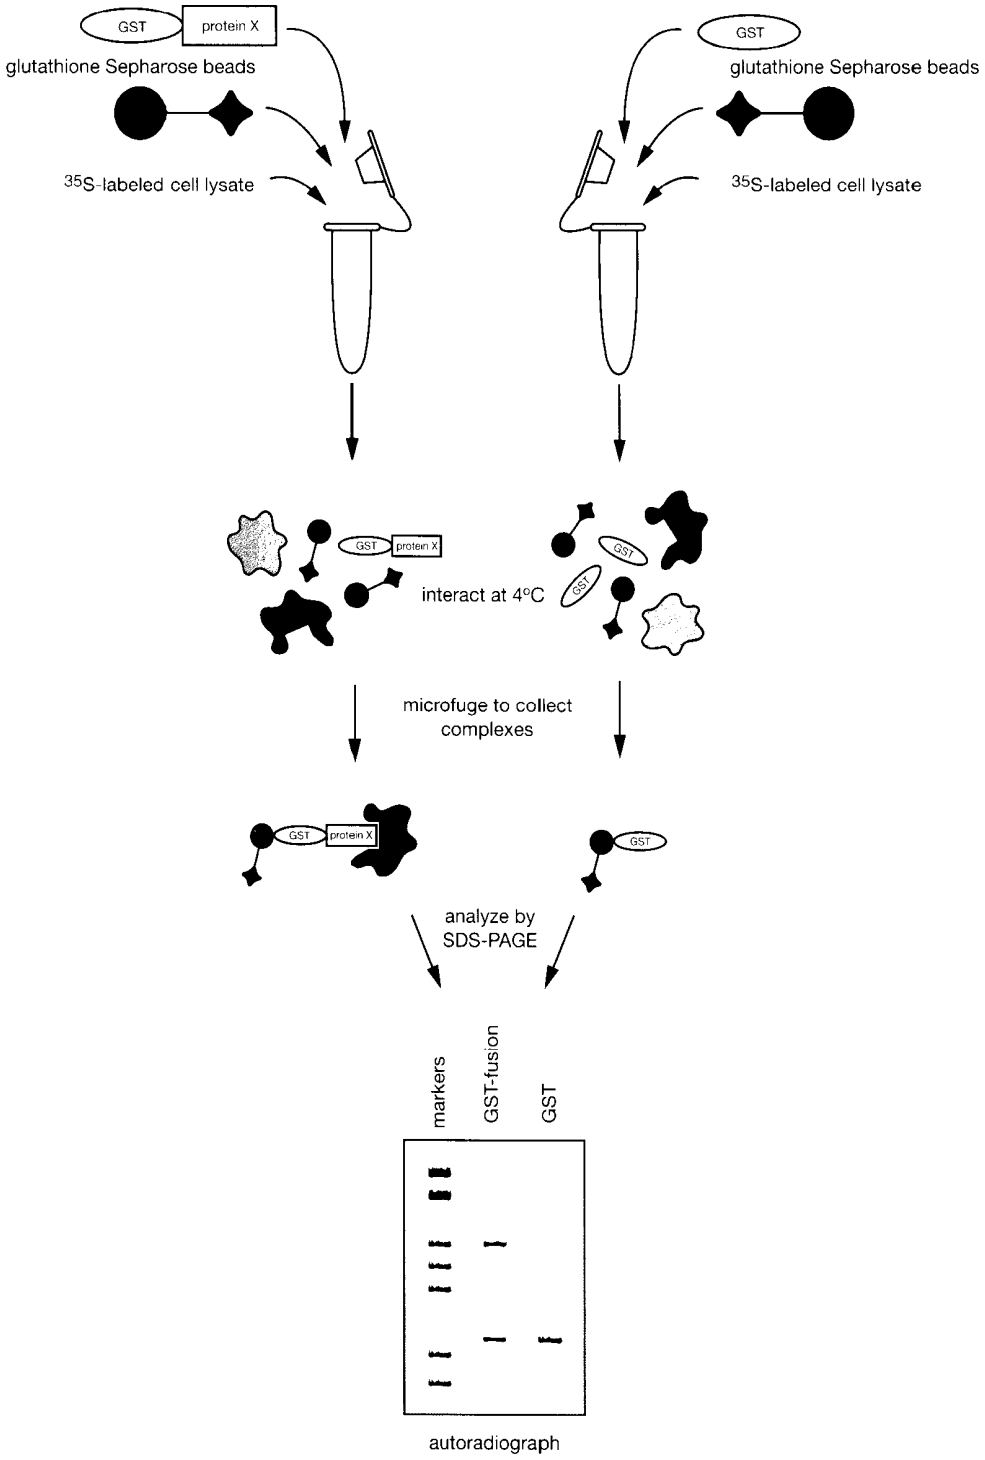

FIGURE 18-13 Outline of a GST Pulldown

The recombinant GST fusion protein (*left*) or control GST (*right*) is incubated with a cell lysate in the presence of glutathione-agarose beads. The proteins are allowed to associate during end-over-end mixing at 4°C, and the reaction is then centrifuged to collect the GST or GST fusion proteins and associated proteins. The proteins are resolved on an SDS-polyacrylamide gel and subjected to autoradiography. The signals on the gel that are specific to the GST fusion protein (and not GST) represent potential interacting proteins. Variations of this protocol are described in the text.

availability of antibodies to the target protein. If none are available, then ^{35}S-labeled in-vitro-translated protein can be utilized or the target protein can be tagged with an epitope. If necessary, cells in culture can be transfected with a plasmid encoding the target protein to increase the abundance of that protein for analysis. However, it is important to control for effects of mass action (e.g., nonspecific aggregation) and to ensure the specificity of the association between the probe protein and its putative partner. The best control for specificity of binding is the inclusion of a GST fusion protein with a mutated interaction domain. Loss of binding with this mutated probe protein suggests that the normal association between target and probe is specific. It is also important to test for binding between the putative target protein and GST.

The GST pulldown technique must be optimized for each protein complex being assayed. One important variable is the buffer in which the interactions will take place. This is often the buffer in which the potential partner proteins are prepared and can vary from a cell lysis buffer (such as RIPA) to an in vitro translation reaction mixture. A wide variety of buffers work; however, the efficiency of the interaction may be affected by the buffers used. Another variable to consider is the amount of target protein mixed with the fusion (probe) protein. The amount of material required is determined chiefly by the abundance of the target protein and the affinity of the interaction (both parameters are generally unknown when the experiment is initiated). Finally, the conditions used to wash the beads should be optimized. In this protocol, the cell lysis buffer is used to wash the GST-pulldown complexes; however, buffers of varying salt and detergent concentrations can be used at this step to eliminate nonspecific interactions. GST pulldown experiments have an advantage over far westerns (Protocol 2): The probe protein is incubated with potential partner proteins in a more native environment, thereby enhancing the efficiency of interactions.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Lysis buffer

20 mM Tris-Cl (pH 8.0)
200 mM NaCl
1 mM EDTA (pH 8.0)
0.5% Nonidet P-40
Just before use, add protease inhibitors to the following final concentrations: 2 µg/µl aprotinin, 1 µg/µl leupeptin, 0.7 µg/ml pepstatin, and 25 µg/ml phenylmethylsulfonyl fluoride (PMSF) <!>.

Reduced glutathione (20 mM) in 50 mM Tris-Cl (pH 8.0)

Optional, please see Step 8.

2x SDS-PAGE gel-loading buffer

Gels

SDS polyacrylamide gel <!>

For details on SDS-polyacrylamide gel electrophoresis, please see Appendix 8.

Special Equipment

Boiling water bath
End-over-end sample rotator
Glutathione agarose beads

Prepare as a 50% slurry in lysis buffer.

Probes

GST protein

GST fusion protein carrying the "bait" or probe sequence

Construct as described in Chapter 15, Protocol 1.

Cells and Tissues

Cell lysate in which the proteins are ^{35}S-labeled

It is possible to use unlabeled cell lysates depending on the goals of the experiment and the desired detection method. For additional details, please see the protocol introduction.

Additional Reagents

Step 11 of this protocol requires reagents for immunoblotting and staining proteins separated by SDS-polyacrylamide gel electrophoresis as listed in Appendix 8.

METHOD

Preclearing the Cell Lysate

1. Incubate the cell lysate with 50 µl of a 50% slurry of glutathione agarose beads and 25 µg of GST for 2 hours at 4°C with end-over-end mixing. The amount of lysate needed to detect an interaction is highly variable. Start with a volume of lysate equivalent to 1×10^6 to 1×10^7 cells.

   Because the aim of the experiment is to compare GST with a GST fusion protein, it is necessary to prepare enough precleared lysate for each reaction. Efficient mixing of reagents is the key to success. This is best achieved if the reaction is carried out in a reasonable volume: 500–1000 µl is a good starting point.

   This preclearing step is designed to remove proteins from the lysate that interact nonspecifically with the GST moiety or the beads alone. It is not always necessary to preclear the lysates with GST or glutathione agarose beads if the interaction will be detected primarily with antibodies directed to a candidate interacting protein. However, when ^{35}S-labeled cell lysates are used to identify novel protein-protein interactions, these steps can help to reduce background. If the interaction will be detected with antibodies to a candidate interacting protein, it is important to include two controls: GST plus beads and only beads.

   If the interacting protein of interest is known to be confined to a specific cellular compartment, the probe can be mixed with a fraction of the cell lysate corresponding to that compartment.

2. Centrifuge the mixture at maximum speed for 2 minutes at 4°C in a microfuge.

3. Transfer the supernatant (i.e., the precleared cell lysate) to a fresh microfuge tube.

Probing the Cell Lysate

4. Set up two microfuge tubes containing equal amounts of precleared cell lysate and 50 µl of glutathione agarose beads. To one tube add ~10 µg of GST protein; to the other tube add ~10 µg of the GST fusion probe protein. The amount of probe and control protein added should be equimolar in the two reactions (i.e., the final molar concentration of GST should be the same as the GST fusion probe protein). Incubate the tubes for 2 hours at 4°C with end-over-end mixing.

   ▲ **IMPORTANT** If the bound proteins will be removed from the beads by boiling (Step 10), it is important to include a control tube containing only glutathione agarose beads and cell lysate. This allows the detection of proteins that bind nonspecifically to the beads.

5. Centrifuge the samples at maximum speed for 2 minutes in a microfuge.

6. Save the supernatants at 4°C in fresh microfuge tubes. These samples will be analyzed by SDS-polyacrylamide gel electrophoresis analysis in Step 10.
7. Wash the beads with 1 ml of ice-cold lysis buffer. Centrifuge the tubes at maximum speed for 1 minute in a microfuge. Discard the supernatants. Repeat the washes three times.
8. (*Optional*) Elute the GST fusion protein and any proteins bound to it by adding 50 µl of 20 mM reduced glutathione in 50 mM Tris-Cl (pH 8.0) to the beads. Centrifuge the tubes at maximum speed for 2 minutes in a microfuge.
9. Mix the beads (from Step 7) or the eluted proteins (from Step 8) with an equal volume of 2× SDS-PAGE gel-loading buffer.

Detecting Interacting Proteins

10. Boil the samples for 4 minutes and analyze them by SDS-polyacrylamide gel electrophoresis.
11. The method of detecting proteins associated with the GST fusion protein will depend on whether or not the cell lysate was radiolabeled and on the goal of the experiment.
    - If the goal is to detect all of the ^{35}S-labeled proteins associated with the fusion protein, dry the gel on a gel dryer and expose it to X-ray film to produce an autoradiograph.
    - If the goal is to detect specific associated proteins, transfer the proteins from the SDS-polyacrylamide gel to a membrane and perform immunoblotting (Appendix 8).
    - If the goal is to determine the sizes and abundance of proteins associated with the fusion protein from a nonradioactive lysate, stain the gel with Coomassie Blue or silver nitrate (Appendix 8).

TROUBLESHOOTING GST PULLDOWN EXPERIMENTS

Troubleshooting a GST pulldown experiment is facilitated by analyzing and comparing aliquots from various stages of the experiment using SDS-polyacrylamide gel electrophoresis. For example, separate the following samples by electrophoresis through an SDS-polyacrylamide gel, loading approximately equivalent amounts (e.g., 1%) of the total cell lysate from each sample:

- the total cell lysate (Step 1)
- the supernatant saved at Step 6
- the eluate (Step 8)
- the eluate from the control containing GST (Step 8)
- the eluate from the control containing beads and cell lysate (Step 8)
- the beads after elution (Step 9)

Comparing each of these samples for the quantity of a target protein that binds to the GST fusion protein may suggest the causes and remedies of various problems. For example, a low signal, even though the target protein is abundant in the total cell lysate, may indicate that the binding conditions are not optimal. A change in salt and detergent concentrations, in addition to increasing the time allowed for association, may improve the result. By contrast, the complex may be retained on the glutathione agarose beads due to inefficient elution. This can be determined by SDS-polyacrylamide gel electrophoresis analysis of the "fusion-protein-beads post elution" fraction. The problem may be remedied by pooling multiple elutions. Preclearing a lysate with GST and/or beads can help to reduce nonspecific interactions. Decreasing the amount of lysate added and increasing the stringency of the wash conditions can also reduce background.

Finally, if the interaction is analyzed by western blotting, it is important to probe the membrane with anti-GST antibodies after probing with antibody specific for the target protein. This control will reveal whether all samples were incubated with the same amount of GST fusion protein and will help to determine whether the fusion protein is degraded during incubation with the cell lysate.

Protocol 4

Identification of Associated Proteins by Coimmunoprecipitation

Peter D. Adams
Fox Chase Cancer Center, Philadelphia, Pennsylvania 19111

Michael Ohh
Dana-Farber Cancer Institute and Harvard Medical School, Boston, Massachusetts 02115

WHEN A CELL IS LYSED UNDER NONDENATURING CONDITIONS, many of the protein-protein associations that exist within the intact cell are conserved. This fact can be used to advantage to detect and identify physiologically relevant protein-protein interactions. As illustrated in Figure 18-14, if protein X is immunoprecipitated with an antibody to X, then protein Y, which is stably associated with X in vivo, may also precipitate (please see Figure 18-14, Complex 1). The immunoprecipitation of protein Y, based on a physical interaction with X, is referred to as coimmunoprecipitation. This approach is most commonly used to test whether two proteins of interest are associated in vivo, but it can also be used to identify novel interacting partners of a particular protein. Examples of the latter approach include the identification of p21cip1 as a protein that interacts with cyclin D/Cdk4 kinase (Xiong et al. 1993); elongins B and C, Cul2, and fibronectin as partners with the von Hippel-Lindau tumor suppressor protein (pVHL) (Duan et al. 1995; Kibel et al. 1995; Pause et al. 1997; Lonergan et al. 1998; Ohh et al. 1998); and transformation/transcription domain-associated protein (TRRAP) as a protein that interacts with the E2F1 and c-Myc transcription factors (McMahon et al. 1998).

Perhaps the most rigorous demonstration of a physiological interaction between two proteins is their coimmunoprecipitation from cell extracts. A putative interaction might first be identified by use of a powerful high-throughput approach such as a yeast two-hybrid screen and subsequently shown by coimmunoprecipitation of the two proteins to be a true physiological interaction. Detection of a protein-protein interaction in this manner can often be facilitated by transient transfection of cells with plasmids encoding the relevant proteins, followed by expression of the proteins. However, overexpression of the proteins from the plasmids might drive interactions between the two proteins that are not physiological. Thus, it is always preferable to demonstrate the interaction of the two proteins within their native untransfected cells.

The use of coimmunoprecipitation to search for novel proteins that interact with a known protein is a powerful way to identify physiological interactions within the intact cell. The major disadvantages of the method, however, are that it is relatively laborious, time-consuming, often requires a very large number of cultured cells, and may not detect low-affinity and transient protein-protein interactions. Moreover, coimmunoprecipitation only works with proteins that per-

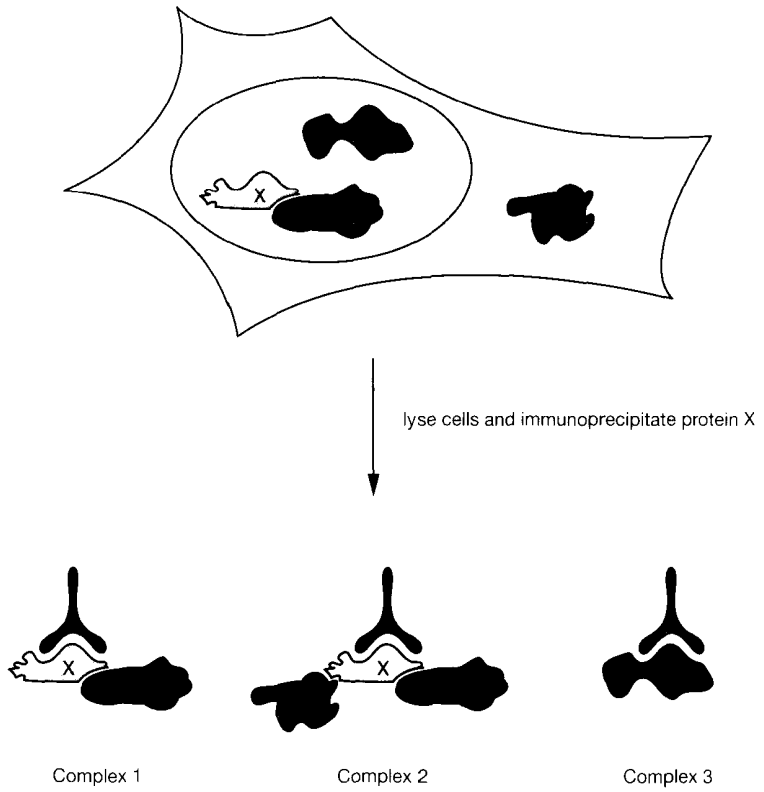

FIGURE 18-14 Principle and Pitfalls of Detection of Proteins by Coimmunoprecipitation

In the intact cell, protein X is present in a complex with protein Y. This complex is preserved after cell lysis and allows protein Y to be coimmunoprecipitated with protein X (Complex 1). However, the disruption of subcellular compartmentalization could allow artifactual interactions to occur between some proteins, for example, protein X and protein B (Complex 2). Furthermore, the antibody that is used for the immunoprecipitation may cross-react nonspecifically with other proteins, for example, protein A (Complex 3). The key to identification of protein:protein interactions by coimmunoprecipitation is to perform the proper controls so as to identify protein Y but not proteins A and B.

sist in physiological complexes after they have been solubilized from the cell. Thus, coimmunoprecipitation may not be appropriate for the detection of protein-protein interactions that make up large, insoluble macromolecular structures of the cell, such as the nuclear matrix.

OUTLINE OF THE PROCEDURE

Whether the goal is to test for a specific interaction between two known proteins or to identify novel proteins that interact with a known protein, the principle of coimmunoprecipitation is the same. The cells are harvested and lysed under conditions that preserve protein-protein interactions, a protein of interest is specifically immunoprecipitated from the cell extracts, and the immunoprecipitates are then fractionated by polyacrylamide gel electrophoresis. In the past, this has generally been by one-dimensional SDS-polyacrylamide gel electrophoresis. However, two-dimensional gels using isoelectric focusing (IEF) and SDS-polyacrylamide gel electrophoresis offer improvements in both resolution and sensitivity, and the development of proteomics technologies is making such gels more commonplace.

Coprecipitation of a protein of known identity is most commonly detected by western blotting with an antibody directed against that protein. Alternatively, if the cells are metabolically

labeled with [^{35}S]methionine before lysis, then coprecipitating proteins can be visualized by autoradiography. The identity of certain radiolabeled proteins can be determined using immunological techniques (e.g., reimmunoprecipitation of the protein in question with a relevant antibody) (Beijersbergen et al. 1994; Ginsberg et al. 1994; Vairo et al. 1995) or by comparative peptide mapping.

If the goal is to identify novel interacting proteins, then the putative associated protein is first detected in the gel, usually as a ^{35}S-labeled or stained band. Subsequently, coimmunoprecipitation is carried out on a scale large enough to obtain sufficient material for identification of the associated protein by Edman degradation or mass spectrometry.

The remainder of this introduction serves as a guide for optimizing and troubleshooting coimmunoprecipitation reactions and the subsequent identification of the precipitated proteins. Also included is a discussion of the controls that should be performed to ensure that a coprecipitating protein is truly a physiologically relevant partner. For detailed discussions and protocols on cell lysis, immunoprecipitation, and related techniques, please see Harlow and Lane (1988, 1999). The coimmunoprecipitation protocol, which follows the introduction, is based on one that was used to identify Cul2 and fibronectin as proteins associated with pVHL, a tumor suppressor protein whose loss of function is responsible for tumor formation in von Hippel-Lindau disease. The protocol was originally performed using 786-O renal carcinoma cells that were stably transfected with a plasmid expressing hemagglutinin-tagged pVHL (786-O/HA-pVHL). Control cells, that were stably transfected with the empty vector alone, were processed in parallel.

VHL GENE PRODUCT AND VON HIPPEL-LINDAU DISEASE

von Hippel-Lindau disease is a hereditary cancer syndrome that is characterized by the development of renal carcinomas, pheochromocytomas, and vascular tumors of the central nervous system and retina (Ohh and Kaelin 1999). Tumors result from functional inactivation of both copies of the VHL gene. The protein product of the VHL gene, pVHL, interacts with a number of cellular proteins, including elongins B and C, Rbx1, and a member of the Cullin family of proteins, Cul2 (Duan et al. 1995; Kibel et al. 1995; Pause et al. 1997; Lonergan et al. 1998; Kamura et al. 1999b). Recent work suggests that the pVHL/elongin B and C/Rbx1/Cul2 complex serves as an E3 ubiquitin ligase and targets certain proteins for degradation (Iwai et al. 1999; Kamura et al. 1999a,b; Lisztwan et al. 1999; Tyers and Willems 1999). This activity of pVHL is thought, at least in part, to underlie its tumor suppressor function. The pVHL protein also interacts stably with the extracellular matrix protein, fibronectin (Ohh et al. 1998).

CELL LYSIS AND IMMUNOPRECIPITATION

When lysing cells, a major consideration is that the conditions used for solubilization extract the protein to be immunoprecipitated, but do not disrupt all of the protein-protein interactions that exist within the cell. Thus, it is best to determine in advance the mildest lysis conditions that efficiently solubilize the majority of the protein of interest. These pilot experiments can generally be performed on a small scale, requiring cell extract derived from 10^6 to 10^7 cells for each immunoprecipitation. In general, a higher salt concentration (200–1000 mM NaCl) and the presence of an ionic detergent (0.1–1% SDS or sodium deoxycholate) are more disruptive than lower amounts of salt (120 mM NaCl) and the presence of a nonionic detergent (0.1–1% Nonidet P-40 or Triton X-100). Similarly, mechanical processes, such as sonication, tend to denature and disrupt protein-protein interactions. However, it is important to note that the lysis conditions that solubilize and yet do not dissociate a particular protein complex should be determined empirically.

Once the lysis conditions have been determined, the cleared cell lysate is subjected to a standard immunoprecipitation with an antibody directed against the protein of interest. It is impor-

tant to perform a parallel immunoprecipitation with the relevant control antibodies (please see Controls for Coimmunoprecipitation, below). When establishing the conditions for cell lysis and protein solubilization, bear in mind that high concentrations of ionic detergent (e.g., >0.2% SDS) and the presence of reducing agents will tend to denature the antibody and interfere with the immunoprecipitation.

DETECTION OF ASSOCIATED PROTEINS

If the purpose of the experiment is to test whether two particular proteins interact in vivo, then the presence of the second protein is usually detected by western blotting or, if the cells were metabolically labeled with [^{35}S]methionine before lysis, by autoradiography. Western blotting is straightforward and, assuming that the antibody used for the western blot is well-characterized (please see below), relatively unambiguous. Autoradiography has the advantage that the ^{35}S-labeled protein of interest can be compared by tryptic mapping with ^{35}S-labeled protein derived from in vitro transcription and translation of a defined cDNA, resulting in unambiguous confirmation of the protein's identity (Xiong et al. 1992, 1993; Kibel et al. 1995).

If the purpose is to identify novel associated proteins, then these can be detected by direct staining of the proteins in the gel. At this stage, before scaling up the procedure, only the more sensitive stains, such as silver staining (Appendix 8) and imidazole-zinc negative staining, generally have the required level of sensitivity (Matsui et al. 1999). Alternatively, if the cells are labeled before lysis with [^{35}S]methionine, then radiolabeled associated proteins can be visualized by autoradiography or with a phosphorimager.

CONTROLS FOR COIMMUNOPRECIPITATION

The major pitfall associated with identification of novel associated proteins by coimmunoprecipitation is the identification of false positives. These false positives arise from the presence of proteins in the washed immunoprecipitate that are not normally associated with the protein of interest in the intact cell. Such contaminants result from formation of nonphysiological protein-protein interactions after cell lysis (Figure 18-14, Complex 2) or as a result of cross-reactivity and nonspecific binding of the antibody to cellular proteins (Figure 18-14, Complex 3). Fortunately, much can be done to eliminate or control for such confounding interactions.

Using Well-characterized Antibodies

Any antibody that is used for the immunoprecipitation should be well-defined (e.g., Hu et al. 1991; Marin et al. 1998), i.e., it should be proven to immunoprecipitate from crude cell extracts, the protein against which it was raised. There are a number of ways that this ability can be demonstrated:

- Showing that multiple antibodies, independently raised to the same protein, recognize the *same* polypeptide.
- Showing that the antibodies fail to detect their target protein in a cell line that lacks that protein. Cell lines lacking a particular protein are commonly available as human cell lines derived from individuals with cancer predisposition syndromes (e.g., 786-O renal carcinoma cells lack the pVHL tumor suppressor protein) or from mice with a targeted knock-out of a particular gene.

- Comparing the peptide map generated by proteolytic digestion of ^{35}S-labeled protein immunoprecipitated from metabolically labeled cells with that derived from ^{35}S-labeled in vitro translation of a defined cDNA. In the latter approach, the ^{35}S-labeled protein is digested with a protease, such as V8 protease or chymotrypsin, and the peptides are fractionated by SDS-polyacrylamide gel electrophoresis. The ^{35}S-labeled peptide map is compared with the map obtained from a ^{35}S-labeled protein derived from in vitro transcription and translation of a known cDNA. If the protein immunoprecipitated from the cell extracts is identical to the protein encoded by the cDNA, then the peptide maps should be essentially identical (Xiong et al. 1992, 1993; Kibel et al. 1995).

Using Control Antibodies

Even mouse monoclonal antibodies interact nonspecifically with proteins that are distinct from the immunogen (Figure 18-14, Complex 3). Any putative associated protein that immunoprecipitates with a control antibody as well as the specific antibody is, by definition, nonspecifically binding to the antibody. The more the control antibody and the specific antibody match, the less the chance of erroneously identifying a nonspecifically interacting protein. For a mouse monoclonal antibody, the proper control is another monoclonal antibody of the same subclass; for a rabbit serum, it is the preimmune serum from the same rabbit, and for a purified rabbit polyclonal, it is another purified rabbit polyclonal antibody.

Using Multiple Antibodies

The ability to coprecipitate a protein (such as protein Y in Figure 18-14) using more than one antibody against protein X increases the level of confidence that proteins X and Y are associated in vivo. A caveat here is that different antibodies recognize different epitopes, some of which might be obscured in a particular protein complex. Thus, not all antibodies should be expected to coprecipitate the same panel of associated proteins.

Using Cell Lines Lacking the Target Protein

A coprecipitating protein should not be precipitated from lysates of a cell line lacking the protein that is the primary target of the antibody (Kibel et al. 1995). Thus, control immunoprecipitates should be performed from cell lines known to lack the target protein.

Testing Biologically Relevant Mutants

A protein that associates with the immunoprecipitated protein in a functionally significant way might fail to interact with biologically inactive mutants of the protein and consequently may not coprecipitate. Thus, if possible, obtain or generate cell lines containing biologically inactive mutants of the target protein. Such mutants might be naturally expressed in certain human cell lines (e.g., tumor-derived cells lines containing mutant versions of a protein) or, alternatively, can be expressed as epitope-tagged proteins by transient transfection of cells. The epitope-tagged mutant proteins can then be specifically immunoprecipitated with antibodies directed against the epitope tag. For example, the Cullin family member, Cul2, and other physiologically relevant pVHL-binding proteins, such as fibronectin and elongins B and C, failed to interact with a naturally occurring point mutant of pVHL derived from a tumor (Figure 18-15).

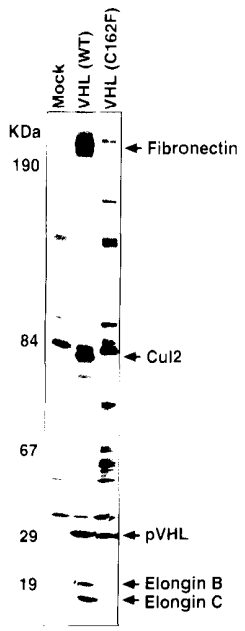

FIGURE 18-15 Coimmunoprecipitation of pVHL-associated Proteins

786-O renal carcinoma cells stably transfected with a backbone expression plasmid (*left lane*), a plasmid encoding HA-epitope-tagged wild-type pVHL (*middle lane*), and a plasmid encoding HA-epitope-tagged tumor-derived pVHL (C162F) were labeled with [^{35}S]methionine, lysed, and immunoprecipitated with anti-HA antibody. Coimmunoprecipitates were washed with NETN+900 mM NaCl. Bound proteins were resolved by electrophoresis in a 7.5–15% discontinuous SDS-polyacrylamide gel and detected by fluorography.

Testing Whether Association Occurs Before or After Cell Lysis

Cell lysis involves a massive disruption of cellular compartmentalization, bringing into proximity proteins that might never normally be in the same subcellular location. This provides an opportunity for nonphysiological complexes to form after cell lysis (Figure 18-14, Complex 2). In principle, it is possible to suppress such postlysis interactions by inclusion of the relevant protein in the cell lysis buffer. For example, Ohh et al. (1998) included purified, nonradiolabeled fibronectin in the cell lysis buffer and showed that it was unable to prevent coprecipitation with pVHL of the endogenous ^{35}S-labeled fibronectin present in the cell before lysis. From this, and other cell lysate mixing experiments, these authors concluded that the ^{35}S-labeled fibronectin was associated with pVHL before cell lysis.

Reducing the Backgound of Nonspecific Proteins

The number of proteins that coprecipitate by virtue of nonspecific interaction with the antibody (Figure 18-14, Complex 3) or nonphysiological association with the protein to which the antibody is raised (Figure 18-14, Complex 2) can be reduced by careful optimization of the conditions for immunoprecipitation. Three procedures are commonly adopted.

- ***Increase the ionic strength of the immunoprecipitate wash buffer.*** Just as a higher concentration of salt in the lysis buffer is generally more disruptive of protein-protein associations, so a higher concentration of salt in the wash buffer will, in general, reduce nonspecific protein-protein interactions. The salt concentration in the wash buffer should be titrated from 120 to 1000 mM NaCl. However, high concentrations of salt can perturb SDS-polyacrylamide gel electrophoresis. Therefore, the immunoprecipitates should be washed with a standard salt buffer (120 mM NaCl) immediately before loading on the gel.

- ***Decrease the amount of primary antibody in the immunoprecipitation.*** Decreasing the concentration of the primary antibody in the immunoprecipitate will decrease the total number of proteins that nonspecifically coprecipitate. The concentration of the antibody should be decreased to a point where the signal obtained from any specific protein is maximized relative to any nonspecific protein.
- ***Preclear the cell lysate with the control antibody.*** Before performing the immunoprecipitation with the specific antibody directed against the protein of interest, carry out an immunoprecipitation of the cell lysate with an excess of the control antibody and protein A–Sepharose (Harlow and Lane 1988).

PROTEIN IDENTIFICATION

If a novel coprecipitated protein was originally detected by silver staining or labeling with [^{35}S]methionine, then it can be identified by obtaining primary sequence information, either by direct Edman degradation (Aebersold et al. 1987; Kamo and Tsugita 1999; Loo and Muenster 1999) or by mass spectrometry (Courchesne and Patterson 1999; Jensen et al. 1999; Wilkins et al. 1999; Yates et al. 1999). Usually, sequence information is obtained on the peptides that result from internal proteolytic cleavage of the protein with trypsin.

The minimum amount of protein required to obtain useful information by either Edman sequencing or mass spectrometry depends on a number of factors, including the properties and character of the protein concerned and the method of sample preparation. In general, Edman sequencing requires ~10 pmoles of protein for sequencing of internal proteolytic fragments (500 ng of a 50-kD protein). State-of-the-art mass spectrometry methods are more sensitive and can be used for sequencing at picomole or subpicomole amounts. As a result, mass-spectrometry-based approaches are increasingly the method of choice. *M*atrix-*a*ssisted *l*aser *d*esorption *i*onization–*t*ime *o*f *f*light (MALDI-TOF) mass spectrometry can be used to obtain a peptide "mass map," which contains the masses of all of the peptides derived from digestion of the protein (Courchesne and Patterson 1999). This mass map provides a unique "fingerprint" of that protein, which can be compared against the predicted mass maps of all known proteins to aid in identifying the protein. Once the Human Genome Project is completed, the predicted sequence and therefore the predicted mass maps of all human proteins will be available in databases. Alternatively, *l*iquid *c*hromatography–tandem MS (LC-MS/MS) can be used to obtain primary sequence information on peptides within the digest (Jensen et al. 1999; Yates et al. 1999). This sequence information can also be used to identify a protein. At least until the completion of the Human Genome Project, there will still be a place for traditional Edman sequencing as a tool for protein identification.

Although sequence data can be obtained using picomole amounts of protein, larger quantities of protein consistently provide better and more unambiguous data. Thus, a significant scaling-up from the initial immunoprecipitation is generally required. For example, to obtain enough protein (2 μg) to generate primary sequence information of the cyclin D/Cdk4-associated p21cip1, Beach and co-workers started with 400 15-cm plates of human WI38 cells (Xiong et al. 1993). Obviously, the number of cells required depends on the abundance of the proteins concerned and the efficiency of the immunoprecipitation, underscoring the importance of optimizing the immunoprecipitation protocol for the particular protein of interest.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Acetonitrile (50%) <!>

Coomassie Blue R-250

EBC lysis buffer

50 mM Tris-Cl (pH 8.0)
120 mM NaCl
0.5% (v/v) Nonidet P-40
5 µg/ml leupeptin
10 µg/ml aprotinin
50 µg/ml PMSF <!>
0.2 mM sodium orthovanadate
100 mM NaF <!>

NETN

20 mM Tris-Cl (pH 8.0)
1 mM EDTA
100 mM NaCl
0.5% (v/v) Nonidet P-40

NETN containing 900 mM NaCl

Phosphate-buffered saline

1x SDS gel-loading buffer

Trifluoroacetic acid (TFA) (0.1% w/v, sequencing grade) <!>

Enzymes and Buffers

Trypsin

Prepare bovine trypsin at 250 µg/ml in 200 mM ammonium bicarbonate (pH 8.9) (sequencer grade; Boehringer Mannheim)

Trypsin digestion buffer

0.02% (v/v) Tween-20
200 mM ammonium bicarbonate (pH 8.9)

Antibodies

Antibody or antibodies that will precipitate the target protein

Control antibody

Gels

Discontinuous SDS-PAGE gradient gel <!>

The separation gel (a discontinuous 7.5–15% gel at pH 8.8) should be 20–30 cm long, the stacking gel (5% at pH 6.8) should be 10 cm long, and the well itself should be 1–2-cm deep (the % of the gel will vary with the protein of interest). Pour the stacking gel without a multiwell comb, and construct the wells by inserting spacers vertically between the glass plates, so that they form a well that is large enough for the sample. For further details on SDS-PAGE gels, please see Appendix 8.

Special Equipment

Boiling water bath

Protein A–Sepharose

Prepare the protein A–Sepharose as a 1:1 slurry in NETN buffer.

Rocking platform

Additional Reagents

Steps 10 and 11 of this protocol require the reagents and equipment for mapping, purification, and sequencing of peptides (please see Spector et al. 1998, Chapters 62 and 63).

Cells and Tissues

Appropriate cell line(s) growing in culture

METHOD

▲ **IMPORTANT** This protocol was used to identify pVHL-associated proteins. Conditions should be optimized for the protein of interest.

1. Wash 30 10-cm plates of the appropriate cells (a total of ~6×10^7 cells) in phosphate-buffered saline. Scrape each plate of cells into 1 ml of ice-cold EBC lysis buffer.
2. Transfer each milliliter of cell suspension into a microfuge tube, and centrifuge the tubes at maximum speed for 15 minutes at 4°C in a microfuge.
3. Pool the supernatants (~30 ml) and add 30 μg of the appropriate antibody. Rock the immunoprecipitate for 1 hour at 4°C.
4. Add 0.9 ml of the protein A–Sepharose slurry. Rock the immunoprecipitate for another 30 minutes at 4°C.
5. Wash the protein A–Sepharose mixture in NETN containing 900 mM NaCl. Repeat this wash five more times. Finally, wash the mixture once in NETN.
6. Remove the liquid portion of the mixture by aspiration. Add 800 μl of 1x SDS gel-loading buffer to the beads, and boil them for 4 minutes.
7. Load the sample into the large well of the discontinuous SDS-PAGE gradient gel, and run the gel at 10 mA constant current overnight.
8. Visualize the protein bands by staining with Coomassie Blue (Appendix 8).
9. Excise the band of interest from the gel, place it in a microfuge tube, and wash it twice for 3 minutes each in 1 ml of 50% acetonitrile.
10. Digest the protein with trypsin while it is still in the gel, and electroelute the peptides.
    a. Remove the gel slice to a clean surface and allow it to partially dry.
    b. Add 5 μl of trypsin digestion buffer and 2 μl of trypsin solution.
    c. After the gel absorbs the trypsin solution, add 5-μl aliquots of trypsin buffer until the gel slice regains its original size.
    d. Place the gel slice in a microfuge tube, immerse it in trypsin digestion buffer, and incubate it for 4 hours at 30°C. Stop the reaction by addition of 1.5 μl of 0.1% trifluoroacetic acid.

    Procedures for visualization and digestion of the protein vary greatly. In particular, digestion can be performed while the protein is still in the polyacrylamide gel or after it has been transferred to a nitrocellulose or PVDF membrane.
11. Fractionate the peptides by narrow-bore high-performance liquid chromatography. Subject the collected peptides to automated Edman degradation sequencing on an ABI 477A or 494A machine.

    Processing of the samples for Edman sequencing or MS analysis also varies and this is best discussed with the individual who is operating the machinery. For a review of methods, please see Matsudaira (1993), Link (1999), and Spector et al. (1998, Chapters 62 and 63).

Protocol 5

Probing Protein Interactions Using GFP and Fluorescence Resonance Energy Transfer

Alisa G. Harpur and Philippe I.H. Bastiaens
Imperial Cancer Research Fund, London

FOLLOWING THE DISCOVERY AND CLONING OF THE GREEN FLUORESCENT PROTEIN (GFP) from the jellyfish, *Aequorea victoria* (Prasher et al. 1992), many opportunities for the analysis of gene function and protein-protein interactions have emerged. Such opportunities range from the visual tracking of proteins in a spatial and temporal manner to the quantitation of the intrinsic photophysical properties of the GFPs themselves, allowing them to be used as indicators or sensors of biological activities/processes and protein interactions.

GFP: IMPACT ON MOLECULAR AND CELLULAR BIOLOGY AND APPLICATION TO PROTEIN INTERACTIONS

GFP is intrinsically fluorescent and does not require exogenous cofactors or substrates, a property that renders it highly useful as a genetically encoded reporter tag (please see the information panel on **GREEN FLUORESCENT PROTEIN** in Chapter 17). This is particularly valuable for analysis of gene expression in embryonic and intact organisms using either endogenously regulated (gene trapping) or tissue-specific promotors (Chalfie et al. 1994; Moss et al. 1996). The utility of GFP has also been demonstrated in establishing the subcellular localization of fusion proteins (Chalfie et al. 1994; Moss et al. 1996; Arnone et al. 1997). Organelle-specific localization signals have been successfully fused to GFP mutants, thus targeting the GFP to locations such as the endoplasmic reticulum, the Golgi apparatus (Dayel et al. 1999), mitochondria (Niwa et al. 1999), and the plasma membrane (Okada et al. 1999). In addition to localization of proteins, GFP has been used as an intracellular sensor of biological activity by exploiting its photophysical properties. For example, GFP can be used as an indicator of protein proximity by detection of the excited-state reaction, fluorescence resonance energy transfer (FRET). To date, this technique has been used in the analysis of calcium-sensitive constructs (Miyawaki et al. 1997, 1999) and protease substrates (Heim and Tsien 1996; Mitra et al. 1996; Xu et al. 1998; Mahajan et al. 1999) and for detecting the interaction between a number of proteins (Day 1998; Mahajan et al. 1998). Additionally, FRET between GFP and Cy3 has been used to image cellular processes such as the phosphorylation of intracellular and transmembrane proteins (Ng et al. 1999; Wouters and Bastiaens 1999). In this protocol, a detailed description of the latter type of experiment is given using fluorescence lifetime imaging microscopy (FLIM).

FLUORESCENCE RESONANCE ENERGY TRANSFER

Photophysical Principles of FRET

Until recently, molecular and cellular biologists have had to address the question of specific protein-protein interactions with a limited number of techniques that rely heavily upon the use of chemical cross-linking agents and antibodies (please see Protocols 2 through 4 of this chapter). However, techniques such as immunoprecipitation or affinity chromatography do not preserve the physiological conditions under which proteins may normally interact in the cell. In addition, these approaches do not provide information on the spatial distribution of the interacting proteins. Immunocytochemical colocalization, while providing indirect evidence of the presence of two particular proteins within the same cellular compartment, fails to confirm whether the suspected components actually interact directly. FRET can be measured to address such questions of specificity in intact cells (Bastiaens and Squire 1999).

FRET is a nonradiative, dipole-dipole coupling process whereby energy from an excited donor fluorophore is transferred to an acceptor fluorophore in close proximity (typically within 10 nm). Excitation of the donor will thus produce sensitized emission from the acceptor that ordinarily would not occur in the absence of FRET. If proteins are fused to genetically encoded GFP variants or chemically modified by covalent attachment of synthetic fluorophores with appropriate characteristics to allow visualization of donor-acceptor interactions (Bastiaens and Jovin 1998; Griffin et al. 1998), then the molecular interaction of the proteins in question can be inferred by FRET between the fluorophores. The rate (k_t; ns^{-1}) at which Förster-type energy transfer occurs is given by the equation:

$$k_t = \tau_D^{-1} \left(\frac{R_0}{R}\right)^6 \tag{1}$$

such that

$$R_0 = (\kappa^2 \cdot J(\lambda) \cdot n^{-4} \cdot Q)^{1/6} \cdot 9.7 \cdot 10^2 \tag{2}$$

where R (nm) is the actual distance between the centers of the fluorophores, R_0 (nm) is the distance at which energy transfer efficiency (E) is 50% (Figure 18-16), and τ_D(ns) is the fluorescence lifetime of the donor in the absence of the acceptor. Substitution of Equation 1 into the definition of energy transfer efficiency (Equation 3) shows that there is also a steep distance-dependence in the FRET efficiency (E):

$$E = \frac{k_t}{(k_t + \tau_D^{-1})} = \frac{R_0^6}{(R_0^6 + R^6)} \tag{3}$$

Factors such as the quantum yield (Q) of the donor, the relative orientation of the transition dipoles of the fluorophores (κ^2), the refractive index of the intervening medium (n), and the overlap integral ($J(\lambda)$; $cm^6\ mole^{-1}$) of the donor emission and acceptor absorption spectra will affect R_0 (Clegg 1996). The overlap integral ($J(\lambda)$;$cm^6\ mole^{-1}$) is given by:

$$J(\lambda) = \frac{\int_0^\infty F(\lambda)\varepsilon(\lambda)\lambda^4 d\lambda}{\int_0^\infty F(\lambda) d\lambda} \tag{4}$$

where $\varepsilon(\lambda)$ ($M^{-1}cm^{-1}$) is the extinction coefficient of the acceptor, and $F(\lambda)$ is the fluorescence intensity of the donor, at wavelength λ.

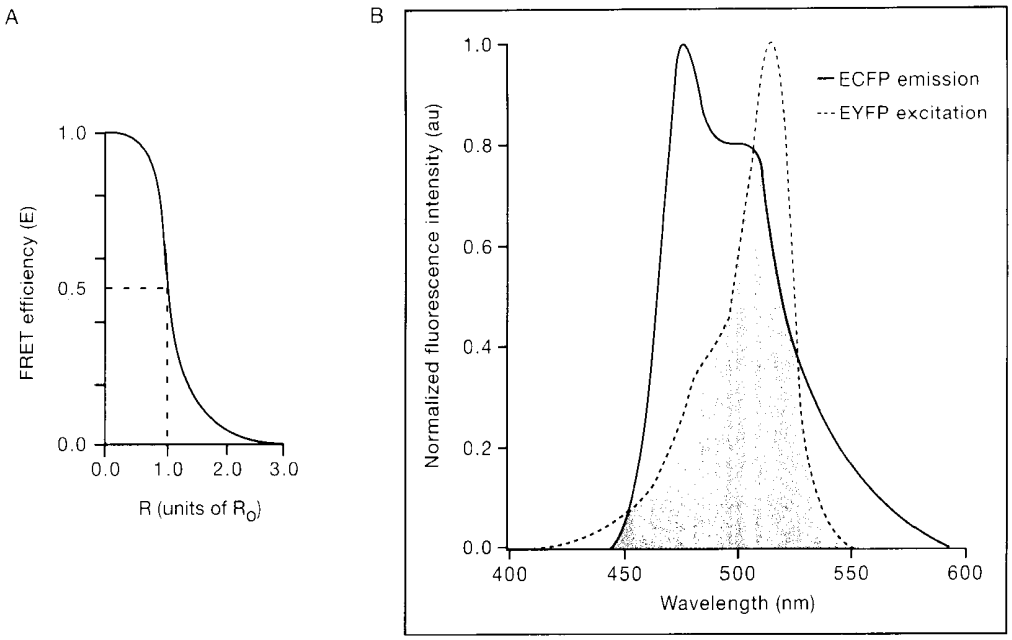

FIGURE 18-16 Fluorescence Emission and Absorption Spectra

(*A*) FRET efficiency (E) as a function of interchromophore distance in units of R_0. (*B*) Spectral overlap (*shaded area*) between the fluorescence emission spectrum of ECFP and the absorption spectrum of EYFP.

To select a suitable chromophore pair for FRET-based protein interaction detection, two main factors must be considered in order to optimize R_0; (1) the quantum yield of the donor Q and (2) the spectral overlap between donor emission and acceptor absorption determined by the overlap integral $J(\lambda)$, which is dependent on the acceptor extinction coefficient $\varepsilon(\lambda)$. In addition to these considerations, the choice also depends on the pair being spectrally distinct enough to facilitate unambiguous detection of the donor with an appropriate band pass filter. Final considerations are practicalities such as the feasibility of the construction of functional fusion proteins or fluorophore conjugates and their delivery into cells. Therefore, the optimal R_0 must be considered bearing in mind the examined protein system.

The engineering of blue- and red-shifted variants of GFP, such as cyan (CFP) and red (DsRed) fluorescent protein, has facilitated the measurement of FRET between GFP mutants (for review, please see Heim and Tsien 1996; Tsien 1998; Matz et al. 1999; Pollok and Heim 1999) (these variants are available commercially from CLONTECH). An example of a genetically encoded, spectrally compatible, chromophore combination is the enhanced cyan fluorescent pro-

TABLE 18-10 R_0 Values (nm) for GFP and Cy Dyes

⇓ Donor / Acceptor ⇒	ECFP	EGFP	EYFP	Cy3	Cy3.5	Cy5
ECFP	n.d.	4.7	4.9	n.d.	n.d.	n.d.
EGFP		4.6	5.5	6.0	5.7	n.d.
EYFP			5.1	n.d.	n.d.	n.d.
Cy3				4.4	5.1	5.3
Cy3.5					4.6	6.4

The values were calculated as described by Bastiaens and Jovin (1996), using published extinction coefficients for GFP variants (Tsien 1998) and those supplied by the manufacturer for the Cy dyes (Amersham Pharmacia Biotech). n.d. indicates not determined.

tein (ECFP) as a donor to enhanced yellow fluorescent protein (EYFP). The R_0 value for this pair is 4.9 nm (Table 18-10) which enables FRET detection over distances of ~1.6 x R_0 = 7.8 nm corresponding to a detection limit of 5% FRET efficiency (Figure 18-16). The application for genetically encoded fluorescent FRET pairs is evident: It allows the analysis of protein interactions without the need to conjugate fluorophores to purified proteins and reintroduce them into cells. If, however, the use of sulfoindocyanine dye conjugates is feasible, the large extinction coefficient and spectral overlap makes Cy3 (Amersham Pharmacia Biotech) a suitable acceptor for energy transfer from the donor EGFP (Ng et al. 1999; Wouters and Bastiaens 1999). The R_0 of this pair is 6 nm enabling efficient FRET detection over a distance up to 9.6 nm. Obviously, the higher the R_0, the greater the distance over which FRET can be detected. However, even under optimal donor/acceptor spectral conditions, R_0 will generally not exceed 7 nm, which confers an upper distance limit of ~11 nm for the detection of FRET. In practical terms, these factors may be considered in relation to average protein sizes. Assuming that the specific volume of a protein is ~0.74 cm^3/g, the radius of a 100-kD molecular-mass globular protein can be calculated by substitution of the following equation, where R is the radius (nm):

$$R = 6.76 \times 10^{-2} \sqrt[3]{MW} \quad (5)$$

resulting in a radius of 3.1 nm. A protein of 200 kD has a calculated radius of 3.95 nm. These calculations of radii demonstrate that FRET is likely to occur between fluorophores on two interacting proteins with molecular masses below 100 kD, whereas the likelihood of FRET between dyes on proteins of molecular masses above 200 kD is low.

FRET DETECTION METHODS

Steady-state Fluorescence Intensity Measurements

FRET is detectable and quantifiable using a range of techniques, typically by analyzing the donor/acceptor emission ratios of steady-state fluorescence (Adams et al. 1991; Miyawaki et al. 1997). Preferential excitation of a donor fluorophore that is located in molecular proximity to an appropriate acceptor fluorophore will result in sensitized emission from the acceptor and quenching of the donor fluorescence. The change in the ratio of the donor and acceptor emissions can be measured following an event that induces protein association. This measurement has a number of limitations. For instance, because the ratio is not an absolute determination of the FRET efficiency, such measurements must be performed over a time course whereby a change in ratio is detected that can be ascribed to protein association. Since fluorescence intensity is proportional to concentration, the donor/acceptor intensity ratio will depend on local concentrations of labeled proteins. This is particularly problematic when there is differential redistribution of the fluorescent proteins as a result of biological activity during the measurement. Ratiometric concentration effects are not an issue with the use of reporter probes that encode the donor and acceptor GFPs on the same polypeptide, as is the case with molecules such as the calcium sensing "cameleons" (Miyawaki et al. 1997, 1999). These types of probes consist of a donor and acceptor flanking an "activity"-specific module. The stoichiometry of the donor/acceptor is constant for all pixels, and any change in emission ratio, therefore, can be ascribed to changes in FRET efficiency. However, care should be taken to ensure that observed changes in ratio are not due to alterations in pH, which differentially affect the intensity of GFP variants (Llopis et al. 1998). Alternatively, the detection of acceptor-sensitized emission alone can be used as a measure of FRET (Mahajan et al. 1998; Xu et al. 1998). This approach is useful in situations where donor intensities are low and/or there is contamination with high background (auto)fluorescence in the donor channel. However, absorption spectra characteristically exhibit long tails in the shorter

wavelength (blue) region, which may cause the direct excitation of both donor and acceptor molecules, thus resulting in mixing of direct and sensitized emission. Conversely, fluorescence emission tends to tail into the red part of the spectrum, causing donor fluorescence bleedthrough into the acceptor detection channel. Corrections for these effects have been documented (Gordon et al. 1998) and involve the acquisition of fluorescence images of samples containing the donor, the acceptor, and both for three different filter settings. A quantity that is proportional to the FRET efficiency can then be derived.

Donor Quenching and Acceptor Photobleaching

FRET detection is also possible by examining quenching of the donor emission (Bastiaens and Squire 1999). Should FRET occur, then the intensity of detectable donor emission is reduced in proportion to the efficiency of the energy transfer:

$$E_i = 1 - \left(\frac{I_i}{I_{i0}}\right) \tag{6}$$

where I_i and I_{i0} represent the steady-state donor fluorescence intensity in the presence and absence of FRET. The intensity (I_i) at each pixel i is proportional to the donor concentration and requires calibration with the intensity in the absence of acceptor (I_{i0}) in order to calculate the FRET efficiency at each pixel using Equation 6. This reference measurement (I_{i0}) is made on the same specimen by specifically photobleaching the acceptor by excitation at its absorption maximum (Bastiaens et al. 1996; Bastiaens and Jovin 1998; Wouters et al. 1998). In practice, this approach involves (1) the acquisition of a donor image, (2) photobleaching of the acceptor, and then (3) acquisition of a second donor image. The FRET efficiency map is calculated as one minus the ratio of the donor images before and after photobleaching of the acceptor. By contrast to sensitized emission measurements, photobleaching can be performed with high selectivity of the acceptor since absorption spectra tend to tail in the blue part of the spectrum but are steep at their red edge. Care should be taken with acceptor photobleaching FRET measurements that the photochemical product of the bleached acceptor does not have residual absorption at the donor emission and, more importantly, that it does not fluoresce in the donor spectral region. Because of mass movement of protein during the extended time required for photobleaching (typically 1–20 minutes), this type of FRET determination is preferably performed on fixed cell samples. Live-cell FRET measurements are more feasible using fluorescence lifetime imaging because lifetimes are independent of probe concentration and light path length.

Fluorescence Lifetime

FRET reduces the fluorescence lifetime of the donor fluorophore (τ, a measure of the excited-state duration), since it depopulates its excited state (Clegg 1996). This effect is also manifest as a reduction in the donor *quantum yield* (the ratio of the number of fluorescence photons emitted compared to the number of photons absorbed). Given that τ is an intrinsic fluorescence parameter — that it is independent of probe concentration and light path length, but dependent on excited state processes — FRET can be detected purely via donor fluorescence. Since the acceptor fluorescence is not detected, specificity of the acceptor probe is not an issue. Experiments can therefore be carried out using saturating amounts of acceptor molecules or pools of acceptor-labeled protein with nonfunctional subpopulations. By imaging donor fluorescence lifetimes using fluorescence lifetime imaging, it is possible to calculate FRET efficiencies at each pixel of an image:

$$E_i = 1 - \frac{\tau_i}{\langle \tau_R \rangle} \tag{7}$$

The FRET efficiency is calculated at every pixel i from the lifetime τ_i scaled by the average donor reference lifetime $\langle \tau_R \rangle$ in absence of acceptor. This reference lifetime can be obtained at the end of an experiment by acceptor photobleaching.

FLUORESCENCE LIFETIME IMAGING MICROSCOPY

Frequency versus Time-Domain FLIM

Fluorescence lifetime imaging microscopy (FLIM) is well-established as a nondestructive, noninvasive method for the localization and behavior of fluorescent probes or cellular components. By extending such detection methods to fluorescence lifetime determination, it has become possible to resolve biochemical processes and activities. FLIM enables the quantitation of fluorescence lifetimes on a pixel-by-pixel basis (Lakowicz and Berndt 1991; Clegg et al. 1992; Gadella et al. 1993, 1994) and the calculation of a FRET efficiency map from that image (Wouters and Bastiaens 1999). Broadly speaking, determination of fluorescence lifetimes can be performed by two general approaches

- ***In the time domain,*** a delayed, gated measurement of the fluorescence intensity is made following excitation of the sample with a short pulse of light (Sytsma et al. 1998). The fluorescence intensity is sampled at sequential time points along the exponential fluorescence decay. Where a sample contains a single fluorescence species, the fluorescence lifetime is given as the time over which the fluorescence intensity falls to ~37% of its initial value. In this scenario, repetition of excitation ensures an adequate ratio of signal to noise. In practice, an average lifetime (τ) can be calculated from the ratio of the integrated intensities (R) for two equally time-gated segments (Δt) of the fluorescence decay such that

$$\tau = \frac{\Delta t}{\ln R} \tag{8}$$

- ***In the frequency domain*** (Lakowicz and Berndt 1991; Gadella et al. 1993; please see the panel on AN EXPERIMENTAL SETUP FOR FREQUENCY DOMAIN FLIM), a sample is excited by a sinusoidally modulated light source. The resultant fluorescence emission is sinusoidally modulated at the same frequency as the excitation source, but is phase-shifted and has a reduced modulation depth. The phase (τ_i^{ϕ}) and modulation (τ_i^{M}) fluorescence lifetimes can be calculated from this phase shift and demodulation according to:

$$\tau_i^{\phi} = \frac{\tan(\Delta\phi_i)}{\omega} \tag{9}$$

$$\tau_i^{M} = \frac{\sqrt{\frac{1}{M_i^2} - 1}}{\omega} \tag{10}$$

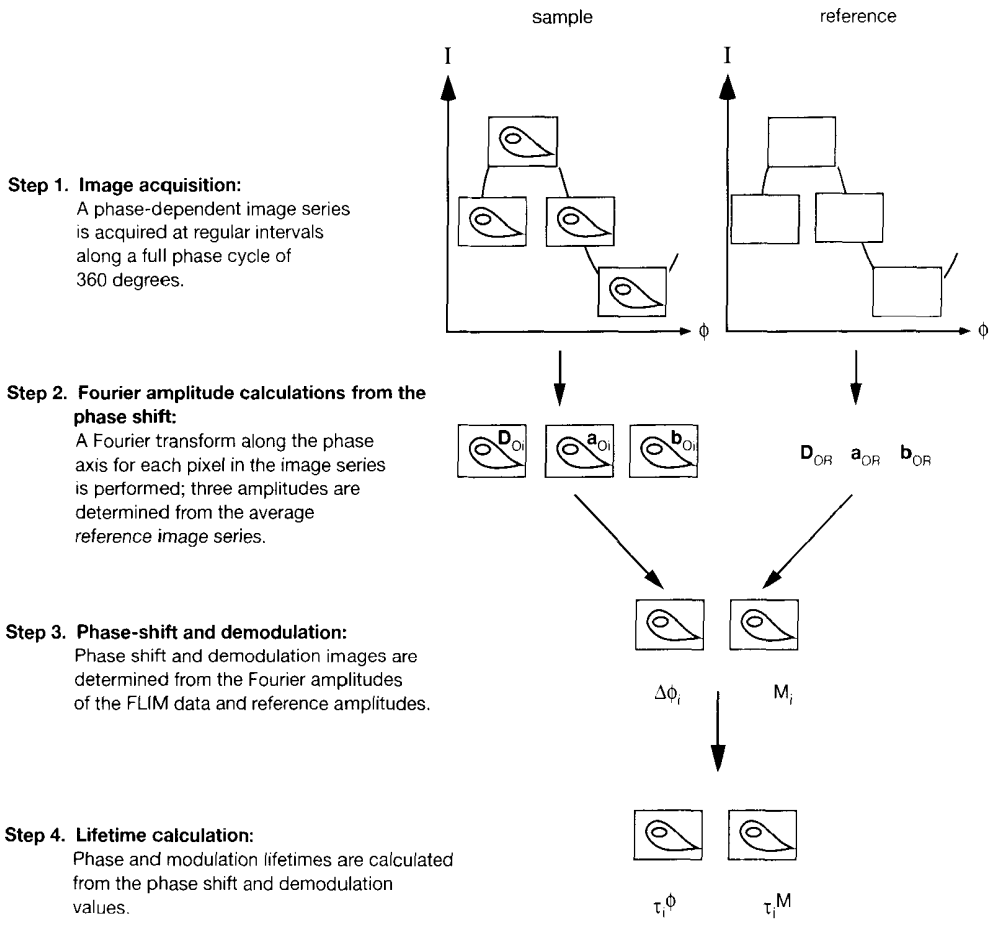
where $\Delta\phi_i$ and M_i represent the phase shift and demodulation, respectively, at each pixel i, and ω is the angular modulation frequency.

Image Processing

FLIM data consist of a sequence of phase-dependent images over a full cycle (2π radians) of a sinus (Figure 18-17, Step 1). From these data, the phase shifts ($\Delta\phi_i$), and modulations (M_i) of each sinus at each pixel (i) are extracted in order to calculate the fluorescence lifetimes using Equations 9 and 10. Standard Fourier transformations are used to calculate these parameters from the raw data. Formally, the phase-dependent raw FLIM data $D_i(k)$ can be written as a Fourier series:

$$D_i(k) = D_{0i} + \sum_{n=1}^{N/2} [a_{ni} \cos(kn\Delta\psi) + b_{ni} \sin(kn\Delta\psi)] \quad (11)$$

The signal is sampled by acquiring an image at each sequential step ($k = 0,1,2,3...N\text{-}1$) of $\Delta\psi$ in the phase of the image intensifier modulation. The critical parameters D_{0i}, a_{ni} and b_{ni} at the harmonic frequency (n) are calculated with discrete sine and cosine transformations using standard computer algorithms (such as those described by Press et al. 1990) (Figure 18-17, Step 2):



Step 1. Image acquisition: A phase-dependent image series is acquired at regular intervals along a full phase cycle of 360 degrees.

Step 2. Fourier amplitude calculations from the phase shift: A Fourier transform along the phase axis for each pixel in the image series is performed; three amplitudes are determined from the average *reference image series*.

Step 3. Phase-shift and demodulation: Phase shift and demodulation images are determined from the Fourier amplitudes of the FLIM data and reference amplitudes.

Step 4. Lifetime calculation: Phase and modulation lifetimes are calculated from the phase shift and demodulation values.

FIGURE 18-17 Image Processing Flow Diagram

See text for details.

AN EXPERIMENTAL SETUP FOR FREQUENCY DOMAIN FLIM

The key elements of a frequency domain fluorescence lifetime imaging system are (1) a standing wave acousto-optic modulator (SW-AOM) that modulates the intensity of the excitation light source at high frequency and (2) a frequency mixing device such as an image intensifier to perform phase-sensitive detection of the fluorescence emission.

Figure 18-18 is a schematic of a single-frequency FLIM configuration. The instrument is based on a vibrationally isolated, inverted microscope (e.g., Zeiss Axiovert 135 TV). The basic light source requirement is an argon laser with sufficient output power (>100 mW per line). The 457.9-nm , 488.0-nm, and 514.5-nm lines are ideal for excitation of the GFP variants, ECFP, EGFP, and EYFP, respectively. The output of this light source is sinusoidally modulated by the SW-AOM (Intra-Action Corp. Belwood). A minimal setup requires a single SW-AOM with a central resonant frequency at 80 MHz (optimal for GFP fluorescence lifetimes ~2 nsec). An iris diaphragm placed ~1.5 meters from the SW-AOM is used selectively to isolate the central (zero-order) modulated beam from the higher-order diffracted beams. To minimize thermal phase drift, the SW-AOM is coupled to a thermostatic water bath/circulator, and the microscopy room is temperature-stabilized. This keeps the SW-AOM to within ±0.1°C of a set temperature that is essential for phase coherence between the fluorescent signal and the modulated gain of the detector. The modulated central light beam is then directed into a 1.5-meter step index silica fiber with a 1-mm core and numerical aperture of 0.37 (Technical Video Ltd.) using a 12-cm focal length lens. The coherence of the laser light is disrupted by vibrating the fiber at frequencies of ~100 Hz, resulting in a randomly moving speckled illumination of the specimen, which is integrated during detection.

Koehler illumination at the sample plane is achieved by incorporating an achromatic lens (7.6-cm focal length) just before the epi-illumination port of the microscope to collect and collimate the laser light. This focal length is sufficient for the fiber core to appear as a point source, thus giving a collimated beam resulting in flat illumination in the sample plane. A 100-W mercury arc lamp (Zeiss HBO 100 W/2) attached to the second epi-illumination port provides an alternate illumination source. A rotating mirror facilitates rapid switching between the laser and the lamp. The laser illumination is used for donor fluorescence lifetime imaging, whereas the lamp is used for imaging and bleaching the acceptor. A large part of the microscope is enclosed within a perspex thermostatic chamber heated to 37°C to facilitate live-cell experiments. Enclosing most of the microscope in this chamber eliminates temperature gradients between the microscope components (such as objectives) and the sample.

The provision of a CO_2 source to the chamber is optional. The TV port situated directly below the sample and objectives is used for coupling the detector, thus providing the shortest route for fluorescence emission with minimal losses. Light from the sample is imaged onto the photocathode of a high-frequency-modulated image intensifier head (Hamamatsu C5825 or LaVision Picostar HR). This device uses proximity focusing of photoelectrons ejected from the photocathode onto the face of a micro-channel plate (MCP). The electron image at the output of the MCP strikes a phosphor screen to generate an intensified light image. For homodyne detection, the effective gain of the image intensifier is modulated at a frequency equal to that of the SW-AOM (80 MHz) by the application of a biased sinusoidal voltage to the photocathode. The amplified, phase-locked outputs from high-frequency synthesizers (2023 Marconi) provide highly stable sinusoidal voltage sources for modulating both the excitation field via the SW-AOM and the gain of the image intensifier unit. Using a telescopic lens with a magnification of 0.5, the amplified image at the phosphor screen of the MCP is projected onto the chip of a scientific-grade CCD camera (Quantix, Photometrics). Magnification of 0.5 matches the full surface area of the CCD chip to that of the phosphor on the MCP. The 12-bit CCD camera houses a Kodak KAF1400 chip with a 1317 x 1035 array of 6.8-μm square pixels. Typically, two-by-two binning is applied during image acquisition on the CCD in order to accommodate the lower resolution (12 lp/mm) of the MCP. A phase-dependent signal at each pixel of the image is achieved by sequentially phase stepping the gain source and recording a series of images throughout an entire cycle (0–360°).

Fourier analysis is applied to each pixel in the image sequence in order to obtain the phase and modulation images, from which the fluorescence lifetimes are calculated. Typically, 16 phase-dependent images of ~300 x 300 pixels are acquired in a FLIM sequence. With a maximal readout rate of 5 Mpixels s^{-1}, each phase-dependent image can be read in ~20 msec. Photobleaching is minimized by illuminating the sample only during image acquisition. This is achieved with an external high-speed shutter (UNIBLITZ VS25 and D122 shutter and driver, Vincent Associates) located between the filter block and the epi-illumination port of the microscope. Synchronous triggering of the shutter is controlled with a BNC output on the CCD, indicating shutter status. The phase setting of the frequency synthesizer modulating the image intensifier gain is precisely stepped via commands sent over a GPIB interface housed in a PC. The incorporation of extensions into IPLab Spectrum (Scanalytics Inc.) for phase-stepping control and downloading images from the CCD provides the software interface for the collection of FLIM data.

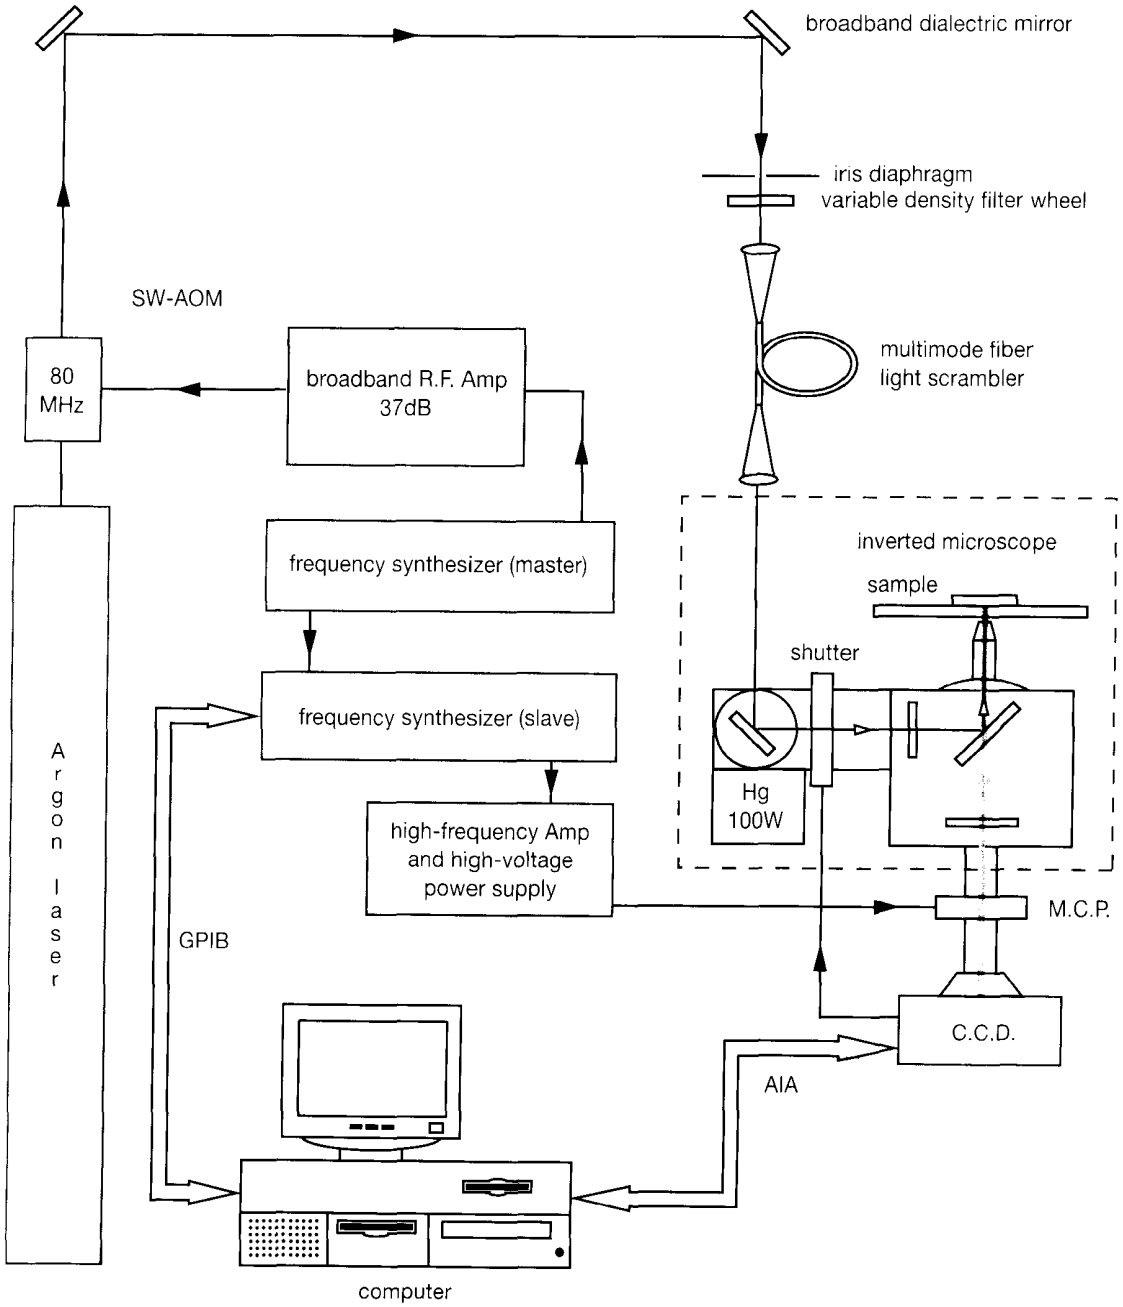


FIGURE 18-18 Schematic of a Single-frequency FLIM Configuration

See text for details.

$$D_{0i} = \frac{1}{N} \sum_{k=0}^{N-1} D_i(k) \tag{12}$$

$$a_{ni} = \frac{2}{N} \sum_{k=0}^{N-1} D_i(k)\cos(kn\Delta\psi) \tag{13}$$

$$b_{ni} = \frac{2}{N} \sum_{k=0}^{N-1} D_i(k)\sin(kn\Delta\psi) \tag{14}$$

The phase shifts and modulations at each pixel (i) are found from these parameters (Figure 18-17, Step 3):

$$\Delta\phi_i = \arctan(b_{1i}/a_{1i}) - \Delta\phi_R \tag{14}$$

$$M_i = \sqrt{a_{1i}^2 + b_{1i}^2}/D_{0i}M_R \tag{15}$$

where $\Delta\phi_R$ and M_R are the calculated phase shift and modulation, respectively, of a reflective reference sample (foil) that has a zero lifetime value. The phase and modulation lifetime images can now be calculated by substitution of the phase shifts and demodulations into Equations 9 and 10, respectively (Figure 18-17, Step 4).

Imaging Protein Phosphorylation with FLIM-FRET

FRET can be used as a highly specific indicator of protein modifications, such as phosphorylation, through the interaction of a target protein with an antibody recognizing the modified residues. Signal specificity for protein modification is achieved by FRET between chromophores present upon the phosphorylated protein and an antibody. Typically, this type of experiment is generally carried out using a GFP moiety, fused to the phosphoprotein as the donor, and Cy3 conjugated to an antibody as the acceptor. The antibody-Cy3 conjugate is introduced by either microinjection into live cells or by incubation with permeabilized, fixed cells. In this approach, FRET can only be detected by changes in the quantum yield of the donor, typically measured by changes in fluorescence lifetime. FLIM is particularly suited to live-cell FRET measurements, since the acceptor-bearing antibody is present in large molar excess over the donor fusion protein. In addition, the antibody need not necessarily be uniquely specific for the epitope, as is often the case. Semipurified antibody preparations are accommodated that possess only minor quantities of specific IgG molecules. We describe the detection of interactions with (1) one genetically encoded donor component and one microinjected, labeled acceptor component and (2) two labeled donor/acceptor components. These procedures are equally compatible with the detection of interactions between two genetically encoded probes such as ECFP and EYFP, or EGFP and DsRed. Although we present here a specific protocol for measuring the activation state of protein kinase Cα (PKCα) by following the phosphorylation of Thr-250 (Ng et al. 1999), the approach is generic for measuring covalent protein modification(s) and can also be applied to the detection of protein interactions per se. Examples are described for both a live- and a fixed-cell experiment using EGFP-tagged PKCα and a labeled antibody specific for phosphorylated Thr-250, and also for a fixed-cell experiment using two labeled antibodies (one to PKCα and the other to phospho-Thr-250).

For any FLIM-FRET experiment, the sample and reagent preparation follow a basic order. The various alternatives at each point in the sequence are outlined in a flow chart (please see Figure 18-19). We have divided the protocol into three stages: Stage 1 describes the preparation of proteins and their labeling with fluorescent dyes; Stage 2, the delivery of the appropriate probe components into cells by transfection or microinjection; and Stage 3, the process of image collection and analysis.

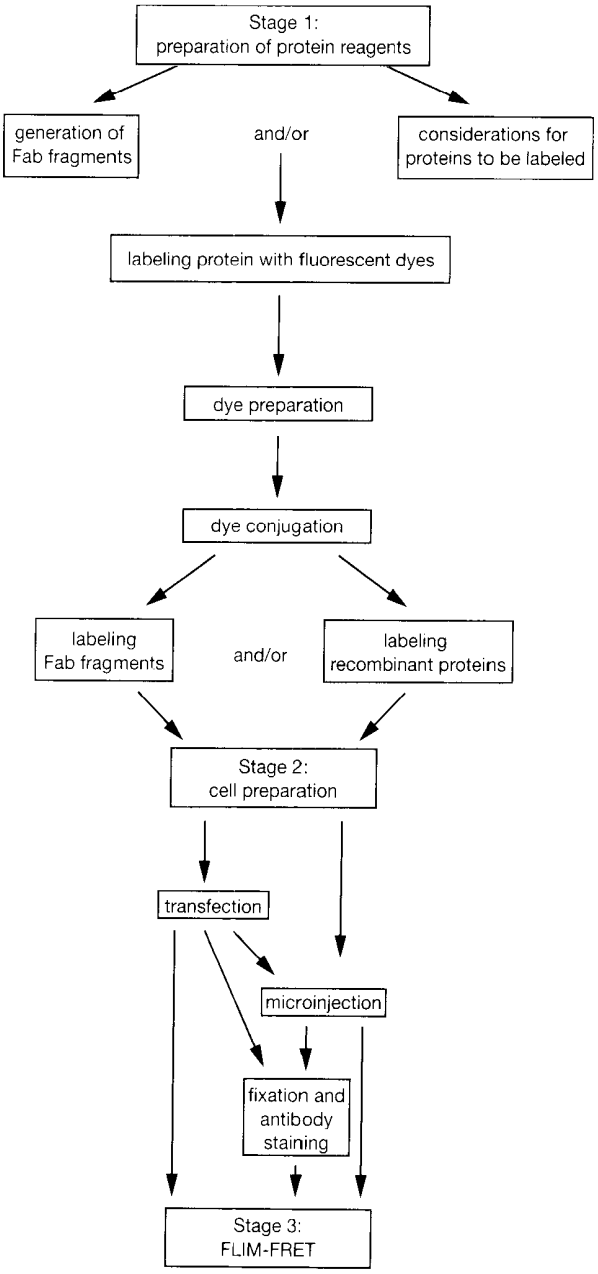

FIGURE 18-19 A Flow Diagram Representing the Possible Protocol Options for Performing the Three Stages of a FLIM-FRET Experiment

See text for full details.

STAGE 1: Labeling Proteins with Fluorescent Dyes

The first stage of this protocol describes the preparation of labeled components (usually antibodies or other proteins) that may be introduced into the cells of interest in Stage 2. Fab fragments (if they are required) must be produced before the fluorescence labeling, as described in Steps 1–7. Fab fragments are preferred for FRET experiments in live cells in order to prevent potential cross-linking of antigen by intact antibodies. Although this procedure may be used to prepare Fab fragments from most types of antibodies, the example given here describes conditions for preparing Fab fragments of the polyclonal phospho-Thr-250 antibody (T[p]250). The second sequence of steps (10–16) describes labeling the amino groups of these fragments or other purified proteins with fluorescent sulfoindocyanine (Cy) dyes. If antibodies or proteins are to be labeled directly, omit Steps 1–7 and proceed to Step 8. If the probe components are encoded in a plasmid DNA, proceed directly to Stage 2.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Bicine (0.1 M, pH 7.5) adjusted with NaOH

Bicine (1 M, pH 9.0–9.5) adjusted with NaOH

Digestion buffer

20 mM Na-phosphate
10 mM EDTA
20 mM cysteine/HCl buffer (pH 7.0)

N,N-*Dimethylformamide (DMF)* <!>

DMF is dried with the addition of ~1/3 volume of hygroscopic resin to the storage vessel. For example, AG 501-X8 mixed bed resin (from Bio-Rad) can be placed permanently in the stock DMF bottle. If there is any doubt as to the integrity of the DMF, either add further fresh resin or replace with fresh resin. This issue is a consideration should problems be encountered labeling proteins to a desired ratio. The presence of H_2O in the labeling reaction (potentially from the DMF) will compete for the free dye.

Na-phosphate (20 mM) with 10 mM EDTA (pH 7.0)

Phosphate-buffered saline (PBS)

TE (pH 7.0)

Enzymes and Buffers

Papain immobilized to agarose beads (50% slurry in digestion buffer; Sigma)

Labeled Compounds

Cy3 and Cy5 OSu monofunctional sulfoindocyanine succinimide esters (Amersham)

Succinimide esters of sulfoindocyanine (Cy) dyes covalently bind to free amino groups (the α-amino terminal or ε-amino groups on lysine side chains). Cy dyes are provided as lyophilized samples that must be maintained in a desiccated environment at all times to prevent reaction with H_2O. The amount of dye in each vial must be individually quantitated as there can be variations between batches. In the example given here, the succinimide ester of Oregon Green (Molecular Probes) is used to label the MC5 PKCα antibody.

Antibodies

Purified antibody such as MC5, monoclonal or T250, polyclonal or protein to be labeled

The labeling reaction must be performed in a buffer free of amine groups. Many commercial antibody preparations are provided with stabilizing agents that contain free amino groups (such as bovine serum albumin or gelatin) which will compete for the Cy dye. A number of suppliers provide the antibody preparations free of these compounds upon request; in this case, request that they are provided at 1 mg/ml in phosphate-buffered saline.

Gels

SDS-polyacrylamide gel <!>

For preparation of SDS-polyacrylamide gels for resolution of proteins, please see Appendix 8.

Special Equipment

Centricon concentrators, YM10, YM30, and YM100 (10-, 30-, and 100-kD molecular-mass cut-off, respectively; Amicon)

Gel filtration/size exclusion chromatography columns (prepacked Econo-Pac 10DG disposable; Bio-Rad)

Protein A–Sepharose column (Econo-Pac 2-ml column from Bio-Rad)

Equilibrate the column by washing with 20 bed volumes of 20 mM Na-phosphate. Protein G is recommended for purifying mouse antibodies.

UV/visible absorption spectrophotometer

Additional Reagents

Step 7 of this protocol requires the reagents for determining protein concentration (e.g., Bradford assay reagents) (Spector et al. 1998, Chapter 56).

METHOD

Generation and Purification of Fab Fragments

1. Concentrate the antibodies to 15–20 mg/ml in 20 mM Na-phosphate, 10 mM EDTA (pH 7.0), by centrifugation using a disposable concentrator such as a Centricon YM100.

2. To 250 µl of the concentrated antibody preparation (~4–5 mg), add 500 µl of digestion buffer and 500 µl of a 50% slurry (in digestion buffer) of papain immobilized on agarose beads. Allow the digestion to proceed for 6–10 hours at 37°C with shaking (300–400 rpm in a shaking incubator).

   ▲ **IMPORTANT** Excessive digestion (i.e., in excess of 16 hours) will result in the cleavage of the Fab fragments into smaller polypeptides. It is therefore advisable to perform a pilot experiment where small aliquots of the digestion (~5 µl) are withdrawn at 1-hour intervals for analysis by reducing SDS-polyacrylamide gel electrophoresis. Under reducing conditions, the heavy and light chains of IgG migrate as 50-kD and 25-kD polypeptides. The papain-digested antibody migrates at ~25 kD.

3. Purify the Fab fragments from the Fc portion and nondigested antibodies by passage through a protein A–Sepharose column. Apply the digestion mixture to the equilibrated column and immediately begin collecting 1-ml fractions of the flowthrough.

   Protein A will bind the Fc portion of the antibody, thereby removing both the whole antibody and the Fc fragments from the digestion mixture. The resultant flowthrough should contain Fab fragments alone. Beware! A number of subclasses of IgG molecules do not bind to protein A (please see Appendix 9). Use protein G when generating Fab fragments of mouse monoclonal antibodies.

4. To identify which fraction contains the purified Fab fragments, measure the OD_{280} of each fraction. Collect and pool three or four fractions containing the highest concentration of Fab.

   Typically, the Fab fragments are found in approximately three to four fractions.

5. Concentrate the pooled fractions by centrifugation through a Centricon YM10 (10-kD cut-off; Amicon) to a volume of <0.5 ml.

6. Apply the sample to a low-molecular-mass (6-kD exclusion) gel filtration chromatography column equilibrated in PBS. Elute the Fab fragments with PBS (according to manufacturers instructions).

   To label the Fab fragments, they must be exchanged into a buffer that does not contain free amino groups (i.e., the free cysteine must be removed from the digestion buffer).

7. Following elution, concentrate the Fab fragments through a Centricon concentrator and determine the protein concentration. Add 1/10 volume of 1 M bicine (pH 9.0).

   The IgG concentration determined by Bradford assay, using bovine serum albumin as a standard, must be multiplied by a factor of 2.

   The concentrated preparation of Fabs is now ready to be labeled with fluorescent sulfoindocyanine (Cy) dyes.

Dye Preparation

8. Resuspend the contents of a single vial of lyophilized dye in 20 µl of dry *N,N*-dimethylformamide, to give a Cy solution with a concentration of ~10 mM.

9. Dilute 1 µl of the dye mixture 1:10,000 in PBS and calculate the dye concentration from the visible peak absorption.

   The extinction coefficients for Cy3 and Cy5 are 150,000 mM^{-1} and 250,000 mM^{-1} at 554 nm and 650 nm, respectively.

Dye Conjugation

10. To label the proteins, suspend them in a buffer that does not contain free amino groups. If the protein solution is not in an appropriate buffer, perform Steps 6–7.

    If the protein has a special buffer requirement for stability, the gel filtration column can be equilibrated with that particular buffer. Take care that no buffer component has free amino groups or factors that are inhibitory to the labeling reaction. It is worth noting that reducing agents such as dithiothreitol or β-mercaptoethanol interfere with the labeling reaction. However, if a reducing agent must be included to maintain biological/protein function, β-mercaptoethanol has the lower interference and is the reducing agent of choice. Both T(p)250 and MC5 are exchanged into PBS before labeling in 0.1 M bicine (pH 9.0).

    It is advisable to maintain an alkaline pH (while maintaining protein integrity) in the labeling reaction to promote deprotonation of ε-amino groups of lysines and thereby efficient coupling.

11. React the protein sample (antibody, Fab fragment, or protein) with a 10–40-fold molar excess of Cy3 for 30 minutes at room temperature (prepared as described in Steps 8–9). Add the dye very slowly while stirring the solution with a pipette tip (carefully avoiding direct dye contact with the microfuge tube).

    To avoid protein denaturation by DMF, the volume of Cy3/DMF added must not exceed 10% of the total volume.

    The determination of the optimal molar excess and reaction time is empirical. The goal is to label each protein with 1–3 dye molecules (for a discussion of labeling ratio criteria, please see the introduction to this protocol). The level of labeling will vary greatly with individual proteins or antibodies. If the final labeling ratio is too low, it is possible to re-label the antibody. Monoclonal antibodies such as T(p)250 and MC5 have been labeled successfully with a 40-fold molar excess of dye.

12. Terminate the labeling reaction by the addition of a free-amine-containing buffer such as Tris, to a final concentration of 10 mM.

13. Remove the excess unreacted dye by exchanging the buffer using gel filtration column chromatography (10DG, Bio-Rad), and eluting the protein into PBS.

    a. Equilibrate the column with three bed volumes of PBS or the buffer of choice (~30 ml).

    b. To maximize separation, load the labeling reaction mixture directly onto the resin, taking care to apply it in as small a volume as possible.

    c. Wash the column with 2.5 ml of buffer (~3.3 ml is void) and discard.

    d. Add a further 2 ml of buffer and collect the visible protein fraction, discarding the remainder. The labeled product will run at the leading front and should be visible. Free dye migrates more slowly through the column.

14. Concentrate the labeled protein once again using a Centricon concentrator (of the appropriate molecular-mass cut-off).

15. Analyze the labeled product by electrophoresis through an SDS-acrylamide gel to verify successful covalent labeling of the protein. Following electrophoresis, examine the gel directly on a UV transilluminator (302 nm) to visualize the labeled product.

    A fluorescent band should migrate at the expected molecular weight of the protein. There should be no fluorescence from free dye at the migration front.

    UV excitation at 302 nm is suboptimal for most dyes. Consider using shorter-wavelength excitation if no bands are visible upon gel illumination.

16. Following the labeling reaction, calculate the labeling ratio using the following formula:

$$A_\lambda \times M/[(A_{280} - f \times A_\lambda) \times \varepsilon_\lambda]$$

Where A_λ is the absorption of the dye at its absorption maximum at wavelength λ, A_{280} is the absorption of the protein at 280 nm, M is the molecular mass of the protein in kD, ε_λ is the molar extinction coefficient of the dye at wavelength λ in $mM^{-1}cm^{-1}$. The equation also corrects for absorption of the dye at 280 nm. This factor f is the ratio between absorption of the dye at 280 nm and its maximal visible absorption at wavelength λ. For example, the labeling ratio formula for Cy3-labeled antibody becomes:

$$A_{554} \times 170/[(A_{280} - 0.05 \times A_{554}) \times 150]$$

To verify that dye coupling has not damaged the biological function of the Fab, whole antibody, or protein, compare the specific activity of the labeled product with its unlabeled counterpart. Specific activity may represent either catalytic activity or a protein-binding activity. These types of protein-binding assays can be performed on agarose-immobilized peptide ligand or phosphotyrosine beads. Standard protocols for testing such binding activities may be found in *Using Antibodies* (Harlow and Lane 1999).

STAGE 2: Cell Preparation for FLIM-FRET Analysis

In preparation for FLIM-FRET analysis, the appropriate donor and acceptor components must be introduced into the live or fixed cells under study. The selected method of introduction depends on the nature of the components as well as the state of the cells, i.e., whether the component is plasmid DNA encoding the protein of interest fused to a GFP variant or whether it is a protein or antibody labeled as described in Stage 1. For live cells, the introduction of plasmid DNA is accomplished using either transfection or nuclear microinjection, whereas protein or antibody is delivered by microinjection. For studies on fixed cells, plasmid DNA is introduced into cells by tranfection or microinjection, and the cells are subsequently fixed in paraformaldehyde before staining with labeled protein or antibody. The following method describes the introduction of plasmid DNA into live cells by transfection. The first alternative protocol at the end of this protocol describes the processing of fixed cells and treatment with antibodies in preparation for FLIM-FRET analysis. A second alternative protocol describes the delivery of either plasmid DNA or protein into cells by microinjection. Each approach is outlined independently and can be applied as appropriate to a specific experimental regime.

GFP CLONING VECTORS

A wide range of GFP variants are now commercially available from CLONTECH (details can be found on the Web Site: http://www.clontech.com/techinfo/vectors/catlc.html) including various spectrally optimized versions (enhanced green, yellow, and cyan fluorescent protein); a red-shifted isolate from the coral species, *Anthozoa*; and forms fused to intracellular compartment targeting sequences (such as the farnesylation sequence of Ha-*ras* for plasma membrane localization, a nuclear localization sequence, and Golgi complex or endoplasmic reticulum retention sequences). These cloning vectors contain promoter sequences compatible with high-level mammalian expression, and the GFP variants have been modified to contain human codon preferences for further enhancement of expression in mammalian cells. Standard molecular cloning protocols (Chapter 1) may be used to generate amino- or carboxy-terminal fusions of the protein of interest with the various GFP mutants (please see the information panel on **GREEN FLUORESCENT PROTEIN** in Chapter 17).

MATERIALS

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Gelatin solution (0.1%)

Optional, please see Step 1.

Dissolve 0.5 g of gelatin (Porcine, Sigma) in 500 ml of 1x phosphate-buffered saline. Sterilize by autoclaving.

Phosphate-buffered saline (PBS)

Poly-L-lysine

Optional, please see Step 1.

Available commercially from Sigma as a 0.1% (w/v) solution in H_2O; dilute 1:10 in H_2O before use.

Nucleic Acids and Oligonucleotides

Plasmid DNA carrying the probe

GFP fusion vector (CLONTECH) encoding the protein of interest.

Media

CO_2-independent imaging medium

This low-background fluorescence medium is commercially available from Life Technologies or adjust the standard formulation of Dulbecco's modified Eagle's medium by omitting each of the following: pH indicator phenol red, penicillin, streptomycin, folic acid, and riboflavin. Just before use, supplement the medium with sterile HEPES (final concentration 50 mM) adjusted with NaOH to pH 7.4.

The imaging medium must not contain components that are autofluorescent.

Special Equipment

Tissue culture plates (6- or 12-well) (Nunc) or
Glass bottomed tissue culture dishes (35-mm, MatTek Corporation) or
Glass chamber slides or coverglass chamber slides (Labtek, Nunc)

Additional Reagents

Step 2 of this protocol requires the reagents for a transfection method as described in Chapter 16.

Cells and Tissues

Cell line (adherent or suspension culture) to be transfected

The only consideration for the choice of cell type, other than their suitability for the system to be investigated, is that a facility be available to immobilize them in some manner (see notes to Step 1 for suggestions).

METHOD

1. Seed the cells onto an appropriate surface for microscopy:

   For live cell preparations: Seed cells onto glass-bottomed dishes or coverglass chamber slides.

   For cell preparations to be fixed after transfection: Seed the cells onto glass coverslips placed in 6- or 12-well tissue culture dishes.

   The final choice of vessel depends on whether the cells are to be microinjected after transfection; if so, consider the shape and clearance space for needle access.

   For suspension cells, immobilization can be facilitated with the use of media such as gelatin (0.1% w/v in PBS; autoclaved) or poly-L-lysine (0.01% w/v in H_2O). In either case, coat the surface by covering either the wells, coverslips, or coverglass slides for ~30 minutes with the chosen medium and then aspirate the excess. Cells can then be directly seeded onto the coated surface. The cells can also be maintained in suspension throughout the transfection procedure and then immobilized immediately before imaging. Once immobilized, microinjection is also possible.

   Plate cells at a density such that the cells are ~40% confluent the following day.

2. Transfect the cells with the plasmid(s) encoding the GFP-tagged protein(s) of interest, using any one of the transfection methods described in Chapter 16.

3. Incubate the transfected cells under the appropriate conditions for 16–24 hours to allow the cells to express the protein of interest.

   In some cases, the level of protein expression must be controlled accurately. If this is the case, it is advisable to consider optimizing transfection efficiencies as well as the expression period before the FLIM measurement, using a regulated promoter to drive expression of the protein (please see

Chapter 17) or using nuclear microinjection rather than transfection (please see the panel on **ALTERNATIVE PROTOCOL: MICROINJECTION OF LIVE CELLS** at the end of this protocol).

4. Identify cells that are expressing the protein of interest.
5. (*Optional*) If appropriate for the experimental design, introduce another probe (e.g., labeled protein) using one of the alternative protocols following Step 6: microinjection (for live cells) or fixation and staining (for fixed cells).
6. Immediately before performing an experiment at the microscope, replace the culture medium with CO_2-independent imaging medium (commercial medium or Dulbecco's modified Eagle's medium adjusted as described in the Materials list).

   If the experimental design requires serum starvation of the cells before the relevant treatment, starve the cells for the prescribed time frame before imaging. If, however, the cells undergo apoptosis in response to serum deprivation, then maintain the cells in 0.5% fetal calf serum for this period and replace with serum-free medium immediately before imaging.

ALTERNATIVE PROTOCOL: PREPARATION OF FIXED CELLS FOR FLIM-FRET ANALYSIS

The reagents used for the preparation of fixed cells for FLIM-FRET experiments have been optimized to minimize the quenching of GFP mutants and fluorescent dyes. This protocol can be applied easily to the preparation of fixed cell samples that do not require treatment with labeled antibodies, for example, samples that have both the donor and acceptor fluorophores expressed as fluorescent fusion proteins. If this is the case, omit the Triton X-100 permeabilization step (Step 5 below) and proceed with the remainder of the protocol for fixing and mounting. Paraformaldehyde is the fixative of choice when performing FRET experiments, as it is a cross-linking agent that preserves the integrity of protein interactions and does not precipitate cellular proteins.

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Additional Materials

Cy3-labeled Fab fragments or whole antibody diluted in 1% (w/v) bovine serum albumin in PBS
Labeled protein is prepared as described in Stage 1.

Mowiol mounting medium
Mowiol is the desired mounting medium as it does not quench GFP fluorescence.

i. Mix 6 ml of glycerol, 2.4 g of Mowiol 4-88 (Calbiochem, 475904), and 6 ml of distilled deionized H_2O.
ii. Shake the mixture for 2 hours at room temperature, then add 12 ml of 200 mM Tris-HCl (pH 8.5), and incubate at 50°C with occasional shaking until the Mowiol dissolves (~3 hours).
iii. Filter the solution through a 0.45-µm membrane filter and store in aliquots for weeks at 4°C or for months at –20°C.

Paraformaldehyde (4%) fixative solution <!>

i. Dissolve 4 g of paraformaldehyde (Sigma) in 50 ml of distilled deionized H_2O, and then add 1 ml of 1 M NaOH solution.
ii. Stir the mixture gently on a heating block (~65°C) until the paraformaldehyde is dissolved.
iii. Next add 10 ml of 10x PBS and allow the mixture to cool to room temperature. Adjust the pH to 7.4 using 1 M HCl (~1 ml is needed) and then adjust the final volume to 100 ml with distilled deionized H_2O.
iv. Filter the solution through a 0.45-µm membrane filter to remove any particulate matter, and store in aliquots at –20°C for several months. Avoid repeated freeze/thawing of the paraformaldehyde solution.

Permeablization solution
0.1% (w/v) Triton X-100 (Sigma) in PBS

Quenching solution
50 mM Tris-Cl (pH 8.0)
100 mM NaCl

Rubber cement or molten 1% (w/v) agarose
Optional, please see Step 10.

Stimulus for biological activity to be monitored

Method

1. Seed the cells onto either glass coverslips or glass chamber slides and, if necessary, transfect as described in the preceding protocol.
2. Following transfection and incubation to allow expression of the transfected gene, treat the cells with the desired stimulus for an appropriate period of time.
3. Wash the cells twice in PBS, aspirate the fluid, and add 4% paraformaldehyde to fix the cells. Incubate the cells for 10 minutes at room temperature.
4. Quickly wash the cells with quenching solution to rinse the excess fixative and then wash again for 5 minutes to quench the remaining aldehyde groups.

   If it is not necessary to introduce labeled protein into the cells, proceed to Step 8.
5. Incubate the cells in permeabilization solution for 15–20 minutes.
6. Wash the cells twice with PBS to remove the permeabilization solution.
7. Incubate the coverslips or chamber slides in a labeling solution of Cy3-labeled Fab fragments or whole antibody diluted in 1% bovine serum albumin in PBS for 1 hour at room temperature in a humidified chamber.

   To minimize the quantity of antibody or Fab used, place the coverslips cell-side down on 25-µl droplets of the antibody solution. This can be performed on a sheet of Parafilm or other clean, nonstick surface. To retrieve the cov-

erslips at the end of the incubation, place a 100-µl droplet of PBS at the edge of the coverslip; this will raise the coverslip sufficiently to grasp the edge with jeweler's forceps.

Typical concentration ranges for incubation are between 1 and 100 nM corresponding to 0.15–15 µg/ml for a whole antibody. It is advisable to perform a titration to determine the optimal dilution that results in epitope saturation. For example, to detect the activation state of PKCα, incubate MCF10A cells with 10 µg/ml Cy3-labeled T250 antibody (αT250-Cy3) and 10 µg/ml Oregon-Green-labeled anti-PKCα (MC5-OG) in PBS containing 1% bovine serum albumin.

8. Wash the coverslips five times in PBS.

9. Blot off excess PBS with a tissue at the edge of the coverslip, taking care not to allow the cells to dry out.

10. Mount the coverslips on 10 µl of Mowiol on glass microscope slides, and allow the mounting medium to harden overnight at 4°C. The Mowiol must solidify before imaging or the coverslip must be secured by rubber cement or molten agarose (1% in H_2O).

Alternatively, if glass chamber slides have been used to prepare the cells, place 10-µl drops of Mowiol over each well of cells and then place a long, square coverslip over the entire slide, taking care to minimize air bubbles. The slides are now ready to image; proceed to Stage 3.

▲ **IMPORTANT** Do not use nail polish as this has been shown to quench GFP fluorescence.

ALTERNATIVE PROTOCOL: MICROINJECTION OF LIVE CELLS

The introduction of DNA into cells by microinjection is the method of choice when a high level of controlled protein expression is required (for a detailed technical description of microinjection, please see Pepperkok et al. [1998] and Spector et al. [1998, Chapter 83]). When live-cell FRET experiments are to be performed, labeled proteins, such as Fab fragments or recombinant proteins, must also be microinjected. Labeled proteins are injected into the cytoplasm at its highest point near the nucleus. Conversely, DNA is injected directly into the nucleus.

The number of cells to be injected must be determined empirically for each experiment. If single cells are to be imaged in a time course, only a few cells will need to be injected; however, allowances must be made for unsuccessful injections and cell damage or death as a result of injection.

Additional Materials

Cells of interest seeded onto glass-bottomed cell culture vessels
GELloader tips (Eppendorf)
HEPES (1 M)/NaOH (pH 7.4)
High-purity (e.g., HPLC-grade) H_2O
Inverted microscope with 10x and 40x air objectives
Microinjector (Eppendorf model 5246)
Microinjection needles

If a needle-pulling device is available, pull needles that have an opening of ~0.25-µm diameter. The opening varies with the filament temperature setting and can be determined empirically using a syringe-operated bubble meter by measuring the air pressure required to expel air bubbles from the pipette into a liquid. Alternately, Eppendorf supplies commercially produced microinjection needles (Femtotip).

Micromanipulator (Eppendorf model 5171)
Micropipette bubble meter (Clark Electromedical Instruments)
Micropipettes (Eppendorf, Femtotip)
Millex-GV4 (0.22 µm) syringe filtration units
Millipore syringe filter units (0.22 µm, Millex-GV4)
Sample to be injected (plasmid DNA or labeled protein)

Successful microinjection depends on the purity of the DNA used and on the removal of aggregates from protein solutions. Therefore, we recommend that DNA be purified by either double cesium chloride–ethidium bromide gradients (Chapter 1, Protocol 10) or Qiagen ion-exchange columns (midiprep or maxiprep) (Chapter 1, Protocol 9) and that both the DNA and protein solutions be filtered of particulate matter as described in Step 2.

(Continued on following page.)

Method

1. For plasmid samples, dilute the purified DNA in HPLC-grade H_2O to a concentration appropriate for the experimental design. For optimal expression overnight, dilute to 1 μg/ml and for expression after a few hours, dilute to 100 μg/ml.
2. To avoid blockage of the microinjection needle, clear the DNA or protein solution of particulate matter.
   a. Place a 0.22-μm Millipore syringe filter unit within a 0.5-ml microfuge tube, and place this inside a 1.5-ml microfuge tube.
   b. Filter the DNA or protein solution by centrifugation at maximum speed for 1 minute in a microfuge.

      As little as 10 μl may be filtered this way. If filter units are unavailable, clarification may also be performed by centrifugation of the DNA solution at 25,000g for 20 minutes.

      We favor the use of 0.22-μm Millipore syringe filter units (Millex-GV4) for their ease of use and low-protein-binding characteristics.
3. Load the glass needle with 2 μl of the DNA or protein solution using GEL loader pipette tips. Avoid air bubbles (which interrupt and prevent microinjection) by placing the end of the pipette as close to the needle opening as possible when loading the solution. Fit the needle directly into the holder of the microinjection device.
4. Adjust the settings for microinjection.

   The optimal pressure and injection time settings will vary with cell type and needle diameter; however, a typical range would be 0.3 second and 150–400 hPa injection pressure. A back pressure of ~20 hPa is needed to prevent the medium from entering the needle by capillary action. During optimization of injection conditions, try to achieve injection without disruption of the integrity of the cellular structure (i.e., without excessive pressure). Injection is ideally performed on an inverted microscope using either 40x or 10x air objectives.

   A visual indication of excessive pressure during nuclear injection is an apparent separation of the nucleus from the surrounding cellular material visible by a light ring around the nucleus.
5. Carry out injection at room temperature in standard CO_2-dependent growth medium for intervals of ~10 minutes to avoid acidification of the medium. If prolonged periods of injection are necessary, substitute a CO_2-independent medium.
6. If protein or antibody was injected, proceed to Step 7. If plasmid DNA was injected, incubate the transfected cells under the appropriate conditions for 16–24 hours to allow the cells to express the protein of interest.

   The time frame for expression is determined empirically for the protein under study.
7. Immediately before performing an experiment at the microscope, replace the culture medium with CO_2-independent imaging medium (commercial medium or Dulbecco's modified Eagle's medium adjusted as described in the Materials list of the main protocol).

STAGE 3: FLIM-FRET Measurements

Stage 3 presents a basic plan for capturing a fluorescence lifetime imaging microscopy (FLIM) series of images using the microscopy setup described in the introduction to this protocol (please see the panel on **AN EXPERIMENTAL SETUP FOR FREQUENCY DOMAIN FLIM**, p. 18.76). The protocol specifically describes the data acquisition for EGFP or Oregon Green as a donor fluorophore; however, it can be adapted for image acquisition of other chromophore systems by adjusting the excitation wavelength and filter sets (please see Table 18-11). For further details on immunofluorescence microscopy, please see Spector et al. (1998, Chapter 102).

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Special Equipment

Amplifier (ENI 403LA or Intra-action PA-4)
Argon laser (Coherent, Innova 70C) **<!>**
Broad-band dielectric mirrors (2; Newport Corporation)
Detectors
- MCP, Hamamatsu C5825 or LaVision Picostat HR
- CCD, Photometrics Quantix with Kodak KAF 1400 chip

Filters
- GFP, OG (Q495LP, HQ510/20; Chroma)
- Cy3 (HQ545/30, Q565LP, HQ610/75; Chroma)
- half-silvered mirror (Zeiss)

Flexure mirror mounts (2), lens holders (2), posts (5), and post holders (5) (Newport)
Inverted microscope (Zeiss 135TV)
IPLab Spectrum (Signal Analytics)
Iris diaphragm (Comar)
Lenses (12 and 7.6 cm focal length, 2.5 and 3.8 cm focal length, respectively; Newport)
Mercury arc lamp (100 W Zeiss; HBO 100 AttoArc)
Multimode fiber step-indexed 1-mm core (Newport)
Oil objective (100x/1.4 NA; Zeiss Fluar)
Optical breadboard (2 x 1 m; TMC)
Power meter and head (Ophir, Nova Display and 2A-SH)
Power PC (Macintosh) equipped with PCI-GPIB card (National Instruments)
Shutter (high-speed, Vincent Associates, Uniblitz VS25)
Shutter driver (Vincent Associates, Uniblitz D122)
Standing wave acousto-optic modulator (AOM) (Intra-action, 80 MHz)
Two-frequency synthesizers (IFR 2023)
Variable density filter wheel (Laser Components)
Water circulating cooler (Grant)

Cells and Tissues

Cells (live or fixed) expressing the probe proteins, prepared as described in Stage 2

TABLE 18-11 Filter Specifications for FLIM–FRET Using Selected Donor and Acceptor Pairs

FRET Pair Donor and Acceptor	Donor Filter Set			Acceptor Filter Set		
	Excitation	Dichroic	Emission	Excitation	Dichroic	Emission
ECFP and EYFP	laser line	455DRLP	480DF30	HQ500/40	Q525LP	HQ555/50
	457.9 nm	(Omega)	(Omega)	(Chroma)	(Chroma)	(Chroma)
EGFP and DsRed	laser line	Q495LP	HQ510/20	HQ545/30	HQ565LP	HQ610/75
	488 nm	(Chroma)	(Chroma)	(Chroma)	(Chroma)	(Chroma)
Cy3 and Cy5	laser line	HQ565LP	HQ610/75	HQ620/60	HQ660LP	HQ700/75
	514.5 nm	(Chroma)	(Chroma)	(Chroma)	(Chroma)	(Chroma)
EGFP and Cy3	laser line	Q495LP	HQ510/20	HQ545/30	HQ565LP	HQ610/75
	488 nm	(Chroma)	(Chroma)	(Chroma)	(Chroma)	(Chroma)

METHOD

1. Select the 488-nm excitation wavelength on the argon laser by adjusting the wavelength selector prism. Optimize the output power by fine tuning the position of the high-reflector mirror using the control knobs at the back of the laser.
2. Set the frequency synthesizer to drive the AOM to ~40 MHz at a resonance frequency (for the experiments described herein, a driving frequency of 40.112 MHz is used). This gives rise to intensity oscillations in the laser light beam at twice the driving frequency (80.224 MHz).
3. Optimize the diffraction in the AOM and thereby the modulation depth by adjusting the angle of incidence and monitoring the intensity of the undiffracted zero order beam with a power meter. The optimal angle of diffraction (corresponding to maximal diffraction) gives rise to a minimum in the output power of the zero-order beam.
4. Turn on the MCP and the CCD. Set the bias of the photocathode voltage to –2 V and adjust the gain to match the full dynamic range on the CCD. This is dependent on the fluorescence intensity of the sample and must be determined empirically. Ideally, keep the gain as low as possible to reduce noise. Typically, the gain is set at 1 for the Hamamatsu C5825, with the gain of the Photometrics Quantix CCD set at 3. Set the readout of the CCD to 2 x 2 binning.
5. Set the master frequency synthesizer driving the MCP to a value exactly double (for the above example: 80.224 MHz) that driving the AOM.
6. Choose the most suitable objective for the experiment. For this example, a Zeiss Fluar 100x/1.4 NA oil objective is used.
7. To obtain a zero lifetime reference image, record a cycle of 16 phase-dependent images, each separated by 22.5° from a strong scatterer (e.g., a small piece of aluminum foil placed on the imaging surface of a coverslip or glass bottom dish).
   a. Exchange the fluorescence filter set for a half-silvered mirror and reduce the intensity of the incident beam to a minimum with a variable density filter wheel. Adjust the focus on the foil surface.

      ▲ **WARNING** When setting up the foil image, take extreme care not to look directly into the microscope occular until the incident laser source has been reduced to a minimum.

b. Take a single image of the aluminum foil with an exposure time of ~100 msec. This image is taken to select an ROI and to gauge the likely exposure time required. Because the phase of the master frequency synthesizer may not be at a maximum, and to avoid saturation of the detector, select an exposure time that generates ~1000 counts.

c. Record a cycle of 16 phase images, each separated by 22.5°. Determine the phase setting at which maximum intensity is reached in the image series. Reset this phase to zero degrees on the master frequency synthesizer.

d. Record another cycle of 16 phase images from the foil to save as a zero lifetime reference.

While performing lifetime imaging, we recommend that phase stability be monitored over time. In our setup, the phase is stable within 0.3° during a period of 1 hour. For our set-up, a reference foil sequence is recorded and saved each hour.

8. Restore the incident excitation source to a maximum (using the variable density filter wheel); the system is now ready for the acquisition of cell imaging data.

9. Acquire a donor image using the GFP filter set (Dichroic: Q495LP, emission: HQ510/20). Select an exposure time such that 75% of the dynamic range of the CCD (3000 counts for a 12-bit CCD) is filled. Select a region of interest in the image on which to measure fluorescence lifetimes.

10. Create a donor fluorescence lifetime map:

a. Take two contiguous series of 16 phase-dependent images (45° phase-stepped), one forward and one reverse cycle to correct for photobleaching. Optimize the set exposure time for each phase image as in Step 9.

b. Take an additional image in the absence of sample illumination. This background offset image is subtracted from all phase images in the series. Each of the pairs of equivalent phase images of the forward and reverse cycles are then summed to first-order to correct for bleaching of the donor.

c. From these data and the zero lifetime reference (foil), calculate a donor fluorescence lifetime map as described in the discussion on Image Processing in the protocol introduction.

11. Record an image of the acceptor, and then photobleach the acceptor by changing to the 100-W mercury arc lamp (Zeiss Attoarc) as a source of illumination. Move the Cy3 filter set (excitation: HQ545/30, dichroic: Q565LP, emission: HQ610/75 chroma) into the detection path. Take an image of the acceptor by optimizing the exposure time to occupy the full dynamic range of the CCD. Close the detector port and illuminate the acceptor until there is no discernible Cy3 fluorescence.

▲ **IMPORTANT** When performing acceptor photobleaching experiments, it is crucial to establish that there is no fluorescence from the photoproduct of the photobleached acceptor in the donor channel.

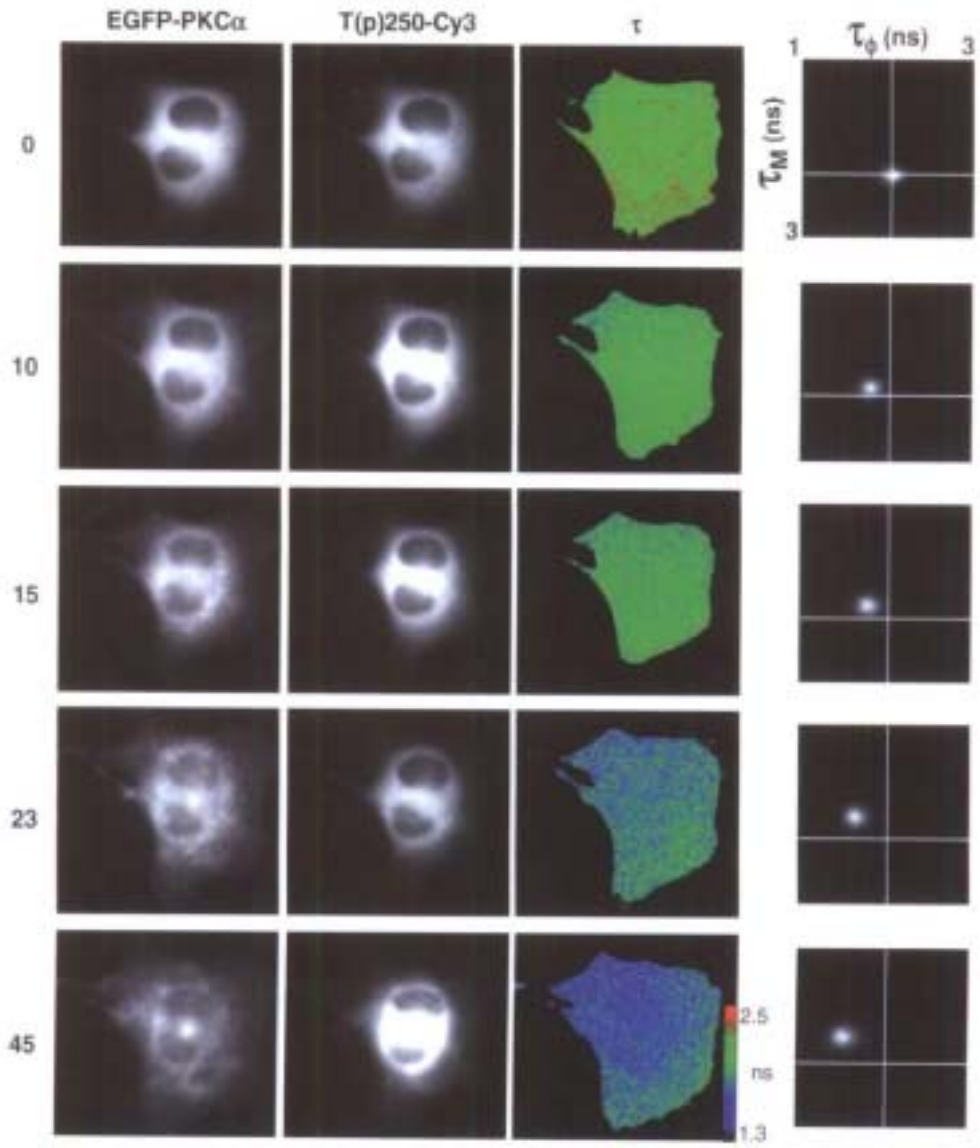

FIGURE 18-20 FLIM Experiment on Live Cells Monitoring the Activation Status of PKCα following PMA Treatment

COS-7 cells transfected with donor EGFP-PKCα were microinjected with acceptor antibodies, T(p)250-Cy3. FLIM data at 101.118 MHz were acquired before (0 minutes) and after (10, 15, 23, 45 minutes) treatment with 100 nM PMA. Average fluorescence lifetime maps were calculated (τ) for each cell and these are depicted as a pseudo-color map corresponding to average lifetimes ranging from 1.3 nsec (*dark blue*) to 2.5 nsec (*red*). Phase and modulation lifetimes (before and after treatment) are also plotted as two-dimensional histograms. The change from higher lifetimes (*green* and *red*, 0 minutes) to lower lifetimes (*blue*, 45 minutes) in this cell demonstrates the progressive phosphorylation of Thr-250, and hence an induction of FRET resulting in a reduction in the donor fluorescence lifetimes. We thank Tony Ng and Sandra Schmidt (Protein Phosphorylation and Cell Biophysics Laboratories, Imperial Cancer Research Fund) for the experimental results presented in this figure.

EXAMPLE: FLIM-FRET EXPERIMENT ON LIVE CELLS

An example of a FLIM-FRET experiment to monitor the activation status of PKCα in live cells via its phosphorylation on Thr-250 is shown in Figure 18-20. The donor in this experiment is EGFP fused to the amino terminus of PKCα, and the acceptor is Cy3 conjugated to Fab fragments against phosphorylated Thr-250 (αT(p)250-Cy3). This protocol can be adapted to other protein systems in live cells.

1. Prepare the cells by transfection of the GFP-PKCα fusion construct as described in Stage 2.
2. Identify the transfected cells that are expressing GFP-tagged PKCα and microinject selected cells with αT(p)250-Cy3 (0.5 mg/ml) as described in the panel **ALTERNATIVE PROTOCOL: MICROINJECTION OF LIVE CELLS** in Stage 2.
3. Following microinjection, acquire a phase image series of the foil as a zero lifetime reference.
4. Proceed to acquire fluorescence phase image sequences of the donor (GFP filter set) as described in Stage 3, before and after treatment with the desired stimulus (100 nM PMA for PKCα). Include at least one uninjected cell in the imaged region of interest as a donor reference lifetime measurement in the absence of acceptor.
5. Calculate fluorescence lifetime maps as described in the discussion on Image Processing in the protocol introduction.

EXAMPLE: FLIM-FRET EXPERIMENT ON FIXED CELLS

An example of a fixed-cell FLIM-FRET experiment to monitor the activation status of PKCα via its phosphorylation on Thr-250 is shown in Figure 18-21. In this experiment, the donor and acceptor components are carried on two different antibodies; the donor Oregon Green is conjugated to the PKCα-specific monoclonal antibody (MC5-OG) and the acceptor Cy3 is conjugated to the polyclonal antibody directed against phosphorylated Thr-250 (αT(p)250-Cy3). This protocol can be adapted for analysis of other protein interaction systems in fixed cells.

1. Prepare the cells as described in the panel in Stage 2 on **ALTERNATIVE PROTOCOL: PREPARATION OF FIXED CELLS FOR FLIM-FRET ANALYSIS**, completing the desired stimulus and time regime. Modify the antibody incubation to incorporate 1:1 (10 μg/ml) mix of donor (MC5-OG) and acceptor-labeled (αT(p)250-Cy3) antibodies.
2. Acquire a phase-image series of the foil as a zero lifetime reference.
3. Use the GFP filter set (dichroic: Q495LP, emission: HQ510/20) to acquire an Oregon Green donor phase-image sequence for a region of interest as described above.
4. Record an image of the acceptor, and then photobleach the acceptor by changing to the 100-W mercury arc lamp (Zeiss AttoArc) as a source of illumination. Move the Cy3 filter set (excitation: HQ545/30, dichroic: Q565LP, emission: HQ610/75 chroma) into the detection path. Take an image of the acceptor by optimizing the exposure time to occupy the full dynamic range of the CCD. Close the detector port and illuminate the acceptor until there is no discernible Cy3 fluorescence.
5. Return to the donor filter set and acquire a second, postbleach donor phase image series. This constitutes the donor reference lifetime image, in the absence of acceptor.
6. Proceed to calculate fluorescence lifetime maps as described in the discussion on Image Processing in the protocol introduction.
7. Calculate FRET efficiency maps by taking the ratio (R_i) of the lifetime maps acquired before and after acceptor photobleaching. The FRET efficiency equals $1 - R_i$.

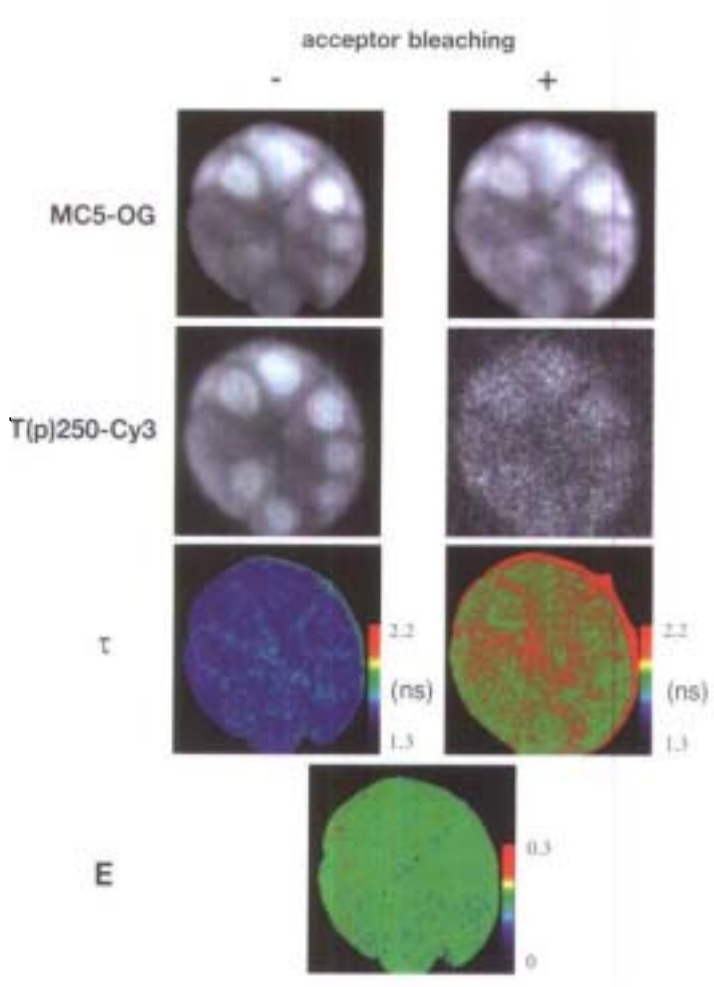

FIGURE 18-21 FLIM Experiment on Fixed Cells Demonstrating the Activation Status of PKCα

MCF 10A cells were fixed and incubated with the donor, Oregon-Green-labeled anti-PKCα antibodies (MC5-OG, 10 μg/ml) and the acceptor, Cy3-labeled PKCα phospho-Thr-250 antibodies (T(p)250-Cy3, 10 μg/ml). FLIM data at 80.244 MHz were acquired from which average fluorescence lifetime maps (τ) were calculated before (*left panels*) and after (*right panels*) acceptor photobleaching; a calculated FRET efficiency image map (E) is shown. The data presented here represent a cluster of cells, and the nuclei of these cells are visible in the Cy3 and OG images. It is apparent in the lifetime maps (τ) that each cell prior to acceptor photobleaching has lower fluorescence lifetimes than following acceptor photobleaching, thus demonstrating the presence of FRET as a result of phosphorylation of Thr-250. We thank Tony Ng and Sandra Schmidt (Phosphorylation and Cell Biophysics Laboratories, Imperial Cancer Research Fund) for the experimental results presented in this figure.

Protocol 6

Analysis of Interacting Proteins with Surface Plasmon Resonance Spectroscopy Using BIAcore

Maxine V. Medaglia and Robert J. Fisher*

National Cancer Institute-FCRDC, Frederick, Maryland 21702

PROTEIN-TO-PROTEIN BINDING INTERACTIONS HAVE BEEN STUDIED using many different methods, both qualitative (gel filtration) and quantitative (calorimetry and ultracentrifugation). The introduction of commercial instruments, such as BIAcore (Jonsson et al. 1991), that are capable of measuring surface plasmon resonance (SPR) has simplified the study of macromolecular interactions by providing a format that may be used to measure molecular interactions in real time with small analytical amounts of material. Several SPR instruments are available, ranging from very simple and inexpensive models to more integrated instruments with attendant robotics, optical interfaces, and software. The simplest device, called a Spreeta chip, was developed by Texas Instruments (www.ti.com/spreeta). Texas Instruments maintains an informative Web Site with an interesting description of the physical basis of SPR. A somewhat more sophisticated instrument is the IBIS Biosensor, which is offered by XanTec Instruments (www.xantec.com). The IBIS Biosensor uses cuvettes, but it is also compatible with BIAcore sensor chips. Two instruments utilize cuvettes rather than chips. One is a programmable biosensor called Plasmoon, which is manufactured by BioTul (www.biotul.de). The other, Iasys, is an optical biosensor that uses a stirred cuvette (www.affinity-sensors.com/iasys.htm).

Three major quantitative approaches are used to study the interaction between macromolecules: analytical ultracentrufgation, isothermal titration calorimetry, and SPR spectroscopy. The strength of SPR spectroscopy is the ability to obtain kinetic data, i.e., the microscopic rate constants for an interaction between macromolecules. Analytical ultracentrifugation provides the best evidence for the aggregation state of a protein, and isothermal titration calorimetry provides a complete thermodynamic profile including the equilibrium constant, reaction stoichiometry, enthalpy, and entropy. Ideally, these methods should be used together to characterize a molecular interaction completely. Calorimetry and analytical ultracentrifugation require milligram amounts of pure protein, and SPR spectroscopy requires microgram amounts of protein.

*The authors prepared this protocol with the help of M. Fivash, C. Hixson, and L. Wilson (National Cancer Institute-FCRDC, Frederick, Maryland).

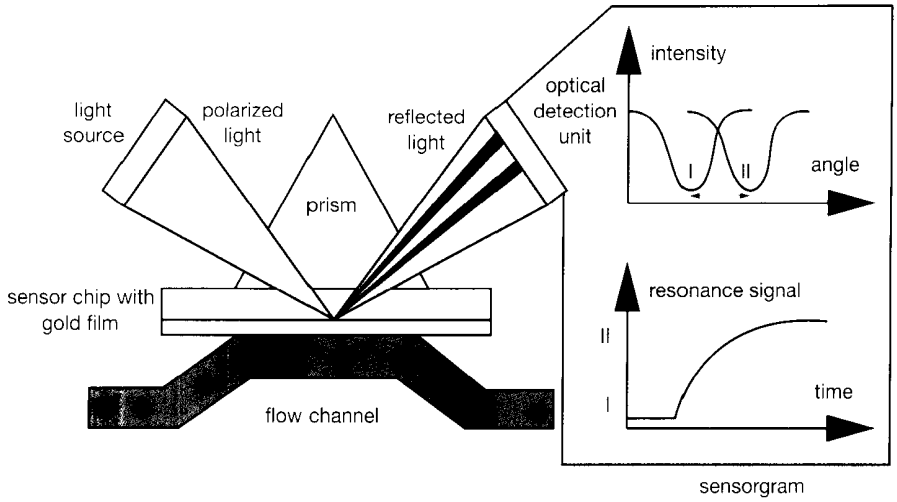

FIGURE 18-22 Schematic of SPR

BIAtechnology relies on the phenomenon of surface plasmon resonance (SPR), which occurs when surface plasmon waves are excited at a metal/liquid interface. Light is directed at, and reflected from, the side of the surface not in contact with sample, and SPR causes a reduction in the reflected light intensity at a specific combination of angle and wavelength. Biomolecular binding events cause changes in the refractive index at the surface layer, which are detected as changes in the SPR signal. (Redrawn, with permission, from BIAcore, Inc.)

SURFACE PLASMON RESONANCE SPECTROSCOPY

SPR is an optical resonance effect in which the backside of a thin conductive mirror affects the angle at which there is a minimum of reflected light (Figure 18-22). The SPR response is extremely sensitive to any change in the dielectric constant of the medium adjacent to the gold surface of a sensor chip. Changes in the SPR signal are monitored by recording the angular changes where the reflected light is minimum. A resonance unit (RU) is arbitrarily defined as 1/3000 of a degree in the BIAcore instrument. The BIAtechnology Handbook includes a chapter that discusses the phenomenon of SPR and how the SPR signal relates to the interactions between the analyte (free) and ligand (bound) molecules. Another discussion of SPR can be found in the *Encyclopedia of Life Sciences* (www.els.net). There are four major components of a BIAcore instrument:

- an optical interface unit to mount the sensor chip
- a microfluidics system (Sjolander and Urbaniczky 1991) to deliver analyte (molecule of interest) precisely to the ligand (molecule attached to the surface of the chip)
- an autosampler to transfer samples from the sample rack to the microfluidics delivery system
- data collection and data analysis software

It is difficult to predict how long it should take to perform a BIAcore experiment and analyze the data obtained. After preparing the appropriate sensor chip and optimizing conditions for the interaction between the ligand and analyte, the regeneration conditions must be determined. Once these preliminary studies are completed, the actual experiment is run, and the data are analyzed using the BIAevaluation software. For some systems, such as epitope mapping, once the optimal conditions have been estimated, the experimental design and analysis of the results are quite straightforward. However, experiments designed to elucidate the kinetics of an interaction

may lead to the development of kinetic pathways that are more complex than the initial model. The BIAsimulation software (available on the Web Site) provides a means to predict what the results of the interaction would look like with different kinetic models.

BIAcore analysis has been used for protein–protein, protein–small molecule, protein–nucleic acid, and protein–lipid interactions (Celia et al. 1999; Raut et al. 1999; Saenko et al. 1999). More than 1300 references to these applications as well as others can be found in a reference list kept at www.biacore.com. These references illustrate the wide range of experimental designs that have utilized BIAcore SPR technology. In addition, the site can be used to learn more about the technology and applications of SPR and BIAcore instrumentation. The company offers instruction in the use of BIAcore and the BIAevaluation software, and BIAcore application scientists are available to help with questions or problems that may arise.

THE SENSOR CHIP

The chip technology introduced by BIAcore consists of a 1-cm^2 glass slide coated with gold and embedded in a plastic support for ease of handling. The standard is the CM-5 sensor chip, but several varieties of chips are available for specialized purposes (www.biacore.com). The CM-5 sensor chip has the equivalent of 2% carboxymethlyated dextran covalently attached to the gold surface. A number of protocols have been developed for attaching ligand molecules to the dextran surface (O'Shannessy et al. 1992); these create active groups on the carboxymethyl dextran that are capable of reacting covalently with the ligand molecule. The choice of coupling chemistry to be used depends on the characteristics of the ligand molecule (Figure 18-23). Each chip has four different flow cells so that ligand density may be varied on three of the surfaces and the fourth may be used for a control or blank surface.

It is important to give careful consideration to the method used to immobilize the ligand to the CM-5 sensor chip. Whenever possible, the method of choice should minimize the hetero-

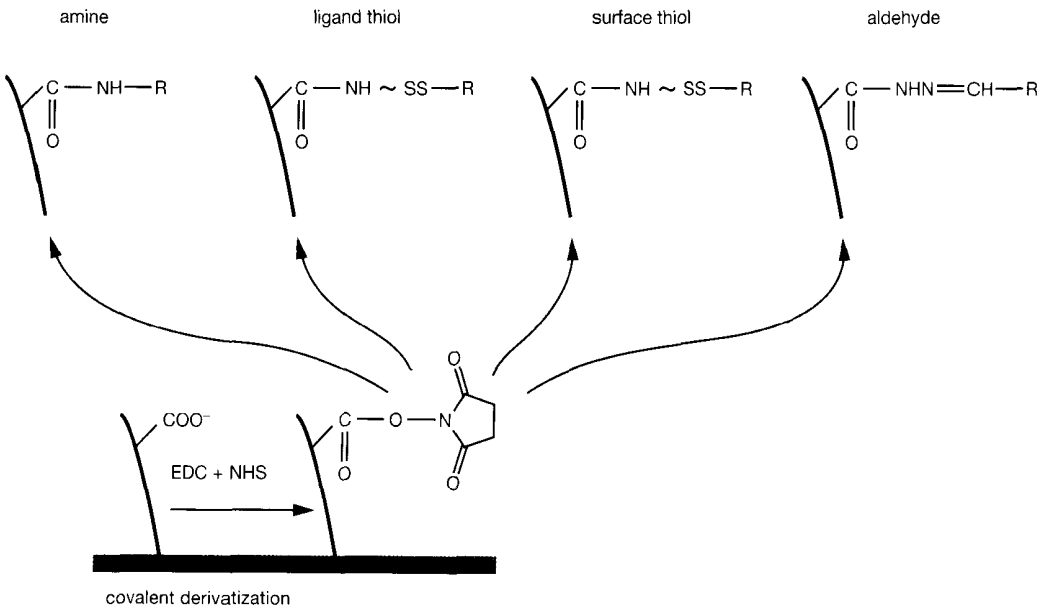

FIGURE 18-23 Ligand Immobilization via Native -NH_2 -SH_2 -CHO and COOH

(Redrawn, with permission, from BIAcore, Inc.)

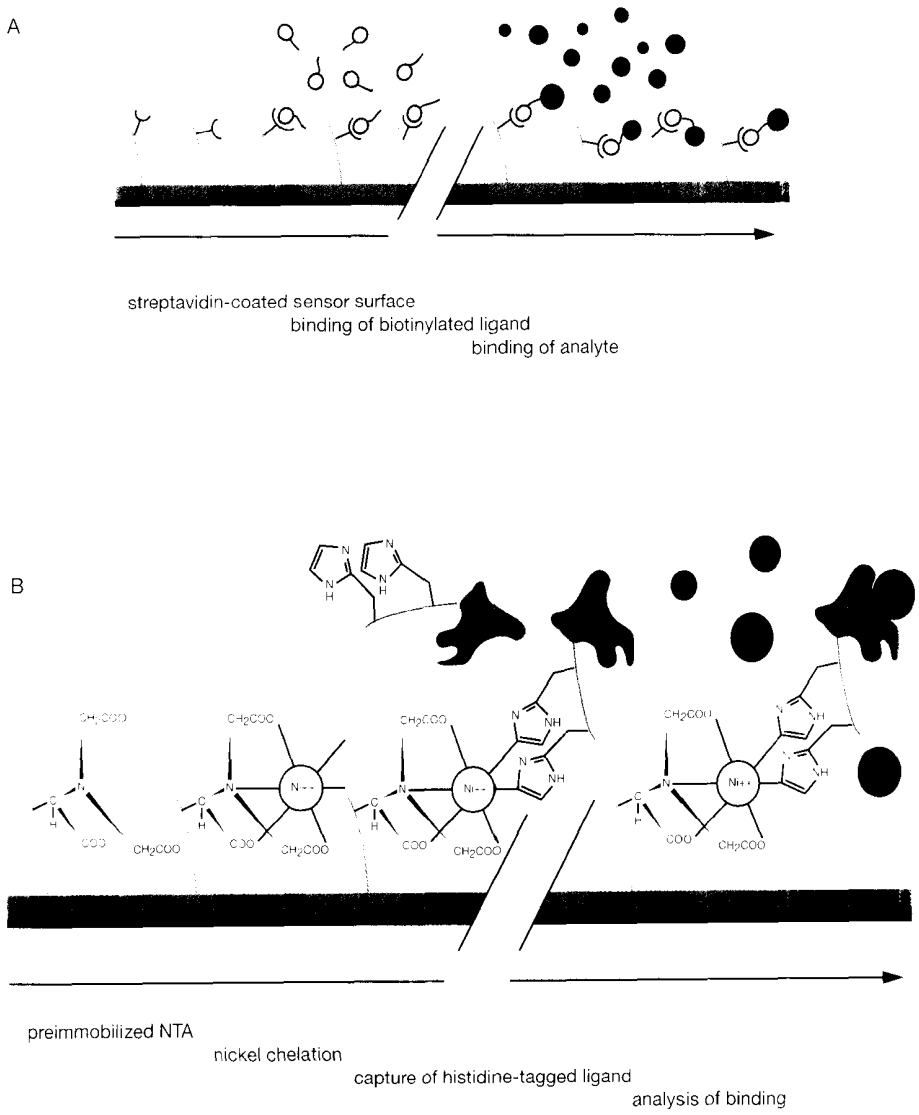

FIGURE 18-24 Capture of Target Molecules

(*A*) Capture of biotinylated macromolecules. (*B*) Capture of histidine-tagged protein. (Redrawn, with permission, from BIAcore, Inc.)

geneity of the bound ligand. Techniques that allow capture of the ligand by another molecule covalently bound to the carboxymethyl dextran are useful because they result in uniform orientation of the ligand and are preferred over direct coupling of the ligand to the chip surface. Examples of such capture surfaces are streptavidin (Morgan and Taylor 1992; O'Shannessy et al. 1992), nickel-chelate (NTA) (Nieba et al. 1997), rabbit anti-mouse C domain (RAMc), and anti-GST. Chips can be purchased with the streptavidin (Figure 18-24A) or NTA (Figure 18-24B) already coupled to the carboxymethyl dextran. Capture molecules such as antibodies and streptavidin can be coupled to the surface through primary amine groups (as described in the protocol below). When a capture molecule is used, surface heterogeneity is not an issue, as it would be if a heterogeneous ligand were directly coupled to the carboxymethyl dextran.

Chips are available that offer additional features. For example, certain chips promote the formation of a lipid bilayer (HPA) (Figure 18-25); others have shorter dextran molecules (Pioneer

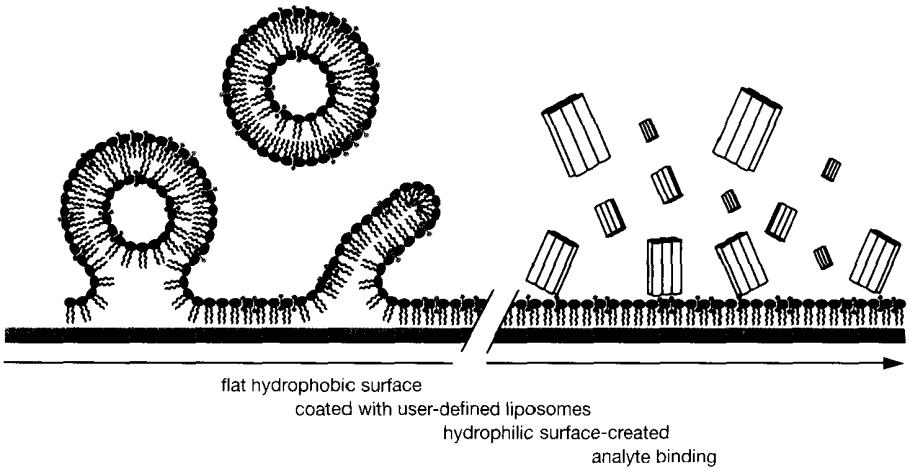

FIGURE 18-25 Membrane Biochemistry and Membrane-bound Receptor Studies
(Redrawn, with permission, from BIAcore, Inc.)

Chip F1), dextran molecules with a lower charge (Pioneer Chip B1), a carboxymethylated surface with no dextran matrix (Pioneer Chip C1), or a flat gold surface without any attached molecules (Pioneer Chip J1).

REGENERATION OF THE CHIP SURFACE

To take full advantage of the CM-5 sensor chip, it is important to develop a robust regeneration system so that the chip surfaces may be reused. A wide variety of materials (acid, base, solvents, salt, detergents, or combinations of these reagents) may be used for regeneration. To determine if the ligand remains bound to the surface, an experiment should be designed to test the robustness of the regeneration by repeated injections of analyte and regeneration solution in order. It should be possible to reuse a surface for up to 100 regeneration cycles.

COLLECTION OF DATA

The instrumentation uses a flow system and a sensor chip to which a ligand has been attached (immobilized). The analyte solution is injected through the system and moves by diffusion from the buffer flow to the chip surface, where it interacts with the ligand. Figure 18-26 illustrates the progress of an interaction as monitored by a BIAcore sensorgram. The interaction between the ligand and analyte molecules is followed in real time as a change of the SPR angle. Regeneration is accomplished by removal of noncovalently bound material from the surface in as gentle a manner as possible, allowing reuse of the ligand in subsequent binding/regeneration cycles.

The process of diffusion of the analyte is called material transport, and all binding systems are affected to some degree by this phenomenon. Part of the experimental design for BIAcore studies involves finding a low enough surface density of ligand and a high enough flow rate to minimize transport effects. After satisfying the minimal criteria for an experiment, data are collected for subsequent fitting to an appropriate binding model. We strongly recommend that three channels (also referred to as flow cells) of the sensor chip be modified to contain different levels of ligand and that the fourth channel be used as an appropriately modified control surface.

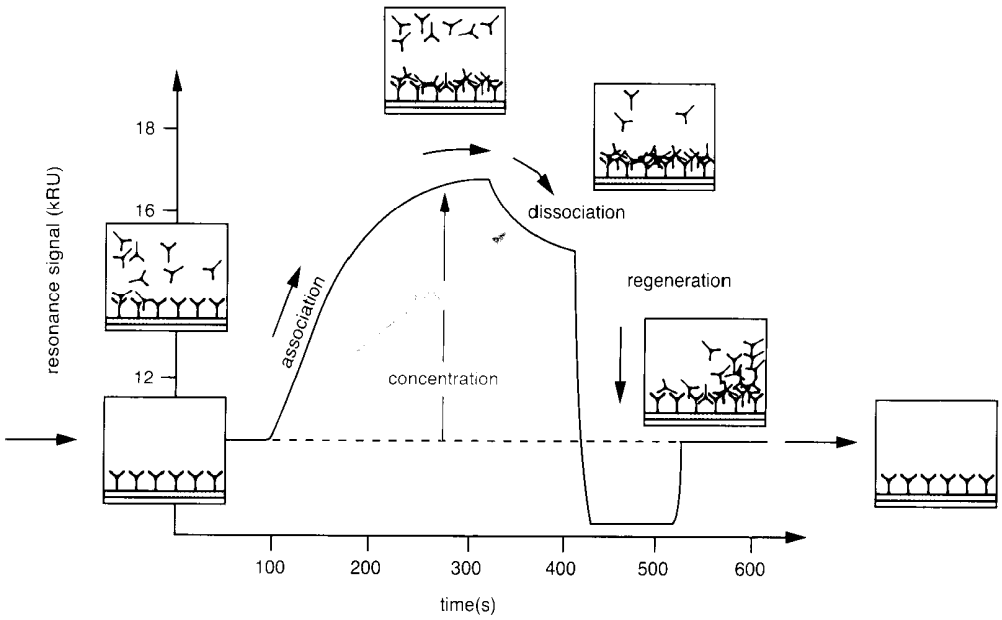

FIGURE 18-26 Progress of an Interaction Monitored as a Sensorgram

Analyte binds to the surface-attached ligand during sample injection, resulting in an increase in signal. At the end of the injection, the sample is replaced by a continuous flow of buffer and the decrease in signal now reflects dissociation of interactant from the surface-bound complex. A response of 1000 RU corresponds to a change in surface concentration of 1 ng/mm^2. (Redrawn, with permission, from BIAcore, Inc.)

Myszka (1999) has suggested that results obtained from a low-density ligand surface should be corrected by double referencing. The signal from the analyte injection over a reference channel is subtracted from the specific binding signal of the analyte injection over the active surface. A further subtraction of a buffer injection from each of the injections of analyte is used to reduce machine effects in the data. Care must be taken when applying any of these techniques, especially when the signal noise is greater than the binding signal itself. If there is nonspecific binding to the reference channel (the control surface), this technique of subtracting the reference channel's signal from that of the active surface must be used cautiously.

The resulting sensorgram or series of sensorgrams may be modeled using one of several binding models provided with the BIAevaluation software or by user-defined models. When analyzing data from the BIAcore, it must be remembered that the sensitivity of the instrument returns a very low noise signal that is profoundly sensitive to machine effects, such as the opening and closing of valves, injection noise, temperature, and pressure, as well as refractive index mismatch between the running buffer and the sample itself. The interpretation of the binding signal can be complicated by the presence of these frequently unavoidable disturbances. Basic training in the use of the BIAcore and specialized training in the BIAevaluation software are excellent resources for learning instrument operation, experimental design, and data evaluation.

KINETIC MEASUREMENTS

When BIAcore instruments were first introduced, they had few applications and only a rudimentary method for analysis of the data. This situation generated discussions as to whether data should be analyzed using nonlinear methods (O'Shannessy et al. 1993) or linear methods

(Karlsson et al. 1991; Altschuh et al. 1992; Pellequer and Van Regenmortel 1993). The models now used are nonlinear, and they utilize actual data rather than replotted data as do the linear models. The modeling of kinetic data was much improved after Fisher and Fivash (1994) proposed a two-compartment model to describe the delivery of analyte from the flow buffer (compartment 1) to the binding region of the chip (compartment 2). Their work also introduced a new method of analysis to be applied to BIAcore data. In this method, known as global analysis, a series of sensorgrams scaled by different surface ligand densities and different analyte concentrations are solved with a single set of association and dissociation rate constants (Fisher and Fivash 1994; Fisher et al. 1994). The two-compartment model (Myszka et al. 1998b) and global modeling (Roden and Myszka 1996; Karlsson and Falt 1997) have been widely accepted in the field.

The consensus on appropriate modeling of BIAcore data has led to improvements in the BIAcore evaluation software that allow data grooming (baseline adjustment, time zeroing, and subtraction of a blank injection for a set of sensorgrams), and kinetic analysis using a set of models included in the software. This allows calculation of k_t (k transport-delivery of analyte to the chip surface), and the microscopic rate constants k_a (k association-association rate constant), and k_d (k dissociation-dissociation rate constant). The ratio of k_a to k_d can be used to estimate K_d, the equilibrium constant. The possibility of obtaining these microscopic rate constants for a molecular interaction (sometimes referred to as the on and off rates) excites the imagination of researchers. However, the kinetic constants obtained using BIAcore analysis should be regarded as tentative until verified using other methods. The Molecular Interactions Research Group (MIRG) within the Association of Biomolecular Resource Facilities (ABRF) plans to address this issue by sending samples for analysis by SPR spectroscopy, analytical ultracentrifugation, and isothermal titration calorimetry. These results should provide a direct comparison of these different methodological approaches.

Finally, an SPR measurement is derived from an analyte that comes out of solution and binds to a surface matrix, which involves mixed phases (solid phase and solution phase). The relationship of measurements made using mixed phases to those made using single phase has been and will continue to be a source of controversy (Ladbury et al. 1995; Nieba et al. 1996; Muller et al. 1998).

MEASUREMENT OF CONCENTRATION

Under conditions where binding is limited by material (mass) transport, the initial slope of the binding curve should be linearly related to the concentration of analyte (Karlsson et al. 1993; Nieba et al. 1996; Christensen 1997). When the analyte and free ligand molecules are incubated before injection (to allow the system to reach equilibrium), the initial slope shows the amount of free (un-complexed) analyte. This concept is particularly useful because it allows the calculation of an equilibrium constant for a ligand-analyte interaction without any assumptions about a particular binding model. This technique also allows the use of a calibrated system to determine the concentration of an analyte in solution.

The equilibrium association constant may be calculated, without resorting to modeling, in at least three ways. One useful method is finding the concentration of analyte in a competition experiment (see above). The constant found in this way is a solution constant. For a surface constant, one may inject sufficient analyte to show about half of the saturation signal. Then a second injection with the correct analyte concentration will keep the signal steady, and thus demonstrate the equilibrium association constant. An alternative to this method is to actually circulate the analyte in the flow buffer over long periods of time to attain equilibrium (Myszka et al. 1998a; Schuck et al. 1998).

DESIGNING A PROTOCOL

Developing a well-behaved experimental protocol can require some care and include several preliminary experiments to characterize the reagents. We present here the sequence of steps for analyzing a typical antibody-antigen system and illustrate several details involved in the development of a BIAcore experiment. The antibody and antigen are available commercially and could be used to reproduce the results shown below for optimizing the parameters of the system under study.

The protocol is divided into two stages: Stage 1 describes the preparation of a RAMc capture surface, followed by tests for the binding of a specific antibody (anti-TSH) to the RMAc surface, and binding of the antigen (TSH) to the antibody (anti-TSH). Stage 2 presents a series of method blocks or analysis programs that allow the determination of the equilibrium constants for the interaction. In summary,

Stage 1:

1. Prepare RAMc capture surface on CM5 chip.
2. Test binding of the anti-TSH to the RAMc surface.
3. Test binding of TSH to the anti-TSH surface; regenerate and repeat.

Stage 2:

1. Run analysis programs for preparing three levels of anti-TSH and binding concentration series of TSH.
2. Determine equilibrium constants of the interaction.

STAGE 1: Preparation of the Capture Surface and Test Binding

The following protocol describes a method to capture antithyroid-stimulating hormone (anti-TSH) on a rabbit anti-mouse C domain (RAMc) surface, to prepare the anti-TSH surface for later use in the kinetic analysis of the binding of thyroid-stimulating hormone (TSH) with anti-TSH. The RAMc is immobilized to the carboxymethyl dextran of the sensor chip by primary amine coupling, and, when used as the capture molecule for the antibody, results in the divalent antibody molecules being oriented in a manner that allows binding of two antigen molecules to each antibody molecule. An alternative method of preparing a surface for kinetic analysis would be to couple one of the reactants directly to the sensor chip with the primary amine. If this method were to be used with an antibody, the heterogeneity of the resulting surface would result in less than two antigen molecules binding to each of the antibody molecules.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

EDC (0.2 M N-ethyl-N′-(dimethylaminopropyl)-carbodiimide in H_2O) <!>

Ethanolamine (1 M ethanolamine hydrochloride, adjusted to pH 8.5 with NaOH) <!>

Extraclean

Extraclean is a solution for surface regeneration and is commercially available from BIAcore.

HEPES-buffered saline buffer

10 mM HEPES pH (7.4)
150 mM NaCl
3 mM EDTA
0.005% (v/v) Tween-20

This buffer is commercially available from BIAcore.

HCl (20 mM) <!>

NHS (0.05 M N-hydroxysuccinimide in H_2O)

EDC, Ethanolamine, and NHS are commercially available as part of the Amine-Coupling Kit from BIAcore.

Antibodies

The Molecular Interactions Research Group (MIRG) within the Association of Biomolecular Resource Facilities (ABRF) (www.abrf.org) recommends that protein samples be prepared for BIAcore analysis by buffer exchange dialysis (3 times in 500 volumes) against HEPES-buffered saline, and then centrifuged at maximum speed in a refrigerated microfuge and finally passed through a 0.22-μm filter. The resulting protein concentration is determined by absorbance at 280 nm using the calculated extinction coefficient for the particular protein or peptide.

Mouse anti-TSH monoclonal antibody (1 mg/ml in HEPES-buffered saline)

This antibody is commercially available from Alexon Trend, Inc.

Rabbit anti-mouse Fc domain (RAMc) (30 μg/ml in 10 mM Na-acetate pH 5.0)

This antibody is commercially available from BIAcore.

TSH (20 μM in HEPES-buffered saline)

TSH is commercially available from Alexon Trend, Inc.

Special Equipment

BIAcore instrument

The instrument includes the BIAcore control software and the BIAevaluation software.

The equipment and software are available from BIAcore, Inc. Information is available at www.biacore.com.

Sensor Chip CM-5

METHOD

Primary Amine Coupling of RAMc to Sensor Chip CM-5 Surface

This procedure takes ~45 minutes. The commands are accessed through the pulldown menus or by the icons of the toolbar of the BIAcore control software.

1. Dock Sensor Chip CM-5 in the BIAcore instrument.
2. Prime using filtered and degassed HEPES-buffered saline.
3. Place tubes containing 100 µl each of NHS, EDC, ethanolamine, and RAM Fc and 20 mM HCl in appropriate positions in the autosampler rack in the BIAcore.
4. Place an empty tube in the autosampler rack in the BIAcore.

   The Immobilization Wizard, if available, can be used to perform this procedure. (The Wizards are standard with BIAcore control software versions 3.0 and higher for the BIA2000 and BIA3000.) If using the Wizard, dispense the volumes specified. The target number of RUs of bound RAM Fc is 13,000.
5. Start the instrument at a flow of 5 µl/minute over one flow cell.
6. Transfer 75 µl of NHS to the empty tube.
7. Transfer 75 µl of EDC to the same tube.
8. Mix the contents of the tube containing the NHS and EDC.
9. Inject 35 µl of the NHS/EDC mixture to activate the surface.
10. Inject 35 µl of the RAM Fc to couple the antibody to the activated surface.
11. Inject 35 µl of ethanolamine to deactivate excess reactive groups.
12. Quickinject 10 µl of 20 mM HCl followed by Extraclean to remove noncovalently bound material.
13. Determine the level of RAMc bound by placing a baseline report point before the start of the RAMc injection and a second report point 2 minutes after the end of the 20 mM HCl injection.

    The final RUs of RAMc immobilized should be between 10,000 and 13,000; if a lower level is obtained, it could be due to a lower concentration of RAMc used, or using NHS and EDC solutions that have been stored for longer than 2 months. A surface with fewer RUs of RAMc is useable, but the volumes of anti-TSH used will need to be adjusted empirically; in general, more will be required to achieve the desired level of binding.
14. Stop the flow, close the command queue window, and save the report file.

    The BIAcore can be left on Standby (Continue) at this point, or the surface can be used directly in the next section. The RAMc surface is quite stable left in the machine with buffer flowing through the instrument. Alternately, the chip can be undocked and stored at 4°C in a 50-ml conical tube containing a small amount of H_2O; the surface will be stable for several weeks stored in this way.

Testing Binding of the Anti-TSH to the RAMc Surface

This procedure takes ~20 minutes. The commands are accessed through the pulldown menus or by the icons of the toolbar of the BIAcore control software.

15. Start the instrument at a flow of 10 µl/minute over the flow cell with the coupled RAMc.

16. Inject 10 µl of 2 µg/ml anti-TSH (this requires a total of 40 µl of anti-TSH solution).

    10 µl of the anti-TSH should result in an increase of ~250 RUs. If this level of binding to the RAMc surface is not obtained, regenerate (see Step 17) and repeat the injection of anti-TSH using different volumes until the necessary injection volume is determined.

17. Quickinject 10 µl of 20 mM HCl followed by Extraclean to regenerate the RAMc surface.

18. To test the reproducibility of the binding to the RAMc surface, repeat the injection using the volume of anti-TSH required to give 250 RUs bound to anti-TSH.

19. Quickinject 10 µl of 20 mM HCl followed by Extraclean to regenerate the RAMc surface.

20. Stop the flow, close the command queue window, and save the report file.

Testing Binding of TSH to the Captured Anti-TSH Surface

This procedure takes ~20 minutes. The commands are accessed through the pulldown menus or by the icons of the toolbar of the BIAcore control software.

21. Start the instrument at a flow of 10 µl/minute over the flow cell with the coupled RAMc.

22. Inject 10 µl of 2 µg/ml anti-TSH (or the volume determined to give 250 RUs bound anti-TSH as determined in Steps 15–20).

23. Inject 25 µl of 200 nM TSH, specifying a 120-second dissociation time (this requires a total of 65 µl of TSH solution). The 120-second dissociation time allows the rate at which the antibody-antigen complex dissociates to be gauged.

    After ~20 µl of 200 nM TSH has been injected, the curve should flatten (the slope should approach zero), representing a stochastic steady state of the interaction between the antibody and antigen molecules. If the curve does not flatten, regenerate the surface and repeat Steps 21–23 using 400 nM TSH in Step 23 (Figures 18-26 and 18-27).

24. Quickinject 10 µl of 20 mM HCl followed by Extraclean to regenerate the RAMc surface.

25. Stop the flow, close the command queue window, and save the report file.

DISCUSSION OF THEORY

The binding of the TSH to the anti-TSH is expected to have a 2:1 stoichiometry due to the bivalent nature of the antibody. To determine the efficiency of the binding of the TSH (M_r = 50,000) to the anti-TSH (M_r = 150,000), calculate the maximum number of resonance units (RUs) of analyte that can bind to the captured antibody.

= (MWanalyte)/(MWligand) x (RUs ligand) x 2

= 2/3 x RUs anti-TSH bound

In the case of 250 RUs of anti-TSH captured by the RAMc surface, 167 RUs of TSH would be expected to bind if all of the antibody were active.

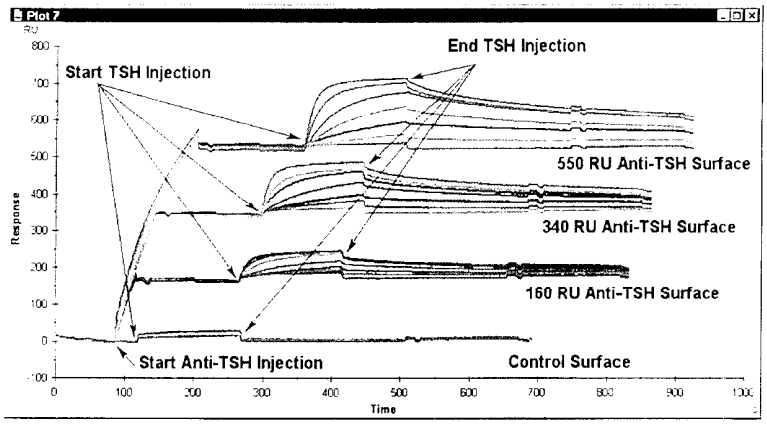

FIGURE 18-27 Anti-TSH Binding to RAM Fc

This plot shows the results when the same concentration series of TSH is injected over three levels of anti-TSH captured by a RAM Fc surface as well as over the RAM Fc surface itself. The data have been Y-transformed and the regeneration injection has been removed from each cycle. The high level of reproducibility of the anti-TSH binding to the RAM Fc is apparent, as is the stability of the interaction of these two molecules. The low level of interaction between the TSH and the RAM Fc surface is also illustrated in this diagram.

STAGE 2: Kinetic Analysis of the Antibody-Antigen Interaction

Running the Experiment

This experiment is designed to allow capture of a known number of resonance units (RUs) of anti-TSH by the RAMc surface at the start of each cycle, followed by an injection of TSH. The RAMc surface is regenerated at the end of each cycle by the injection of 20 mM HCl. A total of six different concentrations of TSH (prepared by serial dilution) are injected over identically prepared anti-TSH surfaces. The high degree of reproducibility of the binding of the antibody to the capture surface results in essentially the same anti-TSH surface being available for the interaction of the different concentrations of TSH injected in each cycle.

The Interaction Wizard (available with BIAcontrol software version 3.0 and higher for the BIA2000 and BIA3000) can be used to design this type of experiment under the Kinetic Analysis, Concentration Series, Binding Using Capture Molecule choices. If the Wizard is used, however, only one surface density of anti-TSH can be used in the experiment. An advantage of writing a method directly is that different anti-TSH surface densities can be created that are then exposed to the same concentration series of TSH, thus satisfying the data requirements of global analysis. The BIAcore Instrument Handbook gives a thorough discussion of writing methods using the BIAcore Method Definition Language (MDL). The increased flexibility in experimental design realized by writing BIAcore methods directly is worth the time spent becoming familiar with MDL.

Preparation and Injection of Samples

The following protocol consists of four different analysis programs (aprogs), each of which requires that a different volume of mouse anti-TSH monoclonal antibody be injected over the same RAMc surface. The injection of each volume of anti-TSH is followed by the injection of a series of TSH dilutions. If replicate injections of the TSH samples are desired, the appropriate lines of the sample loops should be added. As the method is written, 1000 µl of the anti-TSH dilution is required: 400 µl for APROG1 (eight 20-µl injections, each requiring 50 µl), 320 µl for APROG2 (eight 10-µl injections, each requiring 40 µl), and 280 µl for APROG3 (eight 5-µl injections, each requiring 35 µl). If a different volume of the anti-TSH is needed to achieve the target RUs, the aprogs will need to be modified and the total volume of antibody required will differ. It is important to remember that each INJECT command requires the specified volume plus an additional 30 µl for each injection. There are two buffer injections before the TSH series is injected over each anti-TSH level, to allow the binding level of antibody to stabilize.

MATERIALS

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

HEPES-buffered saline buffer or appropriate running buffer

10 mM HEPES pH (7.4)
150 mM NaCl
3 mM EDTA
0.005% (v/v) Tween-20
This buffer is commercially available from BIAcore.

Antibodies

Mouse anti-TSH monoclonal antibody (1 mg/ml in HEPES-buffered saline)

This antibody is commercially available from Alexon Trend, Inc.

Dilute the antibody to 2 µg/ml and prepare 1000 µl (or the volume required) to achieve the target resonance units as determined in Steps 15–20 of Stage 1.

TSH (20 µM in HEPES-buffered saline)

TSH is commercially available from Alexon Trend, Inc.

Prepare serial dilutions of TSH for injection:

i. Prepare serial dilutions of 200, 100, 50, 25, 10, and 5 nM TSH, each in 280 µl of the running buffer used for the experiment.
ii. Dispense 70 µl of each concentration into four plastic 7-mm vials and cap each vial.
iii. Place the vials in the appropriate position in the BIAcore rack, as directed by the sample loop parameters.

Special Equipment

BIAcore instrument

This includes the BIAcore control software and the BIAevaluation software.

The equipment is available from BIAcore Inc. Information is available at www.biacore.com.

Sensor Chip CM-5, coupled to RAMc as described in Stage 1

METHOD

The sequence below consists of three method blocks or sections: the MAIN, the DEFINE APROG, and the DEFINE SAMPLE. Note that there are four DEFINE APROG blocks, one for each of the four APROGs referred to in the MAIN (bind1, bind2, bind3, and bind4). When the BIAcore software edits a method, the method commands will be written in capitals and the user-defined parameters will be in lowercase letters.

The comments following an exclamation point (!) are seen by the instrument as text rather than command code, and are inserted to explain the significance of the preceding command.

ANALYSIS OF DATA

After the run is completed, open the BIAevaluation software and import the cycles from the report file. If the method was run as presented above, the file will consist of 64 cycles. For a preliminary evaluation of the data, bring all the cycles (sensorgrams) into one plot, and *Y*-transform the curves just before the start of the injection of the anti-TSH. This should show the results of the injections of the different concentrations of TSH over the three different surface densities of anti-TSH and the control surface (Figure 18-27).

To perform a more detailed evaluation, select the cycles corresponding to each of the surface densities of anti-TSH into separate plots; there should be four plots corresponding to the three different levels of anti-TSH captured by the RAMc surface and the control surface. Working with one plot at a time, remove the regeneration injection and any air spikes that may be present. It may also be helpful to remove the region corresponding to the binding of the anti-TSH. The sensorgrams (curves) should then be *Y*-transformed before the TSH injection start. Finally, the sensorgrams should be *X*-transformed so that each of the injections starts at the same time. When examining these plots, it is apparent that the level of binding of the TSH to the antibody surface is lower than anticipated from the stoichiometry and ratio of molecular weights of the molecules. For example, for the plot corresponding to the TSH concentration series injected over 340 RUs of captured anti-TSH (Figure 18-28), the maximum response is ~140 RUs, whereas 230 RUs is expected (2/3 x 340 = 227). This difference reflects a lower degree of interaction between the antigen and antibody than 2:1.

Once these procedures are completed, the data can be reference-corrected by *subtracting* the sensorgram resulting from the injection of each concentration of TSH over the RAMc surface *from* the sensorgram resulting from the injection of the same concentration of TSH over the anti-TSH surfaces. This subtraction is valid because the TSH does not bind to the RAMc control surface. Care must be exercised when using the in-line subtraction feature of the BIA2000 and BIA3000, and the response of the individual flow cells must be examined before the subtracted data are analyzed further. For each of the three plots representing the anti-TSH interacting with TSH, a further correction can be made by subtracting the buffer injection sensorgram from those resulting from the TSH concentration series (Figure 18-29). This subtraction will remove any changes that are common in all the curves such as drift or a machine effect.

The resulting plots are now ready to fit to the kinetic model that best describes the reaction kinetics for the determination of the k_a and k_d. The BIAevaluation software comes with a number of models and allows the user to make modifications to these or to add others. In the case of TSH in the flow binding to the anti-TSH captured by the RAMc surface, although each antibody is bivalent, the binding of each of the two TSH molecules is independent of the other. Therefore, the appropriate models to use are the 1:1 (Langmuir) binding models ($A + B \leftrightarrow AB$). Other predefined models provided in the BIAevaluation software should be tested to see what differences the various modifications make in the fitting of the data.

The model selected to illustrate the fitting was Langmuir binding with a correction for mass transport and refractive index differences at both the start and end of the injection. This model was used to fit data from both uncorrected (raw) data (Figure 18-28) and double-referenced data (Figure 18-29) using global settings for k_a and k_d. The only difference in the analysis of the raw and corrected data was that the value of k_t for the raw data was kept constant at 1×10^8 (the default value); this ensured a reasonable value for this parameter. The actual value for k_t depends on the molecular mass and the flow rate; for TSH at a flow of 10 µl/minute, the value is 5.4×10^8. If k_t is not kept constant, the value obtained is greater than the maximum possible rate of diffusion. The model fits the corrected data more closely than it does the raw data, as the lines representing the fit data more closely follow the lines from the actual data (Figure 18-28) than the lines of the raw data (Figure 18-29). The residual plot shows the difference between the experimental and fitted data for each curve and is another means of assessing the goodness of the fit. The residual plot for the corrected data (Figure 18-29) shows less deviation than that of the raw data (Figure 18-28), confirming the appropriateness of the double referencing.

For a test of the global fitting of the data, the curves resulting from the injections of 5, 50, and 100 nM TSH over the three anti-TSH surfaces were combined for analysis. The model fits the combined corrected sensorgrams similarly to the fit seen for the individual corrected surfaces (Figure 18-30).

In Table 18-12, the values obtained for the kinetic rate constants for all three levels of anti-TSH are compared for the data before and after the corrections were performed, as well as those obtained from the combined data. For the 340 RU surface, the values obtained for the constants for both sets of data are within 30% of each other, indicating that the model fits both sets of data similarly. When the values for the combined data are examined, the constants for the raw and corrected data are within 20% of each other. The high degree of consistency between the rate constants for the combined and individual anti-TSH surfaces reflects the appropriateness of the selected model.

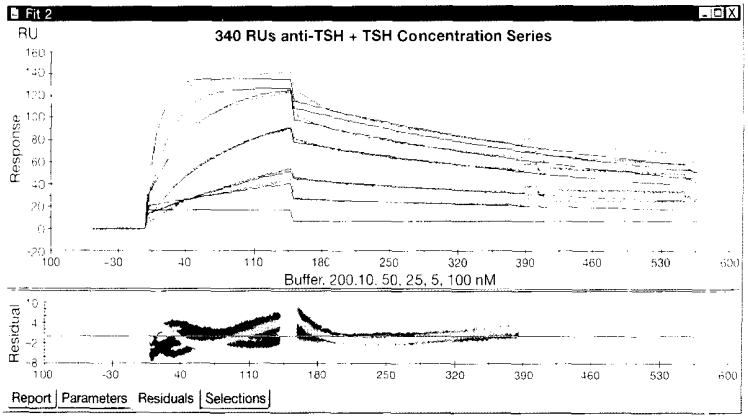

FIGURE 18-28 Langmuir-binding Model

This plot shows the results of fitting the sensorgrams resulting from the raw data to a 1:1 (Langmuir) binding model with a correction for mass transport and refractive index differences at both the start and end of the injection. The data in the analysis only included the first 380 seconds because of apparent machine effects resulting in higher RUs for the latter part of the dissociation part of the sensorgrams. Differences between the experimental and fitted data are apparent both in the curves and in the residual plot. Both show systematic deviations in the association and dissociation phases.

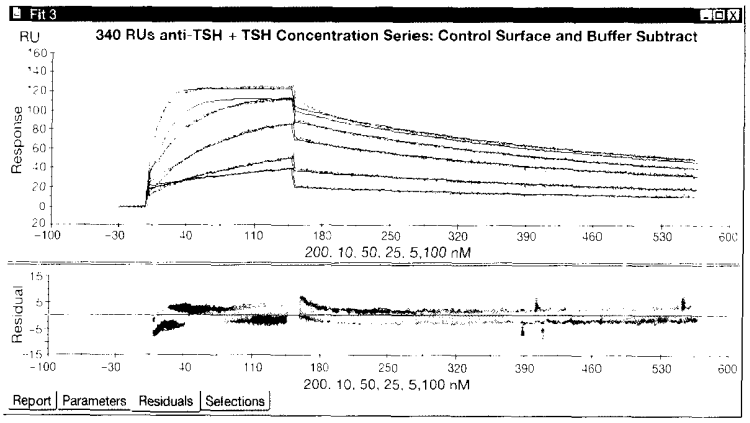

FIGURE 18-29 Corrected Langmuir-binding Model

This plot shows the results of fitting the double reference subtracted data to the same model as used in Figure 18-28 (1:1 [Langmuir] binding with a correction for mass transport and refractive index differences at both the start and end of the injection). The corrected data show better fitting to the curves and in the residual plot.

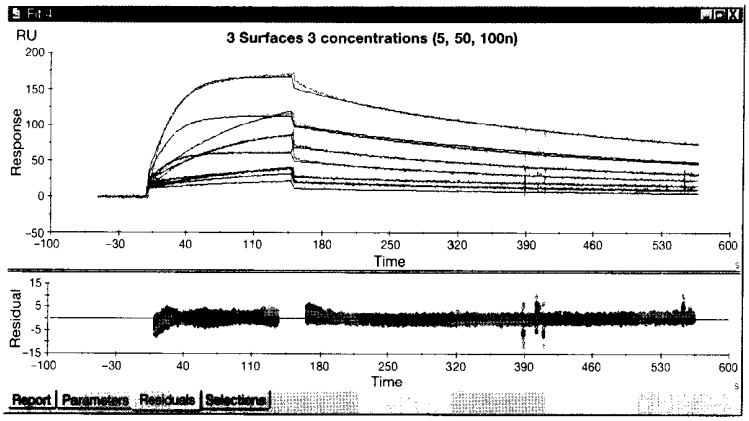

FIGURE 18-30 Global Fitting of the Binding Model

To illustrate an approximation of global fitting, this plot combines the corrected sensorgrams obtained when the same three concentrations of TSH (5, 50, and 100 nM) were injected over the three different surface levels of anti-TSH (160, 340, and 550 RUs). The values for R_{max} obtained from the fits of the individual surfaces were used as constant parameters in the fit. The values obtained for the combined data are quite close to those obtained for each individual surface, indicating that the rate constants for interaction between the antigen and antibody are constant for different ligand and analyte concentrations.

TABLE 18-12 Kinetic Rate Constants for All Three Levels of Anti-TSH

Anti-TSH Surface	Source	R_{max}	K_A M^{-1} S^{-1}	K_D S^{-1}	K_T S^{-1}	$K_A M^{-1}$	K_D M	χ^2
160 RUs	Raw data[a]	62.8	$4.42e^5$	$1.81e^{-3}$	$1.00e^8$	$2.44e^8$	$4.10e^{-9}$	1.18
	Corrected data	43.9	$7.01e^5$	$3.80e^{-3}$	$3.37e^7$	$1.85e^8$	$5.41e^{-9}$	1.08
340 RUs	Raw data[a]	111	$5.02e^5$	$2.25e^{-3}$	$1.00e^8$	$2.23e^8$	$4.48e^{-9}$	2.71
	Corrected data	89.9	$6.23e^5$	$3.19e^{-3}$	$6.51e^7$	$1.95e^8$	$5.12e^{-9}$	1.74
550 RUs	Raw data[a]	166	$4.90e^5$	$2.58e^{-3}$	$1.00e^8$	$1.90e^8$	$5.26e^{-9}$	3.35
	Corrected data	142	$5.73e^5$	$3.06e^{-3}$	$8.08e^7$	$1.87e^8$	$5.34e^{-9}$	2.28
Combined	Raw data[a]		$5.35e^5$	$2.34e^{-3}$	$1.00e^8$	$2.29e^8$	$4.37e^{-9}$	2.06
	Corrected data		$5.72e^5$	$2.82e^{-3}$	$8.34e^7$	$2.03e^8$	$4.93e^{-9}$	1.45

Shown here are the values for the kinetic constants and χ^2 for both the raw and corrected data for all three surface levels of anti-TSH, as well as the combined values representing a global fit. For the raw data fits, the k_t was held constant at $1e^8$, which provides a good estimate and eliminates numerical difficulties based on the sum-squared algorithm. The high degree of consistency between the rate constants for the combined and individual anti-TSH surfaces reflects the appropriateness of the selected model. Despite the improvement seen in the fit and in the residuals when the data were double-reference subtracted, the kinetic constants are quite close, again indicating that the selected model is appropriate. The χ^2 values are on the same order of magnitude as instrument noise (typically <2 RU), which is consistent with a good fit.

[a]For fitting the raw data, the material transport value (k_t) was held constant at $1e^8$.

FILAMENTOUS PHAGE DISPLAY

Since the method was first described by George Smith (1985), the display of foreign peptides and proteins on the surface of filamentous bacteriophages has become a cornerstone of techniques to investigate molecular interactions — in particular, those involving surface structures of proteins. Phage display is used:

- ***To identify and analyze features on the surfaces of proteins*** that interact with other proteins.
- ***To isolate new ligands that bind to particular amino acid sequences.*** These ligands may be antigenic epitopes, inhibitors, antagonists, agonists, or substrates.
- ***To improve the affinity and specificity of the interaction*** between ligands and their target structures.

The strength of the phage display system results from the powerful combination of affinity selection and biological amplification. Because filamentous bacteriophages can be exposed to ligand at concentrations in excess of 10^{13} particles/ml, a vast number of foreign peptides can be displayed on the surface of the viral particles and surveyed for their ability to interact with a target ligand. Although bacteriophages that bind to the target may be very rare in the original population, they can be recovered and enriched by repeating rounds of affinity selection and growth.

Filamentous Bacteriophages

In filamentous phage display, a segment of foreign DNA is inserted into a phagemid or an infectious filamentous bacteriophage genome, between the sequences encoding the leader peptide and the mature sequences of protein gpIII or gpVIII. As discussed in detail in the introduction to Chapter 3, the protein encoded by gene III of bacteriophage fd is only a minor component of the virus particle: Between three and five copies of the protein (M_r = 43,000) are present at one end of the filamentous virion (Pratt et al. 1969; Grant et al. 1981; Zaman et al. 1992), where they are involved in absorbtion of the bacteriophage particle to a receptor located on the tip of F pili (Armstrong et al. 1981; for reviews, please see Model and Russel 1988; Russel 1991). Mature pIII is derived from a 424-residue precursor containing an 18-residue hydrophobic amino-terminal signal sequence that is cleaved posttranslationally by bacterial signal peptidase I. The mature protein folds into a stem and knob structure composed of three domains: The amino-terminal knob (Crissman and Smith 1984) is required for attachment to and penetration of the F pili; the central, linker domain contains several glycine-rich regions, stabilized by disulfide bonds; and the carboxy-terminal domain anchors the mature protein in the envelope of the particle (Hollinger and Riechmann 1997; Lubkowski et al. 1998).

Gene VIII of bacteriophage f1 (pVIII) encodes the major capsid protein of the virus particle. Mature pVIII, which is just 50 amino acids long, is derived from a precursor that carries a 23-residue, amino-terminal leader sequence. After translocation across the bacterial membrane, the leader sequence is removed by bacterial signal peptidase I. Bacteriophage f1 particles contain ~2700 copies of pVIII, which assemble around the single-stranded viral DNA with their basic carboxy-terminal residues in contact with the nucleic acid. The central hydophobic residues of the pVIII are involved in contacts with neighboring pVIII molecules, whereas their acidic amino termini are exposed to solvent (Marvin 1990). The amino acid residues at the amino terminus of pVIII are not critical for translocation, but they are important for phage assembly.

Vectors Used for Phage Display

In the ***bacteriophage display system***, a segment of foreign DNA is inserted into gene III or gene VIII, a few nucleotides downstream from the cleavage site. *E. coli* transfected with the recombinant viral DNA synthesize and secrete a pure population of infectious "fusion phage" particles that display on their surface the amino acids encoded by the foreign DNA (Smith 1985; Parmley and Smith 1988). Every copy of pIII or pVIII on the surface of an infectious bacteriophage particle carries the sequences encoded by the foreign DNA, which are therefore displayed in a densely packed, "multivalent" fashion.

The ***phagemid display system*** consists of a plasmid that carries a single copy of gene III or gene VIII and the viral origin of DNA replication. In phagemid display, as in conventional phage display, a segment of foreign DNA is inserted into gene III or gene VIII just downstream from the cleavage site that separates the hydrophobic signal sequence from the mature protein. The recombinant plasmid is then used to transform an appropriate strain of *E. coli*. Bacteriophage particles displaying the amino acid sequences encoded

by the segment of foreign DNA are obtained by superinfecting the transformed cells with helper phages (e.g., VCSM13 or M13KO7; for details, please see Chapter 3 and Appendix 3). Because replication and packaging of the helper is less efficient than that of the phagemid, the population of bacteriophages secreted from the superinfected cells consists overwhemingly of particles that display the cloned target sequence. However, the form of the display is slightly different from that obtained by cloning into the genomes of conventional infectious bacteriophages. The surface of noninfectious particles generated from phagemids contains two types of pIII or pVIII — one encoded by the phagemid containing the foreign sequences and another, which lacks foreign sequences, encoded by the helper virus. The population of virus particles secreted from superinfected cells are therefore phenotypically mixed and their surfaces are mosaic. At least some of the foreign sequences will therefore be displayed in a "monovalent" fashion, which may have advantages when selecting for ligands that bind to the target sequences with high affinity.

Specialized phagemid display vectors have been developed for particular purposes. The best known of these are phagemid vectors that contain an amber (UAG) chain-terminating mutation immediately downstream from the inserted segment of foreign DNA and upstream of the body of pIII or pVIII. When the recombinant phagemid is used to transform nonsuppressing strains of *E. coli* (e.g., HB2151), the protein encoded by the foreign DNA terminates at the amber codon and is secreted into the culture medium. In the case of phagemids that carry fragments of immunoglobulin genes, the supernatant medium from individual suppressor-minus transformants can be screened for soluble antibody fragments with the capacity to bind antigen (for review, please see Winter et al. 1994). However, when the phagemid is used to transform cells expressing an amber suppressor, the entire fusion protein is sythesized and fragments of antibody are displayed on the surface of secreted bacteriophage particles in the normal way.

Phage Display of Peptides

By inserting into gene III or VIII populations of synthetic oligonucleotides that differ in sequence but are of equal length, it is possible to generate large libraries of recombinant bacteriophages that display tens of millions of peptides (Cwirla et al. 1990; Devlin et al. 1990; Scott and Smith 1990; Houghten et al. 1991; for reviews, please see Hoess 1993; Schatz 1994; Cortese et al. 1995; Rader and Barbas 1997; Smith and Petrenko 1997; Rodi and Makowski 1999). As discussed above, bacteriophages bearing a specific target peptide for a receptor, an antibody, or another protein can be purified from the library by alternating rounds of affinity enrichment and bacteriophage growth. Since the gene encoding the target peptide is part of the bacteriophage genome, bacteriophage peptide display can be used to isolate a specific DNA sequence by affinity selection of its protein product. Among the wide variety of biological systems that have benefited from bacteriophage peptide display are epitope mapping, analysis of protein-protein interaction, and the isolation of inhibitors, agonists, and antagonists.

SUBSTRATE PHAGES

Substrate phages, which are used to analyze and improve protease cleavage sites, display random peptide sequences between pIII and a tag. The library of phage particles are first captured on an immobilized ligand that binds to the tag and then incubated with a protease. The small number of bacteriophages carrying a peptide cleaved by the protease are released from the matrix and amplified. After two or three rounds of selection/amplification, the sequences encoding the peptides in individual bacteriophages are determined. By this means, it has been possible to identify new or improved cleavage sites for proteases such as tissue plasminogen activators (Ke et al. 1997; Coombs et al. 1998), collagenase (Deng et al. 2000), and stromelysin (Smith et al. 1995).

Random Peptides Libraries

Most random peptide libraries have been constructed at or near the amino terminus of the mature gene III protein while larger proteins have been expressed in a flexible hinge between the amino- and carboxy-terminal domains (Smith 1985; Cwirla et al. 1990; Devlin et al. 1990; Scott and Smith 1990; for reviews, please see Gallop et al. 1994; Gordon et al. 1994; Schatz 1994). Because signal cleavage is required to produce infectious bacteriophage particles and because the residues downstream from the cleavage site may influence the efficiency of processing, it is preferable to insert random peptides a few residues downstream from the

mature amino terminus. In the fd bacteriophage gene III display system described by Devlin et al. (1990), synthetic oligonucleotides are cloned into a site two to three amino acid residues downstream from the cleavage site. Peptides encoded by the inserted oligonucleotides are therefore displayed near the amino terminus of mature pIII (^{NH2}Ala-Glu-(XXX)$_n$-Pro-Ala-Glu^{COOH}) in knob-like structures that extend from the surface of the virus particle (Crissman and Smith 1984) and are accessible to antibodies and other large ligands. Although the gene III protein interacts directly with F pili, the presence of short foreign peptides at or near its amino terminus does not automatically bring about a systematic reduction in either bacteriophage yield or infectivity (Parmley and Smith 1988; Cwirla et al. 1990; Devlin et al. 1990; Houghten et al. 1991).

In an ideal world, there should be no selection pressure for or against bacteriophages that express particular peptides on their surfaces. However, sampling of peptide libraries constructed in the pIII protein suggests that cysteine and glutamine are underrepresented, whereas proline is absent from the position immediately carboxy-terminal of the signal sequence cleavage site (Cwirla et al. 1990; Blond-Elguindi et al. 1993; DeGraaf et al. 1993; Kay et al. 1993). Furthermore, bacteriophages that encode recombinant pIII proteins containing a high proportion of positively charged residues grow very poorly — presumably because of a lowered efficiency of the insertion of the pIII preprotein into the bacterial membrane (Peters et al. 1994).

Molecules of pVIII carrying a foreign pentapeptide at the mature amino terminus are able to form a complete bacteriophage capsid (Ilyichev et al. 1992), while at least some of those carrying an octapeptide cannot (Felici et al. 1991). These results suggest that peptides consisting of eight or more residues may deform the pVIII protein to such an extent that it becomes nonfunctional. This problem can be circumvented by forming a mixed capsid composed predominantly of wild-type pVIII (supplied by a helper phagemid) and partly of hybrid pVIII that carries a foreign peptide at its amino terminus (Felici et al. 1991; Greenwood et al. 1991; Kang et al. 1991). The ratio of wild-type:hybrid pVIII in these phenotypically mixed particles varies from 30 to 300, depending on the sequence of the foreign peptide (Felici et al. 1991). An alternative solution is provided by a vector carrying a second copy of gene VIII inserted into a sequence of the intergenic region (Haaparanta and Huse 1995). Because insertion in this region of the vector and subsequent expression of the cloned sequence do not adversely affect replication, the recombinant vector appears to grow normally, producing wild-type plaques.

Bacteriophages displaying foreign peptides at the amino terminus of either pIII or pVIII react with specific polyclonal or monoclonal antibodies directed against the coat proteins. These antibodies can be used to detect recombinant bacteriophages that express a specific ligand and have been captured on appropriate affinity matrices. This assay has been used successfully to study, for example, the interaction of phages displaying IgG-binding domains of staphlyococcal protein A with various subclasses of human IgG (Kushwaha et al. 1994; Bhardwaj et al. 1995). In summary:

- Foreign peptides can be expressed at the amino termini of both minor and major coat proteins of filamentous bacteriophages.
- These altered proteins can be incorporated into infectious virions that display the foreign peptide on their surfaces. In both cases, these peptides can be recognized by antibodies, enzymes, and other specific ligands.
- Gene III protein is a minor component of the bacteriophage coat, but its functions in morphogenesis and infection are not compromised by the presence of foreign peptides at its amino terminus. By contrast, peptides of six or more residues inserted into the amino terminus of pVIII can disturb its conformation and thereby prevent assembly of the viral coat (Ilyichev et al. 1989, 1992; Greenwood et al. 1991). Foreign peptides can, however, be displayed on phenotypically mixed particles whose coat consists predominantly of wild-type pVIII and also contains a small proportion of hybrid pVIII molecules.

The features of various vectors derived from filamentous bacteriophage commonly used for peptide display are summarized in Table 18-13 and are described in detail in a review by Smith and Petrenko (1997).

Construction of Peptide Display Libraries

The steps involved in generating peptide display libraries are simple in principle: Random populations of oligonucleotides of the correct length are synthesized, converted to double-stranded molecules by PCR, digested with a restriction enzyme, and ligated into a compatible restriction site that has been previously engineered at an appropriate location in bacteriophage genes III or VIII. The ligation products are trans-

TABLE 18-13 Classification of Phage-display Vectors

Vector Type[a]	Coat Protein for Display	No. of Genes	Display on Copies	Example	References
Type 3 (phage)	pIII	1	All	M13KE	Cwirla et al. (1990); Scott and Smith (1990); Kay et al. (1993)
Type 8 (phage)	pVIII	1	All	f1	Ilyichev et al. (1992); Petrenko et al. (1996)
Type 33 (phage)	pIII	2	Some	–	(not commonly used)
Type 88 (phage)	pVIII	2	Some	f88-4	McLafferty et al. (1993); Haaparanta and Huse (1995); Blancafort et al. (1999)
Type 3+3 (phagemid)	pIII	2	Some	pCOMB3H	Barbas et al. (1991)
Type 8+8 (phagemid)	pVIII	2	Some	pCOMB8	Kang et al. (1991); Wrighton et al. (1996)

[a]The classification system is based on that described by Smith (1993). Libraries may be constructed such that the inserted sequence is either carried in Gene III and displayed on pIII (Type 3), or carried in Gene VIII and displayed on pVIII (Type 8); in these cases, the inserted sequence is displayed on all copies of the coat protein. Alternatively, a second coat protein gene may be introduced, resulting in display of the foreign protein on only some of the copies of the coat protein. If both the native coat protein gene and the gene carrying an inserted sequence reside in the phage genome, these libraries (or vectors) are designated type "33" or "88." If the recombinant coat protein gene is carried on a phagemid and the native gene is carried on a helper phage, these systems are termed type "3+3" or "8+8."

(Modified, with permission, from Scott and Barbas 2001.)

fected into *E. coli* and the bacteriophages produced by the culture are collected. Many bacteriophage display vectors, for example, those of the fUSE series (Parmley and Smith 1988; Scott and Smith 1990), carry a tetracycline resistance gene (Tc^R) that allows the infected cells to be selected and maintained as colonies on medium containing the antibiotic. The phage genome can then be propagated as if it were a plasmid. This selection minimizes the demand on pIII function that occurs during multiple rounds of infection. Bacteriophage particles can be collected at any time by growing the cells for a few hours in liquid medium.

The pools of synthetic nucleotides inserted into the display vectors consist of mixtures of oligonucleotides whose heterogeneous central portions are flanked at the 5′ and 3′ ends by sequences recognized by restriction enzymes. Completely random populations of oligonucleotides of defined length and composition can be synthesized by utilizing mixtures of all four nucleoside precursors during synthesis of the degenerate region. This approach will generate a population of oligonucleotides that contains approximately equal ratios of all 64 codons at every position of degeneracy. However, this approach has two disadvantages. First, there is a 3 in 64 chance that any one codon will be a chain terminator. This problem is not serious as long as the random oligomers are small in size. However, more than one third of 24-mers (coding for random octapeptides) and two thirds of 48-mers (coding for random hexadecapeptides) will contain at least one chain-terminating codon. Second, because of the degeneracy in the genetic code, amino acids will be represented in the displayed peptides with different frequencies. For example, leucine, serine, and arginine, with six codons apiece, will appear six times more frequently than tryptophan and methionine. At present, the only practicable method of synthesizing pools of degenerate oligonucleotides is to use mixtures of deoxynucleosides as precursors. Yet by using such mixtures, it becomes impossible to synthesize a set of degenerate oligonucleotides that code for peptides in which all 20 amino acids are displayed in each position with equal frequencies.

Because the number of potential peptides is so large (see Table 18-14), it is important to keep the sequence complexity of the pool of degenerate oligonucleotides to a minimum so that peptide "sequence space" can be searched more efficiently. There are two possible ways to reduce the sequence complexity of the oligonucleotide pool: (1) by accepting a limited set of amino acids at some or all of the positions in the peptide; (2) by employing nucleotide "doping" schemes that restrict the third nucleotide in each codon to G or C (Reidhaar-Olson et al. 1991), or G or T (Scott and Smith 1990). These restrictions produce truncated versions of the genetic code (see Table 18-15) that encode the entire set of amino acids using only half as many codons. Only 1 of the 32 codons in the truncated code is a chain terminator, and the maximum ratio between codon-rich and codon-poor amino acids is reduced from six to three.

TABLE 18-14 The Number of Oligonucleotides Required to Code for All Possible Peptides of Various Lengths

Length of Peptide (Amino Acid Residues)	Number of Oligonucleotides in the Degenerate Pool
4	$20^4 = 1.6 \times 10^5$
5	$20^5 = 3.2 \times 10^6$
6	$20^6 = 6.4 \times 10^7$
7	$20^7 = 1.28 \times 10^9$
8	$20^8 = 2.56 \times 10^{10}$
10	$20^{10} = 1.024 \times 10^{13}$
12	$20^{12} = 2.028 \times 10^{14}$

Algorithms and computer programs have been developed to formulate more complex doping schemes to synthesize degenerate pools of oligonucleotides that encode specific subsets of amino acids and exclude others (Arkin and Youvan 1992). In theory, the overall amino acid composition of the displayed peptides should match the distribution of amino acids in the code predicted by the doping algorithms. This can (and should) be checked by sequencing a statistically significant number of randomly chosen bacteriophages (Cwirla et al. 1990; Blond-Elguindi et al. 1993). Significant deviation from the predicted amino acid composition is a sign either of imperfections in the doping scheme, of selection for or against certain classes of peptides during propagation of the bacteriophages, or of both.

So far, bacteriophage display libraries have been produced using only the simplest doping protocols. Devlin et al. (1990) have described the generation and use of a library of 2×10^7 bacteriophages that expresses random 15-residue peptides; Scott and Smith (1990) have generated a library displaying approximately 4×10^7 different hexapeptide epitopes; and Cwirla et al. (1990) have described a library of 3×10^8 recombinants that also expresses hexapeptides. The peptides displayed in these last two display libraries probably cover most of the hexapeptide sequence space. Clones selected from them by affinity panning have already been used to define and explore specific antigenic epitopes and other ligands. However, the potential of the bacteriophage display system cannot be fully exploited until larger libraries have been constructed that explore the sequence space of longer peptides. Complete heptapeptide display libraries can be constructed and screened with present-day technology. For example, New England Biolabs offers a library kit consisting of randomized heptapeptides; the libraries contain $\sim 3 \times 10^9$ independent clones, a sufficent number to encode most, if not all, of the 20^7 possible 7-mer sequences (1.28×10^9). Methods to construct bacteriophage display libraries and to assess their completeness are discussed in Christian et al. (1992) and reviewed by Smith and Petrenko (1997) and Rodi and Makowski (1999).

TABLE 18-15 A Restricted Genetic Code with Only G or C in the Third Position of Each Codon

	T		C		A		G	
T	TTC	Phe	TCC	Ser	TAC	Tyr	TGC	Cys
	TTG	Leu	TCG	Ser	TAG	Stop	TGG	Trp
C	CTC	Leu	CCC	Pro	CAC	His	CGC	Arg
	CTG	Leu	CCG	Pro	CAG	Gln	CGG	Arg
A	ATC	Ile	ACC	Thr	AAC	Asn	AGC	Ser
	ATG	Met	ACG	Thr	AAG	Lys	AGG	Arg
G	GTC	Val	GCC	Ala	GAC	Asp	GGC	Gly
	GTG	Val	GCG	Ala	GAG	Glu	GGG	Gly

An identical genetic code is obtained if codons are restricted to NN\F(G,T) instead of NN\F(G,C).

TABLE 18-16 Commercial Phage Display Systems

Resource/Company	Phage Display System/Kit	Vector/System Components	Comments
Amersham-Pharmacia Biotech www.apbiotech.com	Recombinant Phage Antibody System	pCANTAB 5 phagemid.	The system includes a series of modules provided for cloning, screening, and expression of single-chain fragment variable (ScFv) antibodies.
Display Systems Biotech www.displaysystems.com	displayPHAGE System	pSKAN (pIII phage coat fusion proteins).	Display Systems provides three *E. coli* libraries (6-, 7-, 8-mers), three to four rounds of biopanning, and positive clone identification by ELISA and DNA sequencing.
Invitrogen www.invitrogen.com	FliTrx Random Peptide Display Library	pFliTrx vector (flagella [Fli]-thioredoxin [Trx] fusion proteins are exported and assembled in partially functional flagella).	The bait or protein of interest is screened in successive rounds against peptide clones; positive clones are rescreened and sequenced.
	pDisplay Expression Vector	pDisplay (mammalian expression vector) contains the SV40 origin of replication, T7 promoter/priming sites, and the neomycin resistance marker for stable selection in mammalian cells.	The vector is designed to target recombinant proteins to the surface of mammalian cells. Recombinant proteins encoded by the vector carry an amino-terminal cell surface targeting signal and the carboxy-terminal transmembrane anchoring domain of PDGF.
	pYD1 Yeast Display Vector Kit	pYD1 (yeast expression vector) carries the GAL1 promoter, T7 promoter/priming sites.	The vector is designed to target recombinant proteins to the surface of *S. cerevisiae* via the α-agglutinin yeast adhesion receptor. Recombinant proteins encoded by the vector carry the Aga2 subunit, which associates with Aga1 expressed by the host cell.
New England Biolabs www.neb.com	Ph.D. Phage Display Peptide Library Kits	M13KE vector (pIII phage coat fusion proteins with Gly-Gly-Gly-Ser linker).	Three random peptide libraries are available: 2 of 7 and 1 of 12 residues. One of the 7-mer libraries (C7C) expresses the randomized insert sequence with flanking cysteine residues.
Novagen www.novagen.com	T7 Select Phage Display System	T7 (expresses peptides/proteins as fusions to the carboxyl terminus of the 10B capsid protein).	The system is particularly useful for cDNA source material. Displayed products on mature phage particles are released by cell lysis.
Syncomm Biotechnology Development Labs www.syncommbdl.com	Phage Display System/Service	Filamentous phage cloning vector; libraries generated upon request.	Consultation service; customers provide the bait (target of interest), Syncomm provides libraries (if needed); complete three rounds of panning and amplification, and positive clone identification by ELISA and DNA sequencing.

Constrained Libraries

Linear peptides displayed on the surface of bacteriophages may be identical to a "natural" peptide in amino acid sequence but may adopt a completely different three-dimensional configuration. One solution to this problem is to constrain the mobility and configuration of the displayed peptide by including cysteine residues in the sequences flanking the randomized peptide sequence. The idea is that the cysteine residues will form a rigid disulfide scaffold that will stabilize the peptide in a favorable structure (Felici et al. 1991; McLafferty et al. 1993). Using this strategy, several groups have been able to select peptides that bind to a selector molecule from constrained libraries but not from unconstrained libraries of equivalent complexity (e.g., please see Folgori et al. 1994; Hoess et al. 1994). However, this approach may not be a universal panacea for structural difficulties since the inclusion of cysteine residues in the displayed peptides markedly reduces the infectivity of filamentous phages and so greatly lowers the titer of constrained display libraries.

The search to identify alternative scaffolding systems that allow a proper secondary or tertiary display of constrained peptides has included the use of α helices (Wu et al. 1989; Bianchi et al. 1995; Nord et al. 1995), the β-sheet structure of the amylose inhibitor tendamistat (McConnell and Hoess 1995), the zinc-finger protein (Wu et al. 1989; Rebar and Pabo 1994), and even the use of synthetic supports, known as "peptides on beads" (Needels et al. 1993). The review by Smith and Petrenko (1997) provides a reasonably comprehensive list of constrained peptide libraries.

Affinity Selection and Purification of Bacteriophages

Most of the schemes to select bacteriophages expressing a specific peptide involve screening the display library with a target protein or another ligand, a process known as "panning." In a typical protocol, libraries are exposed overnight to biotinylated antibody or ligand and then panned for a few minutes on plastic surfaces (plates or immunobeads) or paramagnetic beads coated with streptavidin (Parmley and Smith 1988). Unbound bacteriophages are washed away in buffer containing a detergent and the bound bacteriophages are then recovered either by elution with a buffer such as glycine-HCl buffer (pH 2.2) or with a magnetic separator. In principle, it is possible to improve the specificity of recovery by using a buffer containing a ligand or cofactor that will promote dissociation of a particular type of interaction. For example, Blond-Elguindi et al. (1993) screened display libraries for bacteriophages expressing peptides with an ability to bind to an immobilized mammalian chaperone. The bacteriophages were eluted by adding ATP, which causes dissociation of chaperones from their denatured protein substrates.

Whatever the method of dissociation, bacteriophages expressing high-affinity ligands can be expected to elute more slowly from the target protein than those expressing ligands of low affinity. However, the presence of "multivalent" copies of the peptide on the bacteriophage surface fosters the formation of multiple contacts between the bacteriophage particle and the target protein. Nearly all of these contacts would need to be broken at the same time for the bacteriophage to be recovered in the eluate. Recovery of bacteriophages that bind with high affinity may be facilitated by using a "monovalent" 3 + 3 or 8 + 8 display system (please see Table 18-13). In practical terms, however, it is often impossible to distinguish between bacteriophages that bind to the target with different affinities (Barrett et al. 1992; Hawkins et al. 1992).

After neutralization and concentration, the eluted bacteriophages are generally amplified and panned several more times. Depending on the ligand, the fold-overall enrichment after two rounds of panning and amplification can be 10^6 or greater. Eventually, small populations of plaques or, in case of phagemid vectors, transformed bacterial colonies can be screened with ligand, essentially as described by Young and Davis (1983). Single-stranded DNA of individual clones of bacteriophages can then be prepared and sequenced to determine the amino acid sequence of the peptide that binds to the antibody or ligand.

Commercial Display Systems and Kits

A number of commercial systems are now available that provide a variety of resources for construction, display, and analysis of peptide libraries using systems ranging from bacteriophage to yeast to mammalian cells. These systems are summarized in Table 18-16. Unless there is a strong scientific reason to choose a more esoteric display system, we recommend using standard, filamentous phage display libraries (e.g., those sold by New England Biolabs) to work out conditions for panning, screening, and amplification. The manufacturers have accumulated a fund of useful knowledge about these libraries and will be able to suggest possible solutions to most problems that arise.

Bacteriophage Display of Foreign Proteins

Foreign proteins, like peptides, can be displayed in a functional form on the surface of filamentous bacteriophage particles by fusing the coding sequence to gene III or gene VIII (for review, please see Hoess 1993).

Insertion into gene VIII has the advantage that thousands of copies of the protein of interest are expressed on each bacteriophage particle, but it has the marked disadvantage of placing severe constraints on the size of the insert. However, inserts encoding >6 amino acids do not form viable bacteriophage particles (Greenwood et al. 1991) unless the cell is also infected with a helper bacteriophage that codes for wild-type gene VIII protein (Willis et al. 1993). This results in the production of phenotypically mixed particles in which only a minority of the gene VIII coat protein molecules carry the desired insertion.

A cloning site located near the amino terminus of gIII protein has been used to express domains of several mammalian secretory proteins without compromising infectivity of the recombinant bacteriophages. The resulting fusion proteins retain at least some of their original biochemical and enzymatic properties. Bacteriophage particles that display fusion proteins on their surface can be captured by affinity panning or chromatography using specific ligands that bind to the cognate protein with high affinity. These ligands can include inhibitors and substrates in the case of displayed enzymes, antigenic epitopes in the case of antibodies, and receptors in the case of displayed polypeptide ligands.

PHAGE DISPLAY OF ANTIBODIES

Filamentous phage particles and phagemids can be used to display antibodies (usually in the form of scFv or Fab′ fragments). If phagemids are used as vectors, either the V_H-CH1 or V_L-CL chain is fused to pIII, whereas the other chain is expressed without fusion to pIII. Using libraries containing naive and semisynthetic germline variable genes, antibodies with affinities comparable to those in a secondary immune response can be generated against foreign and self antigens. The affinity of single antibodies displayed on bacteriophages can be further improved by random mutagenesis, site-directed mutagenesis (Gram et al. 1992; W.-P. Yang et al. 1995), and fragment or chain shuffling (Burton and Barbas 1994; Winter et al. 1994). For an excellent description of the construction and assay of libraries of antibodies in filamentous bacteriophages, please see Barbas et al. (2001).

Filamentous bacteriophage display systems offer a powerful means to select rare genes encoding proteins with ligand-binding activities. For example, antigen-binding bacteriophages have been selected by affinity chromatography from populations of bacteriophage expressing fragments of single-chain Fv antibodies (McCafferty et al. 1990; Verhaar et al. 1995) and two-chain Fab libraries (Kang et al. 1991). Other uses of this system include the selection of variants of human growth hormone that have a high affinity for the human growth hormone receptor (Bass et al. 1990; Lowman et al. 1991); the assembly of combinatorial Fab libraries on bacteriophage surfaces (Hoogenboom et al. 1991; Kang et al. 1991; for review, please see Johnson and Chiswell 1993; Winter et al. 1994); the selection of bacteriophages expressing potent inhibitors of elastase (Roberts et al. 1992a,b); the selection of DNA-binding proteins with altered specificities (for review, please see Choo and Klug 1995); and the expression of a variety of functionally active proteins on the bacteriophage surface. These include alkaline phosphatase (McCafferty et al. 1991), BPTI (Roberts et al. 1992a,b), the B chain of ricin (Swimmer et al. 1992), trypsin (Corey et al. 1993), plasminogen activator inhibitor-I (Pannekoek et al. 1993; van Meijer et al. 1996), and ciliary neurotrophic factor (Saggio et al. 1995).

INTERACTION RESCUE

As discussed above, bacteriophages lacking the amino-terminal domain of pIII are unable to penetrate F pili and are not infectious. However, infectivity can be restored if the domain is reintroduced to the phage. In interaction rescue, the amino-terminal domain of pIII is fused to a soluble protein whose dimerization partner is fused to the truncated pIII and displayed on the surface of the bacteriophage. When interacting domains (e.g., leucine zippers) of heterologous proteins are cloned into the two parts of the gIIIp gene, the resulting fusion proteins are able to associate and thereby to restore activity to gIIIp and infectivity of the progeny bacteriophage (Dueñas and Borrebaeck 1994; Gramatikoff et al. 1994). Interaction rescue has promise as a method to select clones encoding functionally interacting protein domains from cDNA libraries.

So far, filamentous bacteriophage systems have been successful chiefly for the display of small and moderately sized secretory proteins — presumably because these proteins can be efficiently secreted through the inner membrane of *E. coli*, can fold into their correct three-dimensional structures in the periplasmic space, and can maintain their correct configuration on the surface of the bacteriophage particle after exposure to an oxidizing environment. Whether bacteriophage display can be successfully applied to larger intracellular proteins is therefore rather doubtful.

GENOMICS AND THE INTERACTION TRAP

At this point in the progress of the genome projects, vast quantities of sequence data for genes and proteins have been generated. An extremely high percentage of this information corresponds to novel sequences, with no available hints about potential cellular function to be gleaned from patterns of homology. Of the multiple complementary approaches under development to assign function to the great number of predicted proteins, a systematic use of the two-hybrid system to establish direct physical interactions between novel genes and previously characterized proteins promises to be particularly useful. To this end, a number of strategies have been developed.

Interaction Mating, Arrayed Libraries, and Libraries of Baits

An early entry to the field of genomic analysis for two-hybrid studies was the description of interaction mating (Finley and Brent 1994). This idea exploited the fact that yeast containing panels of baits or panels of preys could be mated in defined grids, allowing the rapid assessment of interactions between a relatively large number of defined baits of interest; furthermore, because the panels could be arrayed conveniently in microtiter plates, the technique was amenable to high-throughput analyses on a scale required for genomic studies. This idea evolved rapidly into the formatting of complete cDNA libraries into pooled subsets, which enables electronic handling of the data (e.g., including tracing back the identity of clones derived from the arrayed high-complexity normalized EST [Hua et al. 1998] or Unigen libraries [Weiner 1998]); allows functional subtraction of the "promiscuous positive" class of interactor from the library; and facilitates the automated handling of samples, which should promote large-scale proteome analysis (Buckholz et al. 1999).

A second development has been the use of libraries of bait proteins, in conjunction with the standard libraries of prey. In general, use of randomly generated bait libraries had been avoided because a high percentage of inserted cDNAs (estimated at 5–10%) possessed the intrinsic ability to activate transcription, leading to high background in conventional two-hybrid screening assays. However, by adapting approaches in which such activating fusions could be avoided (e.g., please see Bartel et al. 1996) or potentially counterselected in a prescreening step (Vidal et al. 1996a,b; Walhout and Vidal 1999), such libraries could be used in interaction mating approaches on the large scale desired for analysis of genome-complexity groups of cDNAs (Figure 18-31).

A Map of All Possible Interactions

Some investigators have begun pilot projects to explore the utility of two-hybrid genomic analysis. The goals of such attempts are in some cases immense in scope, with the objective of solving all possible protein-protein interactions for a given genome. In other cases, a more circumscribed set of goals involve the mapping of interactions between all proteins involved in discrete multiprotein complexes that regulate specific cellular processes.

Two primary papers exemplify the two strategies. In the first, Bartel et al. (1996) attempted to solve the complete protein interaction networks of the ~55 known proteins of *E. coli* bacteriophage T7, using a series of approaches that combined interaction mating and library screening of defined and randomly generated bait and prey fusions. This effort yielded a wealth of information about interactions among different proteins, as well as interactions taking place between separate domains of a single protein that might be taken to be predictive of homomeric interactions occurring during protein folding. However, given that a number of interactions known to occur between T7 proteins were not detected, and given the laboriousness of the general approach, it is not yet clear the degree to which this brute-force interaction solution will be translatable to organisms of higher genome complexity.

In an alternative approach, Fromont-Racine et al. (1997) focused their efforts on identifying a comprehensive set of proteins involved in a discrete part of the cellular machinery, the spliceosome. To this end, these authors built ten targeted baits from discrete *Saccharomyces cerevisiae* proteins implicated in pre-mRNA splicing, each of which was used for a library screen. Preys isolated in the screens were "rated" on a scale that considered the nature of the cDNA and the frequency of isolation; those receiving the highest ratings were used in reiterative screens to isolate new preys. Finally, baits and preys were systematically examined for cross-interactions within the complete group; additionally, sequences of previously undefined open

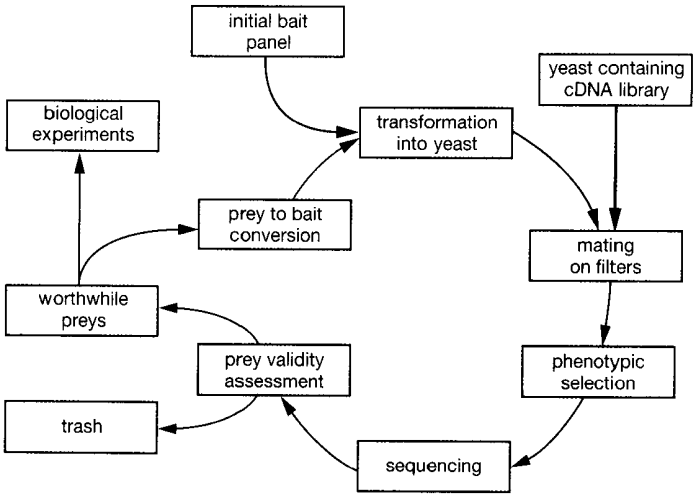

FIGURE 18-31 Strategies for Genomic Analysis

Genomic strategies involve reiterative screening and cross-screening between baits and preys to identify interaction networks. One potential path is shown, in which a panel of baits is initially mated en masse against an activation-domain-fused cDNA library; positives are selected, ranked, and used both as starting point for a second round screen and for directed biological experiments suggested by the interactions.

reading frames were disrupted, followed by genetic analysis of relevance to known splicing factors. This approach was extremely successful in predicting a network of interactions between known and novel splicing factors and may offer a particularly useful paradigm for studies of other cellular "machines" complementary to direct physical assay systems such as mass spectrophotometric analysis.

A larger-scale experiment is under way to map interactions among all the proteins encoded by the *S. cerevisiae* genome, based on the creation of complete sets of DNA-binding domain and activation domain fusions to each of ~6000 yeast genes (Hudson et al. 1997; Uetz et al. 2000). Both libraries are arrayed to be mated to each other, and this approach is meant to be a prototype for even more high-throughput applications, such as mapping interaction of the human proteome. A recent report has demonstrated the possibility of coupling such functionally targeted two-hybrid genomic analysis with the use of oligonucleotide arrays representing the full complement of genes in *S. cerevisiae* (Cho et al. 1998), a development that should greatly speed the general analysis. Finally, another model project to annotate functionally large numbers of uncharacterized proteins predicted by complete genome sequences using large-scale two-hybrid analysis is ongoing for *Caenorhabditis elegans*. Starting with 27 proteins involved in vulval development, a functional annotation for ~100 uncharacterized gene products has been obtained. The resulting map of interacting sequence tags (or ISTs) revealed both known and new potential interactions (Walhout et al. 2000) and has been integrated productively with other forms of annotation available for *C. elegans* through the *ACeDB* database project.

Detection of Inactivating Mutations in Human Genes

In a peripheral approach, the yeast two-hybrid system is being adapted as an additional means of screening (e.g., of clinical samples) for human genes implicated in disease. A simple method detects functional mutations by virtue of their ability to abolish a protein-protein interactions. A high-throughput approach involving use of direct recombinational cloning in yeast of a reverse transcription PCR product is followed by a simple growth selection for the interaction with a functional partner (Schwartz et al. 1998). This method should be able to distinguish both homozygous and heterozygous mutations in any human genes whose encoded proteins have suitable partners in the two-hybrid assay. It has been used successfully to detect mutations in the p53 tumor suppressor gene (Schwartz et al. 1998).

INTERACTION TRAP AND RELATED TECHNOLOGIES

Although the yeast two-hybrid system and its derivatives have clearly been fruitful, a number of complementary technologies have been developed. In particular, nontranscription-based systems (discussed below) circumvent several intrinsic limitations of the two-hybrid applications, including the inability to deal easily with self-activators and proteins excluded from the nucleus. A number of these systems are still in early stages of evaluation.

One-hybrid, One-and-a-half Hybrid, and One-Two Hybrid

The two-hybrid technologies discussed in the introduction to Protocol 1 of this chapter address the interactions of proteins with proteins, peptides, drugs, and RNA. The one-hybrid system allows the identification of proteins that interact with DNA. A number of groups independently described the development of such an approach (Wilson et al. 1991; Li and Herskowitz 1993; Wang and Reed 1993; Dowell et al. 1994; Inouye et al. 1994; Chong et al. 1995). In a general strategy, a DNA sequence of biological interest (known to encompass a specific binding motif for a protein) is cloned as a single copy or multimer upstream of reporter genes, similar to those used in a two-hybrid system (Figure 18-32). Specific selection strains are then generated with the binding-motif-reporter integrated or encompassed in a plasmid, and an activation-domain library essentially equivalent to those used in two-hybrid screening is then used to identify proteins that can bind and activate transcription. Although the need to construct specific motif-reporter strains makes development of screening reagents more laborious, one-hybrid screens work well for a number of proteins. Reflecting the growing popularity of this strategy, Wolf et al. (1996) reported the generation of a series of reporter constructs that allow greater flexibility in the use of a one-hybrid approach with libraries from either the GAL4 or LexA two-hybrid systems.

A related approach combines elements of the one-hybrid and two-hybrid systems to screen for DNA-binding proteins. This approach, termed one-and-a-half hybrid, is intended to identify proteins that bind DNA only when complexed as a heterodimer with a second, known partner or that fail to bind DNA autonomously, but make a stable ternary complex in the presence of an accessory protein. A reporter is first constructed using a heterodimer-binding site to direct transcription, and library transformations are then performed in yeast expressing the known heterodimeric partner. This approach was first used to identify SAP-1, which associates with serum response factor (SRF) to bind the c-*fos* serum response element (SRE) (Dalton and Treisman 1992), and it has been successfully used by other groups (Naya et al. 1995). A somewhat similar approach was used in the double interaction screen (DIS). DIS was successfully used (Yu et al. 1999) to identify simultaneously DNA-binding transregulators of *ftz* gene expression (which would bind to the *ftz* proximal enhancer, placed upstream of reporter genes) and cofactors that directly interact with Ftz protein.

Finally, Luo et al. (1996) has proposed that in some specialized cases, involving identification of proteins that both bind DNA independently and dimerize with a known partner, it may be productive to screen for both parameters simultaneously to eliminate false positives and generally increase specificity of the assay. In this strategy, termed one-two hybrid, yeast selection strains are engineered to contain one reporter driven by binding sites for p53, a second standard reporter strain for the two-hybrid system, and a bait fused to the p53 homodimerization sequence. Supertransformation of this strain with wild-type p53 results in simultaneous activation of both reporters, proving that the concept is practicable; it has not yet been broadly tested by library screening.

Split-Ubiquitin

The *u*biquitin-based split-*p*rotein *s*ensor (USPS) method has been proposed as a means of assaying transient protein-protein associations in real time, unconstrained by considerations of intracellular localization (Johnsson and Varshavsky 1994). In this strategy, a protein is fused to a carboxy-terminal fragment of ubiquitin, and a second protein is fused to a mutated amino-terminal fragment of ubiquitin. If the two test proteins interact, the amino- and carboxy-terminal fragments of ubiquitin are brought into proximity, targeting the carboxy-terminal fusion protein for cleavage. This degradation, monitored by western blot analysis, constitutes the reporter for the system (Johnsson and Varshavsky 1994; Dunnwald et al. 1999). This system has not yet attained broad use in the scientific community, and information about its performance with a variety of proteins is lacking. Some features, including the ability to switch between assays in vivo or in vitro,

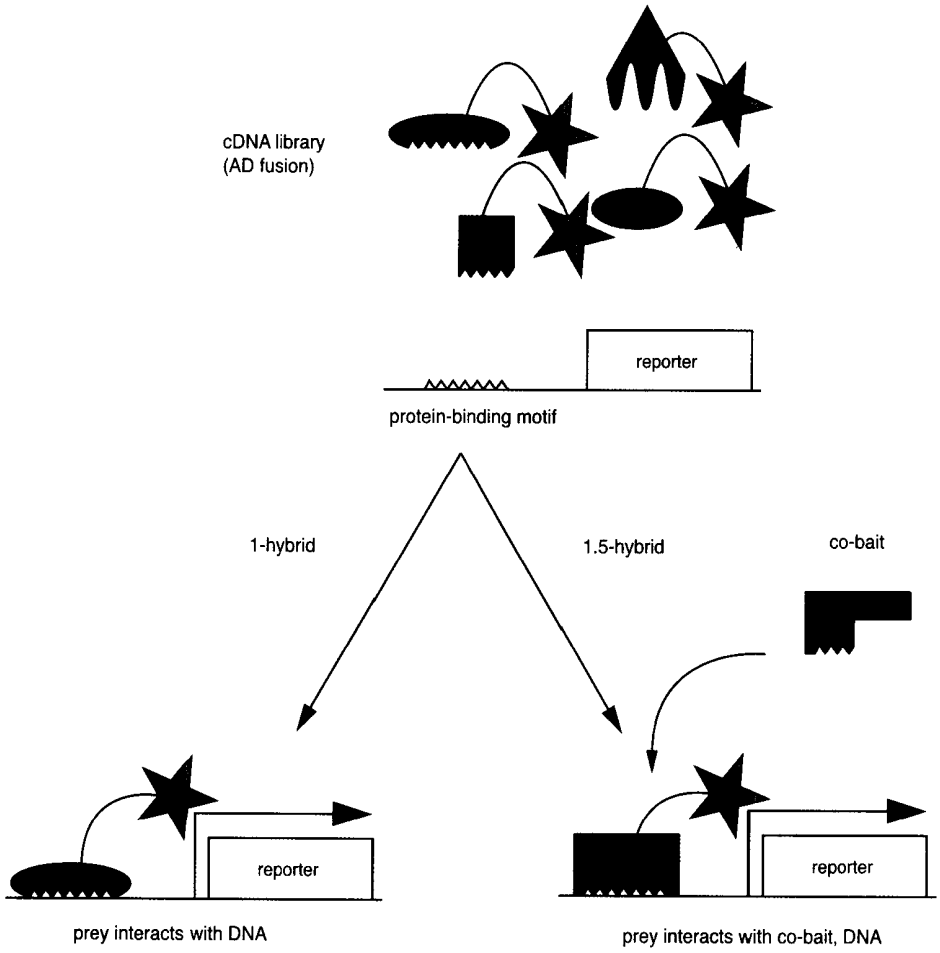

FIGURE 18-32 One Hybrid, One-and-a-Half Hybrid

A specialized yeast strain is constructed with one or more reporters that are transcriptionally responsive to a particular protein-binding motif. In the one-hybrid screen, an activation domain-fused cDNA library is transformed into the selection strain, and preys with the ability to activate transcription of reporters are directly selected (*bottom left*). The one-and-a-half hybrid screen relies on the use of known preys that bind only in the presence of a cofactor that contains the DNA-binding domain and dimerization domain (termed co-bait in figure). In this case, preys from an activation domain library are selected for their ability to activate the transcription of reporters in the presence of the co-bait.

are attractive in some applications. To create a more practical incarnation, a system was devised (Stagljar et al. 1998) where, upon interaction-mediated ubiquitin reconstitution, the cleavage releases a transcription factor, which activates reporter genes in the nucleus. As a result, interaction between membrane proteins can be analyzed by means of auxotrophic selection and a colorimetric assay.

Sos/Ras Recruitment

The recently developed Sos recruitment system (SRS) is designed to study protein-protein interactions of proteins that are not suitable for two-hybrid screens, either because they strongly activate transcription or because they associate strongly with membranes, and cannot be effectively localized to the nucleus (Aronheim 1997; Aronheim et al. 1997). This strategy exploits basic properties of signal transduction as a selective strategy. Yeast require Ras function to be viable; Ras activity depends on the activity of a guanyl nucleotide exchange factor (GEF), which allows conversion to the active GTP-bound form. The normal *S. cerevisiae* GEF for Ras is Cdc25; mutations in Cdc25 can be complemented by the mammalian Cdc25 homolog, Sos, if Sos is effectively localized to the cell membrane. In the SRS strategy (commercially available from Stratagene), the *S. cerevisiae* strains used for selection contain a temperature-sensitive mutation of

Cdc25. Bait proteins are expressed as fusions to a myristylation (membrane-targeting) signal, whereas interacting partners, either defined or from a cDNA library, are expressed as fusions to Sos. If the two protein components interact, Sos is brought to the membrane, allowing viability at the Cdc25 restrictive temperature.

Some difficulties have been encountered with this technique, and in an attempt to overcome a number of problems using SRS, the developers have improved the protein recruitment system, designated the Ras recruitment system (RRS), based on the absolute requirement that Ras be localized to the plasma membrane for its function (Broder et al. 1998). Ras membrane localization and activation can be again achieved through interaction between two-hybrid proteins. Both the SRS and RRS systems have been used effectively both in tests of known interactions and to isolate novel interacting proteins from a library (Aronheim et al. 1997, 1998; Broder et al. 1998; Yu et al. 1998); they are a promising addition to the available panel of interaction assay strategies.

Non-Yeast Two-Hybrid Systems

Because of its genetic robustness and ease of use, yeast has been the organism of choice for development of two-hybrid systems, and will probably remain so. Nevertheless, some applications, foremost among them assay of pharmacological compounds, would benefit from a mammalian counterpart to the yeast two-hybrid system, and a number of groups have developed basic reagents toward this end (Dang et al. 1991; Vasavada et al. 1991; Fearon et al. 1992; Luo et al. 1997). To improve the sensitivity of mammalian two-hybrid assays, allowing interactions between poorly expressed proteins to be detected, a strategy of "bundling" activators has been developed recently. Incorporation of a tetramerization domain (derived from lactose repressor) allowed activation domain fusion proteins to be expressed as noncovalent tetrameric "bundles," which are significantly more potent than simple monomeric activators at similar levels of expression (Natesan et al. 1999). In general, these systems have proven to be most useful in assay of interactions between pre-defined proteins.

Rossi et al. (1997) have recently described a mammalian strategy utilizing two-hybrid principles, but with a very different readout, intended to allow assessment of dimerization in a biologically relevant context. This system exploits a phenomenon called α-complementation, which was been used for many years in prokaryotes (e.g., in the blue-white selection vectors used for cloning). Cells that bear either the α (amino-terminal) fragment or ω (carboxy-terminal) fragment of β-galactosidase (encoded by 3′ or 5′ deletions of the bacterial *lacZ* gene, respectively) show no enzyme activity. However, if a cell expresses α and ω fragments in combination, they can assemble to form an active enzyme (Ullmann et al. 1967). Some β-galactosidase mutants that reduce the affinity of α and ω fragments for each other fail to reconstitute an active enzyme; however, this can be overcome if the interaction is artificially enforced. Fusion of interacting proteins to such noninteracting α and ω mutant fragments provides a tool for enforcement, and the β-galactosidase activity of the reconstituted enzyme serves as measure of protein-protein interaction (Rossi et al. 1997). This application was tested by expressing FRAP and FKBP12 (which are known to form a complex in the presence of rapamycin) as chimeras with *lacZ* deletions and monitoring β-galactosidase activity reflecting FRAP-FKBP12 complex formation.

Although bacterial systems would clearly possess the genetic power and cost-effectiveness of yeast two-hybrid systems, until quite recently, much less effort has gone into developing *E. coli*-based screening technologies. This may derive in part from the fact that the vast majority of proteins studied are derived from higher eukaryotes, which may be expected to be posttranslationally modified or folded more appropriately in yeast than in bacteria, enhancing the chance of obtaining biological results. However, some reagents suitable for studying protein-protein interactions by two-hybrid-related approaches have been developed and may be particularly useful for investigators working with prokaryotic proteins: Some of these systems have been described previously (Hu et al. 1990; Bunker and Kingston 1995; Hu 1995; Dmitrova et al. 1998; Kornacker et al. 1998; Di Lallo et al. 1999). Probably the most sophisticated system currently available (Karimova et al. 1998) is based on reconstitution of adenylyl cyclase signaling functions in *E. coli*. cAMP produced by this enzyme activated CAP and in turn enabled transcription from the *lac* or *mal* operons, which resulted in growth on selective plates and specific color on indicator media. The involvement of a signal transduction pathway step in this system allows spatial separation between interacting hybrid proteins and the transcriptional activation readout. So far, however, only a "model screening" has been performed.

A more dynamic system, based on selection for histidine heterotrophy, is designed to detect either protein-protein or protein-DNA interactions (Joung et al. 2000). In this case, the bait is a modified version of the α-subunit of the *E. coli* RNA polymerase. Prey are selected from libraries encoding either variant protein or DNA-binding domains.

Preparation of Reagents and Buffers Used in Molecular Cloning

BUFFERS

Tris Buffers

Biological reactions work well only within a narrow concentration range of hydrogen ions. Paradoxically, however, many of these reactions themselves generate or consume protons. Buffers are substances that undergo reversible protonation within a particular pH range and therefore maintain the concentration of hydrogen ions within acceptable limits. Perfect buffers are, like the Holy Grail, always beyond reach. An ideal biological buffer should

- have a pK_a between pH 6.0 and pH 8.0
- be inert to a wide variety of chemicals and enzymes
- be highly polar, so that it is both exquisitely soluble in aqueous solutions and also unlikely to diffuse across biological membranes and thereby affect intracellular pH
- be nontoxic
- be cheap
- not be susceptible to salt or temperature effects
- not absorb visible or ultraviolet light

None of the buffers used in molecular biology fulfill all of these criteria. Very few weak acids are known that have dissociation constants between 10^{-7} and 10^{-9}. Among inorganic salts, only borates, bicarbonates, phosphates, and ammonium salts lie within this range. However, they are all incompatible in one way or another with physiological media.

In 1946, George Gomori (Gomori 1946) suggested that organic polyamines could be used to control pH in the range 6.5–9.7. One of the three compounds he investigated was Tris(2-amino-2-hydroxymethyl-1,3-propanediol), which had been first described in 1897 by Piloty and Ruff. Tris turned out to be an extremely satisfactory buffer for many biochemical purposes and today is the standard buffer used for most enzymatic reactions in molecular cloning.

TABLE A1-1 Preparation of Tris Buffers of Various Desired pH Values

DESIRED pH (25°C)	VOLUME OF 0.1 N HCl (ml)
7.10	45.7
7.20	44.7
7.30	43.4
7.40	42.0
7.50	40.3
7.60	38.5
7.70	36.6
7.80	34.5
7.90	32.0
8.00	29.2
8.10	26.2
8.20	22.9
8.30	19.9
8.40	17.2
8.50	14.7
8.60	12.4
8.70	10.3
8.80	8.5
8.90	7.0

Tris buffers (0.05 M) of the desired pH can be made by mixing 50 ml of 0.1 M Tris base with the indicated volume of 0.1 N HCl and then adjusting the volume of the mixture to 100 ml with water.

TRIS BUFFERS

One of Tris' first commercial successes, which received wide attention, was the reduction of mortality during handling and hauling of fish. In the 1940s, live fish were carried to market in tanks of seawater. Unfortunately, many of the fish died because of the decline in pH resulting from an accumulation of CO_2. This problem was only partially alleviated by including anesthetics in the water that minimized the fishes' metabolic activities. What these anesthetics did to the people who ate the fish is not recorded. Tris certainly reduced the mortality rate of the fish (McFarland and Norris 1958) by stabilizing the pH of the seawater and may also have kept the fish eaters more alert. Tris also turned out to be an extremely satisfactory buffer for many biochemical purposes and today is the standard buffer used for most enzymatic reactions in molecular cloning.

Tris [Tris(hydroxymethyl)aminomethane] has a very high buffering capacity, is highly soluble in water, and is inert in a wide variety of enzymatic reactions. However, Tris also has a number of deficiencies:

- ***The pK_a of Tris is pH 8.0 (at 20°C),*** which means that its buffering capacity is very low at pHs below 7.5 and above 9.0.
- ***Temperature has a significant effect on the dissociation of Tris.*** The pH of Tris solutions decreases ~0.03 pH units for each 1°C increase in temperature. For example, a 0.05 M solution has pH values of 9.5, 8.9, and 8.6 at 5°C, 25°C, and 37°C, respectively. By convention, the pH of Tris solutions given in the scientific literature refers to the pH measured at 25°C. When preparing stock solutions of Tris, it is best to bring the pH into the desired range and then allow the solution to cool to 25°C before making final adjustments to the pH.
- ***Tris reacts with many types of pH electrodes*** that contain linen-fiber junctions, apparently because Tris reacts with the linen fiber. This effect is manifested in large liquid-junction potentials, electromotive force (emf) drift, and long equilibration times. Electrodes with linen-fiber junctions, therefore, cannot accurately measure the pH of Tris solutions. Use only those electrodes with ceramic or glass junctions that are warranted by the manufacturer to be suitable for Tris.
- ***Concentration has a significant effect on the dissociation of Tris.*** For example, the pHs of solutions containing 10 mM and 100 mM Tris will differ by 0.1 of a pH unit, with the more concentrated solution having the higher pH.
- ***Tris is toxic to many types of mammalian cells.***
- ***Tris, a primary amine, cannot be used with fixatives*** such as glutaraldehyde and formaldehyde. Tris also reacts with glyoxal. Phosphate or MOPS buffer is generally used in place of Tris with these reagents.

Good Buffers

Tris is a poor buffer at pH values below 7.5. In the mid 1960s, Norman Good and his colleagues responded to the need for better buffers in this range by developing a series of *N*-substituted aminosulfonic acids that behave as strong zwitterions at biologically relevant pH values (Good et al. 1966; Ferguson et al. 1980). Without these buffers, several techniques central to molecular cloning either would not exist at all or would work at greatly reduced efficiency. These techniques include high-efficiency transfection of mammalian cells (HEPES, Tricine, and BES), gel electrophoresis of RNA (MOPS), and high-efficiency transformation of bacteria (MES).

Table A1-2 Properties of Good Buffers

Acronym	Chemical Name	FW	pK_a	Useful Range (in pH units)
MES	2-(*N*-morpholino)ethanesulfonic acid	195.2	6.1	5.5–6.7
Bis-Tris	*bis*(2-hydroxyethyl)imino*tris*(hydroxymethyl)methane	209.2	6.5	5.8–7.2
ADA	*N*-(2-acetamido)-2-iminodiacetic acid	190.2	6.6	6.0–7.2
ACES	2-[(2-amino-2-oxoethyl)amino]ethanesulfonic acid	182.2	6.8	6.1-7.5
PIPES	piperazine-*N,N'-bis*(2-ethanesulfonic acid)	302.4	6.8	6.1–7.5
MOPSO	3-(*N*-morpholino)-2-hydroxypropanesulfonic acid	225.3	6.9	6.2–7.6
Bis-Tris Propane	1,3-*bis*[*tris*(hydroxymethyl)methylamino]propane	282.3	6.8[a]	6.3–9.5
BES	*N,N-bis*(2-hydroxyethyl)-2-aminoethanesulfonic acid	213.2	7.1	6.4–7.8
MOPS	3-(*N*-morpholino)propanesulfonic acid	209.3	7.2	6.5–7.9
HEPES	*N*-(2-hydroxyethyl)piperazine-*N'*-(2-ethanesulfonic acid)	238.3	7.5	6.8–8.2
TES	*N-tris*(hydroxymethyl)methyl-2-aminoethanesulfonic acid	229.2	7.4	6.8–8.2
DIPSO	3-[*N,N-bis*(2-hydroxyethyl)amino]-2-hydroxypropanesulfonic acid	243.3	7.6	7.0–8.2
TAPSO	3-[*N-tris*(hydroxymethyl)methylamino]-2-hydroxypropanesulfonic acid	259.3	7.6	7.0–8.2
TRIZMA	*tris*(hydroxymethyl)aminomethane	121.1	8.1	7.0-9.1
HEPPSO	*N*-(2-hydroxyethyl)piperazine-*N'*-(2-hydroxypropanesulfonic acid)	268.3	7.8	7.1–8.5
POPSO	piperazine-*N,N'-bis*(2-hydroxypropanesulfonic acid)	362.4	7.8	7.2-8.5
EPPS	*N*-(2-hydroxyethyl)piperazine-*N'*-(3-propanesulfonic acid)	252.3	8.0	7.3–8.7
TEA	triethanolamine	149.2	7.8	7.3–8.3
Tricine	*N-tris*(hydroxymethyl)methylglycine	179.2	8.1	7.4–8.8
Bicine	*N,N-bis*(2-hydroxyethyl)glycine	163.2	8.3	7.6–9.0
TAPS	*N-tris*(hydroxymethyl)methyl-3-aminopropanesulfonic acid	243.3	8.4	7.7–9.1
AMPSO	3-[(1,1-dimethyl-2-hydroxyethyl)amino]-2-hydroxypropanesulfonic acid	227.3	9.0	8.3–9.7
CHES	2-(*N*-cyclohexylamino)ethanesulfonic acid	207.3	9.3	8.6–10.0
CAPSO	3-(cyclohexylamino)-2-hydroxy-1-propanesulfonic acid	237.3	9.6	8.9–10.3
AMP	2-amino-2-methyl-1-propanol	89.1	9.7	9.0–10.5
CAPS	3-(cyclohexylamino)-1-propanesulfonic acid	221.3	10.4	9.7–11.1

Data compiled from various sources, including *Biochemical and Reagents for Life Science Research* 1994 (Sigma-Aldrich) and references therein.

[a] pK_a = 9.0 for the second dissociation stage.

Phosphate Buffers (Gomori Buffers)

The most commonly used phosphate buffers are named after their inventor: Gomori (Gomori 1955). They consist of a mixture of monobasic dihydrogen phosphate and dibasic monohydrogen phosphate. By varying the amount of each salt, a range of buffers can be prepared that buffer well between pH 5.8 and pH 8.0 (please see Tables A1-3A and A1-3B). Phosphates have a very high buffering capacity and are highly soluble in water. However, they have a number of potential disadvantages:

- Phosphates inhibit many enzymatic reactions and procedures that are the foundation of molecular cloning, including cleavage of DNA by many restriction enzymes, ligation of DNA, and bacterial transformation.
- Because phosphates precipitate in ethanol, it is not possible to precipitate DNA and RNA from buffers that contain significant quantities of phosphate ions.
- Phosphates sequester divalent cations such as Ca^{2+} and Mg^{2+}.

TABLE A1-3A Preparation of 0.1 M Potassium Phosphate Buffer at 25°C

pH	Volume of 1 M K_2HPO_4 (ml)	Volume of 1 M KH_2PO_4 (ml)
5.8	8.5	91.5
6.0	13.2	86.8
6.2	19.2	80.8
6.4	27.8	72.2
6.6	38.1	61.9
6.8	49.7	50.3
7.0	61.5	38.5
7.2	71.7	28.3
7.4	80.2	19.8
7.6	86.6	13.4
7.8	90.8	9.2
8.0	94.0	6.0

Data from Green (1933).

Dilute the combined 1 M stock solutions to 1 liter with distilled H_2O. pH is calculated according to the Henderson-Hasselbalch equation:

$$pH = pK' + \log \left\{ \frac{\text{(proton acceptor)}}{\text{proton donor}} \right\}$$

where $pK' = 6.86$ at 25°C.

TABLE A1-3B Preparation of 0.1 M Sodium Phosphate Buffer at 25°C

pH	Volume of 1 M Na_2HPO_4 (ml)	Volume of 1 M NaH_2PO_4 (ml)
5.8	7.9	92.1
6.0	12.0	88.0
6.2	17.8	82.2
6.4	25.5	74.5
6.6	35.2	64.8
6.8	46.3	53.7
7.0	57.7	42.3
7.2	68.4	31.6
7.4	77.4	22.6
7.6	84.5	15.5
7.8	89.6	10.4
8.0	93.2	6.8

Data from ISCO (1982).

Dilute the combined 1 M stock solutions to 1 liter with distilled H_2O. pH is calculated according to the Henderson-Hasselbalch equation:

$$pH = pK' + \log \left\{ \frac{\text{(proton acceptor)}}{\text{proton donor}} \right\}$$

where $pK' = 6.86$ at 25°C.

ACIDS AND BASES

TABLE A1-4 Concentrations of Acids and Bases: Common Commercial Strengths

Substance	Formula	M.W.	Moles/ Liter[a]	Grams/ Liter	% by Weight	Specific Gravity	ml/Liter to Prepare 1 M Solution
Acetic acid, glacial	CH_3COOH	60.05	17.4	1045	99.5	1.05	57.5
Acetic acid		60.05	6.27	376	36	1.045	159.5
Formic acid	HCOOH	46.02	23.4	1080	90	1.20	42.7
Hydrochloric acid	HCl	36.5	11.6	424	36	1.18	86.2
			2.9	105	10	1.05	344.8
Nitric acid	HNO_3	63.02	15.99	1008	71	1.42	62.5
			14.9	938	67	1.40	67.1
			13.3	837	61	1.37	75.2
Perchloric acid	$HClO_4$	100.5	11.65	1172	70	1.67	85.8
			9.2	923	60	1.54	108.7
Phosphoric acid	H_3PO_4	80.0	18.1	1445	85	1.70	55.2
Sulfuric acid	H_2SO_4	98.1	18.0	1766	96	1.84	55.6
Ammonium hydroxide	NH_4OH	35.0	14.8	251	28	0.898	67.6
Potassium hydroxide	KOH	56.1	13.5	757	50	1.52	74.1
			1.94	109	10	1.09	515.5
Sodium hydroxide	NaOH	40.0	19.1	763	50	1.53	52.4
			2.75	111	10	1.11	363.6

[a]With some acids and bases, stock solutions of different molarity/normality are in common use. These are often abbreviated "conc" for concentrated stocks and "dil" for dilute stocks.

TABLE A1-5 Approximate pH Values for Various Concentrations of Stock Solutions

Substance	1 N	0.1 N	0.01 N	0.001 N
Acetic acid	2.4	2.9	3.4	3.9
Hydrochloric acid	0.10	1.07	2.02	3.01
Sulfuric acid	0.3	1.2	2.1	
Citric acid		2.1	2.6	
Ammonium hydroxide	11.8	11.3	10.8	10.3
Sodium hydroxide	14.05	13.07	12.12	11.13
Sodium bicarbonate		8.4		
Sodium carbonate		11.5	11.0	

PREPARATION OF BUFFERS AND STOCK SOLUTIONS FOR USE IN MOLECULAR BIOLOGY

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

pH Buffers

Phosphate-buffered Saline (PBS)

137 mM NaCl
2.7 mM KCl
10 mM Na_2HPO_4
2 mM KH_2PO_4

Dissolve 8 g of NaCl, 0.2 g of KCl, 1.44 g of Na_2HPO_4, and 0.24 g of KH_2PO_4 in 800 ml of distilled H_2O. Adjust the pH to 7.4 with HCl. Add H_2O to 1 liter. Dispense the solution into aliquots and sterilize them by autoclaving for 20 minutes at 15 psi (1.05 kg/cm^2) on liquid cycle or by filter sterilization. Store the buffer at room temperature.

PBS is a commonly used reagent that has been adapted for different applications. Note that the recipe presented here lacks divalent cations. If necessary, PBS may be supplemented with 1 mM $CaCl_2$ and 0.5 mM $MgCl_2$.

10x Tris EDTA (TE)

pH 7.4
100 mM Tris-Cl (pH 7.4)
10 mM EDTA (pH 8.0)

pH 7.6
100 mM Tris-Cl (pH 7.6)
10 mM EDTA (pH 8.0)

pH 8.0
100 mM Tris-Cl (pH 8.0)
10 mM EDTA (pH 8.0)

Sterilize solutions by autoclaving for 20 minutes at 15 psi (1.05 kg/cm^2) on liquid cycle. Store the buffer at room temperature.

Tris-Cl (1 M)

Dissolve 121.1 g of Tris base in 800 ml of H_2O. Adjust the pH to the desired value by adding concentrated HCl <!>.

pH	*HCl*
7.4	70 ml
7.6	60 ml
8.0	42 ml

Allow the solution to cool to room temperature before making final adjustments to the pH. Adjust the volume of the solution to 1 liter with H_2O. Dispense into aliquots and sterilize by autoclaving.

If the 1 M solution has a yellow color, discard it and obtain Tris of better quality. The pH of Tris solutions is temperature-dependent and decreases ~0.03 pH units for each 1°C increase in temperature. For example, a 0.05 M solution has pH values of 9.5, 8.9, and 8.6 at 5°C, 25°C, and 37°C, respectively.

Tris Magnesium Buffer (TM)

50 mM Tris-Cl (pH 7.8)
10 mM $MgSO_4$

Tris-buffered Saline (TBS)

Dissolve 8 g of NaCl, 0.2 g of KCl, and 3 g of Tris base in 800 ml of distilled H_2O. Add 0.015 g of phenol red and adjust the pH to 7.4 with HCl. Add distilled H_2O to 1 liter. Dispense the solution into aliquots and sterilize them by autoclaving for 20 minutes at 15 psi (1.05 kg/cm^2) on liquid cycle. Store the buffer at room temperature.

Enzyme Stocks and Buffers

Enzyme Stocks

Lysozyme (10 mg/ml)

Dissolve solid lysozyme at a concentration of 10 mg/ml in 10 mM Tris-Cl (pH 8.0) immediately before use. Make sure that the pH of the Tris solution is 8.0 before dissolving the protein. Lysozyme will not work efficiently if the pH of the solution is less than 8.0.

Lyticase (67 mg/ml)

Purchase from Sigma. Dissolve at 67 mg/ml (900 units/ml) in 0.01 M sodium phosphate containing 50% glycerol just before use.

Pancreatic DNase I (1 mg/ml)

Dissolve 2 mg of crude pancreatic DNase I (Sigma or equivalent) in 1 ml of

10 mM Tris-Cl (pH 7.5)
150 mM NaCl
1 mM $MgCl_2$

When the DNase I is dissolved, add 1 ml of glycerol to the solution and mix by gently inverting the closed tube several times. Take care to avoid creating bubbles and foam. Store the solution in aliquots of –20°C.

Pancreatic RNase (1 mg/ml)

Dissolve 2 mg of crude pancreatic RNase I (Sigma or equivalent) in 2 ml of TE (pH 7.6).

Proteinase K (20 mg/ml)

Purchase as a lyophilized powder and dissolve at a concentration of 20 mg/ml in sterile 50 mM Tris (pH 8.0), 1.5 mM calcium acetate. Divide the stock solution into small aliquots and store at –20°C. Each aliquot can be thawed and refrozen several times but should then be discarded. Unlike much cruder preparations of protease (e.g., pronase), proteinase K need not be self-digested before use. (Please see entry on Proteinase K in Appendix 4.)

Trypsin

Prepare bovine trypsin at a concentration of 250 µg/ml in 200 mM ammonium bicarbonate (pH 8.9) (Sequencer grade; Boehringer Mannheim). Store the solution in aliquots at –20°C.

Zymolyase 5000 (2 mg/ml)

Purchase from Kirin Breweries. Dissolve at 2 mg/ml in 0.01 M sodium phosphate containing 50% glycerol just before use.

Enzyme Dilution Buffers

DNase I Dilution Buffer

10 mM Tris-Cl (pH 7.5)
150 mM NaCl
1 mM $MgCl_2$

Polymerase Dilution Buffer

50 mM Tris-Cl (pH 8.1)
1 mM dithiothreitol
0.1 mM EDTA (pH 8.0)
0.5 mg/ml bovine serum albumin
5% (v/v) glycerol

Prepare solution fresh for each use.

Sequenase Dilution Buffer

10 mM Tris-Cl (pH 7.5)
5 mM dithiothreitol
0.5 mg/ml bovine serum albumin

Store the solution at –20°C.

***Taq* Dilution Buffer**

25 mM Tris (pH 8.8)
0.01 mM EDTA (pH 8.0)
0.15% (v/v) Tween-20
0.15% (v/v) Nonidet P-40

Enzyme Reaction Buffers

▲ **IMPORTANT** Wherever possible, use the 10x reaction buffer supplied by the manufacturer of the enzyme used. Otherwise, use the recipes given here.

10x Amplification Buffer

500 mM KCl
100 mM Tris-Cl (pH 8.3 at room temperature)
15 mM $MgCl_2$

Autoclave the 10x buffer for 10 minutes at 15 psi (1.05 kg/cm^2) on liquid cycle. Divide the sterile buffer into aliquots and store them at –20°C.

10x Bacteriophage T4 DNA Ligase Buffer

200 mM Tris-Cl (pH 7.6)
50 mM $MgCl_2$
50 mM dithiothreitol
0.5 mg/ml bovine serum albumin (Fraction V; Sigma) (*optional*)

Divide the buffer in small aliquots and store at –20°C. Add ATP when setting up the reaction. Add ATP to the reaction to an appropriate concentation (e.g., 1 mM).

10x Bacteriophage T4 DNA Polymerase Buffer

330 mM Tris-acetate (pH 8.0)
660 mM potassium acetate
100 mM magnesium acetate
5 mM dithiothreitol
1 mg/ml bovine serum albumin (Fraction V; Sigma)

Divide the 10x stock into small aliquots and store frozen at –20°C.

10x Bacteriophage T4 Polynucleotide Kinase Buffer

700 mM Tris-Cl (pH 7.6)
100 mM $MgCl_2$
50 mM dithiothreitol

Divide the 10x stock into small aliquots and store frozen at –20°C.

5x BAL 31 Buffer

3 M NaCl
60 mM $CaCl_2$
60 mM $MgCl_2$
100 mM Tris-Cl (pH 8.0)
1 mM EDTA (pH 8.0)

10x Dephosphorylation Buffer (for Use with CIP)

100 mM Tris-Cl (pH 8.3)
10 mM $MgCl_2$
10 mM $ZnCl_2$

10x Dephosphorylation Buffer (for Use with SAP)

200 mM Tris-Cl (pH 8.8)
100 mM $MgCl_2$
10 mM $ZnCl_2$

1x *Eco*RI Methylase Buffer

50 mM NaCl
50 mM Tris-Cl (pH 8.0)
10 mM EDTA
80 µM *S*-adenosylmethionine

Store the buffer in small aliquots at –20°C.

10x Exonuclease III Buffer

660 mM Tris-Cl (pH 8.0)
66 mM $MgCl_2$
100 mM β-mercaptoethanol **<!>**

Add β-mercaptoethanol just before use.

10x Klenow Buffer

0.4 M potassium phosphate (pH 7.5)
66 mM $MgCl_2$
10 mM β-mercaptoethanol **<!>**

10x Linker Kinase Buffer

600 mM Tris-Cl (pH 7.6)
100 mM $MgCl_2$
100 mM dithiothreitol
2 mg/ml bovine serum albumin

Prepare fresh just before use.

Nuclease S1 Digestion Buffer

0.28 M NaCl
0.05 M sodium acetate (pH 4.5)
4.5 mM $ZnSO_4 \cdot 7H_2O$

Store aliquots of nuclease S1 buffer at –20°C, and add nuclease S1 to a concentration of 500 units/ml just before use.

10x Proteinase K Buffer

100 mM Tris-Cl (pH 8.0)
50 mM EDTA (pH 8.0)
500 mM NaCl

10x Reverse Transcriptase Buffer

500 mM Tris-Cl (pH 8.3)
750 mM KCl
30 mM $MgCl_2$

RNase H Buffer

20 mM Tris-Cl (pH 7.6)
20 mM KCl
0.1 mM EDTA (pH 8.0)
0.1 mM dithiothreitol

Prepare fresh just before use.

5x Terminal Transferase Buffer

Most manufacturers supply a 5x reaction buffer, which typically contains:

500 mM potassium cacodylate (pH 7.2) <!>
10 mM $CoCl_2 \cdot 6H_2O$
1 mM dithiothreitol

5x terminal transferase (or tailing) buffer may be prepared according to the following method (Eschenfeldt et al. 1987):

1. Equilibrate 5 g of Chelex 100 (Bio-Rad) with 10 ml of 3 M potassium acetate at room temperature.
2. After five minutes, remove excess liquid by vacuum suction. Wash the Chelex three times with 10 ml of deionized H_2O.
3. Prepare a 1 M solution of potassium cacodylate. Equilibrate the cacodylate solution with the treated Chelex resin.
4. Recover the cacodylate solution by passing it through a Buchner funnel fitted with Whatman No. 1 filter paper.

5. To the recovered cacodylate add in order: H_2O, dithiothreitol, and cobalt chloride to make the final concentrations of 500 mM potassium cacodylate, 1 mM dithiothreitol, and 20 mM $CoCl_2$.

   Store the buffer in aliquots at –20°C.

10x Universal KGB (Restriction Endonuclease) Buffer

1 M potassium acetate
250 mM Tris-acetate (pH 7.6)
100 mM magnesium acetate tetrahydrate
5 mM β-mercaptoethanol <!>
0.1 mg/ml bovine serum albumin

Store the 10x buffer in aliquots at –20°C.

Hybridization Buffers

Alkaline Transfer Buffer (for Alkaline Transfer of DNA to Nylon Membranes)

0.4 N NaOH <!>
1 M NaCl

Church Buffer

1% (w/v) bovine serum albumin
1 mM EDTA
0.5 M phosphate buffer*
7% (w/v) SDS

*0.5 M phosphate buffer is 134 g of $Na_2HPO_4 \cdot 7H_2O$, 4 ml of 85% H_3PO_4 <!> (concentrated phosphoric acid), H_2O to 1 liter.

Denaturation Solution (for Neutral Transfer, Double-stranded DNA Targets Only)

1.5 M NaCl
0.5 M NaOH <!>

HCl (2.5 N)

Add 25 ml of concentrated HCl <!> (11.6 N) to 91 ml of sterile H_2O. Store the diluted solution at room temperature.

Hybridization Buffer with Formamide (for RNA)

40 mM PIPES (pH 6.8)
1 mM EDTA (pH 8.0)
0.4 M NaCl
80% (v/v) deionized formamide <!>

Use the disodium salt of PIPES to prepare the buffer, and adjust the pH to 6.4 with 1 N HCl.

Hybridization Buffer without Formamide (for RNA)

40 mM PIPES (pH 6.4)
0.1 mM EDTA (pH 8.0)
0.4 M NaCl

Use the disodium salt of PIPES to prepare the buffer, and adjust the pH to 6.4 with 1 N HCl.

Neutralization Buffer I (for Transfer of DNA to Uncharged Membranes)

1 M Tris-Cl (pH 7.4)
1.5 M NaCl

Neutralization Buffer II (for Alkaline Transfer of DNA to Nylon Membranes)

0.5 M Tris-Cl (pH 7.2)
1 M NaCl

Neutralizing Solution (for Neutral Transfer, Double-stranded DNA Targets Only)

0.5 M Tris-Cl (pH 7.4)
1.5 M NaCl

Prehybridization Solution (for Dot, Slot, and Northern Hybridization)

0.5 M sodium phosphate (pH 7.2)*
7% (w/v) SDS
1 mM EDTA (pH 7.0)

*0.5 M phosphate buffer is 134 g of $Na_2HPO_4 \cdot 7H_2O$, 4 ml of 85% H_3PO_4 <!> (concentrated phosphoric acid), H_2O to 1 liter.

Prehybridization and Hybridization Solutions

Prehybridization/Hybridization Solution (for Plaque/Colony Lifts)

50% (v/v) formamide (*optional*) <!>
6x SSC (or 6x SSPE)
0.05x BLOTTO

As an alternative to the above solution, use Church Buffer (please see recipe on p. A1.12). For advice on which hybridization solution to use, please see the panel on **PREHYBRIDIZATION AND HYBRIDIZATION SOLUTIONS** in Step 5 of Protocol 32 in Chapter 1. For advice on the use of formamide, please see the information panel on **FORMAMIDE AND ITS USES IN MOLECULAR CLONING** in Chapter 6.

Prehybridization/Hybridization Solution (for Hybridization in Aqueous Buffer)

6x SSC (or 6x SSPE)
5x Denhardt's reagent (see p. A1.15)
0.5% (w/v) SDS
1 µg/ml poly(A)
100 µg/ml salmon sperm DNA

Prehybridization/Hybridization Solution (for Hybridization in Formamide Buffers)

6x SSC (or 6x SSPE)
5x Denhardt's reagent (see A1.15)
0.5% (w/v) SDS
1 µg/ml poly(A)
100 µg/ml salmon sperm DNA
50% (v/v) formamide <!>

After a thorough mixing, filter the solution through a 0.45-µm disposable cellulose acetate membrane (Schleicher & Schuell Uniflow syringe membrane or equivalent). To decrease background when hybridizing under conditions of reduced stringency (e.g., 20–30% formamide), it is important to use formamide that is as pure as possible.

Prehybridization/Hybridization Solution (for Hybridization in Phosphate-SDS Buffer)

0.5 M phosphate buffer (pH 7.2)*
1 mM EDTA (pH 8.0)
7% (w/v) SDS
1% (w/v) bovine serum albumin

Use an electrophoresis grade of bovine serum albumin. No blocking agents or hybridization rate enhancers are required with this particular prehybridization/hybridization solution.
*0.5 M phosphate buffer is 134 g of $Na_2HPO_4 \cdot 7H_2O$, 4 ml of 85% H_3PO_4 <!> (concentrated phosphoric acid), H_2O to 1 liter.

20× SSC

Dissolve 175.3 g of NaCl and 88.2 g of sodium citrate in 800 ml of H_2O. Adjust the pH to 7.0 with a few drops of a 14 N solution of HCl <!>. Adjust the volume to 1 liter with H_2O. Dispense into aliquots. Sterilize by autoclaving. The final concentrations of the ingredients are 3.0 M NaCl and 0.3 M sodium acetate.

20× SSPE

Dissolve 175.3 g of NaCl, 27.6 g of $NaH_2PO_4 \cdot H_2O$, and 7.4 g of EDTA in 800 ml of H_2O. Adjust the pH to 7.4 with NaOH <!> (~6.5 ml of a 10 N solution). Adjust the volume to 1 liter with H_2O. Dispense into aliquots. Sterilize by autoclaving. The final concentrations of the ingredients are 3.0 M NaCl, 0.2 M NaH_2PO_4, and 0.02 M EDTA.

Blocking Agents

Blocking agents prevent ligands from sticking to surfaces. They are used in molecular cloning to stop nonspecific binding of probes in Southern, northern, and western blotting. If left to their own devices, these probes would bind tightly and nonspecifically to the supporting nitrocellulose or nylon membrane. Without blocking agents, it would be impossible to detect anything but the strongest target macromolecules.

No one knows for sure what causes nonspecific binding of probes. Hydrophobic patches, lignin impurities, excessively high concentrations of probe, overbaking or underbaking of nitrocellulose filters, and homopolymeric sequences in nucleic acid probes have all been blamed from time to time, together with a host of less likely culprits. Whatever the cause, the solution is generally simple: Treat the filters with a blocking solution containing a cocktail of substances that will compete with the probe for nonspecific binding sites on the solid support. Blocking agents work by brute force. They are used in high concentrations and generally consist of a cocktail of high-molecular-weight polymers (heparin, polyvinylpyrrolidine, nucleic acids), proteins (bovine serum albumin, nonfat dried milk), and detergents (SDS or Nonidet P-40). The following recommendations apply only to nylon and nitrocellulose filters. Charged nylon filters should be treated as described by the individual manufacturer.

Blocking Agents Used for Nucleic Acid Hybridization. Two blocking agents in common use in nucleic acid hybridization are Denhardt's reagent (Denhardt 1966) and BLOTTO (Bovine Lacto Transfer Technique Optimizer; Johnson et al. 1984). Usually, the filters carrying the immobilized target molecules are incubated with the blocking agents for an hour or two before the probe is added. In most cases, background hybridization is completely suppressed when filters are incubated with a blocking agent consisting of 6× SSC or SSPE containing 5× Denhardt's reagent, 1.0% SDS, and 100 mg/ml denatured, sheared salmon sperm DNA. This mixture should be used

whenever the ratio of signal to noise is expected to be low, for example, when carrying out northern analysis of low-abundance RNAs or Southern analysis of single-copy sequences of mammalian DNA. However, in most other circumstances (Grunstein-Hogness hybridization, Benton-Davis hybridization, Southern hybridization of abundant DNA sequences, etc.), a less expensive alternative is 6× SSC or SSPE containing 0.25–0.5% nonfat dried milk (BLOTTO; Johnson et al. 1984).

Blocking agents are usually included in both prehybridization and hybridization solutions when nitrocellulose filters are used. However, when the target nucleic acid is immobilized on nylon membranes, the blocking agents are often omitted from the hybridization solution. This is because high concentrations of protein are believed to interfere with the annealing of the probe to its target. Quenching of the hybridization signal by blocking agents is particularly noticeable when oligonucleotides are used as probes. This problem can often be solved by carrying out the hybridization step in a solution containing high concentrations of SDS (6–7%), sodium phosphate (0.4 M), bovine serum albumin (1%), and EDTA (0.02 M) (Church and Gilbert 1984).

Heparin is sometimes used instead of Denhardt's solution or BLOTTO when hybridization is carried out in the presence of the accelerator, dextran sulfate. It is used at a concentration of 500 µg/ml in hybridization solutions containing dextran sulfate. In hybridization solutions that do not contain dextran sulfate, heparin is used at a concentration of 50 µg/ml (Singh and Jones 1984). Heparin (Sigma porcine grade II or equivalent) is dissolved at a concentration of 50 mg/ml in 4× SSPE or SSC and stored at 4°C.

DENHARDT'S REAGENT

Denhardt's reagent is used for

- northern hybridization
- single-copy Southern hybridization
- hybridizations involving DNA immobilized on nylon membranes

Denhardt's reagent is usually made up as a 50× stock solution, which is filtered and stored at –20°C. The stock solution is diluted tenfold into prehybridization buffer (usually 6× SSC or 6× SSPE containing 1.0% SDS and 100 µg/ml denatured salmon sperm DNA). 50× Denhardt's reagent contains in H_2O (Denhardt 1966):

1% (w/v) Ficoll 400
1% (w/v) polyvinylpyrrolidone
1% (w/v) bovine serum albumin (Sigma, Fraction V)

BLOTTO <!>

BLOTTO is used for

- Grunstein-Hogness hybridization
- Benton-Davis hybridization
- all Southern hybridizations other than single-copy dot blots and slot blots

1× BLOTTO is 5% (w/v) nonfat dried milk dissolved in H_2O containing 0.02% sodium azide **<!>**. 1× BLOTTO is stored at 4°C and is diluted 10–25-fold into prehybridization buffer before use. BLOTTO should not be used in combination with high concentrations of SDS, which will cause the milk proteins to precipitate. If background hybridization is a problem, Nonidet P-40 may be added to a final concentration of 1% (v/v).

BLOTTO may contain high levels of RNase and should be treated with diethylpyrocarbonate (Siegel and Bresnick 1986) or heated overnight to 72°C (Monstein et al. 1992) when used in northern hybridizations and when RNA is used as a probe. BLOTTO is not as effective as Denhardt's solution when the target DNA is immobilized on nylon filters.

Blocking Agents Used for Western Blotting. The best and least expensive blocking reagent is nonfat dried milk (Johnson et al. 1984). It is easy to use and is compatible with all of the common immunological detection systems. The only time nonfat dried milk should not be used is when western blots are probed for proteins that may be present in milk.

One of the following recipes may be used to prepare blocking buffer. A blocking solution for western blots is phosphate-buffered saline containing 5% (w/v) nonfat dried milk, 0.01% Antifoam, and 0.02% sodium azide.

Blocking Buffer (TNT Buffer Containing a Blocking Agent)

10 mM Tris-Cl (pH 8.0)
150 mM NaCl
0.05% (v/v) Tween-20
blocking agent (1% [w/v] gelatin, 3% [w/v] bovine serum albumin, or 5% [w/v] nonfat dried milk)

Opinion about which of these blocking agents is best varies from laboratory to laboratory. We recommend carrying out preliminary experiments to determine which of them works best. Blocking buffer can be stored at 4°C and reused several times. Sodium azide <!> should be added to a final concentration of 0.05% (w/v) to inhibit the growth of microorganisms.

Extraction/Lysis Buffers and Solutions

Alkaline Lysis Solution I (Plasmid Preparation)

50 mM glucose
25 mM Tris-Cl (pH 8.0)
10 mM EDTA (pH 8.0)

Prepare Solution I from standard stocks in batches of ~100 ml, autoclave for 15 minutes at 15 psi (1.05 kg/cm^2) on liquid cycle, and store at 4°C.

Alkaline Lysis Solution II (Plasmid Preparation)

0.2 N NaOH (freshly diluted from a 10 N stock) <!>
1% (w/v) SDS

Prepare Solution II fresh and use at room temperature.

Alkaline Lysis Solution III (Plasmid Preparation)

5 M potassium acetate	60.0 ml
glacial acetic acid <!>	11.5 ml
H_2O	28.5 ml

The resulting solution is 3 M with respect to potassium and 5 M with respect to acetate. Store the solution at 4°C and transfer it to an ice bucket just before use.

STET

10 mM Tris-Cl (pH 8.0)
0.1 M NaCl
1 mM EDTA (pH 8.0)
5% (v/v) Triton X-100

Make sure that the pH of STET is 8.0 after all ingredients are added. There is no need to sterilize STET before use.

Electrophoresis and Gel-loading Buffers

Commonly Used Electrophoresis Buffers

Buffer	Working Solution	Stock Solution/Liter
TAE	**1x**	**50x**
	40 mM Tris-acetate	242 g of Tris base
	1 mM EDTA	57.1 ml of glacial acetic acid <!>
		100 ml of 0.5 M EDTA (pH 8.0)
TBE[a]	**0.5x**	**5x**
	45 mM Tris-borate	54 g of Tris base
	1 mM EDTA	27.5 g of boric acid
		20 ml of 0.5 M EDTA (pH 8.0)
TPE	1x	**10x**
	90 mM Tris-phosphate	108 g of Tris base
	2 mM EDTA	15.5 ml of phosphoric acid <!>
		(85%, 1.679 g/ml)
		40 ml of 0.5 M EDTA (pH 8.0)
Tris-glycine[b]	**1x**	**5x**
	25 mM Tris-Cl	15.1 g of Tris base
	250 mM glycine	94 g of glycine (electrophoresis grade)
	0.1% SDS	50 ml of 10% SDS (electrophoresis grade)

[a]TBE is usually made and stored as a 5x or 10x stock solution. The pH of the concentrated stock buffer should be ~8.3. Dilute the concentrated stock buffer just before use and make the gel solution and the electrophoresis buffer from the same concentrated stock solution. Some investigators prefer to use more concentrated stock solutions of TBE (10x as opposed to 5x). However, 5x stock solution is more stable because the solutes do not precipitate during storage. Passing the 5x or 10x buffer stocks through a 0.22-μm filter can prevent or delay formation of precipitates.

[b]Use Tris-glycine buffers for SDS-polyacrylamide gels (see Appendix 8).

Specialized Electrophoresis Buffers

10x Alkaline Agarose Gel Electrophoresis Buffer

500 mM NaOH <!>
10 mM EDTA

Add 50 ml of 10 N NaOH and 20 ml of 0.5 M EDTA (pH 8.0) to 800 ml of H_2O and then adjust the final volume to 1 liter. Dilute the 10x alkaline agarose gel electrophoresis buffer with H_2O to generate a 1x working solution immediately before use. Use the same stock of 10x alkaline agarose gel electrophoresis buffer to prepare the alkaline agarose gel and the 1x working solution of alkaline electrophoresis buffer.

10x BPTE Electrophoresis Buffer

100 mM PIPES
300 mM Bis-Tris
10 mM EDTA

The final pH of the 10x buffer is ~6.5. The 10x buffer can be made by adding 3 g of PIPES (free acid), 6 g of Bis-Tris (free base), and 2 ml of 0.5 M EDTA to 90 ml of distilled H_2O and then treating the solution with diethylpyrocarbonate <!> (final concentration 0.1%; for more details, please see the information panel on **DIETHYLPYROCARBONATE** in Chapter 7).

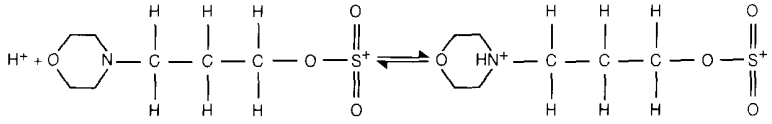
10x MOPS Electrophoresis Buffer

0.2 M MOPS (pH 7.0) <!>
20 mM sodium acetate
10 mM EDTA (pH 8.0)

Dissolve 41.8 g of MOPS in 700 ml of sterile DEPC-treated <!> H_2O. Adjust the pH to 7.0 with 2 N NaOH. Add 20 ml of DEPC-treated 1 M sodium acetate and 20 ml of DEPC-treated 0.5 M EDTA (pH 8.0). Adjust the volume of the solution to 1 liter with DEPC-treated H_2O. Sterilize the solution by passing it through a 0.45-µm Millipore filter, and store it at room temperature protected from light. The buffer yellows with age if it is exposed to light or is autoclaved. Straw-colored buffer works well, but darker buffer does not.

MOPS (3[*N*-MORPHOLINO]PROPANESULFONIC ACID

FW	pK_α (20°C)	ΔpK_α/°C	Molar strength of saturated solution at 0°C
209.3	7.15	–0.013	3.1



MOPS is one of the buffers developed by Robert Good's laboratories in the 1970s to facilitate isolation of chloroplasts and other plant organelles (for reviews, please see Good and Izawa 1972; Ferguson et al. 1980; please also see figure above). In molecular cloning, MOPS is a component of buffers used for the electrophoresis of RNA through agarose gels (Lehrach et al. 1977; Goldberg 1980).

TAFE Gel Electrophoresis Buffer

20 mM Tris-acetate (pH 8.2)
0.5 mM EDTA

Use acetic acid to adjust the pH of the Tris solution to 8.2, and use the free acid of EDTA, not the sodium salt. Concentrated solutions of TAFE buffer can also be purchased (e.g., from Beckman).

▲ **IMPORTANT** The TAFE gel electrophoresis buffer must be cooled to 14°C before use.

Gel-loading Buffers

6x Alkaline Gel-loading Buffer

300 mM NaOH <!>
6 mM EDTA
18% (w/v) Ficoll (Type 400, Pharmacia)
0.15% (w/v) bromocresol green
0.25% (w/v) xylene cyanol

Bromophenol Blue Solution (0.4%, w/v)

Dissolve 4 mg of solid bromophenol blue in 1 ml of sterile H_2O. Store the solution at room temperature.

TABLE A1-6 6× Gel-loading Buffers

Buffer Type	6× Buffer	Storage Temperature
I	0.25% (w/v) bromophenol blue 0.25% (w/v) xylene cyanol FF 40% (w/v) sucrose in H_2O	4°C
II	0.25% (w/v) bromophenol blue 0.25% (w/v) xylene cyanol FF 15% (w/v) Ficoll (Type 400; Pharmacia) in H_2O	room temperature
III	0.25% (w/v) bromophenol blue 0.25% (w/v) xylene cyanol FF 30% (v/v) glycerol in H_2O	4°C
IV	0.25% (w/v) bromophenol blue 40% (w/v) sucrose in H_2O	4°C

Bromophenol Blue Sucrose Solution

0.25% (w/v) bromophenol blue
40% (w/v) sucrose

Cresol Red Solution (10 mM)

Dissolve 4 mg of the sodium salt of cresol red (Aldrich) in 1 ml of sterile H_2O. Store the solution at room temperature.

10X Formaldehyde Gel-loading Buffer

50% (v/v) glycerol (diluted in DEPC-treated <!> H_2O)
10 mM EDTA (pH 8.0)
0.25% (w/v) bromophenol blue
0.25% (w/v) xylene cyanol FF

Formamide-loading Buffer

80% (w/v) deionized formamide <!>
10 mM EDTA (pH 8.0)
1 mg/ml xylene cyanol FF
1 mg/ml bromophenol blue

Purchase a distilled deionized preparation of formamide and store in small aliquots under nitrogen at –20°C. Alternatively, deionize reagent-grade formamide as described in Appendix 8.

RNA Gel-loading Buffer

95% (v/v) deionized formamide <!>
0.025% (w/v) bromophenol blue
0.025% (w/v) xylene cyanol FF
5 mM EDTA (pH 8.0)
0.025% (w/v) SDS

2x SDS Gel-loading Buffer

100 mM Tris-Cl (pH 6.8)
4% (w/v) SDS (electrophoresis grade)
0.2% (w/v) bromophenol blue
20% (v/v) glycerol
200 mM dithiothreitol or β-mercaptoethanol <!>

1x and 2x SDS gel-loading buffer lacking thiol reagents can be stored at room temperature. Add the thiol reagents from 1 M (dithiothreitol) or 14 M (β-mercaptoethanol) stocks just before the buffer is used.

2.5x SDS-EDTA Dye Mix

0.4% (v/v) SDS
30 mM EDTA
0.25% bromophenol blue
0.25% xylene cyanol FF
20% (w/v) sucrose

Special Buffers and Solutions

Elution Buffer (Qiagen)

50 mM Tris-Cl (pH 8.1–8.2)
1.4 M NaCl
15% (v/v) ethanol

KOH/Methanol Solution

This solution is for cleaning the glass plates used to cast sequencing gels. It is prepared by dissolving 5 g of KOH <!> pellets in 100 ml of methanol <!>. Store the solution at room temperature in a tightly capped glass bottle.

λ Annealing Buffer

100 mM Tris-Cl (pH 7.6)
10 mM $MgCl_2$

LB Freezing Buffer

36 mM K_2HPO_4 (anhydrous)
13.2 mM KH_2PO_4
1.7 mM sodium citrate
0.4 mM $MgSO_4 \cdot 7H_2O$
6.8 mM ammonium sulfate
4.4% (v/v) glycerol
in LB broth

LB freezing buffer (Zimmer and Verrinder Gibbins 1997) is best made by dissolving the salts in 100 ml of LB to the specified concentrations. Measure 95.6 ml of the resulting solution into a fresh container and then add 4.4 ml of glycerol. Mix the solution well and then sterilize by passing it through a 0.45-μm disposable Nalgene filter. Store the sterile freezing medium at a controlled room temperature (15–25°C).

$MgCl_2$–$CaCl_2$ Solution

80 mM $MgCl_2$
20 mM $CaCl_2$

P3 Buffer (Qiagen)

3 M potassium acetate (pH 5.5)

PEG–$MgCl_2$ Solution

40% (w/v) polyethylene glycol (PEG 8000)
30 mM $MgCl_2$

Dissolve 40 g of PEG 8000 in a final volume of 100 ml of 30 mM $MgCl_2$. Sterilize the solution by passing it through a 0.22-μm filter, and store it at room temperature.

QBT Buffer (Qiagen)

750 mM NaCl <!>
50 mM MOPS (pH 7.0) <!>
15% (v/v) isopropanol
0.15% (v/v) Triton X-100

Radioactive Ink <!>

Radioactive ink is made by mixing a small amount of ^{32}P with waterproof black drawing ink. We find it convenient to make the ink in three grades: very hot (>2000 cps on a hand-held minimonitor), hot (>500 cps on a hand-held minimonitor), and cool (>50 cps on a hand-held minimonitor). Use a fiber-tip pen to apply ink of the desired activity to the pieces of tape. Attach radioactive-warning tape to the pen, and store it in an appropriate place.

Sephacryl Equilibration Buffer

50 mM Tris-Cl (pH 8.0)
5 mM EDTA
0.5 M NaCl

SM and SM Plus Gelatin

Per liter:

NaCl	5.8 g
$MgSO_4 \cdot 7H_2O$	2 g
1 M Tris-Cl (pH 7.5)	50 ml
2% (w/v) gelatin solution	5 ml
H_2O	to 1 liter

Sterilize the buffer by autoclaving for 20 minutes at 15 psi (1.05 kg/cm^2) on liquid cycle. After the solution has cooled, dispense 50-ml aliquots into sterile containers. SM may be stored indefinitely at room temperature. Discard each aliquot after use to minimize the chance of contamination.

Sorbitol Buffer

1 M sorbitol
0.1 M EDTA (pH 7.5)

STE

10 mM Tris-Cl (pH 8.0)
0.1 M NaCl
1 mM EDTA (pH 8.0)

Sterilize by autoclaving for 15 minutes at 15 psi (1.05 kg/cm^2) on liquid cycle. Store the sterile solution at 4°C.

10× TEN Buffer

0.1 M Tris-Cl (pH 8.0)
0.01 M EDTA (pH 8.0)
1 M NaCl

TES

10 mM Tris-Cl (pH 7.5)
1 mM EDTA (pH 7.5)
0.1% (w/v) SDS

Triton/SDS Solution

10 mM Tris-Cl (pH 8.0)
2% (v/v) Triton X-100
1% (w/v) SDS
100 mM NaCl
1 mM EDTA (pH 8.0)

Sterilize the solution by passing it through a 0.22-μm filter, and store it at room temperature.

Tris-Sucrose

50 mM Tris-Cl (pH 8.0)
10% (w/v) sucrose

Sterilize the solution by passing it through a 0.22-μm filter, and store it at room temperature. Solutions containing sucrose should not be autoclaved since the sugar tends to carbonize at high temperatures.

Wash Buffer (Qiagen)

50 mM MOPS-KOH <!> (pH 7.5–7.6)
0.75 M NaCl
15% (v/v) ethanol

When making this buffer, adjust the pH of a MOPS/NaCl solution before adding the ethanol.

Yeast Resuspension Buffer

50 mM Tris-Cl (pH 7.4)
20 mM EDTA (pH 7.5)

PREPARATION OF ORGANIC REAGENTS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Phenol

Most batches of commercial liquefied phenol **<!>** are clear and colorless and can be used in molecular cloning without redistillation. Occasionally, batches of liquefied phenol are pink or yellow, and these should be rejected and returned to the manufacturer. Crystalline phenol is not recommended because it must be redistilled at 160°C to remove oxidation products, such as quinones, that cause the breakdown of phosphodiester bonds or cause cross-linking of RNA and DNA.

Equilibration of Phenol

Before use, phenol must be equilibrated to a pH of >7.8 because the DNA partitions into the organic phase at acid pH. Wear gloves, full face protection, and a lab coat when carrying out this procedure.

1. Store liquefied phenol at −20°C. As needed, remove the phenol from the freezer, allow it to warm to room temperature, and then melt it at 68°C. Add hydroxyquinoline to a final concentration of 0.1%. This compound is an antioxidant, a partial inhibitor of RNase, and a weak chelator of metal ions (Kirby 1956). In addition, its yellow color provides a convenient way to identify the organic phase.

2. To the melted phenol, add an equal volume of buffer (usually 0.5 M Tris-Cl [pH 8.0] at room temperature). Stir the mixture on a magnetic stirrer for 15 minutes. Turn off the stirrer, and when the two phases have separated, aspirate as much as possible of the upper (aqueous) phase using a glass pipette attached to a vacuum line equipped with appropriate traps (please see Appendix 8, Figure A8-2).

3. Add an equal volume of 0.1 M Tris-Cl (pH 8.0) to the phenol. Stir the mixture on a magnetic stirrer for 15 minutes. Turn off the stirrer and remove the upper aqueous phase as described in Step 2. Repeat the extractions until the pH of the phenolic phase is >7.8 (as measured with pH paper).

4. After the phenol is equilibrated and the final aqueous phase has been removed, add 0.1 volume of 0.1 M Tris-Cl (pH 8.0) containing 0.2% β-mercaptoethanol **<!>**. The phenol solution may be stored in this form under 100 mM Tris-Cl (pH 8.0) in a light-tight bottle at 4°C for periods of up to 1 month.

Phenol:Chloroform:Isoamyl Alcohol (25:24:1)

A mixture consisting of equal parts of equilibrated phenol and chloroform:isoamyl alcohol **<!>** (24:1) is frequently used to remove proteins from preparations of nucleic acids. The chloroform denatures proteins and facilitates the separation of the aqueous and organic phases, and the isoamyl alcohol reduces foaming during extraction. Neither chloroform nor isoamyl alcohol requires treatment before use. The phenol:chloroform:isoamyl alcohol mixture may be stored under 100 mM Tris-Cl (pH 8.0) in a light-tight bottle at 4°C for periods of up to 1 month.

Deionization of Formamide

Many batches of reagent-grade formamide <!> are sufficiently pure to be used without further treatment. However, if any yellow color is present, deionize the formamide by stirring on a magnetic stirrer with Dowex XG8 mixed bed resin for 1 hour and filtering it twice through Whatman No. 1 paper. Store deionized formamide in small aliquots under nitrogen at –70°C.

Deionization of Glyoxal

Commercial stock solutions of glyoxal (40% or 6 M) contain various hydrated forms of glyoxal, as well as oxidation products such as glyoxylic acid, formic acid, and other compounds that can degrade RNA. These contaminants must be removed by treatment with a mixed-bed resin such as Bio-Rad AG-510-X8 until the indicator dye in the resin is exhausted. To deionize the glyoxal:

1. Immediately before use, mix the glyoxal with an equal volume mixed-bed ion-exchange resin (Bio-Rad AG-510-X8). Alternatively, pass the glyoxal through a small column of mixed bed resin, and then proceed to Step 3.
2. Separate the deionized material from the resin by filtration (e.g., through a Uniflow Plus filter; Schleicher & Schuell).
3. Monitor the pH of the glyoxal by mixing 200 µl of glyoxal with 2 µl of a 10 mg/ml solution of bromocresol green in H_2O, and observing the change in color. Bromocresol green is yellow at pH <4.8 and blue-green at pH >5.2.
4. Repeat the deionization process (Steps 1–2) until the pH of the glyoxal is >5.5.

Deionized glyoxal can be stored indefinitely at –20°C under nitrogen in tightly sealed microfuge tubes. Use each aliquot only once and then discard.

CHEMICAL STOCK SOLUTIONS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Acrylamide Solution (45% w/v)

acrylamide (DNA-sequencing grade) <!>	434 g
N,N'-methylenebisacrylamide <!>	16 g
H_2O	to 600 ml

Heat the solution to 37°C to dissolve the chemicals. Adjust the volume to 1 liter with distilled H_2O. Filter the solution through a nitrocellulose filter (e.g., Nalge, 0.45-micron pore size), and store the filtered solution in dark bottles at room temperature.

Actinomycin D (5 mg/ml)

Dissolve actinomycin D <!> in methanol <!> at a concentration of 5 mg/ml. Store the stock solution at –20°C in the dark. Please see the information panel on ACTINOMYCIN D in Chapter 7.

Adenosine Diphosphate (ADP) (1 mM)

Dissolve solid adenosine diphosphate in sterile 25 mM Tris-Cl (pH 8.0). Store small aliquots (~20 µl) of the solution at –20°C.

Ammonium Acetate (10 M)

To prepare a 1-liter solution, dissolve 770 g of ammonium acetate in 800 ml of H_2O. Adjust volume to 1 liter with H_2O. Sterilize by filtration. Alternatively, to prepare a 100-ml solution, dissolve 77 g of ammonium acetate in 70 ml of H_2O at room temperature. Adjust the volume to 100 ml with H_2O. Sterilize the solution by passing it through a 0.22-µm filter. Store the solution in tightly sealed bottles at 4°C or at room temperature. Ammonium acetate decomposes in hot H_2O and solutions containing it should not be autoclaved.

Ammonium Persulfate (10% w/v)

ammonium persulfate <!>	1 g
H_2O	to 10 ml

Dissolve 1 g ammonium persulfate in 10 ml of H_2O and store at 4°C. Ammonium persulfate decays slowly in solution, so replace the stock solution every 2–3 weeks. Ammonium persulfate is used as a catalyst for the copolymerization of acrylamide and bisacrylamide gels. The polymerization reaction is driven by free radicals generated by an oxido-reduction reaction in which a diamine (e.g., TEMED) is used as the adjunct catalyst (Chrambach and Rodbard 1972).

ATP (10 mM)

Dissolve an appropriate amount of solid ATP in 25 mM Tris-Cl (pH 8.0). Store the ATP solution in small aliquots at –20°C.

Calcium Chloride (2.5 M)

Dissolve 11 g of $CaCl_2 \cdot 6H_2O$ in a final volume of 20 ml of distilled H_2O. Sterilize the solution by passing it through a 0.22-µm filter. Store in 1-ml aliquots at 4°C.

Coomassie Staining Solution

Dissolve 0.25 g of Coomassie Brilliant Blue R-250 in 90 ml of methanol:H_2O <!> (1:1, v/v) and 10 ml of glacial acetic acid <!>. Filter the solution through a Whatman No. 1 filter to remove any particulate matter. Store at room temperature. Please see the entry on Coomassie Staining in Appendix 8.

Deoxyribonucleoside Triphosphates (dNTPs)

Dissolve each dNTP in H_2O at an approximate concentration of 100 mM. Use 0.05 M Tris base and a micropipette to adjust the pH of each of the solutions to 7.0 (use pH paper to check the pH). Dilute an aliquot of the neutralized dNTP appropriately, and read the optical density at the wavelengths given in the table below. Calculate the actual concentration of each dNTP. Dilute the solutions with H_2O to a final concentration of 50 mM dNTP. Store each separately at –70°C in small aliquots.

Base	Wavelength (nm)	Extinction Coefficient (E)($M^{-1}cm^{-1}$)
A	259	1.54×10^4
G	253	1.37×10^4
C	271	9.10×10^3
T	267	9.60×10^3

For a cuvette with a path length of 1 cm, absorbance = EM. 100 mM stock solutions of each dNTP are commercially available (Pharmacia).

For polymerase chain reactions (PCRs), adjust the dNTP solution to pH 8.0 with 2 N NaOH. Commercially available solutions of PCR-grade dNTPs require no adjustment.

Dimethylsulfoxide (DMSO)

Purchase a high grade of DMSO <!> (HPLC grade or better). Divide the contents of a fresh bottle into 1-ml aliquots in sterile tubes. Close the tubes tightly and store at –20°C. Use each aliquot only once and then discard.

Dithiothreitol (DTT, 1 M)

Dissolve 3.09 g of dithiothreitol in 20 ml of 0.01 M sodium acetate (pH 5.2) and sterilize by filtration. Dispense into 1-ml aliquots and store at –20°C. Under these conditions, dithiothreitol is stable to oxidation by air.

EDTA (0.5 M, pH 8.0)

Add 186.1 g of disodium EDTA·$2H_2O$ to 800 ml of H_2O. Stir vigorously on a magnetic stirrer. Adjust the pH to 8.0 with NaOH (~20 g of NaOH pellets<!>). Dispense into aliquots and sterilize by autoclaving. The disodium salt of EDTA will not go into solution until the pH of the solution is adjusted to ~8.0 by the addition of NaOH.

EGTA (0.5 M, pH 8.0)

EGTA is ethylene glycol bis(β-aminoethyl ether) *N,N,N′,N′*-tetraacteic acid. A solution of EGTA is made up essentially as described for EDTA above and sterilized by either autoclaving or filtering. Store the sterile solution at room temperature.

Ethidium Bromide (10 mg/ml)

Add 1 g of ethidium bromide <!> to 100 ml of H_2O. Stir on a magnetic stirrer for several hours to ensure that the dye has dissolved. Wrap the container in aluminum foil or transfer the solution to a dark bottle and store at room temperature.

Gelatin (2% w/v)

Add 2 g of gelatin to a total volume of 100 ml of H_2O and autoclave the solution for 15 minutes at 15 psi (1.05 kg/cm^2) on liquid cycle.

Glycerol (10% v/v)

Dilute 1 volume of molecular-biology-grade glycerol in 9 volumes of sterile pure H_2O. Sterilize the solution by passing it through a prerinsed 0.22-µm filter. Store in 200-ml aliquots at 4°C.

IPTG (20% w/v, 0.8 M)

IPTG is isopropylthio-β-D-galactoside. Make a 20% solution of IPTG by dissolving 2 g of IPTG in 8 ml of distilled H_2O. Adjust the volume of the solution to 10 ml with H_2O and sterilize by passing it through a 0.22-µm disposable filter. Dispense the solution into 1-ml aliquots and store them at –20°C.

KCl (4 M)

Dissolve an appropriate amount of solid KCl in H_2O, autoclave for 20 minutes on liquid cycle and store at room temperature. Ideally, this solution should be divided into small (~100 µl) aliquots in sterile tubes and each aliquot thereafter used one time.

Lithium Chloride (LiCl, 5 M)

Dissolve 21.2 g of LiCl in a final volume of 90 ml of H_2O. Adjust the volume of the solution to 100 ml with H_2O. Sterilize the solution by passing it through a 0.22-µm filter, or by autoclaving for 15 minutes at 15 psi (1.05 kg/cm^2) on liquid cycle. Store the solution at 4°C.

$MgCl_2 \cdot 6H_2O$ (1 M)

Dissolve 203.3 g of $MgCl_2 \cdot 6H_2O$ in 800 ml of H_2O. Adjust the volume to 1 liter with H_2O. Dispense into aliquots and sterilize by autoclaving. $MgCl_2$ is extremely hygroscopic. Buy small bottles (e.g., 100 g) and do not store opened bottles for long periods of time.

$MgSO_4$ (1 M)

Dissolve 12 g of $MgSO_4$ in a final volume of 100 ml of H_2O. Sterilize by autoclaving or filter sterilization. Store at room temperature.

Maltose (20% w/v)

Dissolve 20 g of maltose in a final volume of 100 ml of H_2O and sterilize by passing it through a 0.22-µm filter. Store the sterile solution at room temperature.

NaOH (10 N)

The preparation of 10 N NaOH **<!>** involves a highly exothermic reaction, which can cause breakage of glass containers. Prepare this solution with extreme care in plastic beakers. To 800 ml of H_2O, slowly add 400 g of NaOH pellets **<!>**, stirring continuously. As an added precaution, place the beaker on ice. When the pellets have dissolved completely, adjust the volume to 1 liter with H_2O. Store the solution in a plastic container at room temperature. Sterilization is not necessary.

NaCl (Sodium Chloride, 5 M)

Dissolve 292 g of NaCl in 800 ml of H_2O. Adjust the volume to 1 liter with H_2O. Dispense into aliquots and sterilize by autoclaving. Store the NaCl solution at room temperature.

PEG 8000

Working concentrations of PEG <!> range from 13% to 40% (w/v). Prepare the appropriate concentration by dissolving PEG 8000 in sterile H_2O, warming if necessary. Sterilize the solution by passing it through a 0.22-μm filter. Store the solution at room temperature.

Polyethylene glycol (PEG) is a straight-chain polymer of a simple repeating unit $H(OCH_2\ CH_2)_nOH$. PEG is available in a range of molecular weights whose names reflect the number (*n*) of repeating units in each molecule. In PEG 400, for example, n = 8–9, whereas in PEG 4000, n ranges from 68 to 84. PEG induces macromolecular crowding of solutes in aqueous solution (Zimmerman and Minton 1993) and has a range of uses in molecular cloning, including:

- ***Precipitation of DNA molecules according to their size.*** The concentration of PEG required for precipitation is in inverse proportion to the size of the DNA frgaments (Lis and Schleif 1975a,b; Ogata and Gilbert 1977; Lis 1980); please see Chapter 1, Protocol 8, and Chapter 2, Protocol 6.
- ***Precipitation and purification of bacteriophage particles*** (Yamamoto et al. 1970).
- ***Increasing the efficiency of reassociation of complementary chains*** of nucleic acids during hybridization, blunt-end ligation of DNA molecules, and end-labeling of DNA with bacteriophage T4 polynucleotide kinase (Zimmerman and Minton 1993; please see the information panel on **CONDENSING AND CROWDING REAGENTS** in Chapter 1).
- ***Fusion of cultured cells with bacterial protoplasts*** (Schaffner 1980; Rassoulzadegan et al. 1982).

Potassium Acetate (5 M)

5 M potassium acetate	60 ml
glacial acetic acid <!>	11.5 ml
H_2O	28.5 ml

The resulting solution is 3 M with respect to potassium and 5 M with respect to acetate. Store the buffer at room temperature.

SDS (20% w/v)

Also called sodium lauryl sulfate. Dissolve 200 g of electrophoresis-grade SDS <!> in 900 ml of H_2O. Heat to 68°C and stir with a magnetic stirrer to assist dissolution. If necessary, adjust the pH to 7.2 by adding a few drops of concentrated HCl <!>. Adjust the volume to 1 liter with H_2O. Store at room temperature. Sterilization is not necessary. Do not autoclave.

Silver Stain. ***Please see staining section (Appendix 8).***

Sodium Acetate (3 M, pH 5.2 and pH 7.0)

Dissolve 408.3 g of sodium acetate·$3H_2O$ in 800 ml of H_2O. Adjust the pH to 5.2 with glacial acetic acid <!> or adjust the pH to 7.0 with dilute acetic acid. Adjust the volume to 1 liter with H_2O. Dispense into aliquots and sterilize by autoclaving.

Spermidine (1 M)

Dissolve 1.45 g of spermidine (free-base form) in 10 ml of deionized H_2O and sterilize by passing it through a 0.22-μm filter. Store the solution in small aliquots at –20°C. Make a fresh stock solution of this reagent every month.

SYBR Gold Staining Solution

SYBR Gold <!> (Molecular Probes) is supplied as a stock solution of unknown concentration in dimethylsulfoxide. Agarose gels are stained in a working solution of SYBR Gold, which is a 1:10,000 dilution of SYBR Gold nucleic acid stain in electrophoresis buffer. Prepare working stocks of SYBR Gold daily and store in the dark at regulated room temperature. For a discussion of staining agarose gels, please see Chapter 5, Protocol 2.

Trichloroacetic Acid (TCA; 100% solution)

To a previously unopened bottle containing 500 g of TCA <!>, add 227 ml of H_2O. The resulting solution will contain 100% (w/v) TCA.

X-gal Solution (2% w/v)

X-gal is 5-bromo-4-chloro-3-indolyl-β-D-galactoside. Make a stock solution by dissolving X-gal in dimethylformamide <!> at a concentration of 20 mg/ml solution. Use a glass or polypropylene tube. Wrap the tube containing the solution in aluminum foil to prevent damage by light and store at –20°C. It is not necessary to sterilize X-gal solutions by filtration. Please see the information panel on **X-GAL** in Chapter 1.

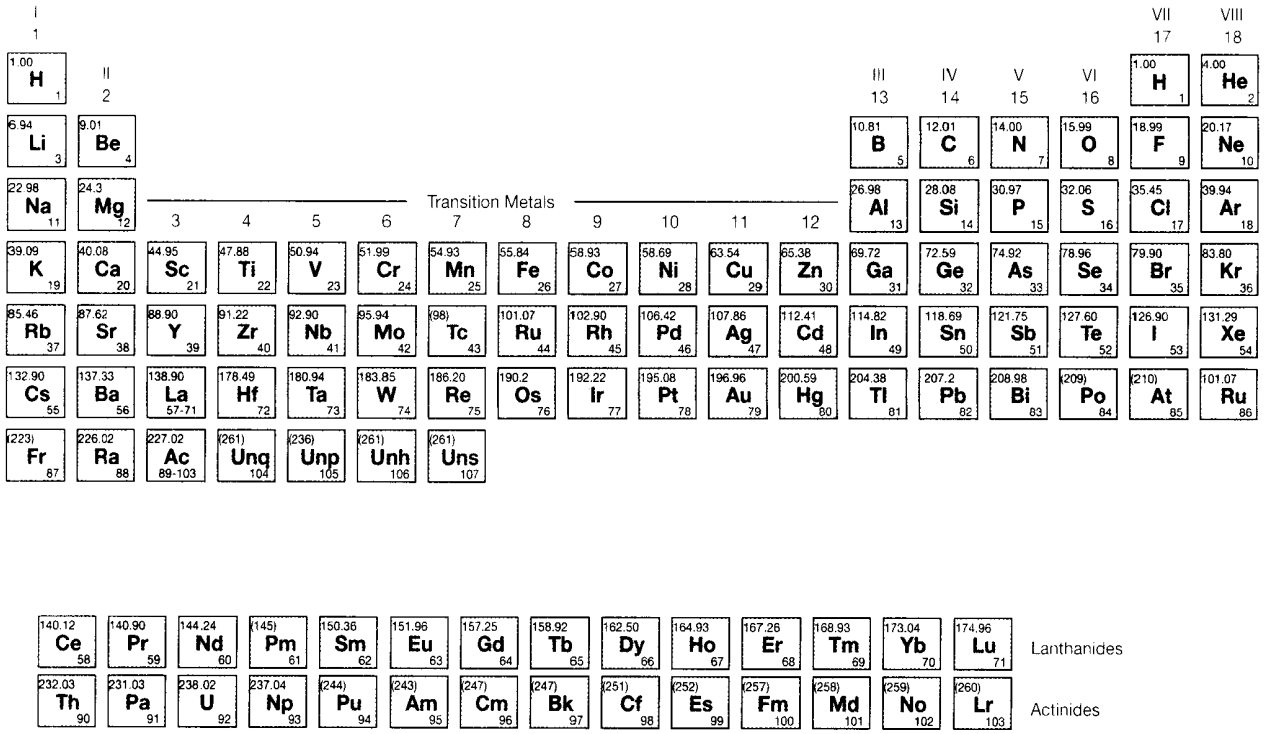


FIGURE A1-1 Periodic Table

Numbers in parentheses are the mass numbers of the most stable isotope of that element.

REAGENTS AND BUFFERS INDEX

Appendix 2

Media

LIQUID MEDIA FOR *E. COLI*

▲ **IMPORTANT** Use distilled deionized H_2O in all recipes. Unless otherwise stated, sterile media can be stored at room temperature.

GYT Medium (Tung and Chow 1995)

10% (v/v) glycerol
0.125% (w/v) yeast extract
0.25% (w/v) tryptone

Sterilize the medium by passing it through a prerinsed 0.22-μm filter. Store in 2.5-ml aliquots at 4°C.

LB Medium (Luria-Bertani Medium)

Per liter:

To 950 ml of deionized H_2O, add:

tryptone	10 g
yeast extract	5 g
NaCl	10 g

Shake until the solutes have dissolved. Adjust the pH to 7.0 with 5 N NaOH (~0.2 ml). Adjust the volume of the solution to 1 liter with deionized H_2O. Sterilize by autoclaving for 20 minutes at 15 psi (1.05 kg/cm^2) on liquid cycle.

M9 Minimal Medium

Per liter:

To 750 ml of sterile H_2O (cooled to 50°C or less), add:

5x M9 salts*	200 ml
1 M $MgSO_4$	2 ml
20% solution of the appropriate carbon source (e.g., 20% glucose)	20 ml
1 M $CaCl_2$	0.1 ml
sterile deionized H_2O	to 980 ml

If necessary, supplement the M9 medium with stock solutions of the appropriate amino acids and vitamins.

*5x M9 salts is made by dissolving the following salts in deionized H_2O to a final volume of 1 liter:

$Na_2HPO_4 \cdot 7H_2O$	64 g
KH_2PO_4	15 g
NaCl	2.5 g
NH_4Cl	5.0 g

Divide the salt solution into 200-ml aliquots and sterilize by autoclaving for 15 minutes at 15 psi (1.05 kg/cm^2) on liquid cycle.

Prepare the $MgSO_4$ and $CaCl_2$ solutions separately, sterilize by autoclaving, and add the solutions after diluting the 5x M9 salts to 980 ml with sterile H_2O. Sterilize the glucose by passing it through a 0.22-μm filter before it is added to the diluted M9 salts.

When using *E. coli* strains that carry a deletion of the proline biosynthetic operon [Δ(*lac-proAB*)] in the bacterial chromosome and the complementing *proAB* genes on the F′ plasmid, supplement the M9 minimal medium with the following:

0.4% (w/v) glucose (dextrose)
5 mM $MgSO_4 \cdot 7H_2O$
0.01% thiamine

NZCYM Medium

Per liter:

To 950 ml of deionized H_2O, add:

NZ amine	10 g
NaCl	5 g
yeast extract	5 g
casamino acids	1 g
$MgSO_4 \cdot 7H_2O$	2 g

Shake until the solutes have dissolved. Adjust the pH to 7.0 with 5 N NaOH (~0.2 ml). Adjust the volume of the solution to 1 liter with deionized H_2O. Sterilize by autoclaving for 20 minutes at 15 psi (1.05 kg/cm^2) on liquid cycle.

NZ amine: Casein hydrolysate enzymatic (ICN Biochemicals). NZCYM, NZYM, and NZM are also available as dehydrated media from BD Biosciences.

NZYM Medium

NZYM medium is identical to NZCYM medium, except that casamino acids are omitted.

NZM Medium

NZM medium is identical to NZYM medium, except that yeast extract is omitted.

SOB Medium

Per liter:

To 950 ml of deionized H_2O, add:

tryptone	20 g
yeast extract	5 g
NaCl	0.5 g

Shake until the solutes have dissolved. Add 10 ml of a 250 mM solution of KCl. (This solution is made by dissolving 1.86 g of KCl in 100 ml of deionized H_2O.) Adjust the pH of the medium to 7.0 with 5 N NaOH **<!>** (~0.2 ml). Adjust the volume of the solution to 1 liter with deionized H_2O. Sterilize by autoclaving for 20 minutes at 15 psi (1.05 kg/cm^2) on liquid cycle. Just before use, add 5 ml of a sterile solution of 2 M $MgCl_2$. (This solution is made by dissolving 19 g of $MgCl_2$ in 90 ml of deionized H_2O. Adjust the volume of the solution to 100 ml with deionized H_2O and sterilize by autoclaving for 20 minutes at 15 psi [1.05 kg/cm^2] on liquid cycle.)

SOC Medium

SOC medium is identical to SOB medium, except that it contains 20 mM glucose. After the SOB medium has been autoclaved, allow it to cool to 60°C or less. Add 20 ml of a sterile 1 M solution of glucose. (This solution is made by dissolving 18 g of glucose in 90 ml of deionized H_2O. After the sugar has dissolved, adjust the volume of the solution to 100 ml with deionized H_2O and sterilize by passing it through a 0.22-μm filter.)

Terrific Broth (also known as TB; Tartof and Hobbs 1987)

Per liter:

To 900 ml of deionized H_2O, add:

tryptone	12 g
yeast extract	24 g
glycerol	4 ml

Shake until the solutes have dissolved and then sterilize by autoclaving for 20 minutes at 15 psi (1.05 kg/cm^2) on liquid cycle. Allow the solution to cool to 60°C or less, and then add 100 ml of a sterile solution of 0.17 M KH_2PO_4, 0.72 M K_2HPO_4. (This solution is made by dissolving 2.31 g of KH_2PO_4 and 12.54 g of K_2HPO_4 in 90 ml of deionized H_2O. After the salts have dissolved, adjust the volume of the solution to 100 ml with deionized H_2O and sterilize by autoclaving for 20 minutes at 15 psi [1.05 kg/cm^2] on liquid cycle.)

2x YT Medium

Per liter:

To 900 ml of deionized H_2O, add:

tryptone	16 g
yeast extract	10 g
NaCl	5 g

Shake until the solutes have dissolved. Adjust the pH to 7.0 with 5 N NaOH <!>. Adjust the volume of the solution to 1 liter with deionized H_2O. Sterilize by autoclaving for 20 minutes at 15 psi (1.05 kg/cm^2) on liquid cycle.

MEDIA CONTAINING AGAR OR AGAROSE

▲ **IMPORTANT** Use distilled deionized H_2O in all recipes.

Prepare liquid media according to the recipes given above. Just before autoclaving, add one of the following:

Bacto Agar (for plates)	15 g/liter
Bacto Agar (for top agar)	7 g/liter
agarose (for plates)	15 g/liter
agarose (for top agarose)	7 g/liter

Sterilize by autoclaving for 20 minutes at 15 psi (1.05 kg/cm^2) on liquid cycle. When the medium is removed from the autoclave, swirl it gently to distribute the melted agar or agarose evenly throughout the solution. *Be careful!* The fluid may be superheated and may boil over when swirled. Allow the medium to cool to 50–60°C before adding thermolabile substances (e.g., antibiotics). To avoid producing air bubbles, mix the medium by swirling. Plates can then be poured directly from the flask; allow ~30–35 ml of medium per 90-mm plate. To remove bubbles from medium in the plate, flame the surface of the medium with a Bunsen burner before the agar or agarose hardens. Set up a color code (e.g., two red stripes for LB-ampicillin plates; one black stripe for LB plates, etc.) and mark the edges of the plates with the appropriate colored markers.

When the medium has hardened completely, invert the plates and store them at 4°C until needed. The plates should be removed from storage 1–2 hours before they are used. If the plates are fresh, they will "sweat" when incubated at 37°C. When this condensation drops on the agar/agarose surface, it allows bacterial colonies or bacteriophage plaques to spread and increases the chances of cross-contamination. This problem can be avoided by wiping off the condensation from the lids of the plates and then incubating the plates for several hours at 37°C in an inverted position before they are used. Alternatively, remove the liquid by shaking the lid with a single, quick motion. To minimize the possibility of contamination, hold the open plate in an inverted position while removing the liquid from the lid.

STORAGE MEDIA

▲ **IMPORTANT** Use distilled deionized H_2O in all recipes.

Liquid Cultures

Bacteria growing on plates, or in liquid culture, can be stored in aliquots of LB medium containing 30% (v/v) sterile glycerol. Aliquots of 1 ml of LB with glycerol should be prepared and vortexed to ensure that the glycerol is completely dispersed. Alternatively, bacterial strains may be stored in LB freezing buffer:

LB freezing buffer:
36 mM K_2HPO_4 (anhydrous)
13.2 mM KH_2PO_4
1.7 mM sodium citrate
0.4 mM $MgSO_4 \cdot 7H_2O$
6.8 mM ammonium sulfate
4.4% (v/v) glycerol
in LB

LB freezing buffer (Zimmer and Verrinder Gibbins 1997) is best made by dissolving the salts in 100 ml of LB to the specified concentrations. Measure 95.6 ml of the resulting solution into a fresh container, and then add 4.4 ml of glycerol. Mix the solution well and then sterilize by passing it through a 0.45-µm disposable Nalgene filter. For more information on storage of bacterial cultures, please see Appendix 8.

Stab Cultures

Prepare stab cultures in glass vials (2–3 ml) with screw-on caps fitted with rubber gaskets. Add molten LB agar until the vials are two-thirds full. Autoclave the partially filled vials (with their caps loosely screwed on) for 20 minutes at 15 psi (1.05 kg/cm^2) on liquid cycle. Remove the vials from the autoclave, let them cool to room temperature, and then tighten the caps. Store the vials at room temperature until needed.

ANTIBIOTICS

TABLE A2-1 Commonly Used Antibiotic Solutions

	Stock Solution[a]		Working Concentration	
	Concentration	Storage	Stringent Plasmids	Relaxed Plasmids
Ampicillin	50 mg/ml in H_2O	–20°C	20 µg/ml	50 µg/ml
Carbenicillin	50 mg/ml in H_2O	–20°C	20 µg/ml	60 µg/ml
Chloramphenicol	34 mg/ml in ethanol	–20°C	25 µg/ml	170 µg/ml
Kanamycin	10 mg/ml in H_2O	–20°C	10 µg/ml	50 µg/ml
Streptomycin	10 mg/ml in H_2O	–20°C	10 µg/ml	50 µg/ml
Tetracycline[b]	5 mg/ml in ethanol	–20°C	10 µg/ml	50 µg/ml

Magnesium ions are antagonists of tetracycline. Use media without magnesium salts (e.g., LB medium) for selection of bacteria resistant to tetracycline.

[a]Sterilize stock solutions of antibiotics dissolved in H_2O by filtration through a 0.22-µm filter.

[b]Antibiotics dissolved in ethanol need not be sterilized. Store solutions in light-tight containers.

TABLE A2-2 Antibiotic Modes of Action

Antibiotic	Molecular Weight	Mode of Action	Further Information
Actinomycin C_1 (actinomycin D)	1255.4	Inhibits synthesis of RNA by binding to double-stranded DNA.	
Amphotericin	924.1	Broad-spectrum antifungal agent from *Streptomyces.*	
Ampicillin	349.4	Inhibits cell-wall synthesis by interfering with peptidoglycan cross-linking.	Please see the information panel on **AMPICILLIN AND CARBENICILLIN** at the end of Chapter 1.
Bleomycin	n.a.[a]	Inhibits DNA synthesis; cleaves single-stranded DNA.	
Carbenicillin (disodium salt)	422.4	Inhibits bacterial wall synthesis.	
Chloramphenicol	323.1	Inhibits translation by blocking peptidyl transferase on the 50S ribosomal subunit; at higher concentrations can inhibit eukaryotic DNA synthesis.	Please see the information panel on **CHLORAMPHENICOL** at the end of Chapter 1.
Geneticin (G418 geneticin disulfate)	692.7	Aminoglycoside is toxic to a broad range of cell types (bacterial, higher plant, yeast, mammaliam, protozoans, helminths); used in selection of eukaryotic cells transformed with neomycin resistance genes.	
Gentamycin	692.7	Inhibits protein synthesis by binding to L6 protein of the 50S ribosomal subunit.	
Hygromycin B	527.5	Inhibits protein synthesis.	
Kanamycin monosulfate	582.6	Broad-spectrum antibiotic; binds to 70S ribosomal subunit and inhibits growth of gram-positive and gram-negative bacteria and mycoplasmas.	Please see the information panel on **KANAMYCINS** at the end of Chapter 1.
Methotrexate	454.45	A folic acid analog; a powerful inhibitor of the enzyme dihydrofolate reductase.	
Mitomycin C	334.33	Inhibits DNA synthesis; antibacterial to gram-positive, gram-negative, and acid-fast bacilli.	
Neomycin B sulfate	908.9	Binds to 30S ribosomal subunit and inhibits bacterial protein synthesis.	
Novobiocin sodium salt	634.62	Bacteriostatic antibiotic; inhibits growth of gram-positive bacteria.	
Penicillin G sodium salt	356.4	Inhibits peptidoglycan synthesis in bacterial cell walls.	
Puromycin dihydrochloride	544.4	Inhibits protein synthesis by acting as an analog of aminoacyl tRNA (causes premature chain termination).	
Rifampicin	823.0	Strongly inhibits prokaryotic RNA polymerase and mammalian RNA polymerase to a lesser degree.	
Streptomycin sulfate	1457.4	Inhibits protein synthesis; binds to 30S ribosomal subunit.	
Tetracycline hydrochloride	480.9	Inhibits bacterial protein synthesis; blocks ribosomal binding of aminoacyl-tRNA.	Please see the information panel on **TETRACYCLINE** at the end of Chapter 1.

[a]n.a. indicates not available.

SOLUTIONS FOR WORKING WITH BACTERIOPHAGE λ

▲ **IMPORTANT** Use distilled deionized H_2O in all recipes.

Maltose

Maltose, an inducer of the gene (*lamB*) that encodes the bacteriophage λ receptor, is often added to the medium during growth of bacteria that are to be used for plating bacteriophage λ. Add 1 ml of a sterile 20% maltose solution for every 100 ml of medium. For a further discussion of the use of maltose, please see the Materials list in Chapter 2, Protocol 1. Make up a sterile 20% stock solution of maltose as follows:

maltose	20 g
H_2O	to 100 ml

Sterilize the solution by passing it through a 0.22-μm filter. Store the sterile solution at room temperature.

SM

This buffer is used for storage and dilution of bacteriophage λ stocks.

Per liter:

NaCl	5.8 g
$MgSO_4 \cdot 7H_2O$	2 g
1 M Tris-Cl (pH 7.5)	50 ml
2% gelatin solution	5 ml
H_2O	to 1 liter

Sterilize the buffer by autoclaving for 20 minutes at 15 psi (1.05 kg/cm^2) on liquid cycle. After the solution has cooled, dispense 50-ml aliquots into sterile containers. SM may be stored indefinitely at room temperature.

A 2% gelatin solution is made by adding 2 g of gelatin to a total volume of 100 ml of H_2O and autoclaving the solution for 15 minutes at 15 psi (1.05 kg/cm^2) on liquid cycle.

TM

Per liter:

1 M Tris-Cl (pH 7.5)	50 ml
$MgSO_4 \cdot 7H_2O$	2 g
H_2O	to 1 liter

Sterilize the buffer by autoclaving for 20 minutes at 15 psi (1.05 kg/cm^2) on liquid cycle. After the solution has cooled, dispense 50-ml aliquots into sterile containers. TM may be stored indefinitely at room temperature.

MEDIA FOR THE PROPAGATION AND SELECTION OF YEAST*

▲ **CAUTION Please see Appendix 12 for appropriate handling of materials marked with <!>,**

▲ **IMPORTANT** Use distilled deionized H_2O in all recipes. Unless otherwise stated, media and solutions are sterilized by autoclaving at 15 psi (1.05 kg/cm^2) for 15–20 minutes.

Complete Minimal (CM) or Synthetic Complete (SC) and Drop-out Media

To test the growth requirements of strains, it is useful to have media in which each of the commonly encountered auxotrophies is supplemented except the one of interest (drop-out media). Dry growth supplements are stored premixed. CM (or SC) is a medium in which the drop-out mix contains all possible supplements (i.e., nothing is "dropped out").

yeast nitrogen base without amino acids*	6.7 g
glucose	20 g
Bacto Agar	20 g
drop-out mix	2 g
H_2O	to 1000 ml

*Yeast nitrogen base without amino acids (YNB) is sold either with or without ammonium sulfate. This recipe is for YNB with ammonium sulfate. If the bottle of YNB is lacking ammonium sulfate, add 5 g of ammonium sulfate and only 1.7 g of YNB.

Drop-out Mix

Combine the appropriate ingredients, minus the relevant supplements, and mix in a sealed container. Turn the container end-over-end for at least 15 minutes; add a few clean marbles to help mix the solids.

Adenine	0.5 g
Alanine	2.0 g
Arginine	2.0 g
Asparagine	2.0 g
Aspartic acid	2.0 g
Cysteine	2.0 g
Glutamine	2.0 g
Glutamic acid	2.0 g
Glycine	2.0 g
Histidine	2.0 g
Inositol	2.0 g
Isoleucine	2.0 g
Leucine	10.0 g
Lysine	2.0 g
Methionine	2.0 g
para-Aminobenzoic acid	0.2 g
Phenylalanine	2.0 g
Proline	2.0 g
Serine	2.0 g
Threonine	2.0 g
Tryptophan	2.0 g
Tyrosine	2.0 g
Uracil	2.0 g
Valine	2.0 g

*Reprinted from Adams et al. (1998).

TABLE A2-3 Components of Supplemented Minimal Media

Constituent	Stock Concentration (g/100 ml)	Volume for 1 Liter of Stock of Medium (ml)	Final Concentration in Medium (mg/liter)	Volume of Stock to Spread on Plate (ml)
Adenine sulfate	0.2[a]	10	20	0.2
Uracil	0.2[a]	10	20	0.2
L-Tryptophan	1	2	20	0.1
L-Histidine HCl	1	2	20	0.1
L-Arginine HCl	1	2	20	0.1
L-Methionine	1	2	20	0.1
L-Tyrosine	0.2	15	30	0.2
L-Leucine	1	10	100	0.1
L-Isoleucine	1	3	30	0.1
L-Lysine HCl	1	3	30	0.1
L-Phenylalanine	1[a]	5	50	0.1
L-Glutamic acid	1[a]	10	100	0.2
L-Aspartic acid	1[a,b]	10	100	0.2
L-Valine	3	5	150	0.1
L-Threonine	4[a,b]	5	200	0.1
L-Serine	8	5	400	0.1

[a]Store at room temperature.
[b]Add after autoclaving the medium.

Supplemented Minimal Medium (SMM)

SMM is SD (please see below) to which various growth supplements have been added. These solutions can then be stored for extended periods. Some should be stored at room temperature, in order to prevent precipitation, whereas the other solutions may be refrigerated. Wherever applicable, HCl salts of amino acids are preferred.

Prepare the medium by adding the appropriate volumes of the stock solutions to the ingredients of SD medium and then adjusting the total volume to 1 liter with distilled H_2O. Add threonine and aspartic acid solutions separately to the medium after it is autoclaved.

Alternatively, it is often more convenient to prepare the medium by spreading a small quantity of the supplement(s) on the surface of an SD plate. Allow the solution(s) to then dry thoroughly onto the plate before inoculating it with yeast strains.

Table A2-3 provides the concentrations of the stock solutions, the volume of stock solution necessary for mixing 1 liter of medium, the volume of stock solution to spread on SD plates, and the final concentration of each constituent in SMM.

Synthetic Dextrose Minimal Medium (SD)

SD is a synthetic minimal medium containing salts, trace elements, vitamins, a nitrogen source (yeast nitrogen base without amino acids), and glucose.

yeast nitrogen base without amino acids*	6.7 g
glucose	20 g
Bacto Agar	20 g
H_2O	1000 ml

*Please see note to recipe for CM on p. A2.9.

X-Gal Indicator Plates for Yeast

Because 5-bromo-4-chloro-3-indolyl-β-D-galactoside (X-gal <!>) does not work for yeast at the normal acidic pH of SD medium, a medium at neutral pH medium is used. This

choice is clearly a trade-off as many yeast strains will not grow well at neutral pH. For each liter of X-gal indicator plates, prepare the following solutions:

Solution I

10x phosphate-buffered stock solution	100 ml
1000x mineral stock solution (see recipe below)	1 ml
drop-out mix (see Drop-out Mix above)	2 g

Adjust the volume to 450 ml with distilled H_2O if the medium is to contain glucose or to 400 ml if it is to contain galactose.

10x Phosphate-buffered Stock Solution

KH_2PO_4 (1 M)	136.1 g
$(NH_4)_2SO_4$ (0.15 M)	19.8 g
KOH (0.75 N) **<!>**	42.1 g
H_2O	1000 ml

Adjust the pH to 7.0 and autoclave.

1000x Mineral Stock Solution

$FeCl_3$ (2 mM)	32 mg
$MgSO_4 \cdot 7H_2O$ (0.8 M)	19.72 g
H_2O	100 ml

Autoclave and store. This solution will develop a fine yellow precipitate, which should be resuspended before use.

Solution II

Mix in a 2-liter flask:

Bacto Agar	20 g
H_2O	500 ml

- Autoclave Solutions I and II separately.
- After cooling to below 65°C, add the following components to Solution I:

glucose or other sugar to a final concentration of 2%	
X-gal (20 mg/ml dissolved in dimethylformamide **<!>**)	2 ml
100x vitamin stock solution	10 ml

- Include any other heat-sensitive supplements at this point.
- Mix Solutions I and II together and pour ~30 ml/plate.

100x Vitamin Stock Solution

thiamine (0.04 mg/ml)	4 mg
biotin (2 µg/ml)	0.2 mg
pyridoxine (0.04 mg/ml)	4 mg
inositol (0.2 mg/ml)	20 mg
pantothenic acid (0.04 mg/ml)	4 mg
H_2O	100 ml

Sterilize by passing the solution through a 0.22-µm filter.

X-Gal Plates for Lysed Yeast Cells on Filters

These plates are used for checking β-galactosidase activity in cells that have been lysed and are immobilized on Whatman 3MM filters.

Bacto Agar	20 g
1 M Na_2HPO_4	57.7 ml
1 M NaH_2PO_4	42.3 ml
$MgSO_4$	0.25 g
H_2O	900 ml

After autoclaving, add 6 ml of X-gal solution (20 mg/ml in dimethylformamide).

YPD (YEPD) Medium

YPD is a complex medium for routine growth of yeast.

yeast extract	10 g
peptone	20 g
glucose	20 g
H_2O	to 1000 ml

To prepare plates, add 20 g of Bacto Agar (2%) before autoclaving.

Appendix 3

TABLE A3-1 (*Continued*)

Mammalian Vectors	Supplier	Application	Features
pCMV-SPORT-β-gal (Chapter 16, Figure 16-2)	Life Technologies	Reporter vector used to monitor transfection efficiency	CMV promoter preceding the *E. coli* β-galactosidase gene
pd2EGFP series (Chapter 17, Figure 17-13)	CLONTECH	Expression: GFP reporter; analysis of cloned regulatory elements	SV40 early promoter and enhancer
pGL3 series (Chapter 17, Figure 17-4)	Promega	Expression: luciferase reporter; analysis of cloned regulatory elements	SV40 early promoter and enhancer
pIND(SP1)/V5-His A (Chapter 17, Figure 17-10)	Invitrogen	Inducible expression: ecdysone regulation; expression of target gene controlled by modified ecdysone (glucocorticoid) receptor	Heat shock minimal and SV40 promoter; ecdysone/glucocorticoid response elements; SP1 enhancer
pSPL3 (Chapter 11, Figure 11-17)	Life Technologies	Exon trapping	Splice donor/splice acceptor sequences
pTet-Splice (Chapter 17, Figure 17-9)	Life Technologies	Inducible expression: tetracycline regulation	Tet promoter
pTet-tTak (Chapter 17, Figure 17-9)	Life Technologies	Inducible expression: produces tetracycline *trans*-activator	Basal CMV promoter and Tet operator
pVgRXR	Invitrogen	Inducible expression: ecdysone regulation; produces the modified ecdysone (glucocorticoid) receptor	RSV, CMV, and SV40 promoters

Yeast Vectors	Supplier	Application	Selection	Regulatory Elements
pB42AD (pJG-4)	CLONTECH	Two-hybrid selection: library construction of genes fused to the B42 activation domain	*TRP1*	GAL1 promoter
PEG202	OriGene, CLONTECH	Two-hybrid selection: fusion of LexA DNA-binding domain to bait	*HIS3*	ADH1 promoter
pGILDA	CLONTECH	Two-hybrid selection: fusion of LexA DNA-binding domain to bait	*HIS3*	GAL1 promoter
pRFHM1	OriGene	Two-hybrid (control): nonactivating fusion of bicoid homeodomain to LexA	*HIS3*	ADH1 promoter
pSH17-4	OriGene	Two-hybrid (control): activating fusion of *GAL4* domain to LexA	*HIS3*	ADH1 promoter
YAC (e.g., pYAC4) (Chapter 4, Figure 4-12)	ATCC, Sigma	Artificial chromosome cloning vector	Amp, *ARS1*	*Tetrahymena* telomere sequence

Shuttle Vectors (replicate in both *E. coli* and *S. cerevisiae*)	Supplier	Application	Selection	Regulatory Elements
YIp (yeast integrating plasmid; e.g., pRS303, 304, 305, 306)	ATCC	Plasmid must integrate into yeast chromosome to be maintained	Yeast: *HIS3*, *TRP1*, *LEU2*, *URA3*, respectively; *E. coli:* Amp	*E. coli:* pBluescript backbone (f1 +/– origin; colE1 origin)

YCp (yeast centromere plasmid; e.g., pRS313, 314, 315, 316)	ATCC	Maintained at low copy number; very stable propagation	Yeast: *HIS3*, *TRP1*, *LEU2*, *URA3*, respectively; *E. coli:* Amp	Yeast: low copy number due to centromere *E. coli:* pBluescript backbone (f1 +/– origin; colE1 origin)
YEp (yeast episomal plasmid; e.g., pRS323, 324, 325, 326)	ATCC	High-copy-number propagation of cloned genes	Yeast: *HIS3*, *TRP1*, *LEU2*, *URA3*, respectively; *E. coli:* Amp	*E. coli:* pBluescript backbone (f1 +/– origin; colE1 origin)
YRp (yeast replicating plasmid)	ATCC	Yeast genetic analysis		
pJK101	Origene	Two hybrid selection: test in repression assay	Yeast: *URA3* *E. coli:* Amp	
pSH18-34 (or pMW111, 112)	OriGene, Invitrogen, CLONTECH	Two hybrid selection: test for transcriptional activation assay	Yeast: *URA3* *E. coli:* Amp (pMW-Kan)	

OTHER VECTORS	SUPPLIERS	APPLICATION	SELECTION	FEATURES
BAC (e.g., pBeloBAC11) (Chapter 4, Figure 4-2)	NEB	Genomic cloning: 120–300 kb	Cam	*loxP, cosN* sites
Cosmid (e.g., SuperCos1) (Chapter 4, Figures 4-4 and 4-8)	Stratagene	Genomic cloning: 30–45 kb	Amp, Neo	T3, T7 promoters, SV40 *ori*
Cosmid (e.g., pJB8) (Chapter 4, Figure 4-7)	ATCC	Genomic cloning: 30–45 kb	Amp	
M13 (Phagescript SK) (Chapter 3, Figure 3-1)	Stratagene	Cloning; sequencing; mutagenesis		T3, T7 promoters
P1 (e.g., pAD10SacBII) (Chapter 4, Figure 4-3)	–	Genomic cloning: 70–100 kb	Kan	*loxP* sites
PAC: (e.g., pCYPAC1) (Chapter 4, Figure 4-4)	–	Genomic cloning: 130–150 kb	Kan, *sacB*	*loxP* sites

The details of Table A3-1 have been assembled from various sources, including the American Type Culture Collection (ATTC) Web Site (www.atcc.org), the Vector Database (www.vectordb.atcg.com), and various company (supplier) Web Sites. Please note that vectors sold by different companies, even with the same name, may vary slightly. Figures for vectors that are included in this manual are cited; for other vector figures, please see appropriate supplier.

[a]n.a. indicates not available.

TABLE A3-2 Bacterial Strains

Strain	Relevant Genotype	Remarks
71/18	*supE thi* Δ(*lac-proAB*) F′ [*ProAB*⁺ *lacI*ᵠ *lacZ* ΔM15]	A strain used for growth of phagemids. The F′ in this strain carries *lacZ* ΔM15, which permits α-complementation with the amino terminus of β-galactosidase encoded in λZAP. The strain makes high levels of Lac repressor and can be used for inducible expression of genes that are under the control of the *lac* promoter and for detection of recombinants expressing β-galactosidase fusion proteins (Messing et al. 1977; Dente et al. 1983; Rüther and Müller-Hill 1983).
BB4	*supF*58 *supE*44 *hsdR*514 *galK*2 *galT*22 *trpR*55 *metB*1 *tonA* Δ*lac*U169 F′ [*ProAB*⁺ *lacI*ᵠ *lacZ* ΔM15 Tn*10*(*tet*ʳ)]	A *recA*⁺ strain used for growth of λZAP and other λ bacteriophages. The F′ in this strain carries *lacZ* ΔM15, which permits α-complementation with the amino terminus of β-galactosidase encoded in λZAP. The F′ allows superinfection with an M13 helper bacteriophage, a step required for converting a recombinant λZAP to a pBluescript plasmid (Bullock et al. 1987).
BHB2688	(N205 *recA* [λ*imm*434 λc*Its b2 red* Eam Sam/λ])	A bacteriophage λ lysogen used to prepare packaging extracts (Hohn and Murray 1977; Hohn 1979).
BHB2690	(N205 *recA* [λ*imm*434 c*Its b2 red* Dam Sam/λ])	A bacteriophage λ lysogen used to prepare packaging extracts (Hohn and Murray 1977; Hohn 1979).
BL21 (DE3 a.k.a. "Origami")	*hsdS gal* (λc*Its*857 *ind*1 Sam7 *nin*5 *lac*UV5-T7 gene *1*)	A strain used for high-level expression of genes cloned into expression vectors containing the bacteriophage T7 promoter (e.g., the pET series). The gene encoding bacteriophage T7 RNA polymerase is carried on the bacteriophage λDE3, which is integrated into the chromosome of BL21 (Studier and Moffatt 1986).
BNN102 (C600*hflA*)	*supE*44 *hsdR thi*-1 *thr*-1 *leuB*6 *lacY*1 *tonA*21 *hflA*150 [*chr*::Tn*10* (*tet*ʳ)]	An *hflA* strain used to select λgt10 recombinants. The *hflA* mutation suppresses plaque formation by *cI*⁺ bacteriophages but allows plaque formation by recombinant *cI*⁻ bacteriophages (Young and Davis 1983a).
C-1a	Wild-type strain	A wild-type clone of *E. coli* strain C that has been maintained on minimal medium for several years. *E. coli* C is F⁻ and lacks host restriction and modification activity. It is a nonsuppressing host strain used in complementation tests with amber mutants of bacteriophage λ (Bertani and Weigle 1953; Borck et al. 1976).
C600 (BNN93)	*supE*44 *hsdR thi*-1 *thr*-1 *leuB*6 *lacY1* *tonA*21	An amber suppressing strain often used for making lysates (Appleyard 1954) and for propagation of λgt10 (Young and Davis 1983a).
CES200	*sbcB*15 *recB*21 *recC*22 *hsdR*	A strain used for growth of Spi⁻ bacteriophages (Nader et al. 1985).
CES201	*recA sbcB*15 *recB*21 *recC*22 *hsdR*	A recombination-deficient strain used for growth of Spi⁻ bacteriophages (Wyman and Wertman 1987).
CJ236	*dut*1 *ung*1 *thi*-1 *relA*1/pCJ105(*cam*ʳ F′)	A *dut ung* strain used to prepare uracil-containing DNA for use as templates in in vitro mutagenesis (Kunkel et al. 1987). pCJ105 carries an F′ and *cam*ʳ; growth of CJ236 in the presence of chloramphenicol selects for retention of the F′.
CSH18	*supE thi* Δ(*lac-pro*) F′ [*ProAB*⁺ *lacZ*⁻]	An amber suppressing strain used to screen recombinants made in bacteriophage λ vectors carrying a *lacZ* gene in the stuffer fragments. These vectors give rise to blue plaques in the presence of the chromogenic substrate X-gal; recombinants in which the stuffer fragment has been replaced by foreign DNA give rise to white plaques (Miller 1972; Williams and Blattner 1979).
DE3 (Origami)	Please see BL21	
DH1	*supE*44 *hsdR*17 *recA*1 *endA*1 *gyrA*96 *thi*-1 *relA*1	A recombination-deficient amber suppressing strain used for plating and growth of bacteria transformed by plasmids and cosmids (Low 1968; Meselson and Yuan 1968; Hanahan 1983).
DH5	*supE*44 *hsdR*17 *recA*1 *endA*1 *gyrA*96 *thi*-1 *relA*1	A recombination-deficient amber suppressing strain used for plating and growth of plasmids and cosmids (Low 1968; Meselson and Yuan 1968; Hanahan 1983). This strain has a higher transformation efficiency than DH1.

DH5α	*supE44* Δ*lacU169* (φ80 *lacZ* ΔM15) *hsdR17 recA1 endA1 gyrA96 thi-1 relA1*	A recombination-deficient amber suppressing strain used for plating and growth of plasmids and *hsdR17 recA1 endA1 gyrA96 thi-1 relA1* cosmids. The φ80 *lacZ* ΔM15 mutation permits α-complementation with the amino terminus of β-galactosidase encoded in pUC vectors (Hanahan 1983).
DH5αMCR	*F⁻ mcrA* Δ(*mrr-hsdRMS-mcrBC*) φ80 Δ*lacZ* ΔM15 (Δ*lacZYA-argF*)*supE44 hsdR17 recA1 endA1 gyrA96 thi-1 relA1*	A host for pUC and other α-complementation vectors; used for generating genomic libraries containing methylated cytosine or adenine residues.
DH10B	Δ(*mrr-hsd RMS-mcrBC*) *mcrA recA1*	A recombination-defective strain used for the propagation of BACs.
DH11S	Δ(*lac-proAB*) Δ(*recA1398*) Δ(*mrr-hsd RMS-mcrBC mcrA deoR rpsL srl⁻*) F′[*proAB lacI^q lacZ* ΔM15]	A recombination-deficient strain used for growth of phagemids; the strain facilitates cloning of methylated genomic DNA and enhances transformation by large plasmids (Lin et al. 1992).
DP50*supF*	*supE44 supF58 hsdS3*($r_B m_B$) *dapD8 lacY1 glnV44* Δ(*gal-uvrB*)*47 tyrT58 gyrA29 tonA* Δ(*thyA57*)	A strain used for isolation and propagation of bacteriophage λ recombinants (Leder et al. 1977; B. Bachmann, pers. comm.).
ED8654	*supE supF hsdR metB lacY gal trpR*	An amber suppressing strain commonly used to propagate bacteriophage λ vectors and their recombinants (Borck et al. 1976; Murray et al. 1977).
ED8767	*supE44 supF58 hsdS3*($r_B^- m_B^-$) *recA56 galK2 galT22 metB1*	A recombination-deficient suppressing strain used for propagation of bacteriophage λ vectors (Murray et al. 1977).
HB101	*supE44 hsdS20*($r_B^- m_B$) *recA13 ara-14 proA2 lacY1 galK2 rpsL20 xyl-5 mtl-1*	An amber suppressing strain commonly used for large-scale production of plasmids. The hybrid strain is isolated from an *E. coli* K12 x *E. coli* B cross, and can be transformed efficiciently by plasmids (Boyer and Roulland-Dussoix 1969; Bolivar and Backman 1979).
HMS174	*recA1 hsdR rif^R*	A recombination-deficient nonsuppressing strain used for high-level expression of genes cloned into expression vectors containing bacteriophage T7 promoter. Bacteriophage T7 RNA polymerase is provided by infection with a bacteriophage λ that carries bacteriophage T7 gene *1* (Campbell et al. 1978; Studier and Moffatt 1986).
JM101[a]	*supE thi* Δ(*lac-proAB*) F′ [*traD36 proAB⁺ lacI^q lacZ* ΔM15]	An amber suppressing F′ strain that will support growth of bacteriophage M13 vectors (Messing 1979).
JM105	*supE endA sbcB15 hsdR4 rpsL thi* Δ(*lac-proAB*) F′ [*traD36 proAB⁺ lacI^q lacZ* ΔM15]	An amber suppressing F′ strain that will support growth of bacteriophage M13 vectors and will modify but not restrict transfected DNA (Yanisch-Perron et al. 1985). The F′ in this strain carried *lacZ* ΔM15, which permits α-complementation with the amino terminus of β-galactosidase encoded in λZAP.
JM107[b]	*supE44 endA1 hsdR17 gyrA96 relA1 thi* Δ(*lac-proAB*) F′ [*traD36 proAB⁺ lacI^q lacZ* ΔM15]	An amber suppressing F′ strain that will support growth of bacteriophage M13 vectors and will modify but not restrict transfected DNA (Yanisch-Perron et al. 1985). The F′ in this strain carried *lacZ* ΔM15, which permits α-complementation with the amino terminus of β-galactosidase encoded in λZAP.
JM109[b,c]	*recA1 supE44 endA1 hsdR17 gyrA96 relA1 thi* Δ(*lac-proAB*) F′ [*traD36 proAB⁺ lacI^q lacZ* ΔM15]	An amber suppressing F′ recombination-deficient strain that will support growth of bacteriophage M13 vectors and will modify but not restrict transfected DNA (Yanisch-Perron et al. 1985). The F′ in this strain carried *lacZ* ΔM15, which permits α-complementation with the amino terminus of β-galactosidase encoded in λZAP.
JM110	*dam dcm supE44 hsdR17 thi leu rpsL lacY galK galT ara tonA thr tsx* Δ(*lac-proAB*) F′ [*traD36 proAB⁺ lacI^q lacZ* ΔM15]	An amber suppressing F′strain that will not methylate adenine in GATC sequences and will support growth of bacteriophage M13 vectors (Yanisch-Perron et al. 1985). The F′ in this strain carried *lacZ* ΔM15, which permits α-complementation with the amino terminus of β-galactosidase encoded in λZAP.

(Continued on following pages.)

TABLE A3-2 (*Continued*)

Strain	Relevant Genotype	Remarks
K802	*supE hsdR gal metB*	An amber suppressing strain used to propagate bacteriophage λ vectors and their recombinants (Wood 1966).
KC8	*hsdR leuB600 trpC9830 pyrF::*Tn*5 hisB463 lacΔ X74 strA galU galK*	A strain for selective rescue of yeast plasmids carrying either the activation domain or DNA-binding domain derived from a GAL4 or LexA two-hybrid screening. KC8 carries the *trpC, leuB,* and *hisB* mutations that may be used for complementation with yeast *TRP1, LEU2,* and *HIS3* wild-type markers. Note that the Tn*5* transposon confers kanamycin resistance.
KK2186	*supE sbcB*15 *hsdR*4 *rpsL thi* Δ(*lac-proAB*) F′ [*traD*36 *proAB*$^+$ *lacI*^{q} *lacZ* ΔM15]	A strain that will support growth of vectors carrying amber mutations and will modify but not restrict transfected DNA (Zagursky and Berman 1984).
KW251	*supE hsdR mcrB mcrA recD*	A recombination-deficient strain that is permissive for vectors carrying amber mutations. Used for propagation of high-titer lysates of bacteriophage λ. Will modify but not restrict DNA at *Eco*RI sites; permits propagation of cytosine-methylated DNA.
LE392	*supE*44 *supF*58 *hsdR*514 *galK*2 *galT*22 *metB*1 *trpR*55 *lacY*1	An amber suppressing strain commonly used to propagate bacteriophage λ vectors and their recombinants. LE392 is a derivative of ED8654 (Borck et al. 1976; Murray et al. 1977).
LG90	Δ(*lac-proAB*)	A strain from which *lacZ* is deleted that is used for detection of recombinants expressing β-galactosidase fusion proteins (Guarente and Ptashne 1981).
M5219	*lacZ trpA rpsL* (λ*bio*252 *cIts*857 ΔH1)	A strain used for regulated expression of genes cloned downstream from the bacteriophage λ p_L promoter. It contains a defective λ prophage that encodes the bacteriophage λ *cIts*857 repressor and N protein, which is an antagonist of transcription termination (Remaut et al. 1981; Simatake and Rosenberg 1981).
MBM7014.5	*hsdR*2 *mcrB*1 *zjj*202::Tn*10* (*tet*^{r}) *araD*139 *araCU*25am Δ*lac*U169	An *mcrB* strain used for construction of libraries in λORF8. Libraries are made with DNA treated with methylases to protect *Hin*dIII and *Bam*H1 sites. M*Alu*I methylase is used to protect *Hin*dIII sites since M*Hin*dIII methylase is not available commercially. This strain is defective in the restriction system that recognizes *Alu*I-methylated DNA sites (Raleigh and Wilson 1986).
MC1061	*hsdR mcrB araD*139 Δ(*araABC-leu*)7697 Δ*lacX74 galU galK rpsL thi*	An *mcrB* strain used for λORF8 primary libraries as described for the strain MBM7014.5 (Meissner et al. 1987).
MM294	*supE*44 *hsdR endA*1 *pro thi*	An amber suppressing strain used for large-scale production of plasmids. It is transformed efficiently by plasmids (Meselson and Yuan 1968).
MV1184[d]	*ara* Δ(*lac-proAB*) *rpsL thi* (φ80 *lacZ* ΔM15) Δ(*srl-recA*)306::Tn*10* (*tet*^{r}) F′ [*traD*36 *proAB*$^+$ *lacI*^{q} *lacZ* ΔM15]	A recombination-deficient strain used to propagate phagemids pUC118/pUC119 and to obtain single-stranded copies of phagemids (Vieira and Messing 1987).
MV1193	Δ(*lac-proAB*) *rpsL thi endA spcB*15 *hsdR*4 Δ(*srl-recA*)306::Tn*10* (*tet*^{r}) F′ [*traD*36 *proAB*$^+$ *lacI*^{q} *lacZ* ΔM15]	A recombination-deficient strain used to propagate phagemids pUC118/pUC119 and to obtain single-stranded copies of phagemids (Zoller and Smith 1984, 1987).
MZ-1	*galK*Δ8*attL*Δ*BamN*$_7$*N*$_{53}$ *cIts*857Δ H1 *his ilv bio N*^{1}	A temperature-sensitive λ-lysogenic strain used as a host for plasmids containing the bacteriophage λ p_L promoter (Nagai and Thøgersen 1984).
NM519	*hsdR recBC sbcA*	A recombination-deficient strain used for growth of Spi$^-$ λ bacteriophages; will modify but not restrict DNA at *Eco*RI sites (Arber et al. 1983).

NM522	*supE* Δ(*lac proAB*) Δ*mcrB hsdSM*)5 F′[*proAB lacI*^{q} *lacZ* ΔM15]	A strain deficient in modification and restriction used for the growth of phagemids; allows enhanced cloning of methylated genomic DNA (Gough and Murray 1983).
NM531	*supE supF hsdR trpR lacY recA*13 *metB gal*	A recombination-deficient suppressing strain used for propagation of bacteriophage λ vectors (Arber et al. 1983).
NM538	*supF hsdR trpR lacY*	A strain used for assay and propagation of bacteriophage λ (Frischauf et al. 1983).
NM539	*supF hsdR lacY* (P2*cox*)	A strain used for selection of Spi$^-$ λ bacteriophages. NM539 is a derivative of NM538 (Frischauf et al. 1983).
NM554	*AraD*139 *galK galU hsd R*2 (*rK*$^-$*Km*$^+$) *recA*13 *rpsL thi*-1 Δ(*ara-leu*)7696 Δ*lacX*74 *F*$^-$	A strain used for plating an unamplified cosmid library for screening.
NS3516	*Cre*$^+$ parent of NS3529	A Cre$^+$ host strain used to prepare large quantities of recombinant DNA cloned in bacteriophage P1 (Sternberg et al. 1994).
NS3529	*recA mcrA* Δ(*mrr-hsdRMS-mcrBC*) (λ*imm*434 *nin*5X1-*Cre*) (λ*imm*λ*LP*1)	A host strain for preparing bacteriophage P1 libraries. The *imm434* prophage produces Cre constitutively; the *imm*λ prophage produces the *lacI*^{q} repressor constitutively (Sternberg et al. 1994).
Q358	*supE hsdR* φ80^r	An amber suppressing host used for growth of bacteriophage λ vectors (Karn et al. 1980).
Q359	*supE hsdR* φ80^r (P2)	An amber suppressing host used to select Spi$^-$ λ recombinants (Karn et al. 1980).
R594	*galK*2 *galT*22 *rpsL*179 *lac*	A nonsuppressing strain used as a nonpermissive host for bacteriophage λ vectors containing amber or ochre mutations (Campbell 1965).
RB791	W3110 *lacI*^{q}L8	A strain that makes high levels of Lac repressor and is used for inducible expression of genes under the control of the *lac* and *tac* promoters (Brent and Ptashne 1981).
RR1	*supE*44 *hsdS*20(r_b^- m_b^-) *ara*-14 *proA*2 *lacY*1*galK*2 *rpsL*20 *xyl*-5 *mtl*-1	A *recA*$^+$ derivative of HB101 that can be transformed with high efficiency (Bolivar et al. 1977; Peacock et al. 1981; B. Bachmann, pers. comm.).
SMR10	*E. coli* C (λ*cos*2 ΔB *xis*1 *red*3 *gam* am210 c1*ts*857 *nin*5 Sam7/λ)	A bacteriophage λ lysogen used to prepare packaging extracts (Rosenberg 1985).
TAP90	*supE*44 *supF*58 *hsdR pro leuB thi*-1 *rpsL lacY*1 *tonA*1 *recD*1903::mini-*tet*	A strain used for production of high-titer bacteriophage λ lysates. This restriction-deficient *supE supF* strain has a mini-*tet* insertion in *recD*, which improves growth of Spi$^-$ λ bacteriophages (Patterson and Dean 1987).
TG1	*supE hsd*Δ5 *thi* Δ(*lac-proAB*) F′ [*traD*36 *proAB*$^+$ *lacI*^{q} *lacZ* ΔM15]	An *Eco*K$^-$ derivative of JM101 that neither modifies nor restricts transfected DNA (Gibson 1984).
TG2	*supE hsd*Δ5 *thi* Δ(*lac-proAB*) Δ(*srl-recA*)306::Tn*10* (*tet*^{r}) F′ [*traD*36 *proAB*$^+$ *lacI*^{q} *lacZ* ΔM15]	A recombination-deficient derivative of TG1 (M. Biggin, pers. comm.).
XL1-Blue	*supE*44 *hsdR*17 *recA*1 *endA*1 *gyrA*46 *thi relA*1 *lac*$^-$ F′ [*proAB*$^+$ *lacI*^{q} *lacZ* ΔM15 Tn*10* (*tet*^{r})]	A recombination-deficient strain that will support the growth of vectors carrying some amber mutations, but not those with the Sam100 mutation (e.g., λZAP). Transfected DNA is modified but not restricted. XL1-Blue is used to propagate λZAPII recombinants, which are unstable in BB4. The F′ in this strain allows blue/white screening on X-gal and permits superinfection with bacteriophage M13 (Bullock et al. 1987).

(*Continued on following page.*)

TABLE A3-2 (*Continued*)

STRAIN	RELEVANT GENOTYPE	REMARKS
XL1-Blue MRF′	*supE*44 *hsdR*17 *recA*1 *endA*1 *gyrA*46 *thi relA*1 *lac*⁻ Δ(*mcrA*)183 Δ(*mcrCB-hsdSMR-mrr*)173 F′ [*proAB*⁺ *lacI*^{q} *lacZ* ΔM15 Tn*10* (*tet*^{r})]	A recombination-deficient strain that is permissive for growth of vectors carrying amber mutations. Will modify but not restrict DNA at *Eco*RI sites; permits α-complementation of β-galactosidase in a *recA*⁻ strain (Jerpseth et al. 1992). It is resistant to tetracycline.
XS101	*recA*1 *hsdR rpoB*331 F′ [*kan*]	A recombination-deficient strain that modifies but does not restrict transfected DNA. It carries an episome conferring resistance to kanamycin and is used for growth of phagemids (Levinson et al. 1984).
XS127	*gyrA thi rpoB*331 Δ(*lac-proAB*) *argE* F′ [*traD*36 *proAB*⁺ *lacI*^{q} *lacZ* ΔM15]	A strain used for growth of phagemids (Levinson et al. 1984).
Y1089	*araD*139 Δ*lac*U169 *proA*⁺ Δ*lon rpsL hflA*150 [*chr*::Tn*10* (*tet*^{r})] PMC9	A strain used for protein production from λgt11 and λgt18-23 recombinants. Expression of the foreign protein is controlled by high levels of Lac repressor made by pMC9, which carries *lacI*^{q}. Y1089 is deficient in the *lon* protease, which may enhance stability of the foreign proteins. Lysogens are formed at a high frequency in this strain (Young and Davis 1983b).
Y1090hsdR	*supF hsdR araD* 139 Δ*lon* Δ*lac*U169 *rpsL trpC*22::Tn*10* (*tet*^{r}) pMC9	A strain used for immunological screening of expression libraries and propagation of λgt11 and λgt18-23 (Young and Davis 1983b; Jendrisak et al. 1987). Expression of the foreign protein is controlled by the high levels of Lac repressor made by pMC9, which carries *lacI*^{q}. Detection of proteins toxic to *E. coli* can be achieved by adding IPTG several hours after initiation of plaque formation. Some proteins are unstable in *E. coli*. Y1090 *hsdR* is deficient in the *lon* protease, which may enhance stability of antigens and facilitate antibody screening. The *supF* marker suppresses Sam100 to allow cell lysis (Young and Davis 1983b).
YK537	*supE*44 *hsdR hsdM recA*1 *phoA*8 *leuB*6 *thi lacY rpsL*20 *galK*2 *ara*-14 *xyl*-5 *mtl*-1	A recombination-deficient suppressing strain used for regulated expression of genes cloned downstream from the *phoA* promoter (Oka et al. 1985).

[a]Strain JM103 (Messing et al. 1981) is a restrictionless derivative of JM101 that has been used to propagate bacteriophage M13 recombinants. However, some cultivars of JM103 have lost the *hsdR4* mutation (Felton 1983) and are lysogenic for bacteriophage P1 (which codes for its own restriction/modification system). JM103 is therefore no longer recommended as a host for bacteriophage M13 vectors. Strain KK2186 (Zagursky and Berman 1984) is genetically identical to JM103 except that it is nonlysogenic for bacteriophage P1.

[b]Strains JM106 and JM108 are identical to JM107 and JM109, respectively, except that they do not carry an F′ episome. These strains will not support the growth of bacteriophage M13 but may be used to propagate plasmids. However, JM106 and JM108 do not carry the *lacI*^{q} marker (normally present on the F′ episome) and are therefore unable effectively to suppress the synthesis of potentially toxic products encoded by foreign DNA sequences cloned into plasmids carrying the *lacZ* promoter.

[c]Strains JM108 and JM109 are defective for synthesis of bacterial cell walls and form mucoid colonies on minimal media. This trait does not affect their ability to support the growth of bacteriophage M13.

[d]The original strain of MV1184, constructed by M. Volkert (pers. comm.), did not carry an F′ episome. However, the strain of MV1184 distributed by the Messing laboratory clearly carries an F′ episome. It is therefore advisable to check strains of MV1184 on their arrival in the laboratory for their ability to support the growth of male-specific bacteriophages.

Appendix 4

Enzymes Used in Molecular Cloning

MODIFICATION/RESTRICTION SYSTEMS IN *E. COLI*

Modification of DNA is used by *Escherichia coli* to distinguish between its own genome and foreign DNAs introduced by bacteriophage infection, plasmid transfer, or transfection. DNAs with familiar patterns of methylation on adenosine or cytosine residues are immune to attack, whereas unmethylated DNAs or DNAs with unfamiliar patterns of methylation are earmarked for degradation by endogenous restriction enzymes.

Methylating Enzymes in *E. coli*

Wild-type strains of *E. coli* express DNA methyltransferases that transfer a methyl group from *S*-adenosylmethionine to an adenine or cytosine residue within a defined target sequence. Described below are several types of methylating enzymes.

dam *Methyltransferase*

In *dam*$^+$ strains of *E. coli*, adenine residues embedded in the sequence ^{5}...GATC...^{3} carry a methyl group attached to the N^6 atom (Hattman et al. 1978). More than 99% of these modified adenine bases, which are found on both strands of the palindromic recognition sequence, are formed by action of DNA adenine methylase, the product of the *dam* gene. DNA adenine methylase is a single-subunit nucleotide-independent (type II) DNA methyltransferase that transfers a methyl group from *S*-adenosylmethionine to adenine residues in the recognition sequence ^{5}.....GATC.....^{3} (for review, please see Marinus 1987; Palmer and Marinus 1994). In *E. coli*, *dam* methylation is required for efficient DNA mismatch repair, for accurate initiation of DNA replication at *oriC*, for segregation and partition of chromosomes carrying *oriC*, and for modulation of gene expression (for review, please see Palmer and Marinus 1994). The transfer of a methyl group to the N^6 atom of adenine places a bulky alkyl residue in the major groove of B-form DNA and prevents cleavage in vitro by some restriction enzymes whose recognition sites contain the sequence ^{5}.....GATC.....^{3}. By contrast, other restriction enzymes require methylation at -GATC- residues to cleave DNA.

The recognition sites of several restriction enzymes (*Pvu*I, *Bam*HI, *Bcl*I, *Bgl*II, *Xho*II, *Mbo*I, and *Sau*3AI) contain this sequence, as do a proportion of the sites recognized by *Cla*I (1 site in 4), *Xba*I (1 site in 16), *Taq*I (1 site in 16), *Mbo*II (1 site in 16), and *Hph*I (1 site in 16). The inhibition of *Mbo*I digestion of prokaryotic DNA presents no practical problem because the restriction enzyme *Sau*3AI recognizes exactly the same sequence as *Mbo*I but is unaffected by *dam* methylation. (*Note:* Mammalian DNA is not methylated at the N^6 position of adenine, and thus, either *Mbo*I or *Sau*3AI can be used effectively.) However, when it is necessary to cleave prokaryotic DNA at every possible site with *Cla*I, *Xba*I, *Taq*I, *Mbo*II, or *Hph*I or to cleave it at all with *Bcl*I, the DNA must be prepared from strains of *E. coli* that are *dam*$^-$ (Backman 1980; Roberts et al. 1980; McClelland 1981).

Lists of restriction enzymes whose pattern of cleavage is affected by *dam* methylation have been assembled by Kessler and Manta (1990) and McClelland and Nelson (1992); additional information is available in the brochures of most commercial suppliers of enzymes and in a database of restriction and modification enzymes (REBASE) that is accessible at rebase.neb.com/rebase.

dcm *Methyltransferase*

dcm introduces methyl groups at the C^5 position of the internal cytosine in the sequence ^{5}...CCAGG...^{3} or ^{5}...CCTGG...^{3} and therefore prevents or suppresses cleavage by restriction

enzymes such as *Eco*RI (Marinus and Morris 1973; May and Hattman 1975). For most purposes, this problem can be avoided by using *Bst*NI, which recognizes exactly the same sequence as *Eco*RII (although it cuts the DNA at a different location within the sequence). If *Bst*NI cannot be substituted for *Eco*RII, the DNA must be prepared from strains of *E. coli* that are *dcm*$^-$ (Marinus 1973; Backman 1980; Roberts et al. 1980). Certain other enzymes may cleave at sequences that partially overlap the modified *dcm* recognition sequence. Detailed information on the methylation sensitivity of individual restriction enzymes is provided by the REBASE Web Site (rebase.neb.com/rebase). *dcm*$^-$ mutants of *E. coli* show no phenotype, and the biological significance of *dcm* methylation is obscure (for review, please see Palmer and Marinus 1994).

The Modification Component of Modification/Restriction Systems

- ***Type I modification/restriction systems.*** The classical type I modification/restriction system in many wild-type strains of *E. coli* is encoded by the three *hsd* (*Eco*K) genes. Two of the polypeptides encoded by these genes (*hsdM* and *hsdS*) are needed to transfer methyl groups to the N^6 position of two adenines in the recognition sequence $^{5'}$AAC(N_6)GTGC$^{3'}$ (Kan et al. 1979). This type of modification, which accounts for ~1% of N^6 adenine methylation in *E. coli*, protects DNA against cleavage by the heterotrimeric *Eco*K restriction endonuclease (encoded by the *hsdRMS* genes), a type I restriction endonuclease which, at the expense of ATP hydrolysis, produces double-stranded breaks at a variable distance from the recognition site (Bickle 1987). Many strains of *E. coli* used for molecular cloning carry mutations in the *hsd* genes.
- ***Type II modification/restriction systems.*** Classical (type II) modification/restriction systems have two components, a restriction endonuclease and a DNA methyltransferase; both components recognize the same target sequence. In vivo, type II restriction endonucleases cleave unmethylated sequences, whereas methyltransferases prefer hemimethylated substrates generated during DNA replication. The modifying enzymes of many prokaryotic type II modification/restriction systems are monomers that transfer a methyl group to the 5-carbon of the pyrimidine ring of cytosine, creating 5-methylcytosine. The catalytic mechanism of this reaction involves nucleophilic attack on C^6 of the target cytosine by a cysteine residue to generate a covalent intermediate. The addition of the nucleophile allows the transfer of a methyl group from *S*-adenosylmethionine to the activated 5-carbon. Abstraction of the proton at the 5-position yields an enzyme that undergoes conjugative elimination to yield the product 5-methylcytosine (Wu and Santi 1987; for reviews, please see Kumar et al. 1994; Verdine 1994; Winkler 1994).

Contacts between type II restriction enzymes and their recognition sequence involve amino acids that are widely separated in the primary protein sequence, resulting in bending and kinking of the target DNA (Kim et al. 1990; Winkler et al. 1993). Type II methylases produce a more radical change in DNA structure by forcing the target cytosine to flip out of the plane of the DNA helix and into the active site of the enzyme. This flipping mechanism, which was first established for M·*Hha*I (Klimasauskas et al. 1994), is believed to be universal among 5-methylcytosine transferases, all of which share a well-conserved set of sequence motifs and a common architecture (for review, please see Winkler 1994).

Methylation-dependent Restriction Systems in *E. coli*

E. coli K contains at least three different methylation-dependent restriction systems that recognize different target sequences only when methylated: *mrr* (6-methyladenine [^{m6}A]), *mcr*A (^{m5}CG [^{m5}C = 5-methylcytosine]), and *mcr*B (PU^{m5}C) (Raleigh and Wilson 1986; Heitman and Model

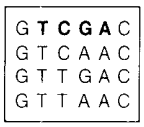
1987; Raleigh et al. 1988). DNAs that are methylated at such sites are inefficiently cloned into wild-type strains of *E. coli* (Whittaker et al. 1988). For example, human DNA, which is extensively methylated in vivo at ^{m5}CG, is restricted by *mcr*A. Nonrestricting strains of *E. coli* (Raleigh and Wilson 1986; Raleigh et al. 1988) are therefore preferred for transformation and cloning of methylated DNA.

M·*Eco*RI methylase catalyzes the transfer of methyl groups from *S*-adenosyl L-methionine (SAM) to the adenines marked with a star (*) in the *Eco*RI recognition sequence in the figure at the right. The modification of adenine to 6-methylaminopurine protects the DNA from cleavage by *Eco*RI (Greene et al. 1975).

Modification of Restriction Sites by DNA Methylation

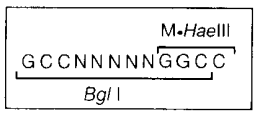
For many of the type II restriction enzymes, a corresponding methylase has been isolated that modifies the cognate recognition sequence and renders it resistant to cleavage. These methylases, a number of which are available from commercial suppliers, are useful in a number of tasks in molecular cloning. For example, in the construction of genomic DNA libraries (Maniatis et al. 1978), random fragments of genomic DNA generated by partial cleavage with the restriction enzymes *Alu*I and *Hae*III can be treated with M·*Eco*RI methylase prior to the addition of synthetic *Eco*RI linkers. When the linkers attached to genomic DNA are subsequently digested with *Eco*RI, the natural restriction sites within the genomic DNA are protected from cleavage. The same strategy may be used to spare natural restriction sites when preparing double-stranded cDNA for cloning.

Methylases can also be used to alter the apparent cleavage specificity of certain restriction enzymes (Nelson et al. 1984; Nelson and Schildkraut 1987). These alterations are accomplished in vitro by methylation of a subset of the sequences recognized by certain restriction enzymes. Only the methylated subsets will be resistant to cleavage. For example, the restriction enzyme *Hinc*II recognizes the degenerate sequence GTPyPuAC and will therefore cleave the four sequences shown at the right.



The M·*Taq*I methylase recognizes only the sequence TCGA and methylates the adenine residue (McClelland 1981). The subset of *Hinc*II recognition sequences that contains the internal sequence TCGA will therefore be resistant to cleavage after methylation by M·*Taq*I, whereas the other three recognition sequences will remain sensitive to *Hinc*II.

A second class of overlapping methylation and restriction sites occurs at the boundaries of the recognition sequences of a restriction enzyme and a methylase. For example, a *Bam*HI site (GGATCC) that happens to be preceded by CC or followed by GG partially overlaps a site (CCGG) that can be methylated by the enzyme M·*Msp*I. Because M·*Msp*I methylates the 5′ cytosine of its recognition sequence (^{m5}CCGG), the *Bam*HI site becomes methylated at an internal cytosine residue (GGAT^{m5}CCGG) and therefore is resistant to cleavage by *Bam*HI. Another example is provided by *Bgl*I and M·*Hae*III illustrated at the left. As in the cases of *Hinc*II/M·*Taq*I and *Bam*HI/M·*Msp*I, the methylation blocks the cleavage of a previously existing restriction site. Finally, certain adenine methylases can be used in conjunction with the methylation-dependent restriction enzyme *Dpn*I to produce highly specific cleavages at sequences 8–12 bp in length (McClelland et al. 1984; McClelland and Nelson 1987; Weil and McClelland 1989).



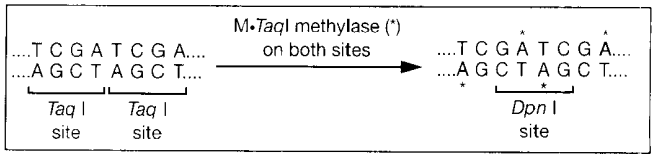


TABLE A4-1 Isoschizomer Pairs That Differ in Their Sensitivity to Sequence-specific Methylation

Methylated Sequence[b]	Isoschizomer Pairs[a]	
	Cut by	Not Cut by
T^{m5}CCGGA	*Acc*III	*Bsp*MII
TC^{m5}CGGA	*Acc*III	*Bsp*MII
GGWC^{m5}C	*Afl*I	*Ava*II (*Eco*47I)
TCCGG^{m6}A	*Bsp*MII	*Acc*III
C^{m5}CWGG	*Bst*NI (*Mva*I)	*Eco*RII
GGTAC^{m5}C	*Kpn*I	*Asp*718I
C^{m5}CGG	*Msp*I	*Hpa*II (*Hap*II)
C^{m4}CGG	*Msp*I	*Hpa*II
G^{m6}ATC	*Sau*3AI (*Fnu*EI)	*Mbo*I (*Nde*II)
TCGCG^{m6}A	*Sbo*13I	*Nru*I
RG^{m6}ATCY	*Xho*II	*Mfl*I
CC^{m5}CGGG	*Xma*I (*Cfr*9I)	*Sma*I

In each row, the first column lists a methylated sequence, the second column lists an isoschizomer that cuts this sequence, and the third column lists an isoschizomer that does not cut this sequence. For references, please see McClelland and Nelson (1988). (Reprinted, with permission, from McClelland and Nelson 1988.)

[a]An enzyme is classified as insensitive to methylation if it cuts the methylated sequence at a rate that is at least one tenth the rate at which it cuts the unmethylated sequence. An enzyme is classified as sensitive to methylation if it is inhibited at least 20-fold by methylation relative to the unmethylated sequence.

[b]Sequences are in 5′→3′ order. R = G or A; Y = C or T; W = A or T; ^{m4}C = 4-methylcytosine, ^{m5}C = 5-methylcytosine, and ^{m6}A = 6-methyladenine.

This example differs from those above in that the strategy *creates* a site in DNA that otherwise would not be cleaved by *Dpn*I. This general strategy of using specific methylases in conjunction with restriction enzymes has produced >60 new cleavage specificities and many more are possible (for references, please see McClelland and Nelson 1988). A compilation of the sensitivities of individual restriction enzymes to site-specific modifications may be found at the REBASE Web Site: rebase.neb.com/rebase.

Several pairs of isoschizomers differ in their sensitivity to site-specific methylation (see Table A4-1). Such endonuclease pairs are useful for studying the level and distribution of site-specific methylation in cellular DNA, for example, ^{m5}CG in mammals, ^{m5}CG and ^{m5}CNG in plants, and G^{m6}ATC in enterobacteria (Waalwijk and Flavell 1978; McClelland 1983; Bird et al. 1985).

Sensitivity to site-specific DNA methylation is clearly not limited to restriction enzymes but is a property of DNA-binding proteins in general (see Sternberg 1985; Wang et al. 1986). ^{m4}C, ^{m5}C, ^{hm5}C, and ^{m6}A site-specific modification at "noncanonical" sites will block several type II methylases. The data are summarized in Table A4-2.

Influence of Methylation on DNA Mapping

Mammalian DNA contains ^{m5}C residues in addition to the four normal bases. These residues are found primarily at the 5′ side of G residues. Although only a portion of CpG doublets are methylated, the pattern of methylation is highly cell-type-specific (Bird and Southern 1978); any given CpG doublet is methylated in the majority of cells of a given population or in only a few of them.

Nearly all restriction enzymes used for long-range mapping of mammalian chromosomal DNA recognize sequences that contain CpG. Because this dinucleotide occurs approximately five-

[a]Sequences are in 5′→3′ order. W = A or T; N = A or C or G or T; ^{m4}C = 4-methylcytosine, ^{m5}C = 5-methylcytosine, ^{hm5}C = 5-hydroxymethylcytosine, and ^{m6}A = 6-methyladenine.

[b]An enzyme is classified as insensitive to methylation if it methylates the methylated sequence at a rate that is at least one tenth the rate at which it methylates the unmethylated sequence. An enzyme is classified as sensitive to methylation if it is inhibited at least 20-fold by methylation relative to the unmethylated sequence.

[c]*E. coli dam* modifies GAT^{m5}C at a reduced rate.

fold less frequently in mammalian DNA than expected (Normore 1976; Setlow 1976; Shapiro 1976), restriction enzyme recognition sites that contain the CpG dinucleotide are extremely rare (Lindsay and Bird 1987; McClelland and Nelson 1987). Furthermore, most of these dinucleotides are methylated, and almost all enzymes with CpG in the recognition sequence fail to cleave ^{m5}CpG-methylated DNA (Nelson and McClelland 1987); for example, *Bsp*MII, *Cla*I, *Csp*I, *Eag*I, *Mlu*I, *Nae*I, *Nar*I, *Not*I, *Nru*I, *Pvu*I, *Rsr*II, *Sal*I, *Xho*I, and *Xor*II are all sensitive to ^{m5}CpG methylation. Finally, methylation of CpG dinucleotides in preparations of mammalian DNA is rarely complete. This variability in methylation of sites that are recognized by rarely cutting restriction enzymes can be a serious problem in mapping of mammalian DNAs by pulsed-field gel electrophoresis. Among the known restriction enzymes suitable for generating very large fragments of mammalian DNA, only a handful are capable of cleaving DNA modified at ^{m5}CpG doublets. These include *Acc*III, *Asu*II, *Cfr*9I, *Sfi*I, and *Xma*I. Propagation of mammalian DNAs in *E. coli* will free CpG dinucleotides from methylation. The pattern of cleavage of the same segment of mammalian genomic DNA will therefore differ in cloned and uncloned preparations.

The CpG dinucleotide is not as rare in many other species as it is in mammalian DNA, and it is not methylated in *Drosophila* and *Caenorhabditis* DNAs. Thus, the fragments produced by digestion of these DNAs with rarely cutting restriction enzymes are less than half the size of those produced from mammalian DNA (see Table A4-3). Enzymes that are not sensitive to certain site-specific methylations are particularly useful for achieving complete digestion of modified DNA. For procedures such as the physical mapping of heavily methylated plant DNA, it is desirable to

TABLE A4-3 Average Sizes of DNA Fragments Generated by Cleavage with Restriction Enzymes

Average size fragments predicted for *Caenorhabditis elegans* (CEL), *Drosophila melanogaster* (DRO), *Escherichia coli* (ECO), human (HUM), mouse (MUS), *Saccharomyces cerevisiae* (YSC), and *Xenopus laevis* (XEL).

Listed are those restriction enzymes that are known or predicted to cleave infrequently in seven commonly studied genomes. Factors affecting the ability of restriction enzymes to cleave a particular genome include (1) percentage G+C content, (2) specific dinucleotide, trinucleotide, and/or tetranucleotide frequencies, and (3) methylation. Using available information on percentage G+C content, dinucleotide frequencies, and a few kilobases of DNA sequence, predictions can be made about potential cleavage with restriction enzymes.

Modified, with permission, from New England Biolabs.

choose restriction enzymes that are insensitive to ^{m5}CG and ^{m5}CNG. Examples of such enzymes are *Bcl*I, *Bst*EII, *Bst*NI, *Cvi*QI, *Eco*RV, *Hinc*II, *Hpa*I, *Kpn*I, *Mbo*II, *Nde*I, *Nde*II, *Rsa*I, *Spe*I, *Sph*I, *Taq*I, *Tth*HBI, and *Xmn*I. The *Ase*I, *Dra*I, *Mse*I, and *Ssp*I enzymes have recognition sequences that do not contain cytosine, so they can be used to cleave heavily cytosine-methylated DNA.

Restriction Endonucleases

Restriction enzymes bind specifically to and cleave double-stranded DNA at specific sites within, or adjacent to, a particular sequence known as the recognition sequence. These enzymes have been classified into three groups or types. Type I and type III enzymes carry modification (methylation) and ATP-dependent restriction activities in the same protein. Type III enzymes cut the DNA at the recognition site and then dissociate from the substrate. However, type I enzymes bind to the recognition sequence but cleave at random sites when the DNA loops back to the bound enzyme. Neither type I nor type III restriction enzymes are widely used in molecular cloning.

Type II modification/restriction systems are binary systems consisting of a restriction endonuclease that cleaves a specific sequence of nucleotides and a separate methylase that modifies the same recognition sequence. An increasingly large number of type II restriction endonucleases have been isolated and characterized, a great many of which are useful for cloning and other molecular manipulations.

The vast majority of type II restriction endonucleases recognize specific sequences that are four, five, or six nucleotides in length and display twofold symmetry. A few enzymes, however, recognize longer sequences or sequences that are degenerate. The location of cleavage sites within the axis of dyad symmetry differs from enzyme to enzyme: Some cleave both strands exactly at the axis of symmetry, generating fragments of DNA that carry blunt ends, whereas others cleave each strand at similar locations on opposite sides of the axis of symmetry, creating fragments of DNA that carry protruding single-stranded termini.

The restriction enzyme database, REBASE, contains a complete listing of all known restriction endonucleases, including the recognition sequences, methylation sensitivity, commercial availability, and references. The database, updated daily, is available at rebase.neb.com/rebase.

DNA POLYMERASES

Many steps in molecular cloning involve the synthesis of DNA in in vitro reactions catalyzed by DNA polymerases. Most of these enzymes require a template and synthesize a product whose sequence is complementary to that of the template. Most polymerases strongly prefer DNA templates, but they will also copy RNA, albeit at lower efficiencies. The most frequently used DNA-dependent DNA polymerases are *E. coli* DNA polymerase I (holoenzyme), the large fragment of *E. coli* DNA polymerase I (Klenow fragment), the DNA polymerases encoded by bacteriophages T4 and T7, modified bacteriophage T7 DNA polymerases (Sequenase and Sequenase version 2.0), and thermostable DNA polymerases. One polymerase, reverse transcriptase (RNA-dependent DNA polymerase), prefers to copy RNA; it will also accept DNA templates and can therefore be used to synthesize double-stranded DNA copies of RNA templates. Finally, one DNA polymerase does not copy a template at all but adds nucleotides only to the termini of existing DNA molecules. This DNA polymerase is called terminal transferase (terminal deoxynucleotidyl transferase).

The properties of the template-dependent polymerases are summarized in Table A4-4 and are described in greater detail in the following pages. The data presented in this table have been collected from several publications. The values serve as accurate guidelines for using the enzymes, but optimal conditions will always vary slightly with the enzyme preparation (degree of purity) and the DNA preparation or when carrying out a sequence of enzymatic reactions in one mixture. For a discussion of the relative advantages of various DNA polymerases used in sequencing reactions, please see Chapter 12.

[a]Sequenase is a derivative of bacteriophage T7 DNA polymerase that has been modified by chemical treatment (Sequenase) or by genetic engineering (Sequenase version 2.0) to suppress 3′→5′ exonuclease activity that is a potent component of wild-type bacteriophage T7 DNA polymerase. Consequently, neither version of Sequenase can be used in exchange reactions.

[b]AmpliTaq and *Taq* DNA polymerase have a polymerization-dependent 5′→3′ exonuclease activity.

[c]n.i. indicates no information available.

[d]Greater activity in the presence of Mn^{2+} instead of Mg^{2+}.

[e]Mn^{2+} may substitute for Mg^{2+}, although rates are lower and the specificity of the polymerases may be changed.

DNA Polymerase I (Holoenzyme)

(*E. coli*)

DNA polymerase I consists of a single polypeptide chain (M_r = 109,000) that can function as a 5′→3′ DNA polymerase, a 5′→3′ exonuclease, and a 3′→5′ exonuclease (Kelley and Stump 1979) and that has an inherent RNase H activity. The RNase H activity is essential for cell viability in *E. coli* but has not been used in molecular cloning. For further details, please see the information panel on ***E. COLI* DNA POLYMERASE I AND THE KLENOW FRAGMENT** in Chapter 9.

Uses

1. Labeling of DNA by nick translation (please see Figure A4-1). Of all the polymerases, only *E. coli* DNA polymerase I can carry out this reaction, since it alone has a 5′→3′ exonuclease activity that can remove nucleotides from the DNA strand ahead of the advancing enzyme.

2. The holoenzyme was originally used for synthesis of the second strand of cDNA in cDNA cloning (Efstratiadis et al. 1976), but it has since been superseded by reverse transcriptase and the Klenow fragment of *E. coli* DNA polymerase I, which do not have 5′→3′ exonuclease activities. The 5′→3′ exonuclease of *E. coli* DNA polymerase I degrades oligonucleotides that may serve as primers for the synthesis of the second strand of cDNA.

3. End-labeling of DNA molecules with protruding 3′ tails. This reaction works in two stages. First, the 3′→5′ exonuclease activity removes protruding 3′ tails from the DNA and creates a recessed 3′ terminus. Then, in the presence of high concentrations of one radiolabeled precursor, exonucleolytic degradation is balanced by incorporation of dNTPs at the 3′ terminus. This reaction, which consists of cycles of removal and replacement of the 3′-terminal nucleotides from recessed or blunt-ended DNA, is sometimes called an exchange or replacement reaction. If this type of reaction is used for the end-labeling, bacteriophage T4 DNA polymerase is the enzyme of choice. Although both *E. coli* DNA polymerase I and bacteriophage T4 DNA polymerase can carry out this type of reaction, the bacteriophage enzyme carries a more potent 3′→5′ exonuclease activity.

   In many cases, a single buffer can be used both for cleavage of DNA with a restriction enzyme and for the subsequent end-labeling. However, not all restriction enzymes work in buffers used for DNA polymerase reactions, and it is advisable to carry out pilot reactions with the particular batch of enzyme on hand. If the restriction enzyme does not work in the DNA polymerase buffer, it will be necessary to carry out the restriction enzyme digestion and end-labeling in two separate steps. In this case, cleave the DNA in the appropriate restriction enzyme buffer, remove the restriction enzyme by extraction with phenol:chloroform, precipitate the DNA with ethanol, dissolve it in TE, and add the appropriate volume of a 10x DNA polymerase buffer.

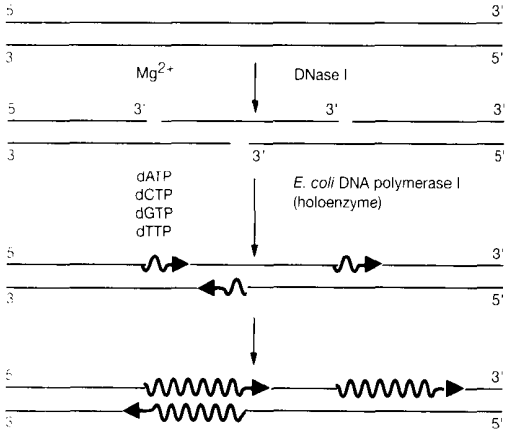

FIGURE A4-1 Nick Translation Using *E. coli* DNA Polymerase

Single-stranded nicks are introduced into the DNA by treatment with DNase I. *E. coli* DNA polymerase (Pol I) binds to the nick or short gap in duplex DNA, and the 5′→3′ exonuclease activity of DNA polymerase I then removes nucleotides from the one strand of the DNA, creating a template for simultaneous synthesis of the growing strand of DNA. The original nick is therefore translated along the DNA molecule by the combined action of the 5′→3′ exonuclease and the 5′→3′ polymerase. In the reaction presented here, the nick in the upper strand of the duplex DNA is translated from left to right by *E. coli* DNA polymerase in the presence of dNTPs. In the lower strand of duplex DNA, nick translation occurs from right to left. The stretches of newly synthesized DNA are represented by the colored arrows.

E. COLI DNA POLYMERASE I (HOLOENZYME)

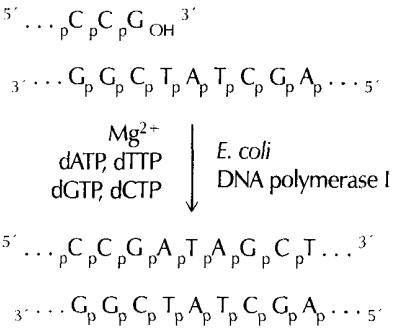
Activity: 5′→3′ DNA polymerase

Substrate: Single-stranded DNA template with a DNA primer bearing a 3′-hydroxyl group.

Reaction:

$$DNA_{OH} \xrightarrow[Mg^{2+}\ dATP,\ dTTP,\ dGTP,\ dCTP]{\textit{E. coli}\ DNA\ polymerase\ I} DNA - ({}_pdN)_n + nPP_i$$

For example:



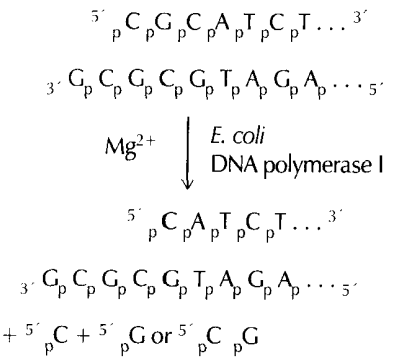
Activity: 5′→3′ Exonuclease

Substrate: Double-stranded DNA or RNA-DNA hybrids. Degrades double-stranded DNA from the 5′ termini; also degrades the RNA component of an RNA-DNA hybrid (i.e., this nuclease possesses inherent RNase H activity).

Reaction:

$$\text{double-stranded DNA} \xrightarrow[Mg^{2+}]{\textit{E. coli}\ DNA\ polymerase\ I} {}^{5'}{}_pN_{OH} + {}^{5'}{}_pN({}_pN)_{np}N_{OH} + \text{single-stranded DNA}$$

For example:



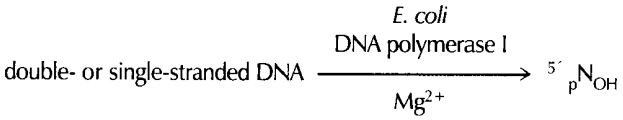
(*Continued on following page.*)

E. COLI DNA POLYMERASE I (HOLOENZYME)

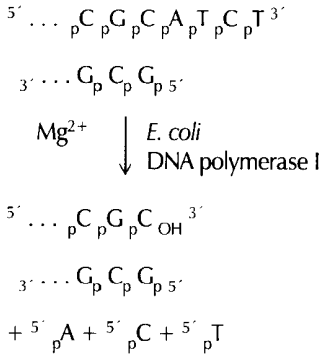
Activity: 3′→5′ Exonuclease

Substrate: Double-stranded or single-stranded DNA containing 3′-hydroxyl termini. Degrades DNA from 3′-hydroxyl termini. Exonuclease activity on double-stranded DNA is blocked by 5′→3′ polymerase activity and is inhibited by dNMPs with 5′ phosphates.

Reaction:



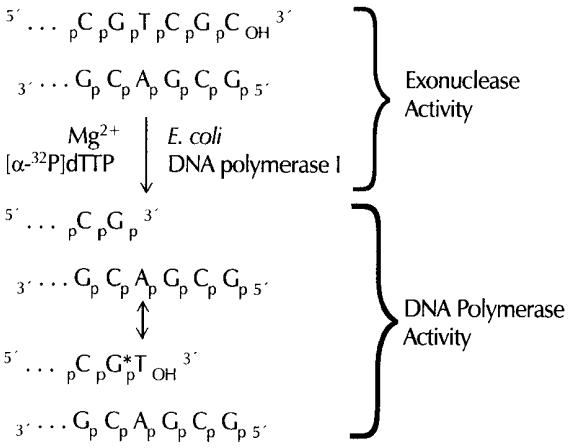
For example:



Activity: Exchange (replacement) reaction

Substrate: If only one dNTP is present, the 3′→5′ exonuclease activity will degrade double-stranded DNA from the 3′-hydroxyl terminus until a base is exposed that is complementary to the dNTP. A continuous series of synthesis and exchange reactions will then occur at that position.

Reaction:



Large Fragment of DNA Polymerase I (Klenow Fragment)

(*E. coli*)

The 5′→3′ exonuclease activity of *E. coli* DNA polymerase I is often troublesome because it degrades the 5′ terminus of primers that are bound to DNA templates and removes 5′ phosphates from the termini of DNA fragments that are to be used as substrates for ligation. The 5′→3′ exonuclease activity can be removed proteolytically from the holoenzyme without affecting either the polymerase activity or the 3′→5′ exonuclease activity (Klenow and Henningsen 1970). The Klenow fragment of *E. coli* DNA polymerase I that is available today from commercial sources consists of a single polypeptide chain (M_r = 76,000) produced by cleavage of intact DNA polymerase I with subtilisin or by cloning (Jacobsen et al. 1974; Joyce and Grindley 1983). For further details, please see the information panel on ***E. COLI* DNA POLYMERASE I AND THE KLENOW FRAGMENT** in Chapter 9.

Uses

1. Filling the recessed 3′ termini created by digestion of DNA with restriction enzymes. In many cases, a single buffer can be used both for cleavage of DNA with a restriction enzyme and for the subsequent filling of recessed 3′ termini (or end-labeling of DNA molecules with protruding 3′ tails [please see Use 3]). The Klenow fragment works well in virtually all buffers used for digestion of DNA with restriction enzymes. However, not all restriction enzymes work in buffers used for DNA polymerase reactions, and it is advisable to carry out pilot reactions with the particular batch of enzyme on hand. If the restriction enzyme does not work in the DNA polymerase buffer, it will be necessary to carry out the restriction enzyme digestion and filling of recessed 3′ termini in two separate steps. In this case, cleave the DNA in the appropriate restriction enzyme buffer, remove the restriction enzyme by extraction with phenol:chloroform, precipitate the DNA with ethanol, dissolve it in TE, and add the appropriate volume of a 10× DNA polymerase buffer.

2. Labeling the termini of DNA fragments by using [^{32}P]dNTPs to fill recessed 3′ termini (end-labeling).

3. End-labeling of DNA molecules with protruding 3′ tails. This reaction works in two stages. First, the 3′→5′ exonuclease activity removes protruding 3′ tails from the DNA and creates a recessed 3′ terminus. Then, in the presence of high concentrations of one radiolabeled precursor, exonucleolytic degradation is balanced by incorporation of dNTPs at the 3′ terminus. This reaction, which consists of cycles of removal and replacement of the 3′-terminal nucleotides from recessed or blunt-ended DNA, is sometimes called an exchange or replacement reaction. If this type of reaction is used for end-labeling, bacteriophage T4 DNA polymerase is the enzyme of choice. Although both the Klenow fragment of *E. coli* DNA polymerase I and bacteriophage T4 DNA polymerase can carry out an exchange reaction, the bacteriophage enzyme carries a more potent 3′→5′ exonuclease activity.

4. Synthesis of the second strand of cDNA in cDNA cloning.

5. Synthesis of double-stranded DNA from single-stranded templates during in vitro mutagenesis. The Klenow fragment can displace hybridized oligonucleotide primers from the template, leading to low frequencies of mutagenesis. This problem can be avoided by using bacteriophage T4 DNA polymerase, which does not cause strand displacement (Nossal 1974).

6. Sequencing of DNA using the Sanger dideoxy-mediated chain-termination method (Sanger et al. 1977).

7. At one time, the 3′→5′ exonuclease activity of the Klenow fragment was used to digest protruding 3′ termini created by some restriction enzymes. Lately, bacteriophage T4 DNA polymerase has become the enzyme of choice for this purpose because of its greater 3′→5′ exonuclease activity.

8. The Klenow fragment has also been used in the polymerase chain reaction to amplify genomic DNA sequences in vitro that are to be used as probes or for direct cloning of mutant alleles of known genes. However, the *Taq* DNA polymerase has now become the enzyme of choice for this purpose because it is stable in heat and therefore need not be freshly added after each round of synthesis and denaturation.

NOTES

- End-labeling with the Klenow fragment provides an alternative to the use of bacteriophage T4 polynucleotide kinase for generating labeled DNA fragments that can be used as size markers during gel electrophoresis. Because DNA fragments are labeled in proportion to their molar concentrations and not their sizes, both small and large fragments in a restriction digest become labeled to an equal extent. It is therefore possible to use autoradiography to locate bands of DNA that are too small to be visualized by staining with ethidium bromide or SYBR dyes.
- The end-filling and end-labeling reactions work well on relatively crude DNA preparations (e.g., minipreparations of plasmids).

E. COLI DNA POLYMERASE I KLENOW FRAGMENT

Activity: 5′→3′ DNA polymerase

Substrate: Single-stranded DNA template with a primer containing a free 3′-hydroxyl group.

Reaction:

$$DNA_{OH} \xrightarrow[\text{dATP, dTTP, dGTP, dCTP}]{\substack{\text{Klenow fragment of } \textit{E. coli} \text{ DNA polymerase I} \\ Mg^{2+}}} DNA - ({}_pdN)_n + nPP_i$$

For example:

$$^{5'}\ldots {}_pC\ {}_pC\ {}_pG\ {}_{OH}{}^{3'}$$

$$^{3'}\ldots G_p\ G_p\ C_p\ T_p\ A_p\ T_p\ C_p\ G_p\ A_p\ldots {}^{5'}$$

Mg^{2+}, dATP, dTTP, dGTP, dCTP ↓ Klenow fragment of *E. coli* DNA polymerase I

$$^{5'}\ldots {}_pC\ {}_pC\ {}_pG\ {}_pA\ {}_pT\ {}_pA\ {}_pG\ {}_pC\ {}_pT\ldots {}^{3'}$$

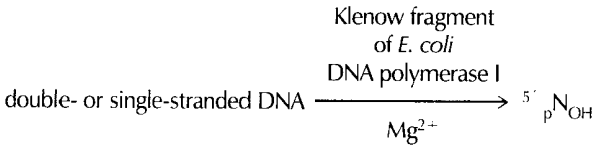
$$^{3'}\ldots G_p\ G_p\ C_p\ T_p\ A_p\ T_p\ C_p\ G_p\ A_p\ldots {}^{5'}$$

E. COLI DNA POLYMERASE I KLENOW FRAGMENT

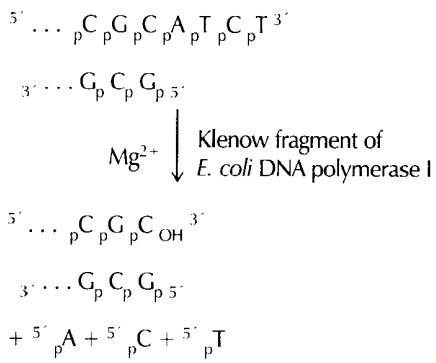
Activity: 3′→5′ Exonuclease

Substrate: Double-stranded or single-stranded DNA degrades from free 3′-hydroxyl termini; exonuclease activity on double-stranded DNAs is blocked by 5′→3′ polymerase activity.

Reaction:



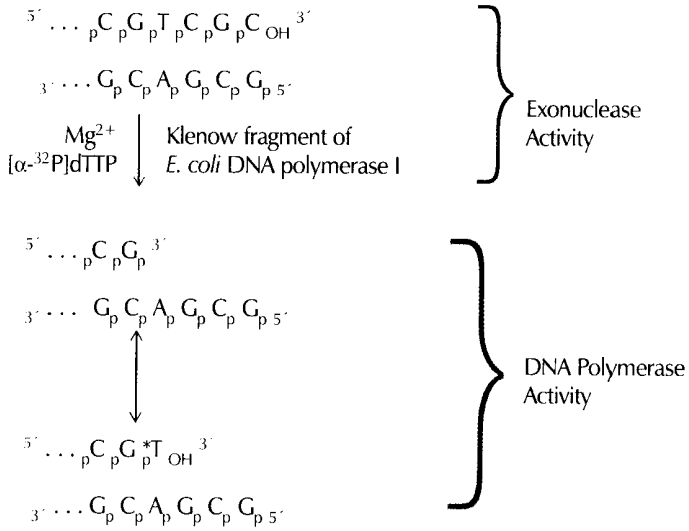
For example:



Activity: Exchange (replacement) reaction

Substrate: If only one dNTP is present, 3′→5′ exonuclease activity will degrade double-stranded DNA from the 3′-hydroxyl terminus until a base is exposed that is complementary to the dNTP. A continuous series of synthesis and exchange reactions will then occur at that position.

Reaction:



Bacteriophage T4 DNA Polymerase

(Bacteriophage T4-infected *E. coli*)

Bacteriophage T4 DNA polymerase (M_r = 114,000) and the Klenow fragment of *E. coli* polymerase I are similar in that each possesses a 5′→3′ polymerase activity and a 3′→5′ exonuclease activity that is more active on single-stranded DNA than on double-stranded DNA. However, the exonuclease activity of bacteriophage T4 DNA polymerase is more than 200 times that of the Klenow fragment. Because it does not displace oligonucleotide primers from single-stranded DNA templates (Nossal 1974), bacteriophage T4 DNA polymerase works more efficiently than the Klenow fragment in mutagenesis reactions in vitro.

Uses

1. Filling or labeling the recessed 3′ termini created by digestion of DNA with restriction enzymes. Labeling reactions must be carried out in the presence of high concentrations of dNTPs in order for the polymerization (filling) reaction to overwhelm the powerful 3′→5′ exonuclease activity.

2. End-labeling of DNA molecules with protruding 3′ tails. This reaction works in two stages. First, the potent 3′→5′ exonuclease activity removes protruding 3′ tails from the DNA and creates a recessed 3′ terminus. Then, in the presence of high concentrations of one radiolabeled precursor, exonucleolytic degradation is balanced by incorporation of dNTPs at the 3′ terminus. This reaction, which consists of cycles of removal and replacement of the 3′-terminal nucleotides from recessed or blunt-ended DNA, is sometimes called an exchange or replacement reaction.

   In many cases, a single buffer can be used both for cleavage of DNA with a restriction enzyme and for the subsequent end-labeling. Bacteriophage T4 DNA polymerase will function at ~50% of maximal activity in many buffers that are commonly used for digestion of DNA with restriction enzymes. However, not all restriction enzymes work in buffers used for DNA polymerase reactions, and it is advisable to carry out pilot reactions with the particular batch of enzyme on hand. If the restriction enzyme does not work in the DNA polymerase buffer, it will be necessary to carry out the restriction enzyme digestion and end-labeling in two separate steps. In this case, cleave the DNA in the appropriate restriction enzyme buffer, remove the restriction enzyme by extraction with phenol:chloroform, precipitate the DNA with ethanol, dissolve it in TE, and add the appropriate volume of a 10x DNA polymerase buffer. Filling and end-labeling reactions with bacteriophage T4 DNA polymerase can be carried out at 12°C to maximize the ratio of polymerase activity to exonuclease activity. However, these reactions are often carried out at room temperature or at 37°C without adverse effects.

3. Labeling DNA fragments for use as hybridization probes. The recessed 3′ termini created by partial digestion of double-stranded DNA with the 3′→5′ exonuclease activity are filled with [^{32}P]dNTPs (replacement synthesis) (O'Farrell et al. 1980). Hybridization probes prepared by this technique have two advantages over probes prepared by nick translation. First, they lack the artifactual hairpin structures that can be produced during nick translation. Second, they can easily be converted into strand-specific probes by cleavage with suitable restriction enzymes (please see Figure A4-2).

   By contrast to nick translation, however, this method does not produce a uniform distribution of label along the length of the DNA. Furthermore, 3′ exonuclease activity degrades single-stranded DNA much faster than it degrades double-stranded DNA, so that after a molecule has been digested to its midpoint, it will dissociate into two half-length single strands that will

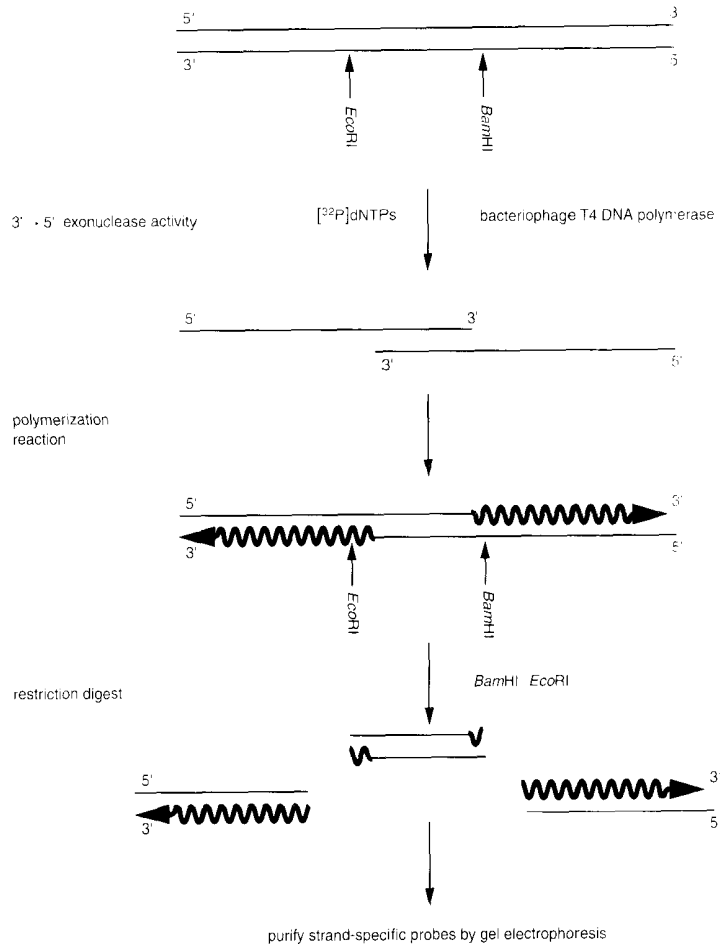


FIGURE A4-2 Production of Strand-specific Hybridization Probes

be rapidly degraded. It is therefore important to stop the exonuclease reaction before the enzyme reaches the center of the molecule. Consequently, the replacement synthesis method yields a population of molecules that are fully labeled at their termini but contain progressively decreasing quantities of label toward their centers.

4. Conversion of termini of double-stranded DNA to blunt-ended molecules. Protruding 3′ termini will be removed from double-stranded DNA by the potent 3′→5′ exonuclease activity of bacteriophage T4 DNA polymerase. In the presence of high concentrations of dNTPs, further degradation of the double-stranded region of the template will be balanced by synthesis. The ability to convert protruding 3′ termini to blunt ends is an extremely valuable reaction that is frequently used when preparing DNAs for addition of synthetic linkers. As described above, molecules with recessed 3′ termini can be repaired by bacteriophage T4 DNA polymerase in a filling reaction similar to that catalyzed by the Klenow fragment. Thus, DNAs with a mixture of protruding 5′ and 3′ termini (e.g., double-stranded cDNAs synthesized from RNA templates) can be converted to blunt-ended molecules (polished) by bacteriophage T4 DNA polymerase in the presence of high concentrations of dNTPs.

5. Extension of mutagenic oligonucleotide primers that are bound to single-stranded DNA templates. Bacteriophage T4 DNA polymerase is preferred in this reaction to the Klenow fragment because it cannot displace the short oligonucleotide from the template. The efficiency of mutagenesis is therefore increased approximately twofold.

BACTERIOPHAGE T4 DNA POLYMERASE

Activity: 5′→3′ DNA polymerase

Substrate: 3′-hydroxyl, single-stranded DNA template-primer complex. The enzyme cannot displace the strand ahead of the nick. However, addition of bacteriophage T4 gene *32* protein allows the enzyme to begin synthesis at a nick in buffers of low ionic strength.

Reaction:

$$DNA_{OH} \xrightarrow[Mg^{2+},\ dATP,\ dTTP,\ dGTP,\ dCTP]{\text{bacteriophage T4 DNA polymerase}} DNA - ({}_pdN)_n + nPP_i$$

For example:

$$^{5'}\ldots {}_pC\ {}_pC\ {}_pG\ {}_{OH}{}^{3'}$$

$$^{3'}\ldots G_p\ G_p\ C_p\ T_p\ A_p\ T_p\ C_p\ G_p\ A_p\ldots {}^{5'}$$

Mg^{2+}, dATP, dTTP, dGTP, dCTP ↓ bacteriophage T4 DNA polymerase

$$^{5'}\ldots {}_pC\ {}_pC\ {}_pG\ {}_pA\ {}_pT\ {}_pA\ {}_pG\ {}_pC\ {}_pT\ldots {}^{3'}$$

$$^{3'}\ldots G_p\ G_p\ C_p\ T_p\ A_p\ T_p\ C_p\ G_p\ A_p\ldots {}^{5'}$$

Activity: 3′→5′ Exonuclease

Substrate: Considerably more active on single-stranded DNA than on double-stranded DNA; exonuclease activity on double-stranded DNAs is blocked by 5′→3′ DNA polymerase activity.

Reaction:

$$\text{single-stranded DNA} \xrightarrow[Mg^{2+}]{\text{bacteriophage T4 DNA polymerase}} {}^{5'}{}_pN_{OH}$$

For example:

$$^{5'}\ldots {}_pC\ {}_pG\ {}_pC\ {}_pA\ {}_pT\ {}_pC\ {}_pT\ {}^{3'}$$

$$^{3'}\ldots G_p\ C_p\ G_{p\ 5'}$$

Mg^{2+} ↓ bacteriophage T4 DNA polymerase

$$^{5'}\ldots {}_pC\ {}_pG\ {}_pC\ {}_{OH}{}^{3'}$$

$$^{3'}\ldots G_p\ C_p\ G_{p\ 5'}$$

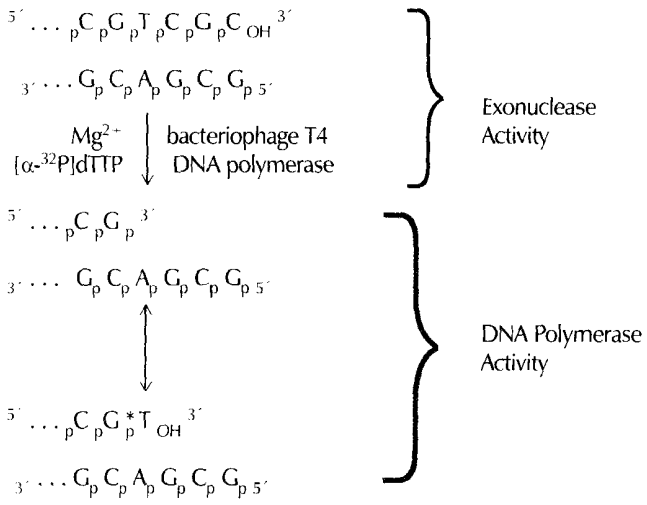
$$+\ {}^{5'}{}_pA + {}^{5'}{}_pC + {}^{5'}{}_pT$$

BACTERIOPHAGE T4 DNA POLYMERASE

Activity: Exchange (replacement) reaction

Substrate: If only one dNTP is present, 3′→5′ exonuclease activity will degrade double-stranded DNA from the 3′-hydroxyl terminus until a base is exposed that is complementary to the dNTP. A continuous series of synthesis and exchange reactions will then occur at that position.

Reaction:



Bacteriophage T7 DNA Polymerase

(Bacteriophage T7-infected *E. coli*)

The DNA polymerase synthesized after infection of *E. coli* by bacteriophage T7 is a complex of two tightly bound proteins, the bacteriophage T7 gene *5* protein and the host protein thioredoxin. This complex is the most processive of all known DNA polymerases. In other words, the average length of DNA synthesized by a single molecule of bacteriophage T7 DNA polymerase is greater than that of DNAs synthesized by other thermolabile DNA polymerases. This property has considerable advantages, for example, when sequencing DNA by the Sanger dideoxy chain-termination method (Sanger et al. 1977) (please see Chapter 12). Bacteriophage T7 DNA polymerase, like the Klenow fragment and the holoenzyme of *E. coli* DNA polymerase I and bacteriophage T4 DNA polymerase, has a 3′→5′ exonuclease activity (encoded by bacteriophage T7 gene 5). As in bacteriophage T4 DNA polymerase, the 3′→5′ exonuclease activity is potent. The degree of activity of the 3′→5′ exonuclease of bacteriophage T7 DNA polymerase is ~1000 times that of the Klenow fragment. Bacteriophage T7 DNA polymerase does not have a 5′→3′ exonuclease activity (Tabor et al. 1987). For illustrations of the 5′→3′ DNA polymerase and 3′→5′ exonuclease activities and exchange reaction encoded by bacteriophage T7 DNA polymerase, please see the panel on **BACTERIOPHAGE T4 DNA POLYMERASE** (p. A4.20). For more information on wild-type and modified T7 DNA polymerase (Sequenase and Sequenase version 2.0), please see the information panel on **SEQUENASE** in Chapter 12.

USES

1. Primer-extension reactions that require the copying of long stretches of template.
2. Rapid end-labeling by either filling or exchange (replacement) reactions such as those described for bacteriophage T4 DNA polymerase.

Thermostable DNA-dependent DNA Polymerases

Thermostable DNA-dependent DNA polymerases have been purified and characterized from a number of organisms, primarily from the thermophilic and hyperthermophilic eubacteria Archaebacteria, whose most abundant DNA polymerases are reminiscent of DNA polymerase I of mesophilic bacteria, and thermophilic Archaea, whose chief DNA polymerases belong to the polymerase α family. Although there is considerable structural variation among thermostable DNA polymerases, all are monomeric with molecular mass values ranging from 60 kD to 100 kD. The significant properties and activities of thermostable DNA polymerases are given in Table A4-5.

The first well-characterized thermostable DNA polymerases were isolated from the extreme thermophile *Thermus aquaticus* (Chien et al. 1976). One of these early isolates, *Taq* DNA polymerase, has, along with a number of genetically engineered variants, become an indispensable component of reactions to amplify specific sequences of DNA in vitro by polymerase chain reaction and in DNA sequencing (please see the introductions to Chapters 8 and 12, respectively). *Taq* and its derivatives have a 5′→3′ polymerization-dependent exonuclease activity. For nucleotide incorporation, the enzyme works best at 75–80°C, depending on the target sequence; its polymerase activity is reduced by a factor of 2 at 60°C and by a factor of 10 at 37°C. In many cases, however, it is necessary to initiate polymerization reactions at suboptimal temperatures in order to prevent dissociation of the primer from the template. For further information on *Taq* and other thermostable polymerases, please see the introduction to Chapter 8 and the information panel on ***TAQ* DNA POLYMERASE** in Chapter 8.

TABLE A4-5 Properties of Thermostable DNA Polymerases

Enzyme	Manufacturer[a]	Organism	Optimum Temperature (°C)	Exonuclease Activity	Error Rate $\times 10^{-6}$	Stability (Minutes at Specified Temperature)	K_m dNTP (μM)	K_m DNA (nM)

[b]Suspected activity.

TAQ DNA POLYMERASE

Activity: 5′→3′ DNA polymerase

Substrate: Single-stranded template, primer with 3′-hydroxyl.

Reaction:

$$DNA_{OH} \xrightarrow[\substack{Mg^{2+} \\ dATP,\ dTTP,\ dGTP,\ dCTP}]{Taq\ DNA\ polymerase} DNA - ({}_pdN)_n + nPP_i$$

Reverse Transcriptase (RNA-dependent DNA Polymerase)

(Murine and avian retroviruses)

Two forms of reverse transcriptases are commercially available: a preparation made from purified avian myeloblastosis virus (AMV) and an enzyme isolated from a strain of *E. coli* that expresses a cloned copy of the reverse transcriptase gene of the Moloney murine leukemia virus (Mo-MLV). Both enzymes lack a 3′→5′ exonuclease active on DNA and catalyze the reactions shown below in the panel on **REVERSE TRANSCRIPTASE**. The murine and avian reverse transcriptases differ from each other in a number of respects:

- The avian enzyme consists of two polypeptide chains that carry both a polymerase activity and a powerful RNase H activity (Verma 1981). The murine enzyme, a single polypeptide chain of M_r = 84,000, has a polymerase activity and a comparatively weak RNase H activity (Gerard 1983). This weak RNase activity is a considerable advantage when attempting to synthesize

REVERSE TRANSCRIPTASE

Activity: 5′→3′ DNA polymerase

Substrate: RNA or DNA template with an RNA or DNA primer bearing a 3′-hydroxyl group.

Reaction:

$$DNA_{OH} \text{ or } RNA_{OH} \xrightarrow[\substack{Mg^{2+}\\ dATP,\ dTTP,\ dGTP,\ dCTP}]{\text{reverse transcriptase}} \begin{matrix} DNA - ({}_pdN)_n + nPP_i \\ RNA - ({}_pdN)_n + nPP_i \end{matrix}$$

For example:

$$^{5'}\ldots {}_pT\,{}_pT\,{}_pT\,{}_pT\,{}_pT_{OH}\ ^{3'}$$

$$^{3'}\ldots A_p\,A_p\,A_p\,A_p\,A_p\,U_p\,C_p\,U_p\,G_p\,U_p\,C_p\,C_p\,U_p\,A_{p\ 5'}$$

Mg^{2+}, dATP, dTTP, dGTP, dCTP ↓ reverse transcriptase

$$^{5'}\ldots {}_pT\,{}_pT\,{}_pT\,{}_pT\,{}_pT\,{}_pA\,{}_pG\,{}_pA\,{}_pC\,{}_pA\,{}_pG\,{}_pG\,{}_pA\,{}_pT_{OH}\ ^{3'}$$

$$^{3'}\ldots A_p\,A_p\,A_p\,A_p\,A_p\,U_p\,C_p\,U_p\,G_p\,U_p\,C_p\,C_p\,U_p\,A_{p\ 5'}$$

Activity: RNase H (5′→3′ and 3′→5′ exoribonuclease)

Substrate: Reverse transcriptase specifically degrades RNA in an RNA-DNA hybrid by a processive mechanism.

Reaction: Degradation of substrates with free ends yielding ribonucleotide products that are 4–20 nucleotides in length and contain 5′-phosphate and 3′-hydroxyl termini.

$$\begin{matrix} RNA\ ^{5'}\ldots {}_pU\,{}_pC\,{}_pC\,{}_pG\,{}_pU\,{}_pA^{3'} \\ DNA\ \ ^{3'}\ldots A_p\,G_p\,G_p\,C_p\,A_p\,T_{5'} \end{matrix} \xrightarrow{\text{reverse transcriptase}} \begin{matrix} ^{5'}\ldots {}_pU\,{}_pC^{3'} \\ ^{3'}\ldots\ A_p\,G_p\,G_p\,C_p\,A_p\,T_{5'} \\ +\ ^{5'}\ {}_pC\,{}_pG\,{}_pU\,{}_pA^{3'} \end{matrix}$$

cDNAs complementary to long mRNAs. At the beginning of the reaction, the hybrids formed between the primer and the template mRNA are substrates for RNase H. Thus, at the beginning of cDNA synthesis, there is a competition between degradation of the template mRNA and initiation of DNA synthesis (Berger et al. 1983). In addition, RNase H can cleave the template near the 3′ terminus of the growing DNA strand if reverse transcriptase pauses during synthesis (Kotewicz et al. 1988). In consequence, the high level of RNase H activity in preparations of the avian enzyme tends to suppress the yield of cDNA and to restrict its length.

- The avian enzyme works efficiently at 42°C (the normal body temperature of chickens), whereas the wild-type murine enzyme is rapidly inactivated at this temperature. RNAs rich in secondary structure are therefore copied more efficiently by the avian enzyme than by the murine enzyme. However, preparations of the avian enzyme can be contaminated by an endonuclease that cleaves DNA. This is now less of a problem than it was in the early 1980s, when cDNA libraries generated with comparatively impure preparations of the avian enzyme seldom exceeded 1 kb in length.
- The avian enzyme works more efficiently at pH 8.3 than at pH 7.6, the pH preferred by the murine enzyme. The length of the cDNA synthesized by either enzyme is greatly reduced when reactions are carried out at a pH that differs from the optimum by as little as 0.2 unit. Since the pH of Tris changes with temperature, it is essential to check that the pH of the reaction mixture is correct at the temperature chosen for incubation.

For more information, please see the information panel on **Mo-MLV REVERSE TRANSCRIPTASE** in Chapter 11.

USES

1. Reverse transcriptase is used chiefly to transcribe mRNA into double-stranded cDNA that can be inserted into prokaryotic vectors. However, reverse transcriptase can also be used with either single-stranded DNA or RNA templates to make probes for use in hybridization experiments. Three types of primers are used in these reactions:
   - ***Oligo(dT)$_{12\text{-}18}$***, which binds to the poly(A) tract at the 3′ terminus of mammalian mRNAs and primes the synthesis of the first strand of cDNA. Depending on the quality of the reverse transcriptase and the reaction conditions, the sequences at the 3′ terminus of the template may be overrepresented in the cDNA.
   - ***Oligonucleotides of random sequence*** (Taylor et al. 1976). The aim is to use a population of oligonucleotides whose sequence diversity is so large that at least some individual oligonucleotides will anneal to the template and serve as primers for reverse transcriptase. Because different oligonucleotides bind to different sequences, a large proportion of the sequences of the template will be copied by the enzyme, and if all of the primers are present at equal concentrations, all sequences of the template should be copied at equal frequencies. Oligonucleotides of random sequence can be synthesized on an automated DNA synthesizer or can be generated by hydrolysis of high-molecular-weight DNA.
   - ***Oligonucleotides of defined sequence.*** Oligonucleotides of defined sequence can be used to prime the synthesis of cDNA corresponding to a particular mRNA. Because the newly synthesized DNA is complementary to the sequences of the mRNA that lie upstream of the primer, this method (primer extension) provides an accurate measurement of the distance between a fixed point on an mRNA and its 5′ terminus.
2. Labeling the termini of DNA fragments with protruding 5′ termini (filling reaction).

3. The enzyme can also be used to sequence DNAs by the dideoxy chain termination method (Sanger et al. 1977) when other enzymes (e.g., the Klenow fragment or Sequenase) yield unsatisfactory results.

NOTES

- Reverse transcriptase lacks 3′→5′ exonuclease activity, which acts as an editing function in *E. coli* DNA polymerase I, and is therefore prone to error. In the presence of high concentrations of dNTPs and Mn^{2+}, ~1 base in every 500 is misincorporated.
- Because the K_m of reverse transcriptase for its dNTP substrates is very high — in the millimolar range — it is essential to include high concentrations of dNTPs in this reaction to prevent premature termination of newly synthesized DNA chains.
- Reverse transcriptase can be used to synthesize single-stranded copies of DNA templates using oligonucleotide primers (please see Figure A4-3, part A). However, both double-stranded and single-stranded cDNAs are generated from RNA templates (please see Figure A4-3, part B). Self-primed synthesis is much less efficient than synthesis from the added oligonucleotide primers. Therefore, self-complementary hairpin molecules usually constitute only a small fraction of the synthesized double-stranded cDNA (see Chapter 11). If necessary, both self-primed and exogenously primed second-strand synthesis can be inhibited by including actinomycin D in the reaction mixture at a final concentration of 50 μg/ml.

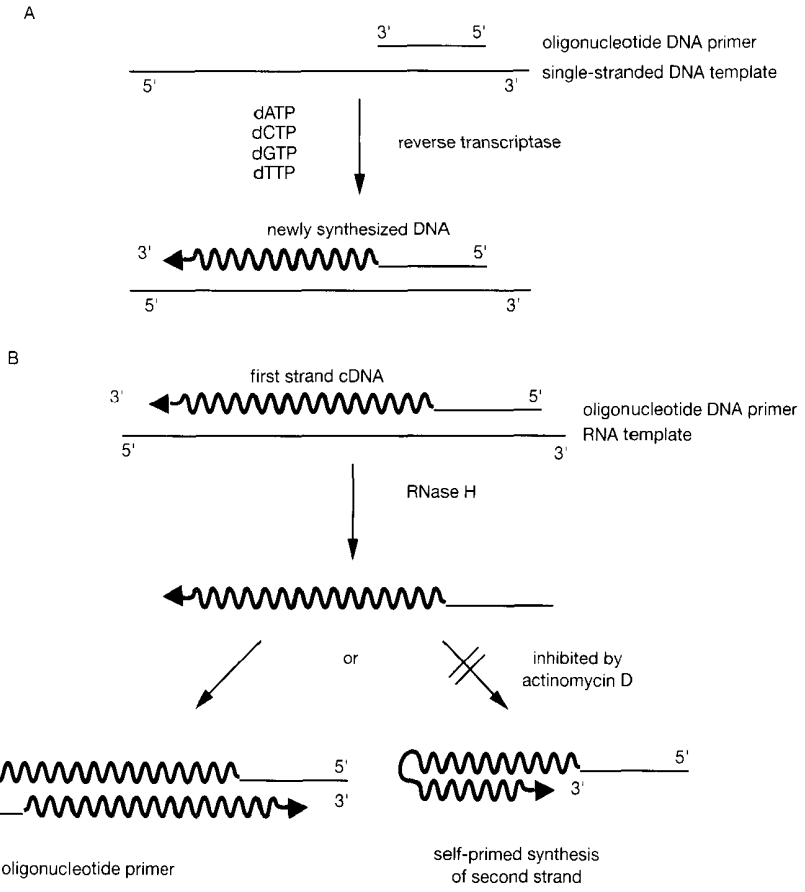

FIGURE A4-3 Use of Reverse Transcriptase to Generate Probes from DNA (*A*) and RNA (*B*) Templates

Terminal Transferase (Terminal Deoxynucleotidyl Transferase)

(Calf thymus)

Terminal transferase (M_r = 60,000) is an unusual DNA polymerase found only in prelymphocytes in early stages of lymphoid differentiation (Chang and Bollum 1986). In the presence of a divalent cation, the purified enzyme catalyzes the addition of dNTPs to the 3′-hydroxyl termini of DNA molecules (Bollum 1974). When the nucleotide to be added is a purine, Mg^{2+} is the preferred cation; when the nucleotide is a pyrimidine, Co^{2+} is used instead. The minimum chain length of the acceptor DNA is three dNTPs, and as many as several thousand dNTPs can be incorporated if the ratio of acceptor to nucleotide is adjusted correctly. Single nucleotides can be added to the 3′ termini of DNA if modified nucleotides (e.g., ddNTPs or cordycepin triphosphate) are used as substrates. Homopolymers of rNTPs can also be synthesized at the 3′ termini of DNA molecules in the presence of Co^{2+} (for references, please see Chang and Bollum 1986). The enzyme strongly prefers to use DNAs with protruding 3′ termini as acceptors. However, blunt or recessed 3′ termini are used, albeit less efficiently, in buffers of low ionic strength that contain Co^{2+} or Mn^{2+} (Roychoudhury et al. 1976; Nelson and Brutlag 1979; Roychoudhury and Wu 1980; Michelson and Orkin 1982; Deng and Wu 1983). For further information, please see the information panel on **TERMINAL TRANSFERASE** in Chapter 8.

Uses

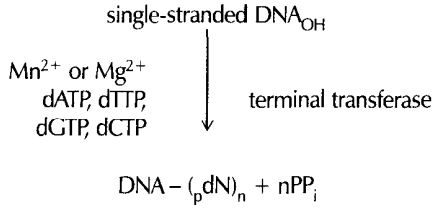
1. Addition of complementary homopolymeric tails to vector and cDNA.
2. Labeling the 3′ termini of DNA fragments with a ^{32}P-labeled dNTP (Tu and Cohen 1980), a ddNTP (Cozzarelli et al. 1969), or an rNTP (Wu et al. 1976). For labeling with rNTPs, [α-^{32}P]rNTP is used in the presence of Co^{2+}, followed by treatment with alkali (please see the panel on **TERMINAL TRANSFERASE** below).

TERMINAL TRANSFERASE

Activity: Terminal transferase

Substrate: Single-stranded DNA with a 3′-hydroxyl terminus or double-stranded DNA with a protruding 3′-hydroxyl terminus is preferred. Blunt-ended, double-stranded DNA or DNA with a recessed 3′-hydroxyl terminus serves as a template if Co^{2+} is supplied as a cofactor (Roychoudhury et al. 1976; Nelson and Brutlag 1979; Roychoudhury and Wu 1980; Michelson and Orkin 1982; Deng and Wu 1983).

Reaction:



DNA-DEPENDENT RNA POLYMERASES

Bacteriophage SP6 and Bacteriophages T7 and T3 RNA Polymerases
(Bacteriophage SP6-infected *Salmonella typhimurium* LT2 and bacteriophage T7- or T3-infected *E. coli*)

Bacteriophage SP6 synthesizes a DNA-dependent RNA polymerase that recognizes and initiates synthesis of RNA on double-stranded DNA templates carrying the appropriate bacteriophage-specific promoter. The polymerase is used in vitro to generate large quantities of RNA complementary to one strand of foreign DNA that has been placed immediately downstream from the promoter. Vectors carrying the promoter are available to synthesize RNA complementary to either strand of the template by changing the orientation of the promoter with respect to the cloned foreign DNA sequences (Butler and Chamberlin 1982; Melton et al. 1984). Alternatively, the promoter can be added to the target DNA during PCR primed by oligonucleotides equipped with a concensus promoter (please see Chapter 9, Protocol 6).

Bacteriophages T7 and T3 also synthesize DNA-dependent RNA polymerases that recognize and initiate synthesis of RNA on double-stranded DNA templates that carry the appropriate bacteriophage-specific promoter (for further details, please see the information panel on **PROMOTER SEQUENCES RECOGNIZED BY BACTERIOPHAGE-ENCODED RNA POLYMERASES** in Chapter 7). These polymerases are used in vitro just like the bacteriophage SP6 RNA polymerase. Bacteriophages T7 and T3 RNA polymerases have been cloned and expressed in *E. coli* (Davanloo et al. 1984; Tabor and Richardson 1985; Morris et al. 1986), and bacteriophage T7 RNA polymerase has been cloned and expressed in yeast (Chen et al. 1987). Vectors carrying the bacteriophage T7 promoter may therefore be used to express cloned genes in vivo (please see point 2 under Uses below).

USES

1. Synthesis of single-stranded RNA for use as hybridization probes, functional mRNAs for in vitro translation systems, or substrates for in vitro splicing reactions. Each of the three RNA polymerases has a high degree of specificity for its cognate promoter.

2. The bacteriophage T7 transcription system has been used to express cloned genes in bacteria (Tabor and Richardson 1985; Studier and Moffatt 1986) and in yeast (Chen et al. 1987). Two types of bacteriophage T7 expression systems have been developed for *E. coli*. In the first system, stable lysogens are established with bacteriophage λ carrying the bacteriophage T7 RNA polymerase gene under the control of the *E. coli lac*UV5 promoter. Plasmids containing the gene of interest under the control of the bacteriophage T7 promoter are then introduced into the lysogens containing the bacteriophage T7 RNA polymerase gene. Activation of the bacteriophage T7 promoter is then achieved by isopropylthio-β-D-galactoside induction of the *lac*UV5 promoter driving the bacteriophage T7 RNA polymerase gene. In the second system, the bacteriophage T7 promoter/plasmid carrying the gene of interest is introduced into bacteria, and the bacteriophage T7 promoter is activated by infecting the bacteria with bacteriophage λ containing the bacteriophage T7 RNA polymerase gene.

   In yeast, the bacteriophage T7 RNA polymerase gene is placed under the control of a yeast promoter and stably introduced into yeast cells on an autonomously replicating vector. Expression is achieved by introducing into the yeast cells a second plasmid that contains the gene of interest under the control of the bacteriophage T7 promoter (Chen et al. 1987).

BACTERIOPHAGES SP6, T3, AND T7 DNA-DEPENDENT RNA POLYMERASES

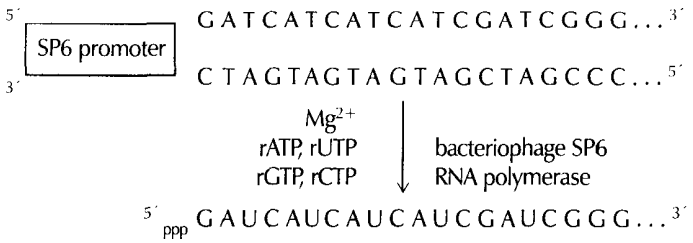
Activity: 5′→3′ RNA polymerase

Substrate: Double-stranded DNA molecules containing bacteriophage SP6, T3, or T7 promoters.

Reaction:

$$\text{double-stranded DNA} \xrightarrow[\substack{Mg^{2+}\\ \text{rATP, rUTP, rGTP, rCTP}}]{\text{bacteriophage SP6, T3, or T7 RNA polymerase}} \text{RNA} + PP_i + \text{template}$$

For example:



LIGASES, KINASES, AND PHOSPHATASES

DNA ligases catalyze end-to-end joining of pieces of DNA. The ligases used most often in cloning are encoded by bacteriophage T4, although there is a less versatile enzyme available from uninfected *E. coli*. Both types of ligases are used primarily on DNA substrates with 5′-terminal phosphate groups.

RNA ligase is a bacteriophage T4 enzyme that is capable of covalently joining single-stranded RNA (or DNA) molecules containing 5′-phosphate and 3′-hydroxyl termini. However, the primary use of this enzyme has been in 3′ end-labeling of RNA. This is accomplished using ^{32}P-labeled mononucleoside 3′,5′-bisphosphate (pNp), which is added to the 3′-hydroxyl terminus of RNA.

The DNA ligases used in molecular cloning differ in their abilities to ligate noncanonical substrates, such as blunt-ended duplexes, DNA-RNA hybrids, or single-stranded DNAs. These and other properties are summarized in Table 1-12 in Chapter 1 and discussed below. For additional information on DNA ligases, please see the information panel on **DNA LIGASES** in Chapter 1.

DNAs that lack the required phosphate residues can be prepared for ligation by phosphorylation with bacteriophage T4 polynucleotide kinase. Conversely, DNAs can be rendered resistant to ligation by enzymatic removal of phosphate residues from their 5′ termini with phosphatases. The properties of bacteriophage T4 polynucleotide kinase are summarized in Table A4-6 and described in greater detail below. The data in this table have been collected from numerous papers published over the years. The values serve as accurate guidelines for using the enzymes, but optimal conditions will always vary slightly with the enzyme preparation (degree of purity) and the DNA preparation, or when carrying out a sequence of enzymatic reactions (e.g., digestion, end-filling, and ligation) in one mixture.

TABLE A4-6 Properties of Bacteriophage Polynucleotide Kinase

	FORWARD REACTION	EXCHANGE REACTION
Nucleic acid substrate	double-stranded DNA single-stranded RNA or DNA nick or gap oligonucleotide 3′ dNMP	double-stranded DNA single-stranded RNA or DNA nick or gap oligonucleotide
K_m	double-stranded DNA, 7.6 μM 5′ dNMP, 22–143 μM ATP, 14–140 μM[b]	ADP, 300 μM[a] ATP, 10 μM[a]
pH optimum	7.4–8.0 (Tris-Cl)	6.4 (imidazole)
Sulfhydryl requirement	+	+
Mg^{2+} requirement	+	+
Effect of ionic strength	stimulated by NaCl and KCl excess KCl inhibits on all substrates except single-stranded DNA	no information
Inhibitors (50% inhibition)	$(NH_4)_2SO_4$, 7 mM P_i, 20 mM PP_i, 5 mM	P_i, 50 mM
Activators	polyamine, 2 mM, 300%	no information

[a]These are concentrations that give optimal activity at pH 6.4, not K_ms.
[b]K_m for ATP varies with substrate.

Bacteriophage T4 DNA Ligase

(Bacteriophage T4-infected *E. coli*)

Bacteriophage T4 DNA ligase, a polypeptide of M_r = 68,000, catalyzes the formation of phosphodiester bonds between adjacent 3′-hydroxyl and 5′-phosphate termini in DNA (Weiss et al. 1968). The properties of the enzymes are summarized in Table 1-12 in Chapter 1.

USES

1. Joining DNA molecules with compatible cohesive termini. Intermolecular ligation is stimulated by low concentrations of agents, such as polyethylene glycol, that promote the efficient interaction of macromolecules in aqueous solutions (please see the information panel on **CONDENSING AND CROWDING REAGENTS** in Chapter 1).

2. Joining blunt-ended double-stranded DNA molecules to one another or to synthetic linkers. This reaction is much slower than ligation of cohesive termini. However, the rate of blunt-end ligation is improved greatly by the addition of monovalent cations (150–200 mM NaCl) and low concentrations of polyethylene glycol (Pheiffer and Zimmerman 1983; Hayashi et al. 1986).

NOTES

- At least three different assays are used to measure the activity of bacteriophage T4 DNA ligase. Most manufacturers (apart from New England Biolabs) now calibrate the enzyme in Weiss units (Weiss et al. 1968). One Weiss unit is the amount of enzyme that catalyzes the exchange of 1 nmole of ^{32}P from pyrophosphate into [γ, β-^{32}P]ATP in 20 minutes at 37°C. One Weiss unit corresponds to 0.2 unit determined in the exonuclease resistance assay (Modrich and Lehman 1970) and to 60 cohesive-end units (as defined by New England Biolabs). 0.015 Weiss unit of bacteriophage T4 DNA ligase therefore will ligate 50% of the *Hin*dIII fragments of bacteriophage λ (5 μg) in 30 minutes at 16°C. Throughout this manual, bacteriophage T4 DNA ligase is given in Weiss units.

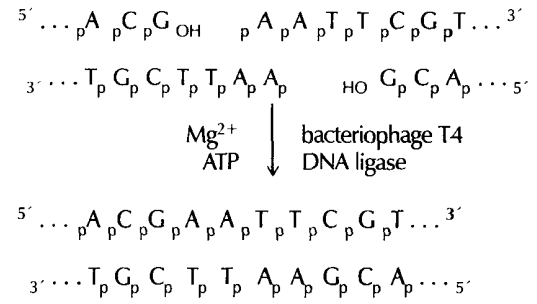
- Bacteriophage T4 DNA ligase is not inhibited by the presence of dNTPs and works adequately in virtually all buffers used for digestion of DNA with restriction enzymes.

BACTERIOPHAGE T4 DNA LIGASE

Activity: Ligation of cohesive DNA termini or nicks

Substrate: Active on double-stranded DNA with complementary cohesive termini that base pair to bring together 3′-hydroxyl and 5′-phosphate termini. In addition, the enzyme is active on nicked DNA and active, albeit far less efficiently, on RNA substrates. (For a more complete description of substrates, see Engler and Richardson 1982.)

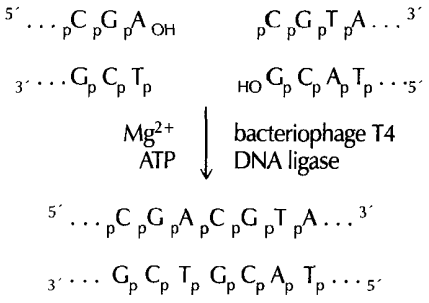
Reaction:



Activity: Ligation of blunt ends

Substrate: High concentrations of blunt-ended, double-stranded DNA containing 5′-phosphate and 3′-hydroxyl termini.

Reaction:



E. coli DNA Ligase

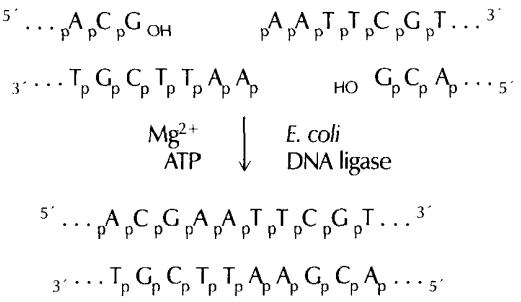
E. coli DNA ligase catalyzes the formation of phosphodiester bonds in double-stranded DNA containing complementary protruding 5′ or 3′ termini (Panasenko et al. 1977, 1978). The reaction requires NAD^+ as a cofactor. Initial studies indicated that this enzyme would not ligate blunt-ended double-stranded DNA, but subsequent studies revealed that blunt-end ligation can be achieved in the presence of polyethylene glycol or Ficoll, compounds that act as volume excluders (please see the information panel on **CONDENSING AND CROWDING REAGENTS** in Chapter 1). This effectively increases the concentration of DNA termini and enzyme (Zimmerman and Pheiffer 1983). *E. coli* DNA ligase has been used in cDNA cloning methods based on replacement synthesis, as described by Okayama and Berg (1982), because of its inability to join adjacent RNA and DNA segments that arise during the synthesis of the second strand of cDNA. It is not, however, widely used in other molecular cloning procedures, since bacteriophage T4 DNA ligase is capable of efficiently joining blunt ends in the absence of volume excluders. *E. coli* DNA ligase does not ligate RNA.

E. COLI DNA LIGASE

Activity: Ligation of cohesive DNA termini or nicks

Substrate: Active on double-stranded DNA with complementary cohesive termini that base pair to bring together 3′-hydroxyl and 5′-phosphate termini. In addition, the enzyme is active on nicked DNA. Blunt termini can be ligated in the presence of crowding reagents.

Reaction:



Bacteriophage T4 RNA Ligase

(Bacteriophage T4-infected *E. coli*)

Bacteriophage T4 RNA ligase catalyzes the covalent joining of 5′-phosphate termini in single-stranded DNA or RNA to 3′-hydroxyl termini in single-stranded DNA or RNA (Uhlenbeck and Gumport 1982).

USES

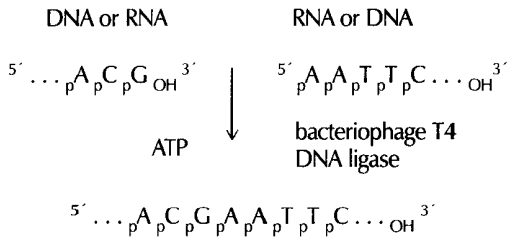
1. Because small molecules (e.g., pNp) are effective substrates, bacteriophage T4 RNA ligase can be used to radiolabel the 3′ termini of RNA molecules in vitro (Uhlenbeck and Gumport 1982).
2. Ligation of oligodeoxyribonucleotides.
3. Bacteriophage T4 RNA ligase has been reported to stimulate the activity of bacteriophage T4 DNA ligase (Sugino et al. 1977). However, agents such as polyethylene glycol that increase macromolecular crowding are equally effective and much less expensive.

BACTERIOPHAGE T4 RNA LIGASE

Activity: RNA ligase

Substrate: 5′-phosphate acceptors include single-stranded DNA and RNA. Phosphate donors include single-stranded DNA and RNA and nucleotides such as pNp.

Reaction:



Thermostable DNA Ligases

The genes encoding thermostable ligases from several thermophilic bacteria have been cloned, sequenced, and expressed to high levels in *E. coli* (e.g., please see Takahashi et al. 1984; Barany and Gelfand 1991; Lauer et al. 1991; Jónsson et al. 1994). Several of these enzymes are available from commercial sources. Like the *E. coli* enzyme, almost all thermostable ligases use NAD^+ as a cofactor and work preferentially at nicks in double-stranded DNA. In addition, thermostable ligases, like their mesophilic homolog, can catalyze blunt-end ligation in the presence of crowding agents, even at elevated temperatures (Takahashi and Uchida 1986). Because thermostable ligases retain activity after multiple rounds of thermal cycling, they are used extensively in the ligase amplification reaction to detect mutations in mammalian DNAs.

Bacteriophage T4 DNA Polynucleotide Kinase

(Bacteriophage T4-infected *E. coli*)

Bacteriophage T4 polynucleotide kinase catalyzes the transfer of the γ-phosphate of ATP to a 5′ terminus of DNA or RNA (Richardson 1971). Two types of reactions are commonly used. In the *forward* reaction, the γ-phosphate is transferred to the 5′ terminus of dephosphorylated DNA (Richardson 1971). In the *exchange* reaction, an excess of ADP causes bacteriophage T4 polynucleotide kinase to transfer the terminal 5′-phosphate from phosphorylated DNA to ADP; the DNA is then rephosphorylated by transfer of a radiolabeled γ-phosphate from [γ-^{32}P]ATP (Berkner and Folk 1977). In addition to its phosphorylation activity, bacteriophage T4 polynucleotide kinase carries a 3′ phosphatase activity (Richardson 1981). The properties of this enzyme are summarized in Table A4-6 and in Richardson (1981).

USES

1. Radiolabeling 5′ termini in DNA for sequencing by the Maxam-Gilbert technique (Maxam and Gilbert 1977), for nuclease S1 analysis, and for other uses requiring terminally labeled DNA.
2. Phosphorylating synthetic linkers and other fragments of DNA that lack terminal 5′ phosphates in preparation for ligation.

NOTES

- Bacteriophage T4 polynucleotide kinase is difficult to purify from infected cells, and impure preparations are not uncommon. Wherever possible, use bacteriophage T4 polynucleotide kinase that has been purified from cells expressing high levels of a cloned copy of the bacteriophage T4 gene.
- When setting up reactions involving the termini of nucleic acid molecules, the concentration of the reacting species can be calculated using Table A4-7 as a guide.
- Spermidine stimulates incorporation of [γ-^{32}P]ATP and inhibits a nuclease present in some preparations of bacteriophage T4 polynucleotide kinase.
- ATP should be present at a concentration of at least 1 μM in the forward reaction and at least 2 μM in the exchange reaction. Maximum enzyme activity requires still higher concentrations (please see Table A4-6).
- The DNA to be phosphorylated should be rigorously purified by gel electrophoresis, density gradient centrifugation, or chromatography on columns of Sepharose CL-4B in order to remove low-molecular-weight nucleic acids. Although such contaminants may make up only a small fraction of the weight of the nucleic acids in the preparation, they provide a much larger proportion of the 5′ termini. Unless steps are taken to remove them, contaminating low-molecular-weight DNAs and RNAs can be the predominant species of nucleic acids that are labeled in bacteriophage T4 polynucleotide kinase reactions.
- Ammonium ions are strong inhibitors of bacteriophage T4 polynucleotide kinase. Therefore, DNA should not be dissolved in, or precipitated from, buffers containing ammonium salts prior to treatment with the kinase.
- Low concentrations of phosphate also inhibit bacteriophage T4 polynucleotide kinase. Imidazole buffer (pH 6.4) is therefore the buffer of choice for the exchange reaction, and Tris buffer is the buffer of choice for the forward reaction.

TABLE A4-7 Concentration of Ends in Kinasing Reactions

Size of Double-stranded DNA (in Base Pairs)	Amount of DNA Required to Contribute 1 pmole of 5′ Termini (in μg)
50	1.7×10^{-2}
100	3.3×10^{-2}
250	8.4×10^{-2}
500	1.7×10^{-1}
1000	3.3×10^{-1}
2500	8.4×10^{-1}
5000	1.7

BACTERIOPHAGE T4 POLYNUCLEOTIDE KINASE

Activity: Kinase (forward reaction)

Substrate: Single- or double-stranded DNA with 5′-hydroxyl terminus; RNA with a 5′-hydroxyl terminus. The enzyme phosphorylates protruding 5′ single-stranded termini more rapidly than blunt ends or recessed 5′ termini; however, with sufficient enzyme and ATP, such termini can be completely phosphorylated. The reaction at nicks or gaps in double-stranded DNA is less efficient than for single-stranded termini; however, with sufficient concentrations of ATP and enzyme, gaps can be completely phosphorylated and nicks can be phosphorylated to 70%.

Reaction:

$$DNA_{OH}{}^{5'} \text{ or } RNA_{OH}{}^{5'} \xrightarrow[\substack{[\gamma\text{-}^{32}P]ATP \\ \text{dithiothreitol} \\ Mg^{2+}}]{\text{bacteriophage T4 polynucleotide kinase}} {}^{5'}[^{32}P]DNA \text{ or } {}^{5'}[^{32}P]RNA + ADP$$

For example:

$$^{5'}HO\,C_p\,G_p\,C\ldots{}^{3'}$$

$$[\gamma\text{-}^{32}P]dATP,\ \text{dithiothreitol},\ Mg^{2+} \downarrow \text{bacteriophage T4 polynucleotide kinase}$$

$$^{5'}{}^{*}_{p}C_p\,G_p\,C\ldots{}^{3'} + ADP$$

Activity: Kinase (exchange reaction)

Substrate: Single-stranded DNA with a 5′-phosphate terminus is most efficiently labeled (96%). Recessed 5′-phosphate termini are labeled to 70% with sufficient enzyme. 5′-phosphate groups at nicks are labeled 30-fold less efficiently than single-stranded 5′-phosphate termini.

Reaction:

$$^{5'}{}_{p}C_p\,G_p\,C\ldots{}^{3'} + \text{excess ADP}$$

$$[\gamma\text{-}^{32}P]dATP,\ \text{dithiothreitol},\ Mg^{2+} \downarrow \text{bacteriophage T4 polynucleotide kinase}$$

$$^{5'}{}^{*}_{p}C_p\,G_p\,C\ldots{}^{3'} + ADP + ATP$$

Alkaline Phosphatases

(*E. coli*, calf intestine, and shrimp)

The three alkaline phosphatases — bacterial alkaline phosphatase (BAP), calf intestinal alkaline phosphatase (CIP), and shrimp alkaline phosphatase (SAP) — catalyze the removal of 5′-phosphate residues from DNA, RNA, rNTPs, and dNTPs. For further details, please see the information panel on **ALKALINE PHOSPHATASE** in Chapter 9.

USES

1. Removing 5′ phosphates from DNA or RNA prior to labeling 5′ termini with ^{32}P.
2. Removing 5′ phosphates from fragments of DNA to prevent self-ligation.

NOTES

- BAP is the most active of the three enzymes, but it is also far more resistant to heat and detergents. It is therefore difficult to inhibit BAP completely at the end of dephosphorylation reactions.
- Proteinase K is used to digest CIP, which must be completely removed if subsequent ligations are to work efficiently. An alternative method is to inactivate the CIP by heating to 65°C for 1 hour (or 75°C for 10 minutes) in the presence of 5 mM EDTA (pH 8.0) and then to purify the dephosphorylated DNA by extraction with phenol:chloroform.
- SAP is extremely heat-labile and can be denatured completely and irreversibly by heating to 65°C for 15 minutes.

ALKALINE PHOSPHATASES

Activity: Phosphatase

Substrate: Single- or double-stranded DNA and RNA; rNTPs and dNTPs.

Reaction:

$$^{5'}{}_{p}\text{DNA or } ^{5'}{}_{p}\text{RNA} \xrightarrow{\text{alkaline phosphatase}} {}^{5'}{}_{OH}\text{DNA or } {}^{5'}{}_{OH}\text{RNA}$$

NUCLEASES

Ribonuclease H

Ribonuclease H (RNase H) catalyzes the endonucleolytic degradation of the RNA moiety of DNA-RNA hybrids, generating oligoribonucleotides of varying chain lengths with 3′-hydroxyl and 5′-phosphate termini. RNase H was first recognized and isolated from calf thymus (Stein and Hausen 1969; Hausen and Stein 1970), but the enzyme is now known to be present in a wide variety of mammalian tissues, yeasts, prokaryotes, and virus particles. Many types of cells contain more than one RNase H.

In many retroviruses, RNase H is associated with the multifunctional enzyme reverse transcriptase and carries out important functions at several stages during the transcription of the viral genome into DNA. In eubacteria, RNase H is believed to be required for the removal of RNA primers from Okazaki fragments, for processing of transcripts into primers that are used by DNA polymerase I to initiate DNA synthesis, and to remove R-loops that provide sites for opportunistic initiation of unregulated DNA synthesis at the chromosomal origin of replication in *E. coli*. RNase H is presumed to carry out similar functions in eukaryotic cells.

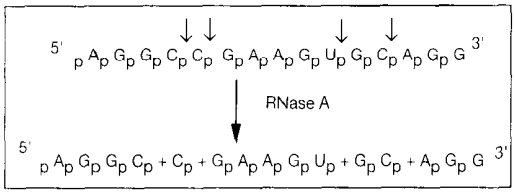
RNase H has been reported to increase markedly the inhibition of gene expression by antisense oligodeoxynucleotides. Hybrids between these oligonucleotides and specific sequences in mRNAs are sensitive to degradation by the enzyme. RNase H is required for initiation of replication at the origin (ori) of colicin E1 (colE1)-type plasmids in vitro. The enzyme also seems to suppress initiation of DNA synthesis at sites other than ori.

X-ray crystallographic analysis shows that *E. coli* RNase H consists of two domains, one of which contains an Mg^{2+}-binding site enmeshed in β strands, a fold previously recognized in DNase I. For further information and references, please see Crouch (1990), Wintersberger (1990), Hostomsky et al. (1993), Jung and Lee (1995), Kanaya and Ikehara (1995), Rice et al. (1996), Crooke (1998), and the information panel on **RIBONUCLEASE H** in Chapter 8.

Ribonuclease A (Pancreatic)

(Bovine pancreas)

Ribonuclease A (RNase A) is an endoribonuclease that specifically attacks single-stranded RNA 3′ to pyrimidine residues and cleaves the phosphate linkage to the adjacent nucleotide. The end products are pyrimidine 3′ phosphates and oligonucleotides with terminal pyrimidine 3′ phosphates (Davidson 1972). RNase A, which works in the absence of cofactors and divalent cations, can be inhibited by placental RNase inhibitor (Blackburn et al. 1977) or by vanadyl-ribonucleoside complexes (Puskas et al. 1982).



USES

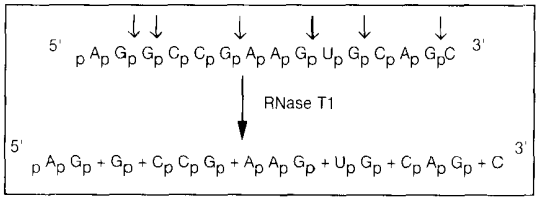
1. Removing unhybridized regions of RNA from DNA-RNA or RNA-RNA hybrids.
2. Mapping single-base mutations in DNA or RNA (Myers et al. 1985; Winter et al. 1985). In this method, single-base mismatches in RNA-DNA or RNA-RNA hybrids are recognized and cleaved by RNase A. A ^{32}P-labeled RNA probe complementary to wild-type DNA or RNA is synthesized in vitro using a plasmid containing a bacteriophage SP6 or T7 promoter. The RNA probe is then annealed to test DNA or RNA containing a single-base substitution. The resulting single-base mismatch is cleaved by RNase A, and the location of the mismatch is then determined by analyzing the sizes of the cleavage products by gel electrophoresis; ~50% of all possible single-base mismatches can be detected by this method.

PREPARATION OF RNASE THAT IS FREE OF DNASE

Dissolve pancreatic RNase (RNase A) at a concentration of 10 mg/ml in 0.01 M sodium acetate (pH 5.2). Heat to 100°C for 15 minutes. Allow it to cool slowly to room temperature. Adjust the pH by adding 0.1 volume of 1 M Tris-Cl (pH 7.4). Dispense into aliquots and store at –20°C. RNase precipitates when concentrated solutions are heated to 100°C at neutral pH.

Ribonuclease T1

Ribonuclease T1 (RNase T1) is an endoribonuclease that specifically attacks the 3′-phosphate groups of guanine nucleotides and cleaves the 5′-phosphate linkage to the adjacent nucleotide. The end products are guanosine 3′ phosphates and oligonucleotides with terminal guanosine-3′-phosphate groups (Davidson 1972).



USE

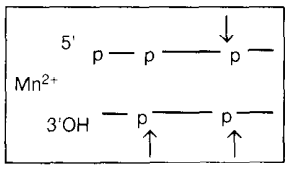
Removing unhybridized regions of RNA from DNA-RNA or RNA-RNA hybrids.

Deoxyribonuclease I (Pancreatic)

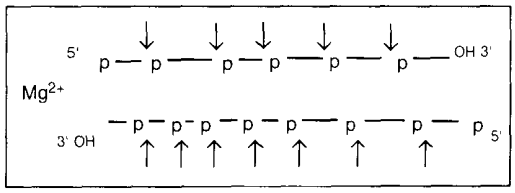
(Bovine pancreas)

The endonuclease DNase I from bovine pancreas is a glycoprotein that degrades double-stranded DNA by an in-line SN-2 mechanism involving nucleophilic attack on the scissile phosphodiester bond. The phosphate group remains attached to the new 5′ terminus. DNase I requires divalent metal ions for DNA hydrolysis (Kunitz 1950) and displays maximal activity in the presence of Ca^{2+} and either Mg^{2+} or Mn^{2+} (Price 1972). These cations work synergistically; in the presence of both Ca^{2+} (0.1 mM) and Mg^{2+} (10 mM), the rate of hydrolysis is greater than the sum of the rates for either cation alone. However, high concentrations of Mg^{2+} (>50 mM), but not of Ca^{2+}, are inhibitory.

The mode of action and the specificity of the enzyme are affected by the type of divalent cations used. In the presence of Mn^{2+}, or when very high concentrations of the enzyme are used in the absence of monovalent cations, DNase I breaks both strands of superhelical double-stranded DNA simultaneously at approximately the same site (Melgar and Goldthwait 1968; Campbell and Jackson 1980).



In the presence of Mg^{2+}, DNase I works in a totally different fashion and introduces nicks into each strand of double-stranded DNA independently. As more and more nicks accumulate, the number of base pairs between adjacent nicks on opposite strands gradually decreases and is eventually insufficient to hold the molecule together. The terminal products of this reaction are a complex mixture of acid-soluble 5′-phosphorylated oligonucleotides.



Whether this nicking activity of DNase I displays sequence specificity remains a surprisingly murky topic, with conflicting data from several groups. On the one hand, biochemical analysis of the digestion products of bulk *E. coli* DNA shows only weak sequence specificity (Ehrlich et al. 1973; Bernardi et al. 1975). On the other hand, footprints generated by digestion of double-stranded DNA with DNase I often show evidence of preferential cleavage by the enzyme. In addition, Scheffler et al. (1968) showed that DNase I has a very marked preference for cleaving poly(d[A-T])·poly(d[A-T]) to the 5′ side of T residues, a result that was confirmed with homopolymeric poly(d[A-T]) by Lomonossoff et al. (1981). However, this apparent specificity may be due more to a special alternating B conformation thought to be associated with the homopolymer, rather than to preference of the enzyme for particular sequences (Klug et al. 1979). Support for this idea comes from analysis of the crystal structure of complexes between DNase I and short double-stranded oligonucleotides (Suck et al. 1984; Suck and Oefner 1986). An exposed loop of the enzyme binds in the minor groove of B-DNA with both strands of the nucleic acid bending to make contact with the enzyme. Suck et al. (1988) have suggested that, in contrast to the results of Scheffler et al. (1968) and Lomonossoff et al. (1981), A-T tracts in double-stranded DNA might be relatively resistant to cleavage with DNase I.

In summary, whether DNase I nicks double-stranded DNA in a sequence-dependent fashion appears to be influenced by the structure of the template. The enzyme introduces nicks into complex DNAs with limited regard for sequence. However, on synthetic oligonucleotides of defined sequence, the enzyme shows a higher degree of preference, perhaps because the conformation of these substrates limits access of the enzyme to certain classes of phosphodiester bonds.

When very short double-stranded DNAs are used as substrates, DNase I also exhibits a topographical specificity that is manifested as "end-effects." The probability that a particular phosphodiester bond will be cleaved increases as a function of its distance from the 5′ end of a DNA strand, at least as far as the eighth phosphodiester bond (Galas and Schmitz 1978; Lomonossoff et al. 1981). This preference exists because the enzyme efficiently cleaves only when it can interact with three or four nucleotides that are 5′ to the cleavage site. The predominant products of complete digestion of double-stranded DNA are therefore 5′-phosphorylated tetranucleotides (Bernardi et al. 1975). Two methods have been used in molecular cloning to limit the action of DNase I to a single endonucleolytic cleavage per molecule of template DNA:

- As discussed above, in the presence of a transition metal ion such as Mn^{2+}, DNase I cleaves both strands of superhelical DNA at approximately the same site (Melgar and Goldthwait 1968) to yield fragments that are blunt-ended or that have protruding termini only one or two nucleotides in length. The resulting linear molecules are relatively resistant to further cleavage by the nuclease. This reaction has been used to generate random deletions in a segment of target DNA cloned in a plasmid or bacteriophage M13 vector (Frischauf et al. 1980; Anderson 1981; Hong 1982). Because the sites of double-stranded cleavage are distributed in a statistically random fashion, the population of closed circular DNAs is converted into a permuted set of linear molecules. These are then digested with a restriction enzyme whose unique site of cleavage lies at one end of the target DNA. Recircularization of the resulting population generates clones that lack sequences lying between the site of DNase I cleavage and the restriction site.
- In the presence of subsaturating quantities of an intercalating dye such as ethidium bromide, DNase I randomly introduces a single nick into one strand of closed circular DNAs. The resulting relaxed circular molecules are then relatively resistant to further cleavage by the enzyme. DNase I can therefore be used to introduce a single nick into closed circular DNAs in preparation for resecting prior to bisulfite-mediated mutagenesis (Greenfield et al. 1975).

USES

1. To remove DNA templates from in vitro transcription reactions and from preparations of mRNA. These RNAs are contaminated with large amounts of DNA that must be removed before analysis by northern hybridization, construction of cDNA libraries, reverse transcriptase (RT)-PCR, etc. Removal of contaminating DNA is particularly important when purifying RNAs from transfected cells or cells infected with DNA viruses. Unfortunately, many commercial preparations of pancreatic DNase I are contaminated with significant amounts of RNase. DNase I that is free of RNase can be obtained commercially but at great cost. If RNase-free DNase is used on a regular basis, please see the panel on **PREPARATION OF DNASE THAT IS FREE OF RNASE** on the following page.
2. To digest DNA that is left unprotected by interaction with proteins (DNA footprinting) (Galas and Schmitz 1978; Schmitz and Galas 1979). DNase I was the reagent originally used to develop DNA footprinting and despite the subsequent discovery of elegant chemical methods to cleave DNA in a sequence-independent fashion, DNA footprinting with DNase I remains by far the most popular way to localize specific interactions between proteins and DNA.
3. To introduce random single-stranded nicks into double-stranded DNA to generate templates for nick-translation reactions (Maniatis et al. 1975; Rigby et al. 1977). In this case, very small amounts of the enzyme are used to prevent wholesale destruction of the template DNA.

PREPARATION OF DNASE THAT IS FREE OF RNASE

mRNA prepared from uninfected mammalian cells contains only small amounts of DNA that generally do not compromise northern hybridization or other types of RNA analysis. However, mRNAs prepared from transfected mammalian cells or from cells infected with DNA viruses are contaminated with large amounts of DNA that must be removed by digestion with DNase I. Unfortunately, many commercial preparations of pancreatic DNase I, even those that claim to be RNase-free, are contaminated with significant amounts of RNase. In addition, the use of commercially prepared RNase-free DNase I can become expensive when many samples are prepared. DNase I can be treated by heating in the presence of iodoacetate to reduce RNase activity by ~98%. The resulting preparations of DNase are acceptable for all but the most stringent applications (e.g., this method should not be used to remove DNA from RNA to be used in construction of a cDNA library). DNase purified in this manner should always be used in the presence of a protein inhibitor of RNase (please see the information panel on **INHIBITORS OF RNASES** in Chapter 7).

1. Dissolve 10 mg of pancreatic DNase (Sigma) in 10 ml of 0.1 M iodoacetic acid, 0.15 M sodium acetate (pH 5.2).
2. Heat the solution to 55°C for 45 minutes. Cool the solution to 0°C, and add 1 M $CaCl_2$ to a final concentration of 5 mM.
3. Dispense the DNase I into small aliquots and store at –20°C.

BAL 31 Nuclease

(Alteromonas espejiana **BAL 31**)

BAL 31 is predominantly a 3′ exonuclease that removes mononucleotides from both 3′ termini of the two strands of linear DNA. BAL 31 is also an endonuclease; thus, the single-stranded DNA generated by the 3′ exonuclease activity is degraded by the endonuclease. The mechanisms of these reactions are complex and are summarized in the information panel on **BAL 31** in Chapter 13.

Degradation is absolutely dependent on the presence of calcium, and the reaction can therefore be stopped at different stages by the addition of the chelating agent EGTA. Because degradation occurs relatively uniformly from the termini of DNA, digestion with BAL 31 can be used to map restriction sites in small fragments of DNA (Legerski et al. 1978). DNA is digested with BAL 31, and samples are withdrawn at different times and placed in a solution containing EGTA. After digestion of these samples with the restriction enzyme of interest, restriction fragments can be seen to disappear in a defined order. By using a DNA consisting of vector sequences at one terminus (for which the restriction map is known) and unmapped sequences at the other, it is possible to distinguish fragments from the two termini and to deduce the order of the fragments in the unmapped DNA.

BAL 31 can also be used to remove unwanted sequences from the termini of DNAs before cloning. After treatment with the exonuclease/endonuclease, the termini of the DNA are repaired with bacteriophage T4 DNA polymerase or the Klenow fragment of *E. coli* DNA polymerase I. Synthetic linkers are added to the DNA, which is then inserted into a suitable vector. In this way, it is possible to generate a set of deletions from a defined endpoint in DNA. Although the enzyme is predominantly a 3′ exonuclease, it also has a DNA endonuclease activity and cleaves internally in single-stranded regions of DNA or in double-stranded DNA that contains helical distortions (Lau and Gray 1979; Gray et al. 1981; Wei et al. 1983). BAL 31 will also digest RNA, albeit inefficiently.

USES

1. Removing nucleotides from the termini of double-stranded DNA in a controlled manner. The shortened molecules can be used for a variety of purposes such as to produce deletions, to position a desired sequence next to a promoter or other controlling element, or to attach synthetic linkers at desired sites in the DNA.
2. Mapping restriction sites in DNA (Legerski et al. 1978).
3. Mapping secondary structure in DNA, for example, junctions between B-DNA and Z-DNA or sites of covalent or noncovalent modifications in double-stranded DNA (Gray et al. 1981; Wei et al. 1983).
4. Removing nucleotides from double-stranded RNA in preparing recombinant RNAs (Miele et al. 1983).

NOTES

- When the products of BAL 31 digestion are to be ligated, it is important to consider that the 3′ exonuclease activity of the enzyme works ~20-fold more efficiently than the DNA endonuclease. Thus, the average length of single-stranded tails created by digestion of linear double-stranded DNA is dependent on the enzyme concentration. At high enzyme concentrations (2–5 units/ml), an average of five nucleotides of single-stranded DNA remain per terminus and 10–20% of the molecules can be ligated to blunt-ended DNA without further treatment. At low enzyme concentrations (0.1–0.2 unit/ml), the single-stranded termini may be very long and the efficiency of blunt-end ligation is very low. Repair with bacteriophage T4 DNA poly-

merase (or, in some cases, the Klenow fragment) is almost obligatory before cloning DNAs treated with either high or low concentrations of BAL 31.

- Most commercial preparations of BAL 31 contain two kinetically distinct forms of the enzyme, a fast and a slow form. The slow form is a proteolytic degradation product of the fast form. Pure preparations of the fast form are available, but they are expensive (Wei et al. 1983). Results using mixed preparations will vary, depending on the relative amounts of the two forms in the initial preparation and the rate of conversion of the fast to the slow form during the assay.

  Preparations rich in the fast form are preferred for such tasks as removal of long (>1000 bp) segments from the termini of double-stranded DNA; degradation of double-stranded RNA; and mapping of restriction sites, B-Z DNA junctions, and lesions in double-stranded DNA. The slow form of the enzyme is used to remove short segments (10–100 bp) from the termini of double-stranded DNA. Mixed preparations of the enzyme can be used for any of these tasks, although the results will vary as mentioned above.

- BAL 31 works asynchronously, generating a population of DNA molecules whose termini have been resected to various extents and whose single-stranded tails vary in length. Following digestion with BAL 31 and repair with bacteriophage T4 DNA polymerase (or the Klenow fragment), it is often more efficient to isolate DNAs of the required size by gel electrophoresis rather than to screen very large numbers of randomly generated clones.

- BAL 31 degrades AT-rich sequences significantly more rapidly than it degrades GC-rich regions. Thus, molecules that terminate in AT-rich regions are underrepresented in populations of DNAs that have been digested with the enzyme.

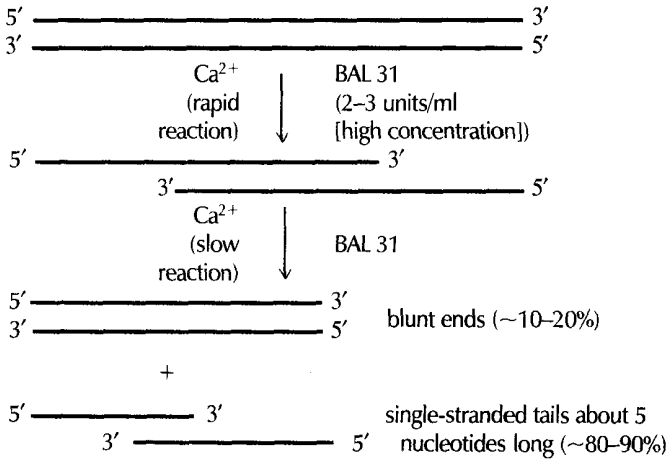
- BAL 31 should not be frozen. Store the enzyme at 4°C.

BAL 31 NUCLEASE

Activity: Exonuclease/endonuclease

Substrate: BAL 31 degrades double-stranded DNA sequentially from both termini. The mechanism is thought to involve a rapid exonucleolytic degradation followed by a slow endonucleolytic reaction on the complementary strand. Double-stranded DNA with blunt or protruding 3′-hydroxyl termini are degraded to shorter double-stranded molecules. The enzyme is also active at nicks, on single-stranded DNA with 3′-hydroxyl termini, and on double-stranded RNA molecules.

Reaction:

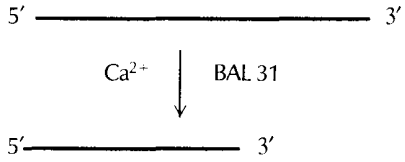


BAL 31 NUCLEASE

Activity: Exonuclease (shortens single-stranded DNA)

Substrate: Single-stranded DNA with 3′-hydroxyl termini.

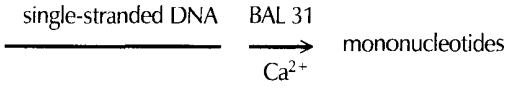
Reaction:



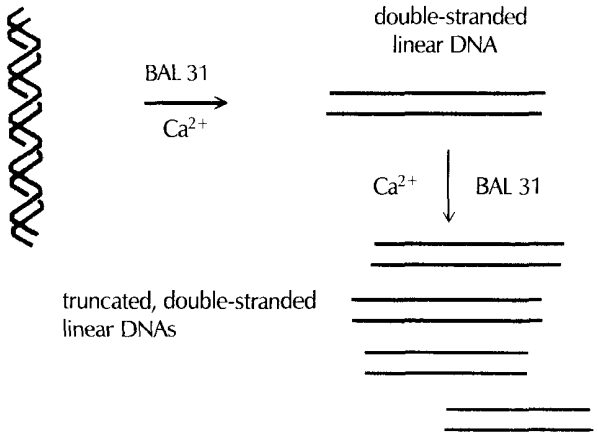
Activity: Endonuclease

Substrate: Single-stranded DNA; supercoiled DNA; DNA with B-DNA, Z-DNA junctions and other non-B-DNA comformations.

Reaction:



superhelical double-stranded DNA



Nuclease S1

(Aspergillus oryzae)

Nuclease S1 degrades single-stranded DNA or RNA (Vogt 1973) to yield 5′-phosphate mono- or oligonucleotides. Double-stranded DNA, double-stranded RNA, and DNA-RNA hybrids are relatively resistant to the enzyme. However, double-stranded nucleic acids are digested completely by nuclease S1 if they are exposed to very large amounts of the enzyme. Moderate amounts of the enzyme will cleave double-stranded nucleic acids at nicks or small gaps (Kroeker and Kowalski 1978). For further information, please see both the introduction to Protocol 10 and the information panel on **NUCLEASE S1** in Chapter 7.

USES

1. Analyzing the structure of DNA-RNA hybrids (Berk and Sharp 1977; Favaloro et al. 1980).
2. Removing single-stranded tails from DNA fragments to produce blunt ends.
3. Opening the hairpin loop generated during synthesis of double-stranded cDNA.

NOTE

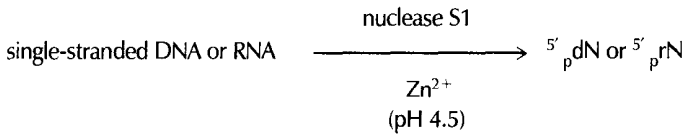
- Since the enzyme works at low pH, depurination often occurs, which limits the usefulness of nuclease S1 for some applications.

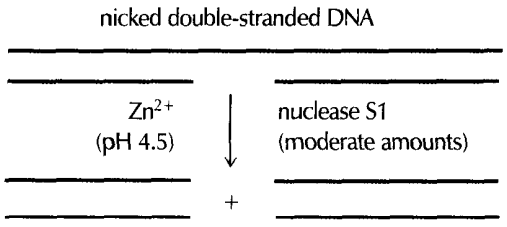
NUCLEASE S1

Activity: Single-strand-specific nuclease

Substrate: Single-stranded DNA or RNA; more active on DNA than on RNA.

Reaction:





Mung Bean Nuclease

(Mung bean sprouts)

Mung bean nuclease degrades single-stranded DNA to mono- or oligonucleotides with phosphate groups at their 5′ termini (Laskowski 1980). Double-stranded DNA, double-stranded RNA, and DNA-RNA hybrids are relatively resistant to the enzyme. However, double-stranded nucleic acids are digested completely by mung bean nuclease if they are exposed to very large amounts of the enzyme (Kroeker and Kowalski 1978).

Although mung bean nuclease and nuclease S1 are similar to each other in their physical and catalytic properties, mung bean nuclease may be less severe in its action than nuclease S1. For example, nuclease S1 has been shown to cleave the DNA strand opposite a nick in a duplex, whereas mung bean nuclease will only attack the nick after it has been enlarged to a gap several nucleotides in length (Kroeker and Kowalski 1978). For further details, please see the information panel on **MUNG BEAN NUCLEASE** in Chapter 7.

USES

1. Converting protruding termini of DNA to blunt ends.
2. Analyzing the structure of DNA-RNA hybrids.

Exonuclease III

(*E. coli*)

Exonuclease III catalyzes the stepwise removal of 5′ mononucleotides from the 3′-hydroxyl termini of double-stranded DNA (Weiss 1976). Linear double-stranded DNA and circular DNAs containing nicks or gaps are substrates. The activity of the enzyme results in the formation of long single-stranded regions in double-stranded DNA. The enzyme also carries three other activities: an endonuclease specific for apurinic DNA, an RNase H activity (Rogers and Weiss 1980), and a 3′ phosphatase activity, which removes 3′-phosphate termini but does not cleave internal phosphodiester bonds. The exonuclease will not degrade single-stranded DNA or double-stranded DNA with a protruding 3′ terminus (Rogers and Weiss 1980).

Exonuclease III is nonprocessive and typically generates populations of molecules that have been resected to similar extents. This property simplifies the task of isolating DNA molecules whose lengths have been reduced by the desired amount. For further details, please see the information panel on **EXONUCLEASE III** in Chapter 13.

USES

1. Generating partially resected DNAs that can be used as substrates for the Klenow fragment (e.g., in the preparation of strand-specific probes) (for a similar application for bacteriophage T4 DNA polymerase, please see Figure A4-2 [p. A4.19]).
2. Generating nested sets of deletions of the terminal sequences of double-stranded linear DNAs. This reaction is usually carried out in conjunction with mung bean nuclease or nuclease S1 and is an alternative to using BAL 31. Because exonuclease III will degrade DNA with recessed 3′ termini but not termini with protruding 3′ single strands, it can be used to create unidirectional sets of deletions (Henikoff 1984). Thus, if the substrate molecule carries a protruding 3′ terminus at one end (e.g., created by digestion with *Pst*I) and a recessed 3′ terminus at the other, exonuclease III will digest only in one direction (from the recessed 3′ terminus). After

removal of the resulting single-stranded segments (with nuclease S1 or mung bean nuclease) and repair with bacteriophage T4 DNA polymerase, the deleted molecules can be inserted into an appropriate vector by blunt-end ligation.

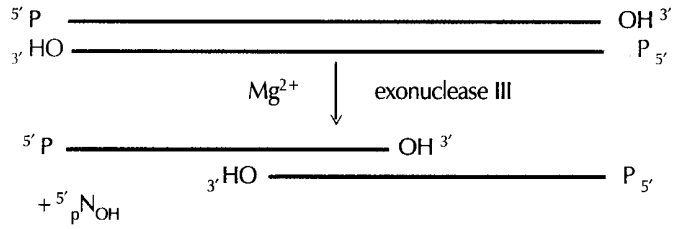
3. Some methods of site-specific mutagenesis use thiophosphate derivatives of the dNTPs for second-strand synthesis primed by the mutagenic primer. The parental template strand can be preferentially degraded with exonuclease III, increasing the frequency of mutants obtained upon transformation of *E. coli*, since exonuclease III will not cleave thioester bonds (please see the information panel on **SELECTING AGAINST WILD-TYPE DNA IN SITE-DIRECTED MUTAGENESIS** in Chapter 13).

EXONUCLEASE III

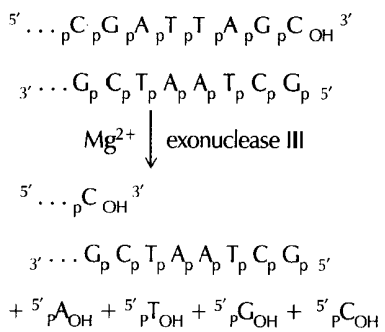
Activity: 3′ Exonuclease

Substrate: This enzyme is active on 3′-hydroxyl termini of double-stranded DNA with blunt ends or with ends containing unpaired 5′ termini and recessed 3′ termini. 3′-hydroxyl termini at nicks in double-stranded DNA are also substrates. The DNA must contain phosphodiester bonds; thioesters are not cleaved.

Reaction:



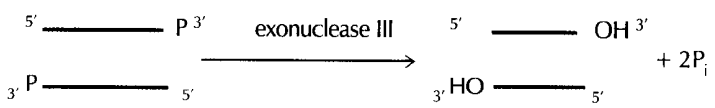
For example:



Activity: 3′ Phosphatase

Substrate: Double- or single-stranded DNA with a 3′-phosphate terminus; internal phosphodiester bonds are not cleaved.

Reaction:



Bacteriophage λ Exonuclease

(Bacteriophage λ-infected *E. coli*)

Bacteriophage λ exonuclease catalyzes the processive, stepwise release of 5′ mononucleotides from double-stranded DNA. Although the preferred substrate is double-stranded DNA with a terminal 5′ phosphate (Little et al. 1967), the enzyme will also work, albeit 100-fold less efficiently on single-stranded DNA. Double-stranded DNAs with nicks or gaps will not serve as substrates.

USE

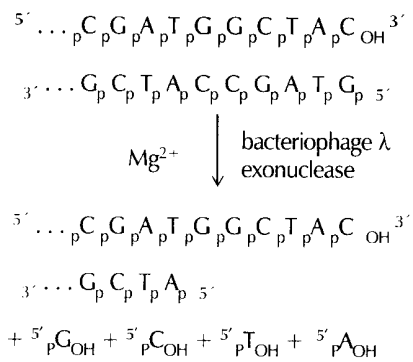
Bacteriophage λ exonuclease was used for a wide variety of purposes in the early days of molecular cloning (for review, please see Little 1981). Today, it is used chiefly to modify the 5′-phosphate termini of DNAs that are to be used as substrates for other enzymes (e.g., terminal transferase).

BACTERIOPHAGE λ EXONUCLEASE

Activity: 5′ Exonuclease

Substrate: Double-stranded DNA with 5′-phosphate termini or with protruding 5′ termini.

Reaction:



PROTEOLYTIC ENZYMES

Proteinase K

Proteinase K is a highly active serine protease of the subtilisin type (for reviews, please see Siezen et al. 1991; Siezen and Leunissen 1997) that is secreted by stationary cultures of the mold *Tritirachium album* var. Limber (Ebeling et al. 1974). The K in the enzyme's name indicates that the protease can supply the mold's total requirement for carbon and nitrogen by hydrolysis of keratin. Proteinase K catalyzes hydrolysis of a wide variety of peptide bonds but exhibits a preference for peptide bonds carboxy-terminal to aromatic and uncharged amino acids.

The mature enzyme consists of 279 amino acid residues (M_r = 28,930) (Jany et al. 1986; Gunkel and Gassen 1989) and has two binding sites for Ca^{2+}, which lie some distance from the catalytic site. The Ca^{2+} ions are not directly involved in catalysis, but they contribute to structural stability of the enzyme (Betzel et al. 1988; Müller et al. 1994). When Ca^{2+} is removed from the enzyme, some of the catalytic activity is lost because of long-range structural changes (Bajorath et al. 1988, 1989). Because the residual activity is sufficient to degrade most proteins, digestion with proteinase K is usually carried out in the presence of EDTA. In addition, proteinase K remains active in the presence of urea (1–4 M) and detergents that are routinely used to lyse mammalian cells (e.g., 0.5% SDS or 1% Triton X-100). Because proteinase K efficiently digests native proteins, it can rapidly inactivate DNases and RNases in cell lysates, which facilitates the isolation of high-molecular-weight DNA and intact RNA (Wiegers and Hilz 1971, 1972; Hilz et al. 1975).

Proteinase K is purchased as a lyophilized powder and should be dissolved at a concentration of 20 mg/ml in sterile 50 mM Tris-Cl (pH 8.0), 1.5 mM calcium acetate. The stock solution should be divided into small aliquots and stored at –20°C. An aliquot can be thawed and refrozen several times, but it should then be discarded. Unlike much cruder preparations of protease (e.g., pronase), proteinase K need not be self-digested before use. The activity of proteinase K is severalfold higher at 50°C than at 37°C. Please see Table A4-8.

TABLE A4-8 Proteolytic Enzymes

	Stock Solution	Storage Temperature	Concentration in Reaction	Reaction Buffer	Temperature	Pretreatment
Pronase[a]	20 mg/ml in H_2O	–20°C	1 mg/ml	0.01 M Tris-Cl (pH 7.8) 0.01 M EDTA 0.5% SDS	37°C	self-digestion[b]
Proteinase K	20 mg/ml in H_2O	–20°C	50 µg/ml	0.01 M Tris-Cl (pH 7.8) 0.005 M EDTA 0.5% SDS	37–56°C	none required

[a]Pronase is a mixture of serine and acid proteases isolated from *Streptomyces griseus*.

[b]Self-digestion eliminates contamination with DNase and RNase. Self-digested pronase is prepared by dissolving powdered pronase in 10 mM Tris-Cl (pH 7.5), 10 mM NaCl to a final concentration of 20 mg/ml and incubating for 1 hour at 37°C. Store the self-digested pronase in small aliquots at –20°C in tightly capped tubes.

OTHER ENZYMES

Lysozymes

Lysozymes are a family of enzymes that catalyze the acid-base hydrolysis of β-(1,4) linkages between *N*-acetylglucosamine and *N*-acetylmuramic acid residues in the proteoglycan of bacterial cell walls (Blake et al. 1967; Fursht 1985). They were discovered by Alexander Fleming (1922), who identified an enzyme activity that rapidly lysed suspensions of bacteria. The products of digestion by vertebrate lysozymes of the cell walls of bacteria were identified in the late 1950s, which allowed the structure and composition of the substrate to be deduced (for review, please see Jollés 1960).

Lysozymes are widely distributed in nature and are expressed wherever there is a need to lyse bacterial cells, for example, during release of bacteriophages from infected cells, on the surface of vertebrate mucosa, and in a great number of secretions of different animals, both vertebrate and invertebrate. There is no structural similarity between vertebrate and bacteriophage-encoded lysozymes such as bacteriophage λ endolysin and bacteriophage T4 endoacetylmuramidase.

In molecular cloning, vertebrate lysozymes (e.g., egg-white lysozyme) are used at pH 8.0 in combination with EDTA and detergents to liberate cosmid and plasmid DNAs from their bacterial hosts (Godson and Vapnek 1973). For further details, please see the information panel on **LYSOZYMES** in Chapter 1.

Agarase

Agarase enzymatically digests molten agarose to produce soluble monomers and oligosaccharides. It is used in the isolation of DNA fragments from agarose gels. The enzyme is available from a number of manufacturers and is active in both Tris-acetate and Tris-borate buffers. Optimum activity is achieved at pH 6.0. Isolation of DNA using agarase is a very gentle method, which makes it suitable for the purification of large fragments. For a protocol on the purification of DNA from pulsed-field gels after agarase digestion, please see Chapter 5, Protocol 19.

Uracil DNA Glycosylase

Uracil DNA glycosylase (UDG) cleaves the *N*-glycosidic bond between the uracil base and the phosphodiester backbone of DNA. UDG removes the uracil residues from the sugar moiety of single- and double-stranded DNAs without destroying the phosphodiester backbone, thus preventing its uses as a hybridization target or template for DNA polymerase. The resulting apyrimidinic DNA becomes susceptible to hydrolysis at high temperatures. UDG will not remove uracil from RNA, and it specifically attacks uracil-containing DNA.

Treatment of uracil-containing DNA with UDG disrupts base pairing in the DNA duplex. The use of dUTP in amplification reactions introduces uracil at the sites opposite to adenine. Subsequent treatment of the duplex with UDG results in single-stranded termini that may be used in cloning the amplified fragments of DNA.

Topoisomerase I

Topoisomerase I (Topo I) is a crucial component of DNA replication. The enzyme works by introducing transient nicks into one strand of the backbone of both positively and negatively supercoiled DNAs, thus allowing the structure to untwist, and then resealing the breaks (for review, please see Wang 1996). During the course of the reaction catalyzed by topoisomerase I, a transient covalent intermediate is formed between a specific tyrosine residue of the enzyme and one end of the break in its DNA substrate. This bond between the enzyme and its substrate is broken by the activity of tyrosine-DNA phosphodiesterase, the gene for which has been cloned and shown to be highly conserved among higher eukaryotes (Pouliot et al. 1999).

In the absence of Mg^{2+}, topoisomerase I works to generate relaxed, covalently closed circles (for review, see Kornberg and Baker 1992). The enzyme is sometimes used in molecular cloning to enhance the electrophoretic separation of plamid DNAs. Thus, fractionation by gel electrophoresis of closed circular DNAs that have been relaxed by treatment with topoisomerase I will resolve molecules that differ in length by a single nucleotide pair (Wang 1979; Luckow et al. 1987). Topoisomerase I is commercially available from Life Technologies, or it can be purified readily from calf thymus as described by Prell and Vosberg (1980).

Appendix 5

Inhibitors of Enzymes

TABLE A5-1 Protease Inhibitors

PROTEASE INHIBITORS	M.W.	INHIBITS	DOES NOT INHIBIT
Antipain dihydrochloride	677.6	Inhibits papain, trypsin, cathepsins A and B, and to a small extent plasmin.	
Antithrombin III	58,000	Inhibits all serine proteases of the blood coagulation system, as well as trypsin and chymotrypsin.	Does not inhibit cysteine proteases, aspartic proteases, or metalloproteases.
APMSF	252.7	Specific and irreversible inhibitor of serine proteases.	Does not inhibit chymotrypsin or acetylcholinesterase.
Aprotinin	~6500	Serine protease inhibitor; inhibits plasmin, chymotrypsin, kallikrein, and trypsin.	Does not inhibit thrombin or Factor X.
Bestatin	344.8	Inhibits metalloproteases, primarily aminopeptidases.	Does not inhibit carboxypeptidases.
Calpain inhibitor I	383.5	Strong competitive inhibitor of calpain I and to a lesser extent calpain II; also inhibits papain, cathepsins B and L, and to a small extent cathepsin H and α-chymotrypsin.	Does not inhibit trypsin.
Calpain inhibitor II	401.6	Strong competitive inhibitor of calpain I and to a lesser extent calpain II; also inhibits papain, cathepsins B and L, and to a small extent cathepsin H; weakly inhibits α-chymotrypsin.	Does not inhibit trypsin.
Chymostatin	607.7	Inhibits serine and cysteine proteases; specific inhibitor of α-, β-, γ-, δ-chymotrypsin, papain, and cathepsins A, B, and C.	
3,4-Dichloroisocoumarin	215.0	Inhibitor of serine proteases.	
Elastatinal	512.6	Irreversible inhibitor of elastase.	
Hirudin	6963.5	Inhibits thrombin.	
Iodoacetic acid	186.0	Inhibits cysteine proteases.	
Leupeptin	475.6	Inhibits serine and cysteine proteases	
α_2-Macroglobulin	~725,000	Universal protease inhibitor blocking all classes of endoproteinases.	Does not inhibit endoproteinases that are highly specific for one or a limited number of sequences, e.g., tissue kallikrein, urokinase, coagulation Factor XIIA, and endoproteinase Lys-C.
Pefabloc SC, AEBSF, 4-(2-aminoethyl)-benzenesulfonyl fluoride hydrochloride	239.5	Inhibits serine proteases and prevents nonspecific covalent modification of proteins.	
Pepstatin A	685.9	Inhibits acid proteases, e.g., pepsin, renin, cathepsin D, chymosin, and many microbial acid proteases.	
PMSF (phenylmethylsulfonyl fluoride)	174.2	Inhibits serine proteases, e.g., chymotrypsin, thrombin, and papin.	
TIMP-2		Inhibits matrix metalloproteinase activity in enzymatic assays and in vitro malignant invasion assays.	
TLCK; 1-chloro-3-tosylamido-7-amino-1-2-heptanone; Nα-*p*-tosyl-l-lysine chloromethyl ketone hydrochloride	369.3	Irreversibly inhibits trypsin as well as many other serine and cysteine proteases, e.g., bromelain, ficin, or papain.	Does not inhibit chymotrypsin.
TPCK; 1-chloro-3-(4-tosylamido)-4-phenyl-2-butanone; N-tosyl-l-phenylalanine chloromethyl ketone	351.9	Irreversibly inhibits chymotrypsin, as well as many other serine and cysteine proteases, e.g., bromelain, ficin, or papain.	Does not inhibit trypsin.

The results represent the ability of various restriction endonucleases to cleave close to the end of a DNA fragment. The cleavage efficiency is given for a particular recognition site placed at x bases from the end of a linearized vector. As a general rule, enzymes not listed above require 6 base pairs on either side of their recognition site to cleave efficiently. (Reproduced, with permission, 1998/99 New England Biolabs Catalog [©NEB].)

TABLE A6-13 Molecular Conversions for Oligonucleotides

SIZE OF OLIGONUCLEOTIDE (NUCLEOTIDES)	MOLECULAR MASS (DALTONS)	MOLECULES OF DNA IN 1 μg	MOLES OF DNA IN 1 μg
8	2.64×10^3	2.28×10^{14}	379 pmoles
10	3.30×10^3	1.82×10^{14}	303 pmoles
12	3.96×10^3	1.52×10^{14}	253 pmoles
14	4.62×10^3	1.30×10^{14}	216 pmoles
16	5.28×10^3	1.14×10^{14}	190 pmoles
18	5.94×10^3	1.01×10^{14}	168 pmoles
20	6.60×10^3	9.12×10^{13}	152 pmoles

NOMOGRAMS

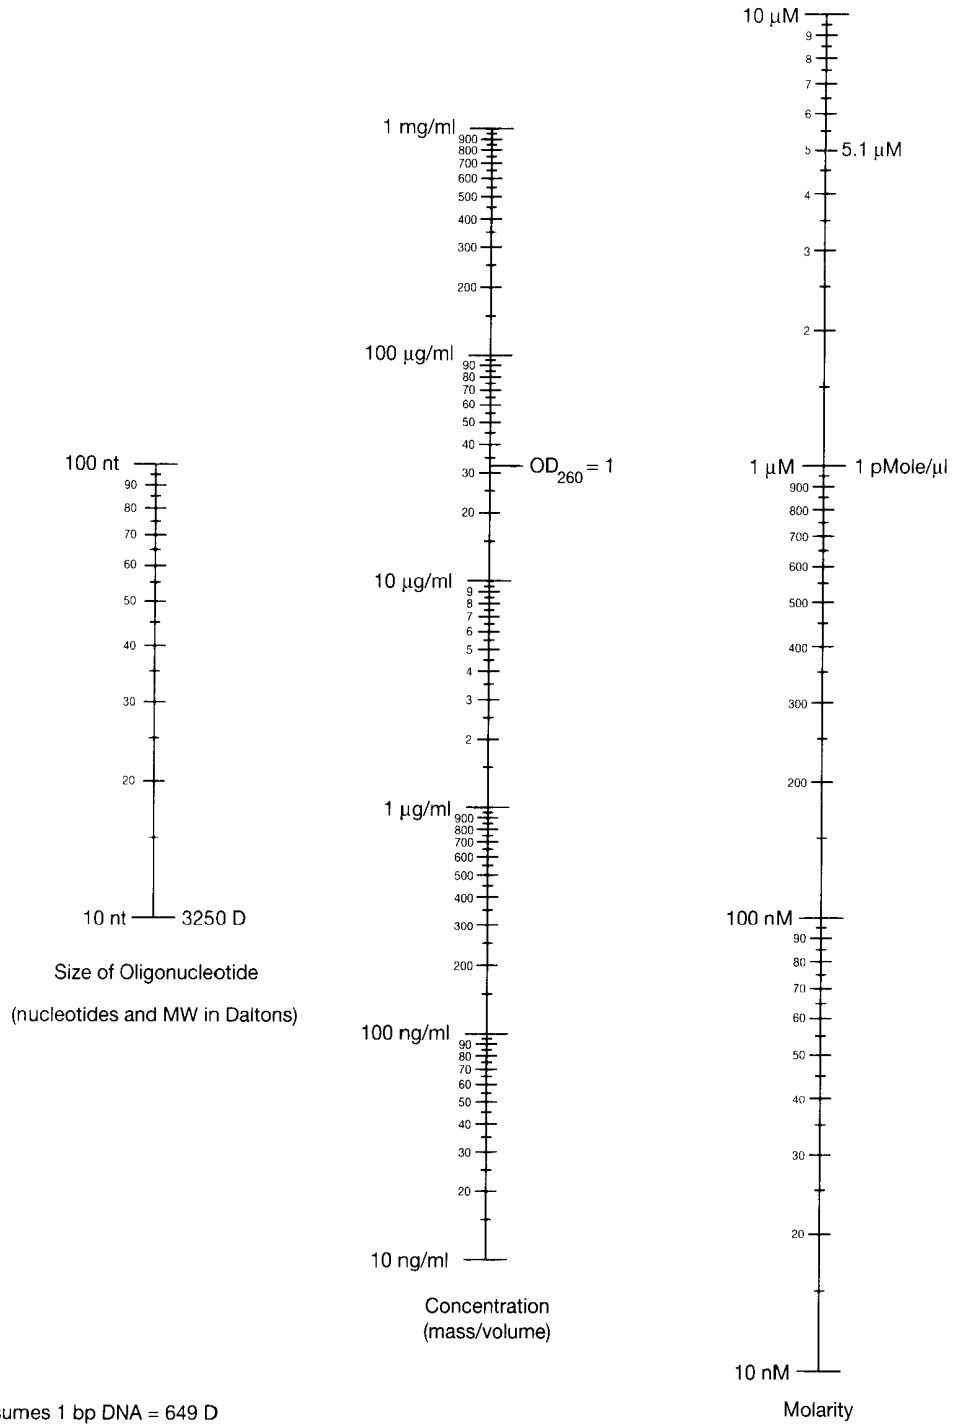

FIGURE A6-2 Nomogram for Single-stranded DNA

This nomogram can be used for the conversion of concentration between different conventions and to obtain approximate values of DNA concentration from OD_{260} readings. For example, a solution of an oligonucleotide 20 nucleotides in length that produces an $OD_{260} = 1$ has a concentration of 33 µg/ml. To calculate the molarity of the solution, draw a line from the size of the molecule (in nucleotides or molecular weight) on the left-hand scale, through the point of known concentration (33 µg/ml) on the middle scale. Extrapolate the line through the third scale and read off the molarity (5.1 µM is equivalent to 5.1 pmoles/µl). (Figure kindly provided by Siân Curtis.)

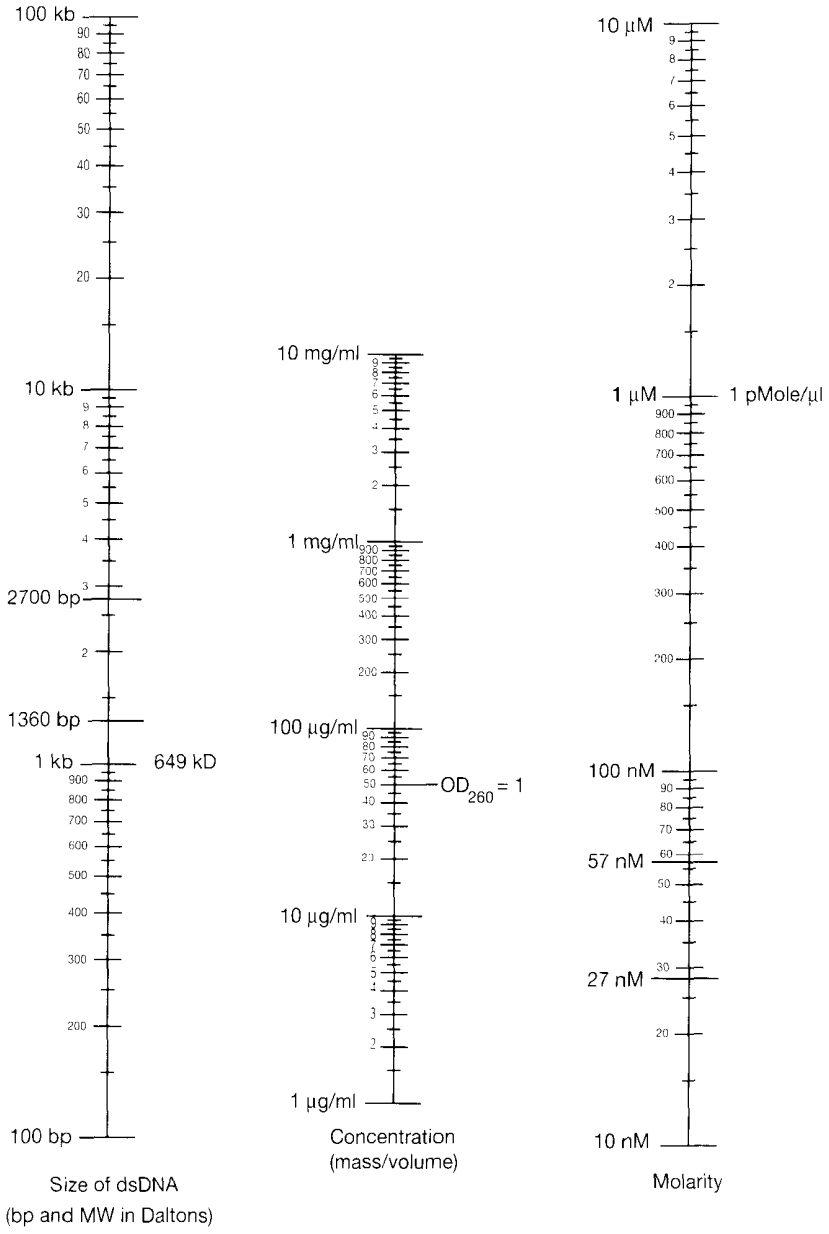

FIGURE A6-3 Nomogram for Double-stranded DNA

This nomogram can be used for the conversion of concentration between different conventions, and also to obtain approximate values of DNA concentration from OD_{260} readings. A solution containing 50 µg/ml of *double-stranded* DNA has an absorbance of 1 at 260 nm, i.e., A_{260} = 1 = 50 µg/ml of double-stranded DNA. For example, a solution of pUC 18/19 (2686 bp) that produces an OD_{260} = 1 has a concentration of 50 µg/ml. To calculate the molarity of the solution, draw a line from the size of the molecule (base pairs or molecular weight) on the left-hand scale through the point of known concentration (50 µg/ml) on the middle scale. Extrapolate the line through the third scale and read off the molarity (57 nM is equivalent to 57 fmoles/µl). (Figure kindly provided by Siân Curtis.)

SIZE MARKERS

Appendix 7

Codons and Amino Acids

CODONS AND CODON USAGE

The genetic code is redundant, using 61 codons to specify 20 amino acids. Only two amino acids (Met and Trp) are specified by a single codon, whereas the remaining 18 amino acids are each specified by multiple codons (please see Figure A7-1).

The synonymous codons that specify a single amino acid are not used with equal frequency (Grantham et al. 1980, 1981). Instead, biased usage of synonymous codons is the rule in all species and is the norm in most genes. In addition, there is considerable variation in codon usage between genes in a single species (Bennetzen and Hall 1982; Gouy and Gautier 1982). This results from variation between genes in the G+C content of the third position of synonymous codons (Ikemura 1985; Mirouchoud and Gautier 1988). The pattern of codon usage is the result of selective forces, mutational bias, and genetic drift. For example:

- ***Selection during translation so that the codons used most frequently match the most abundant tRNAs.*** Highly expressed and weakly expressed genes display different patterns of codon usage in both prokaryotes and eukaryotes (Shields and Sharp 1987; Sharp and Devine 1989; Sharp and Cowe 1991). Direct assays of translatability of mRNAs lend further support to this view (e.g., please see Ikemura 1982; Sørensen et al. 1989).
- ***"Knock-on" or context effects, in which mutation of one base influences other bases in the neighborhood*** (Bulmer 1990; Eyre-Walker 1991).
- ***Any selection that results in a change in GC content in codons.*** Bernardi and Bernardi (1986) have argued that regions of the genome with increased (G+C) content are thermodynamically more stable and that mRNAs rich in (G+C) have more secondary structures and are therefore more stable. If correct, this relationship would have effects both on amino acid composition of proteins and on codon usage. There would be selection for "strong" codons that contain G and C at the first two positions (Gly, Ala, Pro) and a selection against weak codons that have A and T at both positions (Phe, Ile, Lys, Asn, Tyr) (Karlin and Bucher 1992). In addition, there would be a slow drift to replace A and T in the third position with G or C. Over the course of time, this gentle evolutionary wind might blow codons, like fallen leaves, into local clumps within individual genes or organisms. However, there are also stabilizing forces that protect codons rich in (A+T). Chief among these is the strong selection against the sequence CG in mammalian genomes. The cytosine of this sequence tends to be methylated and is then prone to mutation. One result is a bias against C in the third position of codons that precede codons beginning with G (e.g., please see Zhang et al. 1991).

Codon usage is a concern in molecular cloning if a sequence of amino acids is used to design an oligonucleotide for screening cDNA or genomic libraries. No rules guarantee selection of the correct codon at a position of ambiguity. However, a probe of 30 or more oligonucleotides would be expected to have at least 76% homology with its target sequence even if all codon choices were made on a random basis (Lathe 1985). If substitutions are chosen on the statistical basis of known codon utilization in the species of interest, the expected homology increases to 82%; it rises still further (to 86%) if regions lacking Leu, Arg, and Ser are chosen (each of these amino acids is specified by six codons). In yeast, still higher accuracy can be achieved by taking into account whether the gene is highly or weakly expressed. In mammalian cells, this latter refinement is not generally used because of the great variation in the level of expression of genes between tissues.

A database of codon usage in different organisms is available at http://www.kazusa.or.jp/codon/. The list is based on data derived from an analysis of complete coding sequences in GenBank (Nakamura et al. 1999). For a more detailed analysis of the fluctuation of codon usage in different yeast genes, please see Sharp and Cowe (1991). Codon usage in humans is shown in Table A7-1.

TABLE A7-1 Codon Usage in Humans

Amino Acid	Frequency in Human Proteins (%)[a]	Codons and Their Usage in Human Proteins (%)[b]	
Alanine	6.99	GCU (28.0)	GCC (41.6)
		GCA (20.0)	GCG (10.3)
Arginine	5.28	CGU (8.9)	CGC (21.4)
		CGA (5.4)	CGG (10.4)
		AGA (9.9)	AGG (11.1)
Asparagine	3.92	AAU (42.3)	AAC (57.7)
Aspartic Acid	5.07	GAU (42.8)	GAC (57.2)
Cysteine	2.44	UGU (40.6)	UGC (59.4)
Glutamic Acid	6.82	GAA (39.2)	GAG (60.7)
Glutamine	4.47	CAA (24.8)	CAG (75.2)
Glycine	7.10	GGU (15.8)	GGC (35.8)
		GGA (24.1)	GGG (24.3)
Histidine	2.35	CAU (39.6)	CAC (60.4)
Isoleucine	4.50	AUU (33.1)	AUC (54.0)
		AUA (12.9)	
Leucine	9.56	UUA (5.5)	UUG (11.5)
		CUU (11.1)	CUC (20.8)
		CUA (6.5)	CUG (44.5)
Lysine	5.71	AAA (38.9)	AAG (61.1)
Methionine	2.23	AUG (100)	
Phenylalanine	3.84	UUU (41.1)	UUC (58.2)
Proline	5.67	CCU (27.3)	CCC (35.2)
		CCA (25.7)	CCG (11.6)
Serine	7.25	UCU (18.3)	UCC (23.7)
		UCA (12.9)	UCG (5.9)
		AGU (13.2)	AGC (25.9)
Threonine	5.68	ACU (22.4)	ACC (40.5)
		ACA (25.4)	ACG (11.8)
Tryptophan	1.38	UGG (100)	
Tyrosine	3.13	UAU (40.0)	UAC (60.0)
Valine	6.35	GUU (16.4)	GUC (25.7)
		GUA (9.3)	GUG (48.7)

[a] Calculated from an analysis of 1490 human genes (601,683 codons) by Wada et al. (1992). The codon usage for other mammals does not differ greatly from those presented here for human genes.

[b] The figures in parentheses show the frequency with which a particular codon is used to specify a certain amino acid. For example, of the alanine residues present in 1490 human proteins, 28% are specified by GCU, 41.6% by GCC, etc.

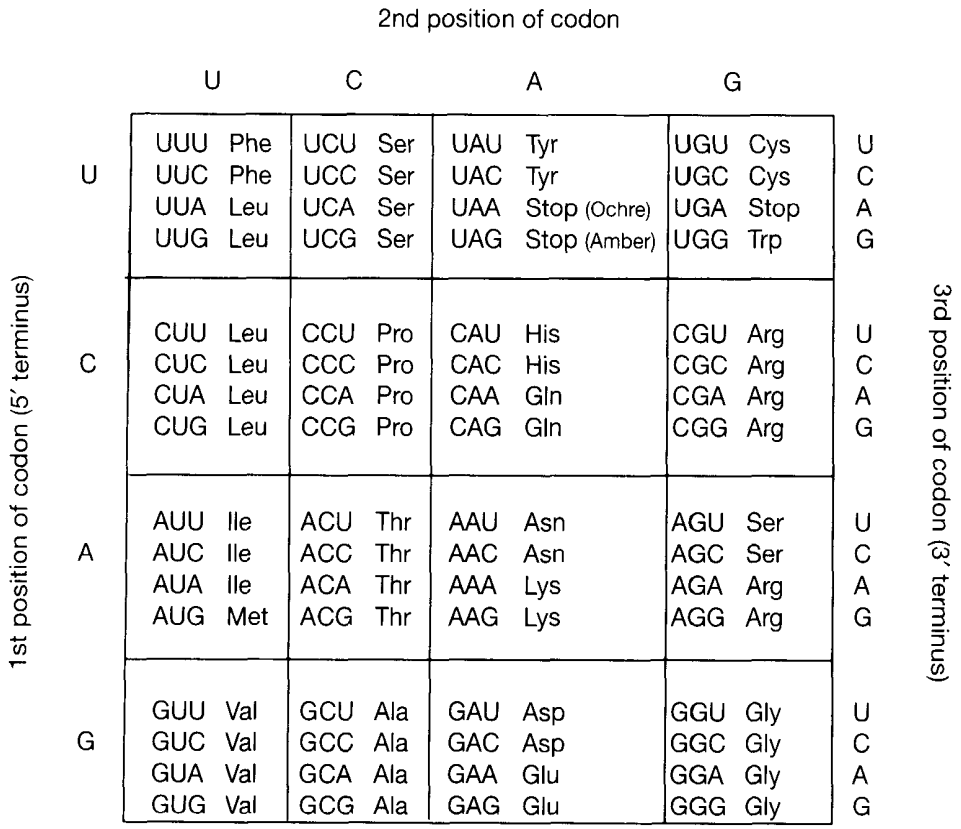

FIGURE A7-1 The Genetic Code

AMBER MUTANTS AND AMBER SUPPRESSORS

In amber mutants, a codon that specifies an amino acid in a protein is replaced by the chain-terminating codon, UAG. Because there is no tRNA that recognizes UAG, translation of mRNA ceases at the position of the chain-terminating codon, thereby generating an incomplete fragment of the protein.

Some strains of *E. coli* can suppress the chain-terminating phenotype of amber codons, irrespective of the gene in which the amber mutation is located. Such strains carry a mutation that changes the sequence of the anticodon loop in a particular species of tRNA. The suppressor tRNA recognizes the amber codon and inserts its cognate amino acid at the chain-terminating codon, allowing protein synthesis to continue. The efficiency of this process is not absolute. In a strain carrying a strong amber suppressor, suppression of polypeptide chain termination might occur 50% of the time. In weakly suppressing strains, the efficiency may be 10% or less. All of the suppressor strains used in molecular cloning are strong suppressors. Different suppressor tRNAs insert different amino acids at the chain-terminating UAG codon. A few amber suppressors can also suppress ochre (UAA) mutations because of wobble in the third position of the codon.

At one time, it was mandatory for bacteriophage λ vectors to carry amber mutations in genes encoding coat proteins. It was believed that such mutations might reduce the risk of recombinant bacteriophages spreading from the laboratory into field strains of *E. coli*. Hosts for these vectors carry one or two strong amber suppressors — *supE* and *supF* — that insert glutamine and tyrosine, respectively, at UAG codons. These suppressors are not interchangeable. Some amber mutations in bacteriophage λ vectors are suppressed only by *supE* (e.g., *P*am3) and others are suppressed only by *supF* (e.g., *S*am7 and *S*am100). The presence of suppressors does not generally affect the growth of the bacteriophage λ vectors that do not carry amber mutations. Most bacteriophage λ vectors can therefore be assayed and propagated on a strain of *E. coli* such as LE392 that carries *supE* and *supF*.

HISTORICAL FOOTNOTE

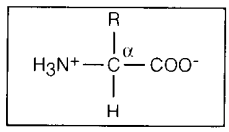
Conditional mutations are a special class of mutations that can occur in a great variety of genes in a single organism. Although temperature-sensitive mutants of *Drosophila*, *Neurospora*, and *E. coli* had been isolated and characterized years before, the full power of temperature-sensitive and amber mutants only became apparent in the early 1960s when Edgar, Epstein, and their colleagues isolated and analyzed a large collection of conditional lethal mutations of bacteriophage T4 (Edgar and Lielausis 1964; Epstein et al. 1964). The first conditional lethal mutants of bacteriophage T4 were isolated quite serendipitously by a CalTech graduate student, Harris Bernstein, during a fruitless search for an entirely different class of phage mutants (Edgar 1966). Bernstein, then a student of *Neurospora* genetics, had wandered into the Epstein-Steinberg laboratory one evening hoping to persuade someone to go with him to the movies. Instead he found himself picking bacteriophage T4 plaques as part of a hunt for "anti-rII" mutants that could grow on *E. coli* K(λ) but not on *E. coli* B. During the course of the evening, there was much debate about whether mutants of this class could exist, with Bernstein arguing strongly that they should. Epstein and Steinberg were more skeptical but, as encouragement to Bernstein, promised that any mutants he isolated would be named after his mother. The next day, when the results of the hunt were analyzed, ~20 mutants with the expected phenotype were found. The promise was kept by translating the German word "Bernstein" into its English equivalent "amber."

Subsequent work showed that the "anti-rII" mutants were not what they first appeared to be, since they grew in many strains of *E. coli* K not lysogenic for λ. Genetic mapping showed that amber mutants were widely distributed over the bacteriophage T4 genome, and physiological tests showed that their replication was blocked at many different stages in nonpermissive hosts. The hunt for parochial "anti-rII" mutants had therefore uncovered a general class of conditionally lethal, suppressor-sensitive mutants located in bacteriophage genes that were previously completely inaccessible. Strangely enough, none of the first group of 20 mutants were picked by Bernstein. It turned out that he had been flaming his bacterial wire too enthusiastically and had killed all of the bacteriophages!

TABLE A7-2 Amber Suppressors Used in Molecular Cloning

Suppressor	Codon Recognized	Amino Acid Inserted	tRNA Gene from which Suppressor Is Derived
supD (*suI*)	amber (UAG)	serine	*serU*
supE (*suII*)	amber (UAG)	glutamine	*glnU*
supF (*suIII*)	amber (UAG)	tyrosine	*tyrT*
supB (*suB*)	amber (UAG) and ochre (UAA)	glutamine	*glnU*
supC (*suC*)	amber (UAG) and ochre (UAA)	tyrosine	*tyrT*

AMINO ACIDS



Of the 20 standard α-amino acids (Table A7-3) that are incorporated into proteins, 19 have the general structure shown in the figure at the right. R represents the side chain of the amino acid. The twentieth acid, proline, is really an imino acid in which the side chain is bonded to the nitrogen atom of the peptide group. Except in glycine, where the side chain is a hydrogen atom, the α-carbon is asymmetric and is always the L-isomer. The α-amino acids can be arranged into several groups according to the chemical properties of their side chains (Table A7-4). The amino acids can also be grouped according to various other criteria, including size and hydrophilicity (Chothia 1976; Kyte and Doolittle 1982; Taylor 1986). The relationships among these groupings of amino acids can be represented in a Venn diagram (Figure A7-2), which is based on the mutational matrix of Dayhoff (1972). The Venn diagram shows the relationships among 20 common amino acids. Cysteine is shown in two locations: The reduced form, cystine (CH), contains a polarizable S-H bond and is therefore similar in some ways to serine (which carries an O-H bond). The oxidized form, cysteine (CS-S), contains no polarizable bond and is therefore more hydrophobic in nature.

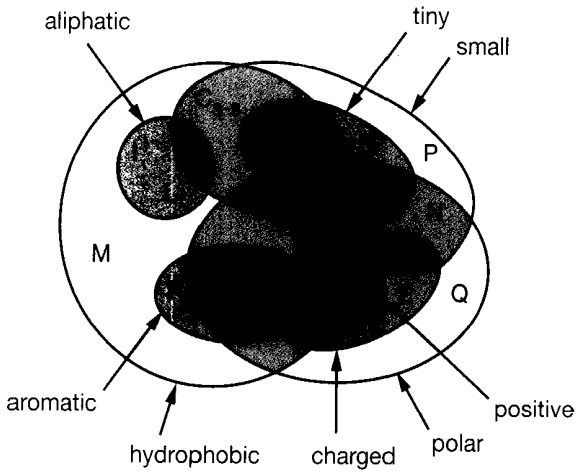


FIGURE A7-2 Venn Diagram

Venn diagram showing the relationships among 20 common amino acids. (Redrawn, with permission, from Taylor 1986.)

TABLE A7-3 Nomenclature of the 20 Standard α-Amino Acids

Amino Acid	Three-letter Symbol	One-letter Symbol	Mnemonic for One-letter Symbol
Alanine	Ala	A	**A**lanine
Arginine	Arg	R	A**R**ginine
Asparagine	Asn	N	AsparagiN**e**
Aspartic acid	Asp	D	AsparD**ic**
Cysteine	Cys	C	**C**ysteine
Glutamic acid	Glu	E	GluEtamic
Glutamine	Gln	Q	**Q**-tamine
Glycine	Gly	G	**G**lycine
Histidine	His	H	**H**istidine
Isoleucine	Ile	I	**I**soleucine
Leucine	Leu	L	**L**eucine
Lysine	Lys	K	before **L**
Methionine	Met	M	**M**ethionine
Phenylalanine	Phe	F	**F**enylalanine
Proline	Pro	P	**P**roline
Serine	Ser	S	**S**erine
Threonine	Thr	T	**T**hreonine
Tryptophan	Trp	W	T**W**yptophan
Tyrosine	Tyr	Y	T**Y**rosine
Valine	Val	V	**V**aline

TABLE A7-4 Properties of L α-Amino Acids

Major Properties of Side Chains	Amino Acids
No side chain	Gly
Aliphatic	Ala, Val, Leu, Ile, Pro
Hydroxyl group	Ser, Thr
Acidic group	Asp, Glu
Amide group	Asn, Gln
Basic group	Lys, Arg
Imidazole group	His
Aromatic group	Phe, Tyr, Trp
Sulfur-containing	Met, Cys

TABLE A7-5 Molar Conversions for Proteins

Molecular Weight of Unmodified Protein	Approximate Number of Residues	Molecules of Protein in 1 ml of a Solution Containing 1 mg/ml	Moles of Protein in 1 ml of a Solution Containing 1 mg/ml	Molar Concentration of Protein Solution Containing 1 mg/ml
100,000	917	6×10^{15}	10^{-8}	10^{-5} M
80,000	734	7.5×10^{15}	1.25×10^{-8}	1.25×10^{-5} M
60,000	550	10^{16}	1.66×10^{-8}	1.66×10^{-5} M
40,000	367	1.5×10^{16}	2.50×10^{-8}	2.5×10^{-5} M
20,000	183	3×10^{16}	50×10^{-8}	5.0×10^{-5} M
10,000	92	6×10^{16}	10^{-7}	10^{-4} M

Appendix 8

Commonly Used Techniques in Molecular Cloning

PREPARATION OF GLASSWARE AND PLASTICWARE

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

All glassware should be sterilized by autoclaving or baking. Some, but not all, plasticware can be autoclaved, depending on the type of plastic. Many items of sterilized plasticware are commercially available. All of the procedures commonly used in molecular cloning should be carried out in sterile glassware or plasticware; there is no significant loss of material by adsorption onto the surfaces of the containers. However, for certain procedures (e.g., handling very small quantities of single-stranded DNA or sequencing by the Maxam-Gilbert technique), it is best to use glassware or plasticware that has been coated with a thin film of silicone. A simple procedure for siliconizing small items such as pipettes, tubes, and beakers is given below. To siliconize large items such as glass plates, please refer to the note at the end of the protocol.

Siliconizing Glassware, Plasticware, and Glass Wool

The following method was supplied by Brian Seed (Massachusetts General Hospital).

1. Place the items to be siliconized inside a large, glass desiccator.
2. Add 1 ml of dichlorodimethylsilane <!> to a small beaker inside the desiccator.
3. Attach the desiccator, through a trap, to a vacuum pump. Turn on the vacuum and continue to apply suction until the dichlorodimethylsilane begins to boil. Immediately clamp the connection between the vacuum pump and the desiccator. Switch off the vacuum pump. The desiccator should maintain a vacuum.

   It is essential to turn off the vacuum pump as soon as the dichlorodimethylsilane begins to boil. Otherwise, the volatile agent will be sucked into the pump and cause irreparable damage to the vacuum seals.

4. When the dichlorodimethylsilane has evaporated (1–2 hours), open the desiccator in a chemical fume hood. After the fumes of dichlorodimethylsilane have dispersed, remove the glassware or plasticware. Bake glassware and glass wool for 2 hours at 180°C before use. Rinse plasticware extensively with H_2O before use; do not autoclave.

NOTES

- Large items of glassware can be siliconized by soaking or rinsing them in a 5% solution of dichlorodimethylsilane in chloroform or heptane. Commercial preparations for siliconizing are also available (e.g., Sigmacoat).
- As the organic solvent evaporates, the dichlorodimethylsilane is deposited on the glassware, which must be rinsed numerous times with H_2O or baked for 2 hours at 180°C before use.

Preparation of RNase-free Glassware

Guidelines for the treatment of glassware for use with RNA are given in the information panel on **HOW TO WIN THE BATTLE WITH RNASE** in Chapter 7.

PREPARATION OF DIALYSIS TUBING

The separation of molecules across a semipermeable membrane is driven by the concentration differential between the solutions on either side of the membrane and is constrained by the size (molecular weight) of the molecules relative to the size of the pores within the membrane. The pore size determines the molecular-weight cut-off, defined as the molecular weight at which 90% of the solute will be retained by the membrane. The exact permeability of a solute is dependent not only on the size of the molecule, but also on the shape of the molecule, its degree of hydration, and its charge. Each of these parameters may be influenced by the nature of the solvent, its pH, and its ionic strength. As a consequence, the molecular-weight cut-off should be used as a guide and not an absolute predictor of performance with every type of solute and solvent. Dialysis membranes are available in an enormous range of pore sizes (from 100 daltons to 2000 kD). For dialysis of most plasmid DNAs and many proteins, a molecular-weight cut-off of 12,000 to 14,000 is suitable.

1. Cut the tubing into pieces of convenient length (10–20 cm).
2. Boil the tubing for 10 minutes in a large volume of 2% (w/v) sodium bicarbonate and 1 mM EDTA (pH 8.0).
3. Rinse the tubing thoroughly in distilled H_2O.
4. Boil the tubing for 10 minutes in 1 mM EDTA (pH 8.0).
5. Allow the tubing to cool, and then store it at 4°C. Be sure that the tubing is always submerged.

   ▲ **IMPORTANT** From this point onward, always handle the tubing with gloves.
6. Before use, wash the tubing inside and out with distilled H_2O.

NOTE

- Instead of boiling for 10 minutes in 1 mM EDTA (pH 8.0) (Step 4), the tubing may be autoclaved at 20 psi (1.40 kg/cm^2) for 10 minutes on liquid cycle in a loosely capped jar filled with H_2O.

STORAGE OF BACTERIAL CULTURES

Stab Cultures

To store a bacterial culture in solid medium, pick a single, well-isolated colony with a sterile inoculating needle and stab the needle several times through the agar to the bottom of a stab vial (for the preparation of stab vials, please see Appendix 2). Replace and tighten the cap, and label both the vial and the cap. Store the vial in the dark at room temperature.

Cultures Containing Glycerol

Storage of Bacterial Cultures Growing in Liquid Media

1. To 1.5 ml of bacterial culture, add 0.5 ml of sterile 60% glycerol (sterilized by autoclaving for 20 minutes at 15 psi [1.05 kg/cm^2] on liquid cycle).
2. Vortex the culture to ensure that the glycerol is evenly dispersed.
3. Transfer the culture to a labeled storage tube equipped with a screw cap and an air-tight gasket.
4. Freeze the culture in ethanol–dry ice or in liquid nitrogen, and then transfer the tube to –70°C for long-term storage.
5. To recover the bacteria, scrape the frozen surface of the culture with a sterile inoculating loop, and then immediately streak the bacteria that adhere to the needle onto the surface of an LB agar plate containing the appropriate antibiotic. Return the frozen culture to storage at –70°C. Incubate the plate overnight at 37°C.

Storage of Bacterial Cultures Growing on Agar Plates

1. Scrape the bacteria growing on the surface of an agar plate into 2 ml of LB medium in a sterile tube. Add an equal volume of LB medium containing 30% sterile glycerol.
2. Vortex the mixture to ensure that the glycerol is completely dispersed.
3. Dispense aliquots of the glycerinated culture into sterile tubes equipped with screw caps and air-tight gaskets. Freeze the cultures as described above.

This method is useful for storing copies of cDNA libraries established in plasmid vectors (for discussion, please see Hanahan 1985).

ESTIMATION OF CELL NUMBER*

The number of mammalian cells in a defined volume of medium can be measured using a hemocytometer. Automated methods using cell-counting devices such as those produced by Coulter are desirable when large numbers of individual samples are to be counted. A method to estimate the number of live cells in a population by staining with a vital dye also is provided here.

Hemocytometry Counting

A hemocytometer contains two chambers, each of which when filled and coverslipped contains a total volume of 9 µl. Each chamber is ruled into nine major squares, and each square is 1 x 1 mm with a depth of 0.1 mm. Thus, when coverslipped, the volume of each square is 0.1 mm^3 or 0.1 µl. Additional subdivisions of the major nine squares are not necessary for counting and can be ignored. A representation of the marking on a hemocytometer is shown in Figure A8-1.

1. Trypsinize the cells (please see Chapter 17, Protocol 8: Stage 1, Step 18) and resuspend them in growth medium.

2. Use Pasteur pipettes to remove two independent samples from the cell suspension to be counted. Deliver each sample of cell suspension into one side of the coverslipped hemocytometer by capillary action.

   Fluid should just fill the chamber and not overflow into the troughs outside the counting face. Load the first sample into one chamber and the second sample into the second chamber.

3. Count the total number of cells in five of the nine large squares in each of two sides of the hemocytometer for a total of ten squares.

   The microscope field using a 10x objective and a 10x ocular should encompass the majority of one of the nine squares of the chamber and is a convenient magnification to use for counting. Cells that overlap the border on two sides of the square should be included in the cell count and not counted on the other two sides. If the initial dilution results in more than 50–100 cells/square, make a further dilution to improve counting accuracy and speed the process of determining cell numbers.

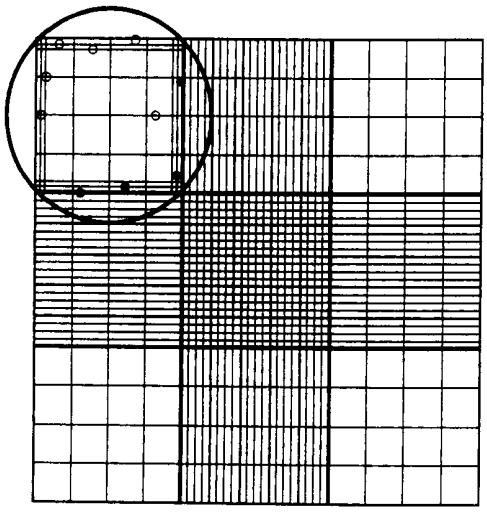

FIGURE A8-1 Standard Hemocytometer Chamber

The circle indicates the approximate area covered at 100x microscope magnification (10x ocular and 10x objective). Count the cells on top and left touching the middle line (*open circles*). Do not count the cells touching the middle line at bottom and right (*closed circles*). Count the 4 corner squares and the middle square in both chambers (only one chamber is represented here).

*Adapted from Spector et al. (1998 *Cells: A Laboratory Manual*).

4. Add the number of cells in a total of ten chambers (five from one side and five from the other) to give the number of cells in 1×10^{-3} ml (1×10^{-4} ml/square x 10 squares = a volume of 10^{-3} ml). Multiply the total number of cells by 1000 to give the number of cells/ml in the sample counted.

   If dilutions from the original cell suspension have been made, this factor must also be incorporated.

   EXAMPLE:

   1 ml of a 10-ml suspension of cells is diluted with 4 ml of medium. The diluted suspension is then sampled with a Pasteur pipette twice. The first sample is delivered to one chamber of the hemocytometer. The second sample is delivered to the second side. Five squares are counted from each side of the hemocytometer.

   Number of cells/square: 45, 37, 52, 40, 60, 48, 54, 70, 58, 60
   Total count: 524
   Dilution factor: (1 + 4)/1 = 5

   Cells/ml (in original): $524 \times 10^3 \times 5 = 2.62 \times 10^6$/ml cells

5. Immediately after use, clean the hemocytometer and coverslip by rinsing in distilled H_2O followed by 70% ethanol. Dry with lens paper.

   ▲ **IMPORTANT** Do not allow the cell suspension to dry on the hemocytometer.

NOTES

Errors that may result from using hemocytometer counts are due to:

- ***Variable sampling from the original cell suspension.*** The cell suspension must be agitated; do not allow the cells to settle to the bottom of the container.
- ***Inadequate or excessive filling of the hemocytometer chamber.*** The volume in the chambers counted is based on the coverslip resting on the sides of the hemocytometer. Overflow increases the volume counted.
- ***Cell clumping.*** Large clumps of cells may be too large to enter the chamber through capillary action and will be excluded from the cell count. Small clumps that are able to enter the chamber are difficult to count with accuracy. It is important to have a monodisperse suspension of cells for accurate counting. The cells must be thoroughly mixed to achieve uniformity.

Viability Staining

Various manipulations of cells, including passaging, freezing, and dissociation from primary tissue, can result in cell death. Exclusion of the dye, Trypan Blue, can be used to determine the number of surviving cells in a population (Phillips 1973). Normal healthy cells are able to exclude the dye, but Trypan Blue diffuses into cells in which membrane integrity has been lost. The dye exclusion method is an approximate estimate of cell viability and often does not distinguish within a 10–20% difference. Additionally, cells that exclude dye are not necessarily capable of attachment and prolonged survival or proliferation.

1. Trypsinize the cells (please see Chapter 17, Protocol 8: Stage 1, Step 18) and aseptically dilute 0.5 ml of cells into phosphate-buffered saline to a concentration from 2×10^5 to 4×10^5 cells/ml.
2. Aseptically transfer 0.5 ml of the diluted cell suspension in phosphate-buffered saline to a fresh tube and add 0.5 ml of a solution of Trypan Blue (0.4% w/v).

3. Allow the cells to remain in the dye solution for no less than 3 minutes and no longer than 10 minutes. Use a Pasteur pipette to sample the cells in dye and deliver them to a hemocytometer by capillary action.
4. Count a total of at least 500 cells, keeping a separate count of blue cells. Determine the frequency of those that are blue, i.e., have not excluded the dye.
5. Determine the percent viability from the number of cells that have not excluded the dye.

EXAMPLE:

A monolayer culture is trypsinized and resuspended in 5 ml of medium; 0.5 ml of cells is mixed with 4.5 ml of PBS, and 0.5 ml of the suspended cells in PBS is transferred to a small tube and mixed with 0.5 ml of Trypan Blue solution. In the sample transferred to the hemocytometer, 540 cells are counted; 62 of the cells fail to exclude the dye and are blue. The percent viability equals 88.5%.

$540 - 62$ = the number of cells that excluded the dye

540 = the total number of cells counted

$$\frac{540 - 62 \times 100}{540} = 88.5\% \text{ viability}$$

PURIFICATION OF NUCLEIC ACIDS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Perhaps the most basic of all procedures in molecular cloning is the purification of nucleic acids. The key step, the removal of proteins, can often be carried out simply by extracting aqueous solutions of nucleic acids with phenol:chloroform <!> and chloroform <!>. Such extractions are used whenever it is necessary to inactivate and remove enzymes that are used in one step of a cloning operation before proceeding to the next. However, additional measures are required when nucleic acids are purified from complex mixtures of molecules such as cell lysates. In these cases, it is usual to remove most of the protein by digestion with proteolytic enzymes such as pronase or proteinase K (please see Appendix 4, Table A4-8), which are active against a broad spectrum of native proteins, before extracting with organic solvents.

Extraction with Phenol:Chloroform

The standard way to remove proteins from nucleic acid solutions is to extract first with phenol:chloroform (optionally containing hydroxyquiniline at 0.1%) and then with chloroform. This procedure takes advantage of the fact that deproteinization is more efficient when two different organic solvents are used instead of one. Furthermore, although phenol denatures proteins efficiently, it does not completely inhibit RNase activity, and it is a solvent for RNA molecules that contain long tracts of poly(A) (Brawerman et al. 1972). Both of these problems can be circumvented by using a mixture of phenol:chloroform:isoamyl alcohol (25:24:1). The subsequent extraction with chloroform removes any lingering traces of phenol from the nucleic acid preparation. Extraction with ether, which was widely used for this purpose for many years, is no longer required or recommended for routine purification of DNA.

1. Transfer the sample to a polypropylene tube and add an equal volume of phenol:chloroform.

   The nucleic acid will tend to partition into the organic phase if the phenol has not been adequately equilibrated to a pH of 7.8–8.0.

2. Mix the contents of the tube until an emulsion forms.

3. Centrifuge the mixture at 80% of the maximum speed that the tubes can bear for 1 minute at room temperature. If the organic and aqueous phases are not well separated, centrifuge again for a longer time.

   Normally, the aqueous phase forms the upper phase. However, if the aqueous phase is dense because of salt (>0.5 M) or sucrose (>10%), it will form the lower phase. The organic phase is easily identifiable because of the yellow color contributed by the 8-hydroxyquinoline that is added to phenol during equilibration (please see Appendix 1).

4. Use a pipette to transfer the aqueous phase to a fresh tube. For small volumes (<200 µl), use an automatic pipettor fitted with a disposable tip. Discard the interface and organic phase.

   To achieve the best recovery, the organic phase and interface may be "back-extracted" as follows: After the first aqueous phase has been transferred as described above, add an equal volume of TE (pH 7.8) to the organic phase and interface. Mix well. Separate the phases by centrifugation as in Step 3. Combine this second aqueous phase with the first, and proceed to Step 5.

5. Repeat Steps 1–4 until no protein is visible at the interface of the organic and aqueous phases.

6. Add an equal volume of chloroform and repeat Steps 2–4.

7. Recover the nucleic acid by standard precipitation with ethanol.

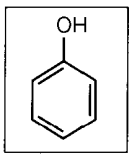
   Occasionally, ether <!> is used to remove traces of chloroform from preparations of high-molecular-weight DNA (please see the Notes below).

NOTES

The organic and aqueous phases may be mixed by vortexing when isolating small DNA molecules (<10 kb) or by gentle shaking when isolating DNA molecules of moderate size (10–30 kb). When isolating large DNA molecules (>30 kb), the following precautions must be taken to avoid shearing (please see also Chapter 6).

- Mix the organic and aqueous phases by rotating the tube slowly (20 rpm) on a wheel.
- Use large-bore pipettes to transfer the DNA from one tube to another.

HISTORICAL FOOTNOTE ON PHENOL (C_6 H_6O, F.W. = 94.11)



Until the mid 1950s, the standard method of purifying DNA involved stripping protein from the nucleic acid with detergent and strong salt solutions (e.g., perchlorate). Final deproteinization was achieved by several extractions with chloroform laced with isoamyl alcohol (Sevag 1934; Sevag et al. 1938). The first reported use of phenol to purify nucleic acids was published by Kirby (1956), who was aware of the power of phenol to extract proteins from aqueous solution (Grassmann and Deffner 1953). In his initial paper, Kirby showed that extraction of homogenates of mammalian tissue with a two-phase phenol-H_2O mixture at room temperature led to partitioning of RNA into the aqueous layer. DNA remained associated with protein at the interface. Kirby quickly realized that replacement of H_2O by solutions of anionic salts released both RNA and DNA into the aqueous phase (Kirby 1957; for review, please see Kirby 1964). Although the use of anionic salts to release proteins from DNA was quickly abandoned in favor of strong anionic detergents such as SDS, Kirby's original description of phenol extraction forms the basis of many purification methods in common use today. The function of the phenol is probably the same as that of a protein solvent: It extracts protein that has been dissociated from nucleic acids by anionic salts or detergents. So efficient is this process that pure preparations of nucleic acid are obtained after just two or three extractions with phenol.

Purified phenol has a specific gravity of 1.07 and therefore forms the lower phase when mixed with H_2O. However, the organic and aqueous phases may be difficult to separate or may invert when phenol is used to extract protein from aqueous solutions containing high concentrations of solutes. This problem is largely alleviated when a 50:50 mixture of phenol:chloroform is used, because the higher density of chloroform (1.47) ensures separation of the two phases. Denatured proteins collect at the interface between the two phases while lipids partition efficiently into the organic layer. Isoamyl alcohol is often added to the phenol:chloroform mixture to reduce foaming.

Pure phenol is supplied as a white crystalline mass (mp 43°C). However, on exposure to air and light, phenol is prone to redden, a process that is accelerated by alkalinity. Crystalline phenol is not recommended because it must be redistilled at 182°C to remove oxidation products such as quinones that cause the breakdown of phosphodiester bonds or promote cross-linking of nucleic acids.

The liquefied form of phenol provided by many manufacturers contains ~8% H_2O and can be stored frozen at –20°C. Liquefied phenol, if colorless, can be used in molecular cloning without redistillation. Today, only occasional batches of liquefied phenol are pink or yellow, and these should be rejected and returned to the manufacturer.

Before use, phenol must be saturated with H_2O and equilibrated with Tris to a pH of >7.8 to suppress partitioning of DNA into the organic phase, which occurs at acidic pH.

Drop Dialysis

Low-molecular-weight contaminants, which may inhibit restriction digestion or DNA sequencing, can be removed from DNA in solution by drop dialysis.

1. Spot a drop (~50 µl) of DNA in the center of a Millipore Series V membrane (0.025 µm), floating shiny side up on 10 ml of sterile H_2O in a 10-cm diameter Petri dish.

2. Dialyze the DNA for 10 minutes.

3. Remove the drop to a clean microfuge tube, and use aliquots of the dialyzed DNA for restriction enzyme digestion and/or DNA sequencing.

CONCENTRATING NUCLEIC ACIDS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Ethanol Precipitation

Precipitation with ethanol is the standard method to recover nucleic acids from aqueous solutions. It is rapid, virtually foolproof, and efficient: Subnanogram amounts of DNA and RNA can be quantitatively precipitated with ethanol, collected by centrifugation, and redissolved within minutes.

Ethanol depletes the hydration shell from nucleic acids and exposes negatively charged phosphate groups. Counterions such as Na^+ bind to the charged groups and reduce the repulsive forces between the polynucleotide chains to the point where a precipitate can form. Ethanol precipitation can therefore only occur if cations are available in sufficient quantity to neutralize the charge on the exposed phosphate residues. The most commonly used cations are shown in Table A8-1 and are described below.

- ***Ammonium acetate*** is frequently used to reduce the coprecipitation of unwanted contaminants (e.g., dNTPs or oligosaccharides) with nucleic acids. For example, two sequential precipitations of DNA in the presence of 2 M ammonium acetate result in the removal of >99% of the dNTPs from preparations of DNA (Okayama and Berg 1982). Ammonium acetate is also the best choice when nucleic acids are precipitated after digestion of agarose gels with agarase. The use of this cation reduces the possibility of coprecipitation of oligosaccharide digestion products. However, ammonium acetate should not be used when the precipitated nucleic acid is to be phosphorylated, since bacteriophage T4 polynucleotide kinase is inhibited by ammonium ions.
- ***Lithium chloride*** is frequently used when high concentrations of ethanol are required for precipitation (e.g., when precipitating RNA). LiCl is very soluble in ethanolic solutions and is not coprecipitated with the nucleic acid. Small RNAs (tRNAs and 5S RNAs) are soluble in solutions of high ionic strength (without ethanol), whereas large RNAs are not. Because of this difference in solubility, precipitation in high concentrations of LiCl (0.8 M) can be used to purify large RNAs.
- ***Sodium chloride*** (0.2 M) should be used if the DNA sample contains SDS. The detergent remains soluble in 70% ethanol.
- ***Sodium acetate*** (0.3 M, pH 5.2) is used for most routine precipitations of DNA and RNA.

Until a few years ago, ethanol precipitation was routinely carried out at low temperature (e.g., in a dry-ice/methanol bath). This is now known to be unnecessary. At 0°C in the absence of carrier, DNA concentrations as low as 20 ng/ml will form a precipitate that can be quantitatively recovered by centrifugation in a microfuge. However, when lower concentrations of DNA or very small fragments (<100 nucleotides in length) are processed, more extensive centrifugation may be necessary to cause the pellet of nucleic acid to adhere tightly to the centrifuge tube. Centrifugation at 100,000*g* for 20–30 minutes allows the recovery of picogram quantities of nucleic acid in the absence of carrier.

TABLE A8-1 Salt Solutions

SALT	STOCK SOLUTION (M)	FINAL CONCENTRATION (M)
Ammonium acetate	10.0	2.0–2.5
Lithium chloride	8.0	0.8
Sodium chloride	5.0	0.2
Sodium acetate	3.0 (pH 5.2)	0.3

When dealing with small amounts of DNA, it is prudent to save the ethanolic supernatant from each step until all of the DNA has been recovered. This retention is especially important after precipitates of DNA have been washed with 70% ethanol, a treatment that often loosens the precipitates from the wall of the tube.

Dissolving DNA Precipitates

Until a few years ago, DNA precipitates recovered after ethanol precipitation were dried under vacuum before being redissolved. This practice has now been abandoned (1) because desiccated pellets of DNA dissolve slowly and inefficiently and (2) because small fragments of double-stranded DNA (<400 bp) become denatured upon drying, probably as a result of loss of the stabilizing shell of bound water molecules (Svaren et al. 1987).

These days, the best practice is to remove ethanol from the nucleic acid pellet and from the sides of the tube by gentle aspiration and then to store the open tube on the bench for ~15 minutes to allow most of the residual ethanol to evaporate. The still-damp pellet of nucleic acid can then be dissolved rapidly and completely in the appropriate buffer. If necessary, the open tube containing the redissolved DNA can be incubated for 2–3 minutes at 45°C in a heating block to allow any traces of ethanol to evaporate.

The precipitated DNA is not all found at the bottom of the tube after centrifugation in an angle-head rotor. In the case of microfuge tubes, for example, at least 40% of the precipitated DNA is plastered on the wall of the tube. To maximize recovery of DNA, use a pipette tip to roll a bead of solvent several times over the appropriate segment of the wall. If the sample of DNA is radioactive, check that no detectable radioactivity remains in the tube after the dissolved DNA has been removed.

Carriers

Carriers (or coprecipitants) are inert substances that are used to improve the recovery of small quantities of nucleic acids during ethanol precipitation. Insoluble in ethanolic solutions, carriers form a precipitate that traps the target nucleic acids. During centrifugation, carriers generate a visible pellet that facilitates handling of the target nucleic acids. This may be their major virtue: As discussed above, ethanol precipitation — even of small amounts of nucleic acids in dilute solution — is remarkably efficient. Carriers do little, other than provide visual clues to the location of the target nucleic acid. Three substances are commonly used as carriers: yeast tRNA, glycogen, and linear polyacrylamide. Their advantages and disadvantages are listed in Table A8-2.

TABLE A8-2 Carriers

Carrier	Working Concentration	Advantages/Disadvantages
Yeast tRNA	10–20 µg/ml	Yeast tRNA is inexpensive, but it has the disadvantage that it cannot be used for precipitating nucleic acids that will be used as substrates in reactions catalyzed by polynucleotide kinase or terminal transferase. The termini of yeast RNA are excellent substrates for these enzymes and would compete with the termini contributed by the target nucleic acid.
Glycogen	50 µg/ml	Glycogen is usually used as a carrier when nucleic acids are precipitated with 0.5 M ammonium acetate and isopropanol. Glycogen is not a nucleic acid and therefore does not compete with the target nucleic acids in subsequent enzymatic reactions. However, it can interfere with interactions between DNA and proteins (Gaillard and Strauss 1990).
Linear polyacrylamide	10–20 µg/ml	Linear polyacrylamide is an efficient neutral carrier for precipitating picogram amounts of nucleic acids with ethanol and proteins with acetone (Strauss and Varshavsky 1984; Gaillard and Strauss 1990).

HISTORICAL FOOTNOTE

Ethanol precipitation predates molecular cloning by ~50 years. It was first used as a method to concentrate biologically active nucleic acid by J. Lionel Alloway, who worked at the Rockefeller Institute in the early 1930s. His project was to prepare active cell-free extracts of S-type *Streptococcus pneumoniae* that would permit bacterial transformation of R-type organisms in vitro. At that time, transformation had been achieved only with intact, heat-killed donor cells. After many frustrating failures, Alloway reported in 1932 that he could get the substance responsible for transformation into solution by heating a freeze/thaw extract of the S organisms to 60°C, removing particulate matter by centrifugation, and passing the solution through a filter made of porous porcelain (Alloway 1932). This last step was included to silence skeptics who believed that transformation was an artifact caused by an occasional S-type organism that survived the extraction procedure.

Alloway's success at eliminating the need for heat-killed donor cells was a major step on the road that eventually led to the discovery of DNA as the transforming material (Avery et al. 1944). However, not all of Alloway's cell-free preparations worked, and, even when transformation was obtained, the efficiency was very low. Alloway must have realized that these problems were caused by the dilute nature of the extract, for he began to search for different ways to lyse the pneumococci and for different methods to concentrate the transforming activity (Alloway 1933). Maclyn McCarty (1985) described Alloway's discovery of ethanol precipitation as follows:

> Alloway then introduced another new procedure that became an indispensable part of all work on the transforming substance from that time forward. He added pure alcohol in a volume five times that of the extract which resulted in precipitation of most of the material that had been released from the pneumococci... . The precipitated material could be redissolved in salt solution and shown to contain the active substance in transformation tests. Alcohol precipitation and resolution could be repeated at will without loss of activity.

Alloway was certainly not the first person to precipitate nucleic acids with ethanol. This technique had already been used as a purification step by several generations of organic chemists who were puzzling over the structure of the bases in DNA. However, Alloway was the first to use ethanol precipitation to prepare material that could change the phenotype of recipient cells. Final proof that the transforming factor was DNA still lay a dozen or more years into the future. But Alloway could fairly claim to be the inventor of a technique that is now second nature to us all.

Standard Ethanol Precipitation of DNA in Microfuge Tubes

1. Estimate the volume of the DNA solution.

2. Adjust the concentration of monovalent cations either by dilution with TE (pH 8.0) if the DNA solution contains a high concentration of salts or by addition of one of the salt solutions shown in Table A8-1.

   If the volume of the final solution is 400 µl or less, carry out precipitation in a single microfuge tube. Larger volumes can be divided among several microfuge tubes, or the DNA can be precipitated and centrifuged in tubes that will fit in a medium-speed centrifuge or ultracentrifuge.

3. Mix the solution well. Add exactly 2 volumes of ice-cold ethanol and again mix the solution well. Store the ethanolic solution on ice to allow the precipitate of DNA to form.

   Usually 15–30 minutes is sufficient, but when the size of the DNA is small (<100 nucleotides) or when it is present in small amounts (<0.1 µg/ml), extend the period of storage to at least 1 hour and add $MgCl_2$ to a final concentration of 0.01 M.

   DNA can be stored indefinitely in ethanolic solutions at 0°C or at –20°C.

4. Recover the DNA by centrifugation at 0°C.

   For most purposes, centrifugation at maximum speed for 10 minutes in a microfuge is sufficient. However, as discussed above, when low concentrations of DNA (<20 ng/ml) or very small fragments are being processed, more extensive centrifugation may be required.

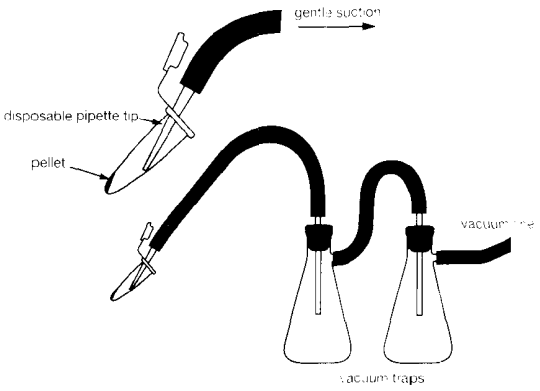


FIGURE A8-2 Aspiration of Supernatants

Hold the open microfuge tube at an angle, with the pellet on the upper side. Use a disposable pipette tip attached to a vacuum line to withdraw fluid from the tube. Insert the tip just beneath the miniscus on the lower side of the tube. Move the tip toward the base of the tube as the fluid is withdrawn. Use a gentle suction to avoid drawing the pellet into the pipette tip. Keep the end of the tip away from the pellet. Finally, vacuum the walls of the tube to remove any adherent drops of fluid.

5. Carefully remove the supernatant with an automatic micropipettor or with a disposable pipette tip attached to a vacuum line (please see Figure A8-2). Take care not to disturb the pellet of nucleic acid (which may be invisible). Use the pipette tip to remove any drops of fluid that adhere to the walls of the tube.

   It is best to save the supernatant from valuable DNA samples until recovery of the precipitated DNA has been verified.

6. Fill the tube half way with 70% ethanol and recentrifuge at maximum speed for 2 minutes at 4°C in a microfuge.

7. Repeat step 5.

8. Store the open tube on the bench at room temperature until the last traces of fluid have evaporated.

   It was once common practice to dry pellets of nucleic acid in a lyophilizer. This step is not only unnecessary, but also undesirable, since it causes denaturation of small (<400-nucleotide) fragments of DNA (Svaren et al. 1987) and greatly reduces the recovery of larger fragments of DNA.

9. Dissolve the DNA pellet (which is often invisible) in the desired volume of buffer (usually TE [pH between 7.6 and 8.0]). Rinse the walls of the tube well with the buffer.

NOTES

- After centrifugation in a microfuge, not all of the DNA is deposited on the bottom of the microfuge tube. Up to 50% of the DNA is smeared on the wall of the tube. To recover all of the DNA, it is necessary to work a bead of fluid backward and forward over the appropriate quadrant of wall. This step can easily be done by pushing the bead of fluid over the surface with a disposable pipette tip attached to an automatic micropipettor.

- One volume of isopropanol <!> may be used in place of 2 volumes of ethanol to precipitate DNA. Precipitation with isopropanol has the advantage that the volume of liquid to be centrifuged is smaller. However, isopropanol is less volatile than ethanol and is therefore more difficult to remove; moreover, solutes such as sucrose or sodium chloride are more easily coprecipitated with DNA when isopropanol is used. In general, precipitation with ethanol is preferable, unless it is necessary to keep the volume of fluid to a minimum.

- In general, DNA precipitated from solution by ethanol can be redissolved easily in buffers of low ionic strength, such as TE (pH 8.0). Occasionally, difficulties arise when buffers containing $MgCl_2$ or >0.1 M NaCl are added directly to the DNA pellet. It is therefore preferable to dissolve the DNA in a small volume of low-ionic-strength buffer and to adjust the composi-

tion of the buffer later. If the sample does not dissolve easily in a small volume, add a larger volume of buffer and repeat the precipitation with ethanol. The second precipitation may help eliminate additional salts or other components that may be preventing dissolution of the DNA.

Precipitation of RNA with Ethanol

RNA is efficiently precipitated with 2.5–3.0 volumes of ethanol from solutions containing 0.8 M LiCl, 5 M ammonium acetate, or 0.3 M sodium acetate. The choice among these salts is determined by the way in which the RNA will be used later. Since the potassium salt of dodecyl sulfate is extremely insoluble, avoid potassium acetate if the precipitated RNA is to be dissolved in buffers that contain SDS, for example, buffers that are used for chromatography on oligo(dT)-cellulose. For the same reason, avoid potassium acetate if the RNA is already dissolved in a buffer containing SDS. Avoid LiCl when the RNA is to be used for cell-free translation or reverse transcription. LiCl ions inhibit initiation of protein synthesis in most cell-free systems and suppress the activity of RNA-dependent DNA polymerase.

NOTE

- Solutions used for precipitation of RNA must be free of RNase (please see Chapter 7).

Precipitation of Large RNAs with Lithium Chloride

Whereas small RNAs (tRNAs and 5S RNAs) are soluble in solutions of high ionic strength, large RNAs (e.g., rRNAs and mRNAs) are insoluble and can be removed by centrifugation.

1. Measure the volume of the sample and add 0.2 volume of RNase-free 8 M LiCl. Mix the solution well and store it on ice for at least 2 hours.
2. Centrifuge the solution at 15,000*g* for 20 minutes at 0°C. Discard the supernatant, and dissolve the precipitated high-molecular-weight RNA in 0.2 volume of H_2O.
3. Repeat Steps 1 and 2.
4. Recover the high-molecular-weight RNA from the resuspended pellet by precipitation with 2 volumes of ethanol.

Concentrating and Desalting Nucleic Acids with Microconcentrators

Ultrafiltration is an alternative to ethanol precipitation for the concentration and desalting of nucleic acid solutions. It requires no phase change and is particularly useful for dealing with very low concentrations of nucleic acids. The Microcon cartridge, supplied by Millipore, is a centrifugal ultrafiltration device that can desalt and concentrate nucleic acid samples efficiently. The protocol presented below and the accompanying notes have been adapted from those provided on the Millipore Web Site (www.millipore.com). Complete directions may be found on this Web Site.

1. Select a Microcon unit with a nucleotide cut-off equal to or smaller than the molecular size of the nucleic acid of interest (please see Table A8-3).
2. Insert the Microcon cartridge into one of the two vials supplied, as shown in Figure A8-3.
3. To concentrate (without affecting salt concentration), pipette up to 500 µl of sample (DNA or RNA) into the reservoir. Centrifuge for the recommended time, not exceeding the *g* force shown in Table A8-3.

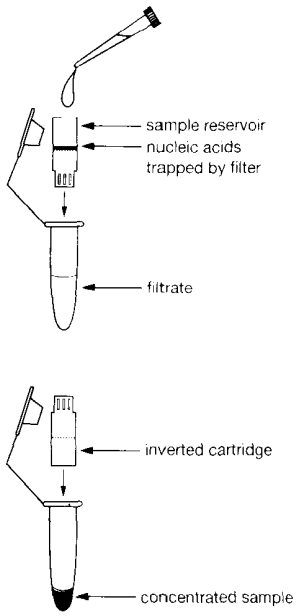

FIGURE A8-3 Concentration/Desalting of Nucleic Acid Solutions Using Micron Ultracentrifugation

4. To exchange salt, add the proper amount of appropriate diluent to bring the concentrated sample to 500 µl. Centrifuge for the recommended time, not exceeding the *g* force shown in Table A8-3. To achieve a lower salt concentration, repeat the entire step as necessary. Please see the footnote below to Table A8-3.

   ▲ **IMPORTANT** Do not overfill the filtrate vial.

5. Remove the reservoir from the vial and invert the reservoir into a new vial (save the filtrate until the sample has been analyzed).

6. Centrifuge at 500–1000*g* for 2 minutes in a microfuge to recover nucleic acid in the vial.

7. Remove reservoir. Cap the vial to store the sample.

TABLE A8-3 Nucleotide Cut-offs for Microcon Concentrators

Microcon Model	Color Code	Nucleotide Cut-off[a]		Maximum Recommended *g* Force	Spin Time in Minutes	
		ss	ds		4°C	25°C
3	yellow	10	10	14,000	185	95
10	green	30	20	14,000	50	35
30	clear	60	50	14,000	15	8
50	rose	125	100	14,000	10	6
100	blue	300	125	500	25	15

Note that ultrafiltration alone does not change buffer composition. The salt concentration in a sample concentrated by spinning in a Microcon will be the same as that in the original sample. For desalting, the concentrated sample is diluted with H_2O or buffer to its original volume and spun again (called discontinuous diafiltration). This removes the salt by the concentration factor of the ultrafiltration. For example, if a 500-µl sample containing 100 mM salt is concentrated to 25 µl (20x concentration factor), 95% of the total salt in the sample will be removed. The salt concentration in the sample will remain at 100 mM. Rediluting the sample to 500 µl in H_2O will bring the salt concentration to 5 mM. Concentrating to 25 µl once more will remove 99% of the original total salt. The concentrated sample will now be in 0.25 mM salt. For more complete salt removal, an additional redilution and spinning cycle will remove 99.9% of the initial salt content.

[a]ss indicates single-stranded and ds indicates double-stranded.

Concentrating Nucleic Acids by Extraction with Butanol

During extraction of aqueous solutions with solvents such as secondary butyl alcohol (isobutanol) or *n*-butyl alcohol (*n*-butanol<!>), some of the water molecules are partitioned into the organic phase. By carrying out several cycles of extraction, the volume of a nucleic acid solution can be reduced significantly. This method of concentration is used to reduce the volume of dilute solutions to the point where the nucleic acid can be recovered easily by precipitation with ethanol.

1. Measure the volume of the nucleic acid solution and add an equal volume of isobutanol. Mix the solution well by vortexing.

   Addition of too much isobutanol can result in removal of all the H_2O and precipitation of the nucleic acid. If this happens, add H_2O to the organic phase until an aqueous phase (which should contain the nucleic acid) reappears.

2. Centrifuge the solution at maximum speed for 20 seconds at room temperature in a microfuge or at 1600*g* for 1 minute in a benchtop centrifuge. Use an automatic micropipettor to remove and discard the upper (isobutanol) phase.

3. Repeat Steps 1 and 2 until the desired volume of aqueous phase is achieved.

   Because isobutanol extraction does not remove salt, the salt concentration increases in proportion to the reduction in the volume of the solution. The nucleic acid can be transferred to the desired buffer by spun-column chromatography or by precipitation with ethanol.

QUANTITATION OF NUCLEIC ACIDS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Two types of methods are widely used to measure the amount of nucleic acid in a preparation. If the sample is pure (i.e., without significant amounts of contaminants such as proteins, phenol, agarose, or other nucleic acids), spectrophotometric measurement of the amount of UV irradiation absorbed by the bases is simple and accurate. If the amount of DNA or RNA is very small or if the sample contains significant quantities of impurities, the amount of nucleic acid can be estimated from the intensity of fluorescence emitted by ethidium bromide or Hoechst 33258. A summary of the methods commonly used to measure the concentrations of DNA in solution are listed in Table A8-4. More detailed discussion of the methods follows after the table.

TABLE A8-4 Measuring Nucleic Acid Concentrations

METHOD	INSTRUMENT	COMMENTS
Absorbance at 260 nm	spectrophotometer	Useful only for highly purified preparations of nucleic acid, since it detects any compound that absorbs significantly at 260 nm, which includes, for example, DNA, RNA, EDTA, and phenol. The ratio of absorbance at 260 nm and 280 nm is often used as a test for contamination of a preparation of DNA and RNA with protein. Despite its popularity, this test is of questionable worth. Nucleic acids absorb so strongly at 260 nm that only a significant level of protein contamination will cause a significant change in the ratio of absorbance at the two wavelengths (Warburg and Christian 1942; Glasel 1995; Manchester 1995, 1996; Wilfinger et al. 1997) (please see the panel on **ABSORPTION SPECTROSCOPY OF NUCLEIC ACIDS** on the following page). The specific absorption coefficients of both DNA and RNA are affected by the ionic strength and the pH of the solution (Beaven et al. 1955; Wilfinger et al. 1997). Accurate measurements of concentration can be made only when the pH is carefully controlled and the ionic strength of the solution is low. It is difficult to measure the absorbance of small volumes of solution and the method is reliable only over a fairly narrow range of concentrations (5 µg/ml to 90 µg/ml).
Emission at 458 nm in the presence of Hoechst 33258	fluorometer	Hoechst 33258 is one of a class of *bis*-benzimidazole fluorescent dyes that bind nonintercalatively and with high specificity to double-stranded DNA. After binding, the fluorescent yield increases from 0.01 to 0.6 (Latt and Wohlleb 1975); Hoechst 33258 is therefore a useful fluorochrome for fluorometric detection and quantitation of double-stranded DNA. Hoechst 33258 interacts preferentially with A/T-rich regions of the DNA helix, with the $\log_{10}$ of the intensity of fluorescence increasing in proportion to the A+T content of the DNA (Daxhelet et al. 1989). The fluorescent yield of Hoechst 33258 is approximately threefold lower with single-stranded DNA (Hilwig and Gropp 1975). Fluorometry assays with Hoechst 33258 do not work at extremes of pH and are affected by both detergents and salts (Van Lancker and Gheyssens 1986). Assays are therefore usually carried out in 0.2 M NaCl, 10 mM EDTA at pH 7.4. The concentration of DNA in the unknown sample is estimated from a standard curve constructed using a set of reference DNAs (10–250 ng/ml) whose base composition is the same as the unknown sample. The intensity of emission is nearly linear over a 1000-fold range of DNA concentrations. The DNAs must be of high molecular weight since Hoechst 33258 does not bind efficiently to small fragments of DNA. All DNAs and solutions must be free of ethidium bromide, which quenches the fluorescence of Hoechst 33258. However, because Hoechst 33258 has little affinity for proteins or rRNA, measurements can be carried out using cell lysates or purified preparations of DNA (Cesarone et al. 1979, 1980; Labarca and Paigen 1980).
Dipstick (a kit from Invitrogen)		This method is good only for solutions containing low concentrations of DNA and RNA (< 10 µg/ml), and is both expensive and relatively slow (30–40 minutes).
Ethidium bromide spot test	UV transilluminator	A fast and sensitive method that utilizes the UV-induced fluorescence emitted by intercalated ethidium bromide molecules. The DNA preparations under test are spotted onto an agarose plate containing 0.5 µg/ml ethidium bromide. A series of DNAs of known concentration are used as standards. Because the amount of fluorescence is proportional to the total mass of DNA, the quantity of DNA can be estimated by comparing the light emitted at 590 nm by the test preparations and the standards. The results of the assay can be recorded on film. In a similar, older test, developed in the early 1970s, DNA samples and standards are spotted onto a sheet of Saran Wrap, mixed with a dilute solution of ethidium bromide, and photographed. The chief problem with the method is that it is sensitive to interference by RNA.

Spectrophotometry of DNA or RNA

For quantitating the amount of DNA or RNA, readings are taken at wavelengths of 260 nm and 280 nm. The reading at 260 nm allows calculation of the concentration of nucleic acid in the sample. An OD of 1 corresponds to ~50 µg/ml for double-stranded DNA, 40 µg/ml for single-stranded DNA and RNA, and ~33 µg/ml for single-stranded oligonucleotides. The ratio between the readings at 260 nm and 280 nm (OD_{260}:OD_{280}) provides an estimate of the purity of the nucleic acid. Pure preparations of DNA and RNA have OD_{260}:OD_{280} values of 1.8 and 2.0, respectively. If there is significant contamination with protein or phenol, the OD_{260}:OD_{280} will be less than the values given above, and accurate quantitation of the amount of nucleic acid will not be possible.

Because it is rapid, simple, and nondestructive, absorption spectroscopy has long been the method of choice to measure the amount of DNA and RNA in concentrated pure solutions. However, absorption spectroscopy is comparatively insensitive and, with most laboratory spectrophotometers, nucleic acid concentrations of at least 1 µg/ml are required to obtain reliable estimates of A_{260}. In addition, absorption spectroscopy cannot readily distinguish between DNA and RNA, and it cannot be used with crude preparations of nucleic acids. Because of these limitations, a number of alternative methods have been devised to measure the concentration of DNA and RNA (please see Table A8-4).

ABSORPTION SPECTROSCOPY OF NUCLEIC ACIDS

Purines and pyrimidines in nucleic acids absorb UV light. As described by the Beer-Lambert Law, the amount of energy absorbed at a particular wavelength is a function of the concentration of the absorbing material:

$$I = I_0 10^{-\varepsilon dc}$$

where I = intensity of transmitted light
I_0 = intensity of incident light
ε = molar extinction coefficient (also known as the molar absorbtion coefficient)
d = optical path length (in cm)
c = concentration of absorbing material (mole/liter)

ε is numerically equal to the absorbance of a 1 M solution in a 1-cm light path and is therefore expressed in M^{-1} cm^{-1}. Absorbance data are collected using a UV spectrometer and are generally reported as the absorbance A ($\log I/I_0$). When D = 1 cm, A is called the optical density or OD at a particular wavelength, λ.

$$OD_\lambda = \varepsilon\ c$$

Because the absorption spectra of DNA and RNA are maximal at 260 nm, absorbance data for nucleic acids are almost always expressed in A_{260} or OD_{260} units. For double-stranded DNA, one A_{260} or OD_{260} unit corresponds to a concentration of 50 µg/ml. The Beer-Lambert law is valid at least to an OD = 2 and the concentration of a solution of nucleic acid is therefore easily calculated by simple interpolation. For example, a solution whose OD_{260} = 0.66 contains 33 µg/ml of double-stranded DNA. For nucleic acids, ε decreases as the ring systems of adjacent purines and pyrimidines become stacked in a polynucleotide chain. The value of ε therefore decreases in the following series:

free base
↓
small oligonucleotides
↓
single-stranded nucleic acids
↓
double-stranded nucleic acids

This means that single-stranded nucleic acids have a higher absorbance at 260 nm than double-stranded nucleic acids. Thus, the molar extinction coefficient of double-stranded DNA at 260 nm is 6.6, whereas the molar extinction coefficient of single-stranded DNA and RNA is ~7.4. Note, however, that the extinction coefficients of both DNA and RNA are affected by the ionic strength and the pH of the solution (Beaven et al. 1955; Wilfinger et al. 1997). Accurate measurements of concentration can be made only when the pH is carefully controlled and the ionic strength of the solution is low.

(Continued on facing page.)

The extinction coefficients of nucleic acids are the sum of the extinction coefficients of each of their constituent nucleotides. For large molecules, where it is both impractical and unnecessary to sum the coefficients of all the nucleotides, an average extinction coefficient is used. For double-stranded DNA, the average extinction coefficient is 50 $(\mu g/ml)^{-1}$ cm^{-1}; for single-stranded DNA or RNA, the average coefficient is 38 $(\mu g/ml)^{-1}$ cm^{-1}. These values mean that

1 OD_{260} unit equals

50 µg/ml double-stranded DNA

or

38 µg/ml single-stranded DNA or RNA

For small molecules such as oligonucleotides, it is best to calculate an accurate extinction coefficient from the base composition. Because the concentrations of oligonucleotides are commonly reported as mmole/liter, a millimolar extinction coefficient (E) is conventionally used in the Beer-Lambert equation.

$$E = A\,(15.3) + G\,(11.9) + C\,(7.4) + T\,(9.3)$$

where A, G, C, and T are the number of times each nucleotide is represented in the sequence of the oligonucleotide. The numbers in parentheses are the molar extinction coefficients for each deoxynucleotide at pH 7.0.

OD_{260}:OD_{280} Ratios

Although it is possible to estimate the concentration of solutions of nucleic acids and oligonucleotides by measuring their absorption at a single wavelength (260 nm), this is not good practice. The absorbance of the sample should be measured at several wavelengths since the ratio of absorbance at 260 nm to the absorbance at other wavelengths is a good indicator of the purity of the preparation. Significant absorption at 230 nm indicates contamination by phenolate ion, thiocyanates, and other organic compounds (Stulnig and Amberger 1994), whereas absorption at higher wavelengths (330 nm and higher) is usually caused by light scattering and indicates the presence of particulate matter. Absorption at 280 nm indicates the presence of protein, because aromatic amino acids absorb strongly at 280 nm.

For many years, the ratio of the absorbance at 260 nm and 280 nm (OD_{260}:OD_{280}) has been used as a measure of purity of isolated nucleic acids. This method dates from Warburg and Christian (1942) who showed that the ratio is a good indicator of contamination of protein preparations by nucleic acids. The reverse is not true! Because the extinction coefficients of nucleic acids at 260 nm and 280 nm are so much greater than that of proteins, significant contamination with protein will not greatly change the OD_{260}:OD_{280} ratio of a nucleic acid solution (please see Table A8-5). Nucleic acids absorb so strongly at 260 nm that only a significant level of protein contamination will cause a significant change in the ratio of absorbance at the two wavelengths (Warburg and Christian 1942; Glasel 1995; Manchester 1995, 1996; Wilfinger et al. 1997).

TABLE A8-5 Absorbance of Nucleic Acids and Proteins

% Protein	% Nucleic Acid	OD_{260}:OD_{280}	% Protein	% Nucleic Acid	OD_{260}:OD_{280}
100	0	0.57	45	55	1.89
95	5	1.06	40	60	1.91
90	10	1.32	35	65	1.93
85	15	1.48	30	70	1.94
80	20	1.59	25	75	1.95
75	25	1.67	20	80	1.97
70	30	1.73	15	85	1.98
65	35	1.78	10	90	1.98
60	40	1.81	5	95	1.99
55	45	1.84	0	100	2.00
50	50	1.87			

Using the predicted values in this table, Glasel (1995) derived an empirical equation to describe $\%N$ for a range of OD_{260}:OD_{280} ratios: $\%N = F(11.16R - 6.32)/(2.16 - R)$, where $R = OD_{260}$:OD_{280}. Note that estimates of purity of nucleic acids based on OD_{260}:OD_{280} ratios are accurate only when the preparations are free of phenol. Water saturated with phenol absorbs with a characteristic peak at 270 nm and an OD_{260}:OD_{280} ratio of 2 (Stulnig and Amberger 1994). Nucleic acid preparations free of phenol should have OD_{260}:OD_{280} ratios of ~1.2.

Fluorometric Quantitation of DNA Using Hoechst 33258

Measuring the concentration of DNA using fluorometry is simple and more sensitive than spectrophotometry, and allows the detection of nanogram quantities of DNA. The assay can only be used to measure the concentration of DNAs whose sizes exceed ~1 kb, as Hoechst 33258 binds poorly to smaller DNA fragments. In this assay, DNA preparations of known and unknown concentrations are incubated with Hoechst 33258 fluorochrome. Absorption values for the unknown sample are compared with those observed for the known series, and the concentration of the unknown sample is estimated by interpolation.

HOECHST 33258

Hoechst 33258 is one of a class of *bis*-benzimidazole fluorescent dyes that bind nonintercalatively and with high specificity into the minor groove of double-stranded DNA. After binding, the fluorescent yield increases from 0.01 to 0.6 (Latt and Wohlleb 1975), and Hoechst 33258 can therefore be used for fluorometric detection and quantification of double-stranded DNA in solution. Hoechst 33258 is preferred to ethidium bromide for this purpose because of its greater ability to differentiate double-stranded DNA from RNA and single-stranded DNA (Loontiens et al. 1990).

Like many other nonintercalative dyes (Müller and Gautier 1975), Hoechst 33258 binds preferentially to A/T-rich regions of the DNA helix (Weisblum and Haenssler 1974), with the $\log_{10}$ of the intensity of fluorescence increasing in proportion to the A+T content of the DNA (Daxhelet et al. 1989). The fluorescent yield of Hoechst 33258 is approximately threefold lower with single-stranded DNA (Hilwig and Gropp 1975).

Facts and Figures

- Hoechst 33258 in free solution has an excitation maximum at ~356 nm and an emission maximum at 492 nm. However, when bound to DNA, Hoechst 33258 absorbs maximally at 365 nm and emits maximally at 458 nm (Cesarone et al. 1979, 1980).
- Fluorometry assays with Hoechst 33258 do not work at extremes of pH and are affected by both detergents and salts (Van Lancker and Gheyssens 1986). Assays are therefore usually carried out under standard conditions (0.2 M NaCl, 10 mM EDTA at pH 7.4). However, two different salt concentrations are required to distinguish double-stranded from single-stranded DNA and RNA (Labarca and Paigen 1980). The concentration of DNA in the unknown sample is estimated from a standard curve constructed using a set of reference DNAs (10–250 ng/ml) whose base composition is the same as the unknown sample. The DNAs must be of high molecular weight since Hoechst 33258 does not bind efficiently to small fragments of DNA. Measurements should be carried out rapidly to minimize photobleaching and shifts in fluorescence emission due to changes in temperature. Either a fixed wavelength fluorometer (e.g., Hoefer model TKO 100) or a scanning fluorescence spectrometer (e.g., Hitachi Perkin-Elmer model MPF-2A) can be used.
- The concentration of Hoechst 33258 (M_r = 533.9) in the reaction should be kept low (5×10^{-7} M to 2.5×10^{-6} M), since quenching of fluorescence occurs when the ratio of dye to DNA is high (Stokke and Steen 1985). However, two concentrations of dye are sometimes used to extend the dynamic range of the assay.
- All DNAs and solutions should be free of ethidium bromide, which quenches the fluorescence of Hoechst 33258. However, because Hoechst 33258 has little affinity for proteins or rRNA, measurements can be carried out using cell lysates or purified preparations of DNA (Cesarone et al. 1979; Labarca and Paigen 1980).
- Unlike ethidium bromide, Hoechst dyes are cell-permeant.

1. Turn the fluorometer on 1 hour before the assay is carried out to allow the machine to warm up and stabilize.

   When bound to high-molecular-weight double-stranded DNA, Hoechst 33258 dye absorbs maximally at 365 nm and emits maximally at 458 nm.

2. Prepare an appropriate amount of diluted Hoechst 33258 dye solution by combining 50 µl of concentrated Hoechst 33258 dye solution per 100 ml of fluorometry buffer (please see Appendix 1). Each tube in the DNA assay requires 3 ml of diluted Hoechst 33258 dye solution. Transfer 3 ml of diluted dye solution to an appropriate number of clean glass tubes. Include six extra tubes for a blank and the standard curve.

The concentrated Hoechst 33258 dye solution is prepared in H_2O at 0.2 mg/ml and can be stored at room temperature in a foil-wrapped test tube.

3. Prepare a standard curve by adding 100, 200, 300, 400, and 500 ng of DNA from the reference stock solution to individual tubes. Mix and read the absorbance on the prewarmed fluorometer of each tube immediately after addition of the DNA.

   The reference stock solution of DNA is prepared in TE to a concentration of 100 µg/ml. Because the binding of Hoechst 33258 dye to DNA is influenced by the base composition, the DNA used to construct the standard curve should be from the same species as the test sample.

4. Add 0.1 µl (i.e., 1 µl of a 1:10 dilution), 1.0 µl, and 10 µl of the preparation of DNA, whose concentration is being determined, to individual tubes containing diluted dye solution. Immediately read the fluorescence.

5. Construct a standard curve plotting fluorescence on the ordinate and weight of reference DNA (in ng) on the abscissa. Estimate the concentration of DNA in the unknown sample by interpolation.

   If the reading for the unknown DNA solution falls outside that of the standard curve, read the fluorescence of a larger sample or make an appropriate dilution of the sample and repeat the assay.

NOTES

- Binding of Hoechst 33258 is adversely influenced by pH extremes, the presence of detergents near or above their critical micelle concentrations, and salt concentrations above 3 M. If these conditions or reagents are used to prepare the DNA and improbable results are obtained in the fluorometry assay, precipitate an aliquot of the DNA with ethanol, rinse the pellet of nucleic acid in 70% ethanol, dissolve the dried pellet in TE, and repeat the assay.
- If the preparation of test DNA is highly viscous, sampling with standard yellow tips may be so inaccurate that the dilutions of unknown DNA will not track with the standard curve. In this case, the best solution is to withdraw two samples (10–20 µl) with an automatic pipettor equipped with a cut-off yellow tip. Each sample is then diluted with ~0.5 ml of TE (pH 8.0) and vortexed vigorously for 1–2 minutes. Different amounts of the diluted samples can then be transferred to the individual tubes containing diluted dye solution. The results obtained from the two sets of samples should be consistent.
- Use scissors or a dog nail clipper (e.g., Fisher) to generate cut-off yellow tips. Alternatively, the tips can be cut with a sharp razor blade. Sterilize the cut-off tips before use, either by autoclaving or by immersion in 70% alcohol for 2 minutes followed by drying in air. Presterilized, purpose-made wide-bore tips can be purchased from a number of commercial companies (e.g., Bio-Rad).

Quantitation of Double-stranded DNA Using Ethidium Bromide

Sometimes there is not sufficient DNA (<250 ng/ml) to assay spectrophotometrically, or the DNA may be heavily contaminated with other substances that absorb UV irradiation and therefore impede accurate analysis. A rapid way to estimate the amount of DNA in such samples is to use the UV-induced fluorescence emitted by ethidium bromide <!> molecules intercalated into the DNA. Because the amount of fluorescence is proportional to the total mass of DNA, the quantity of DNA in the sample can be estimated by comparing the fluorescent yield of the sample with that of a series of standards. As little as 1–5 ng of DNA can be detected by this method. For more information on ethidium bromide, please see Appendix 9 and Chapter 5, Protocol 2.

Saran Wrap Method Using Ethidium Bromide or SYBR Gold

1. Stretch a sheet of Saran Wrap over a UV transilluminator or over a sheet of black paper.
2. Spot 1–5 µl of the DNA sample onto the Saran Wrap.
3. Spot equal volumes of a series of DNA concentration standards (0.1, 2.5, 5, 10, and 20 µg/ml) in an ordered array on the Saran Wrap.

   The standard DNA solutions should contain a single species of DNA approximately the same size as the expected size of the unknown DNA. The DNA standards are stable for many months when stored at –20°C.

4. Add to each spot an equal volume of TE (pH 7.6) containing 2 µg/ml ethidium bromide or an equal volume of a 1:5000 dilution of dimethylsulfoxide <!> (DMSO)/SYBR Gold <!> stock. Mix by pipetting up and down with a micropipette.
5. Photograph the spots using short-wavelength UV illumination for ethidium bromide, or 300-nm transillumination for SYBR Gold (please see Chapter 5, Protocol 2). Estimate the concentration of DNA by comparing the intensity of fluorescence in the sample with that of the standard solutions.

Agarose Plate Method

Contaminants that may be present in the DNA sample can either contribute to or quench the fluorescence. To avoid these problems, the DNA samples and standards can be spotted onto the surface of a 1% agarose slab gel containing ethidium bromide (0.5 µg/ml). Allow the gel to stand at room temperature for a few hours so that small contaminating molecules have a chance to diffuse away. Photograph the gel as described in Chapter 5.

Minigel Method

Electrophoresis through minigels (please see Chapter 5) provides a rapid and convenient way to measure the quantity of DNA and to analyze its physical state at the same time. This is the method of choice if there is a possibility that the samples may contain significant quantities of RNA.

1. Mix 2 µl of the DNA sample with 0.4 µl of Gel-loading buffer IV (bromophenol blue only; please see Table A1-6 in Appendix 1) and load the solution into a slot in a 0.8% agarose minigel containing ethidium bromide (0.5 µg/ml).

   SYBR Gold is too expensive to use routinely in this technique.

2. Mix 2 µl of each of a series of standard DNA solutions (0, 2.5, 5, 10, 20, 30, 40, and 50 µg/ml) with 0.4 µl of Gel-loading buffer IV. Load the samples into the wells of the gel.

   The standard DNA solutions should contain a single species of DNA approximately the same size as the expected size of the unknown DNA. The DNA standards are stable for many months when stored at –20°C.

3. Carry out electrophoresis until the bromophenol blue has migrated ~1–2 cm.
4. Destain the gel by immersing it for 5 minutes in electrophoresis buffer containing 0.01 M $MgCl_2$.
5. Photograph the gel using short-wavelength UV irradiation (please see Chapter 5). Compare the intensity of fluorescence of the unknown DNA with that of the DNA standards and estimate the quantity of DNA in the sample.

MEASUREMENT OF RADIOACTIVITY IN NUCLEIC ACIDS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Radioactive isotopes <!> are used as tracers to monitor the progress of many reactions used to synthesize DNA and RNA. To calculate the efficiency of such reactions, it is necessary to measure accurately the proportion of the radioactive precursor incorporated into the desired product. This goal can be achieved by two methods: (1) differential precipitation of the nucleic acid products with trichloroacetic acid <!> (TCA) and (2) differential adsorption of the products onto positively charged surfaces (e.g., DE-81 paper).

Precipitation of Nucleic Acids with Trichloroacetic Acid

1. Use a soft-lead pencil to label the appropriate number of Whatman GF/C glass fiber filters (2.4-cm diameter). Impale each of the filters on a pin stuck into a polystyrene support.
2. Spot an accurately known volume (up to 5 µl) of each sample to be assayed on the center of each of two labeled filters.

   One of the filters is used to measure the total amount of radioactivity in the reaction (i.e., acid-soluble and acid-precipitable radioactivity). The other filter is used to measure only the acid-precipitable radioactivity. Under the conditions described, DNA and RNA molecules >50 nucleotides long will be precipitated on the surface of the filter.

3. Store the filters at room temperature until all of the fluid has evaporated. This process can be accelerated by using a heat lamp, although this is not usually necessary.
4. Use blunt-end forceps (e.g., Millipore forceps) to transfer one of each pair of filters to a beaker containing 200–300 ml of ice-cold 5% TCA and 20 mM sodium pyrophosphate. Swirl the filters in the acid solution for 2 minutes, and then transfer them to a fresh beaker containing the same volume of the ice-cold 5% TCA/20 mM sodium pyrophosphate mixture. Repeat the washing two more times.

   During washing, the unincorporated nucleotide precursors are eluted from the filters and the radioactive nucleic acids are fixed to them.

   Commercially available, vacuum-driven filtration manifolds that hold up to 24 filters may also be used to wash the filters.

5. Transfer the washed filters to a beaker containing 70% ethanol and allow them to remain there briefly. Then dry the filters either at room temperature or under a heat lamp.
6. Insert each of the filters (washed and unwashed) into a scintillation vial. Measure the amount of radioactivity on each filter.

   ^{32}P can be detected on dry filters by Cerenkov counting (in the ^{3}H channel of a liquid scintillation counter). The efficiency with which Cerenkov radiation can be measured varies from instrument to instrument and also depends on the geometry of the scintillation vials and the amount of H_2O remaining in the filters. With dry filters, the efficiency of Cerenkov counting is ~25% (one radioactive decay in four can be detected). Alternatively, ^{32}P can be measured with 100% efficiency by adding a few milliliters of toluene-based scintillation fluid to the dried filters and counting in the ^{32}P channel of the liquid scintillation counter.

   To measure other isotopes (^{3}H, ^{14}C, ^{35}S, ^{33}P, etc.), it is essential to use toluene-based scintillation fluid and the appropriate channel of a liquid scintillation counter. The efficiency of counting these isotopes varies from counter to counter and should be determined for each instrument.

7. Compare the amount of radioactivity on the unwashed filter with the amount on the washed filter, and then calculate the proportion of the precursor that has been incorporated as described in the panel below.

Adsorption to DE-81 Filters

DE-81 filters are positively charged and strongly adsorb and retain nucleic acids, including oligonucleotides that are too small to be precipitated efficiently with TCA. Unincorporated nucleotides stick less tightly to the filters and can be removed by washing the filter extensively in sodium phosphate. The procedure is essentially identical to that described for precipitation of nucleic acids by TCA, except that the DE-81 filters are washed in 0.5 M Na_2HPO_4 (pH 7.0) instead of TCA/sodium pyrophosphate.

CALCULATION OF THE SPECIFIC ACTIVITY OF A RADIOLABELED PROBE

To calculate the specific activity of a radiolabeled probe in dpm/μg, use the following equation:

$$\text{specific activity} = \frac{L\,(2.2 \times 10^9)\,(PI)}{m + [(1.3 \times 10^3)\,(PI)\,(L/S)]}$$

where

- L = input radioactive label (μCi)
- PI = proportion of the precursor that has been incorporated (cpm in washed filter/cpm in unwashed filter, please see above)
- m = mass of template DNA (ng)
- S = specific activity of input label (μCi/nmole)

The numerator of this equation is the product of three terms: the total dpm in the reaction [$(L)(2.2 \times 10^6$ dpm/μCi)]; the proportion of these dpm which were incorporated (PI); and a factor to convert the final value for specific activity from dpm/ng to dpm/μg (10^3).

The denominator represents the total mass of DNA (in ng) at the end of the reaction, equal to the starting mass (m) plus the mass (in ng) synthesized during the reaction. The latter is calculated from the number of nanomoles of dNMP incorporated [$(PI)(L/S)$] multiplied by four times the average molecular mass of the four dNMPs (4×325 ng/nmole = 1.3×10^3 ng/nmole).

EXAMPLE:

In a random priming reaction in which 50% of the radioactivity has been incorporated into TCA-precipitable material, from a starting reaction containing 25 ng of template DNA and 50 μCi of radiolabeled dNTP with a specific activity of 3000 Ci/mmole: L = 50 μCi, PI = 0.5, m = 25 ng, and S = 3000 Ci/mmole.

$$\text{specific activity of the probe} = \frac{50\,(2.2 \times 10^9)(0.5)}{25 + [(1.3 \times 10^3)(0.5)(50/3000)]}$$

$$= 1.5 \times 10^9 \text{ dpm/μg}$$

DECONTAMINATION OF SOLUTIONS CONTAINING ETHIDIUM BROMIDE

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Removing Ethidium Bromide from DNA

The reaction between ethidium bromide <!> and DNA is reversible (Waring 1965), but the dissociation of the complex is very slow and is measured in days rather than minutes or hours. For practical purposes, dissociation is achieved by passing the complex through a small column packed with a cation-exchange resin such as Dowex AG 50W-X8 (Waring 1965; Radloff et al. 1967) or by extracting with organic solvents such as isopropanol (Cozzarelli et al. 1968) or *n*-butanol <!> (Wang 1969). The former method has been shown to result in the removal of ethidium bromide to a binding ratio below that detectable by fluorescence, a molar ratio of dye:nucleic acid of 1:4000 (Radloff et al. 1967).

Disposing of Ethidium Bromide

Ethidium bromide itself is not highly mutagenic, but it is metabolized by microsomal enzymes to compound(s) that are moderately mutagenic in yeast and *Salmonella typhimurium* (Mahler and Bastos 1974; McCann et al. 1975; MacGregor and Johnson 1977; Singer et al. 1999). A number of methods have been described to decontaminate solutions and surfaces that contain or have been exposed to ethidium bromide. The concentration of ethidium bromide in solution may be reduced to <0.5 µg/ml with activated charcoal, which can then be incinerated (Menozzi et al. 1990). Alternatively, ethidium bromide can be degraded by treatment with sodium nitrite <!> and hypophosphorous acid <!> (Lunn and Sansone 1987).

Decontamination of Concentrated Solutions of Ethidium Bromide
(solutions containing >0.5 mg/ml)

Method 1

This method (Lunn and Sansone 1987) reduces the mutagenic activity of ethidium bromide in the *Salmonella*/microsome assay by ~200-fold.

1. Add sufficient H_2O to reduce the concentration of ethidium bromide to <0.5 mg/ml.
2. To the resulting solution, add 0.2 volume of fresh 5% hypophosphorous acid and 0.12 volume of fresh 0.5 M sodium nitrite. Mix carefully.

   ▲ **IMPORTANT** Make sure that the pH of the solution is <3.0.

   Hypophosphorous acid is usually supplied as a 50% solution, which is corrosive and must be handled with care. Freshly dilute the acid immediately before use.

   Sodium nitrite solution (0.5 M) should be freshly prepared by dissolving 34.5 g of sodium nitrite in H_2O to a final volume of 500 ml.
3. After incubation for 24 hours at room temperature, add a large excess of 1 M sodium bicarbonate. The solution may now be discarded.

Method 2

This method (Quillardet and Hofnung 1988) reduces the mutagenic activity of ethidium bromide in the *Salmonella*/microsome assay by ~3000-fold. However, there are reports (Lunn and Sansone 1987) of mutagenic activity in occasional batches of "blanks" treated with the decontaminating solutions.

1. Add sufficient H_2O to reduce the concentration of ethidium bromide to <0.5 mg/ml.
2. Add 1 volume of 0.5 M $KMnO_4$ **<!>**. Mix carefully, and then add 1 volume of 2.5 N HCl. Mix carefully, and allow the solution to stand at room temperature for several hours.
3. Add 1 volume of 2.5 N NaOH **<!>**. Mix carefully, and then discard the solution.

Decontamination of Dilute Solutions of Ethidium Bromide
(e.g., electrophoresis buffer containing 0.5 μg/ml ethidium bromide)

Method 1

The following method is from Lunn and Sansone (1987).

1. Add 2.9 g of Amberlite XAD-16 (Sigma-Aldrich) for each 100 ml of solution. Amberlite XAD-16 is a nonionic, polymeric absorbent.
2. Store the solution for 12 hours at room temperature, shaking it intermittently.
3. Filter the solution through a Whatman No. 1 filter, and discard the filtrate.
4. Seal the filter and Amberlite resin in a plastic bag, and dispose of the bag in the hazardous waste.

Method 2

The following method is from Bensaude (1988).

1. Add 100 mg of powdered activated charcoal for each 100 ml of solution.
2. Store the solution for 1 hour at room temperature, shaking it intermittently.
3. Filter the solution through a Whatman No. 1 filter, and discard the filtrate.
4. Seal the filter and activated charcoal in a plastic bag, and dispose of the bag in the hazardous waste.

NOTES

- Treatment of dilute solutions of ethidium bromide with hypochlorite (bleach) is not recommended as a method of decontamination. Such treatment reduces the mutagenic activity of ethidium bromide in the *Salmonella*/microsome assay by ~1000-fold, but it converts the dye into a compound that is mutagenic in the absence of microsomes (Quillardet and Hofnung 1988).
- Ethidium bromide decomposes at 262°C and is unlikely to be hazardous after incineration under standard conditions.
- Slurries of Amberlite XAD-16 or activated charcoal can be used to decontaminate surfaces that become contaminated by ethidium bromide.

Commercial Decontamination Kits

Several commercial companies sell devices to extract ethidium bromide from solutions with the minimum of fuss and bother. These devices include the EtBr Green Bag (Q•BIOgene) and the Eliminator Dye Removal System (Stratagene).

GEL-FILTRATION CHROMATOGRAPHY

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

This technique, which employs gel filtration to separate high-molecular weight DNA from smaller molecules, is used most often to separate unincorporated labeled dNTPs from DNA that has been radiolabeled. However, it is also used at several stages during the synthesis of double-stranded cDNA, during addition of linkers to blunt-ended DNA, to remove oligonucleotide primers from polymerase chain reaction (PCR), and, in general, whenever it is necessary to change the composition of the buffer in which DNA is dissolved.

Two methods are available: conventional column chromatography, which is used when it is necessary to collect fractions that contain components of different sizes, and centrifugation through gel matrices packed in disposable syringes, which is a rapid method used to free DNA from smaller molecules. The two most commonly used gel matrices are Sephadex and Bio-Gel, both of which are available in several porosities. Sephadex G-50 and Bio-Gel P-60 are ideal for purifying DNA larger than 80 nucleotides in length. Smaller molecules are retained in the pores of the gel, whereas the larger DNA is excluded and passes directly through the column. Bio-Gel P-2 can be used to separate oligonucleotides from phosphate ions or dNTPs. Bio-Gel is supplied in the form of a gel and need only be equilibrated in running buffer before use. Sephadex is supplied as a powder that must be hydrated before use.

Preparation of Sephadex

1. Slowly add Sephadex of the desired grade to distilled sterile H_2O in a 500-ml beaker or bottle (10 g of Sephadex G-50 granules yields 160 ml of slurry). Wash the swollen resin with distilled sterile H_2O several times to remove soluble dextran, which can create problems by precipitating during ethanol precipitation.
2. Equilibrate the resin in TE (pH 7.6), autoclave at 10 psi (0.70 kg/cm^2) for 15 minutes, and store at room temperature.

Column Chromatography

1. Prepare Sephadex or Bio-Gel columns in disposable 5-ml borosilicate glass pipettes or Pasteur pipettes plugged with a small amount of sterile glass wool. Use a long, narrow pipette (e.g., a disposable 1-ml plastic pipette) to push the wool to the bottom of the glass or Pasteur pipette.
2. Use a Pasteur pipette to fill the column with a slurry of the Sephadex or Bio-Gel, taking care to avoid producing bubbles. There is no need to close the bottom of the column. Keep adding gel until it packs to a level 1 cm below the top of the column. Wash the gel with several volumes of 1x TEN buffer (pH 8.0) (please see Appendix 1).
3. Apply the DNA sample (in a volume of 200 µl or less) to the top of the gel. Wash out the sample tube with ~100 µl of 1x TEN buffer, and load the washing on the column as soon as the DNA sample has entered the gel. When the washing has entered the gel, immediately fill the column with 1x TEN buffer.

▲ **WARNING** Columns used to separate radiolabeled DNA from radioactive precursors should be run behind Lucite screens to protect against exposure to radioactivity.

4. Immediately start to collect fractions (~200 µl) in microfuge tubes.

   If the DNA is labeled with ^{32}P **<!>**, measure the radioactivity in each of the tubes by using either a hand-held minimonitor or by Cerenkov counting in a liquid scintillation counter. Add more 1x TEN buffer to the top of the gel as required from time to time.

   The DNA will be excluded from the gel and will be found in the void volume (usually 30% of the total column volume). The leading peak of radioactivity therefore consists of nucleotides incorporated into DNA, and the trailing peak consists of unincorporated [^{32}P]dNTPs.

5. Pool the radioactive fractions in the leading peak and store at –20°C.

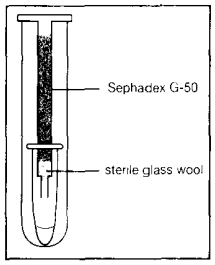
NOTES

Instead of collecting individual fractions, it is possible with practice to follow the progress of the incorporated and unincorporated [^{32}P]dNTPs down the column using a hand-held minimonitor.

- Collect the leading peak into a sterile polypropylene tube as it elutes from the column.
- Clamp the bottom of the column and disconnect the buffer reservoir.
- Discard the column in the radioactive waste.

Spun-column Chromatography

This method is used to separate DNA, which passes through the gel-filtration matrix, from lower-molecular-weight substances that are retained on the column. Spun-column chromatography is particularly useful when separating labeled DNA from radioactive precursors. However, it is also used extensively for other purposes, for example, to remove unwanted nucleotide primers or double-stranded linkers, to change the buffer in which small amounts of DNA are dissolved, or to free crude preparations of minipreparations of plasmid or bacteriophage DNA from inhibitors that prevent cleavage by restriction enzymes. Several samples of DNA can be handled simultaneously. In this respect, spun-column chromatography is much superior to conventional column chromatography.



1. Plug the bottom of a 1-ml disposable syringe with a small amount of sterile glass wool. This is best accomplished by using the barrel of the syringe to tamp the glass wool in place.

2. Fill the syringe with Sephadex G-50 or Bio-Gel P-60, equilibrated in 1x TEN buffer (pH 8.0) (please see Appendix 1). Start the buffer flowing by tapping the side of the syringe barrel several times. Keep adding more resin until the syringe is completely full.

3. Insert the syringe into a 15-ml disposable plastic tube. Centrifuge at 1600*g* for 4 minutes at room temperature in a swinging-bucket rotor in a bench-top centrifuge. Do not be alarmed by the appearance of the column. The resin packs down and becomes partially dehydrated during centrifugation. Continue to add more resin and recentrifuge until the volume of the packed column is ~0.9 ml and remains unchanged after centrifugation.

4. Add 0.1 ml of 1x TEN buffer to the columns, and recentrifuge as in Step 3.

5. Repeat Step 4 twice more.

   Spun columns may be stored at this stage if desired. Several spun columns can be prepared simultaneously and stored at 4°C for periods of 1 month or more before being used. Fill the syringes with 1x TEN buffer and wrap Parafilm around them to prevent evaporation. Store the columns upright at 4°C. Spun columns stored in this way should be washed once with sterile 1x TEN buffer as described in Step 4 just before they are used.

6. Apply the DNA sample to the column in a total volume of 0.1 ml (use 1x TEN buffer to make up the volume). Place the spun column in a fresh disposable tube containing a decapped microfuge tube (please see figure above).

7. Centrifuge again as in Step 3, collecting the effluent from the bottom of the syringe (~100 µl) into the decapped microfuge tube.

8. Remove the syringe, which will contain unincorporated radiolabeled dNTPs or other small components. Using forceps, carefully recover the decapped microfuge tube, which contains the eluted DNA, and transfer its contents to a capped, labeled microfuge tube.

   A rough estimate of the proportion of radioactivity that has been incorporated into nucleic acid may be obtained by holding the syringe and the eluted DNA to a hand-held minimonitor.

9. If the syringe is radioactive **<!>**, carefully discard it in the radioactive waste. Store the eluted DNA at –20°C until needed.

NOTE

- Not all resins are suitable for spun-column centrifugation: DEAE-Sephacel forms an impermeable lump during centrifugation, and the larger grades of Sephadex (G-100 and up) cannot be used because the beads are crushed by centrifugation. If a coarser-sieving resin is required, use Sepharose CL-4B.

SEPARATION OF SINGLE-STRANDED AND DOUBLE-STRANDED DNAs BY HYDROXYAPATITE CHROMATOGRAPHY

Nucleic acids bind to hydroxyapatite by virtue of interactions between the phosphate groups of the polynucleotide backbone and calcium residues in the matrix. Bound nucleic acids can be eluted in phosphate buffers. This step is usually carried out at 60°C, although there is no good reason to do so since the adsorption and elution profiles of nucleic acids are indistinguishable between 25°C and 60°C. The affinity of nucleic acids is determined by the number of phosphate groups that are available to bind to the matrix. Both single- and double-stranded nucleic acids bind to hydroxyapatite in 0.05 M sodium phosphate (pH 6.8). Double-stranded molecules, with their well-ordered and evenly spaced sets of phosphate residues, make many regular contacts with the matrix and therefore require high concentrations of phosphate (0.4 M) for elution. Single-stranded molecules are more disordered and a smaller proportion of their phosphate residues are available for contact with the matrix. Hence, single-stranded DNA is eluted in lower concentrations of phosphate (~0.12 M). Partial duplexes and DNA-RNA hybrid molecules elute at intermediate concentrations.

Nucleic acids are often eluted in such large volumes that they need to be concentrated before they can be used. Ethanol precipitation must be avoided until the phosphate ions have been removed from the solution. This is best achieved by concentrating the eluate by extraction with isobutanol and then removing the salt by chromatography through G-50 Sephadex columns.

Batches of hydroxyapatite vary slightly in their characteristics, and it is therefore important to carry out preliminary experiments to determine the optimal phosphate concentrations for elution of single- and double-stranded nucleic acids. This can be accomplished by setting up two hydroxyapatite columns as described below. One of the columns is loaded with a small amount (~10^5 cpm) of ^{32}P-labeled DNA that has been denatured by boiling for 10 minutes in TE (pH 7.6). The other column receives an equal amount (~10^5 cpm) of ^{32}P-labeled native DNA. Each of the columns is washed with a series of buffers containing increasing concentrations of sodium phosphate (0.01, 0.12, 0.16, 0.20, 0.24, 0.28, 0.32, 0.36, and 0.40 M). The amount of radioactivity eluting at each phosphate concentration is then measured in a liquid scintillation counter (either by Cerenkov counting or in a water-miscible fluor). Usually, single-stranded DNA elutes in 0.14–0.16 M sodium phosphate (pH 6.8), whereas double-stranded DNA is not removed from the column until the phosphate concentration exceeds 0.36 M. In the protocol that follows, SS buffer contains the phosphate concentration that is optimal for elution of single-stranded DNA; DS buffer contains the concentration that is optimal for elution of double-stranded DNA.

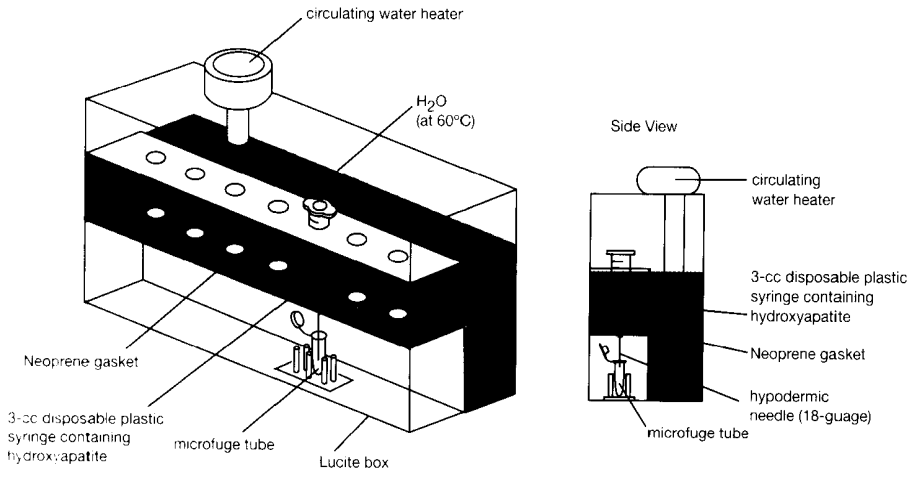


FIGURE A8-4 Apparatus for Hydroxyapatite Chromatography

HYDROXYAPATITE CHROMATOGRAPHY

Hydroxyapatite ($Ca_5[PO_4]_3OH$), the most stable of all calcium phosphates precipitated from aqueous solution, was originally developed as a matrix for protein chromatography by Tiselius et al. (1956). Semenza (1957), working in the Tiselius laboratory, and Main and Cole (1957; Main et al. 1959) seem to have been the first to use hydroxyapatite to fractionate nucleic acids. However, it was work in Bernardi's laboratory (Bernardi 1961, 1965; Bernardi and Timasheff 1961) that led to the widespread and successful use of hydroxyapatite columns to separate single-stranded from double-stranded nucleic acids and to fractionate complex nucleic acids by thermal elution according to their content of (G+C) (Martinson and Wagenaar 1974). During the 1960s and 1970s, hydroxyapatite chromatography became the standard method to investigate the reassociation kinetics of DNAs from many different sources (Britten and Kohne 1966, 1967, 1968; Britten et al. 1974), to construct transcription maps (Sambrook et al. 1972), and to measure the copy number of specific sequences in complex genomes (Gelb et al. 1971; Gallimore et al. 1974). More recently, hydroxyapatite has been used in the preparation of cDNA for subtractive cloning (Davis 1986), as well as for a variety of more menial chores, for example, the isolation of DNA from low-melting-temperature agarose (Wilkie and Cortini 1976) and the removal of contaminants from DNA preparations (Smith 1980). During the decade that led to the development of molecular cloning, hydroxyapatite chromatography was in daily use in many laboratories for a variety of manipulations involving nucleic acids both preparative and analytical. However, there are now better ways to carry out almost all of these tasks, and hydroxyapatite chromatography has all but disappeared from the standard repertoire of laboratory techniques..

1. Determine the concentrations of sodium phosphate that are optimal for elution of single-stranded DNA (SS buffer) and double-stranded DNA (DS buffer) as described above.
2. Prepare SS and DS buffers by diluting 2 M sodium phosphate (pH 6.8).

   2 M sodium phosphate (pH 6.8) is made by mixing equal volumes of 2 M NaH_2PO_4 and 2 M Na_2HPO_4.

3. Suspend the hydroxyapatite powder (Bio-Gel HTP) in 0.01 M sodium phosphate (pH 6.8). Approximately 0.5 ml of packed Bio-Gel HTP is required for each column.

   Bio-Gel HTP has a capacity of 100–200 μg of native DNA/ml of bed volume.

4. Prepare the hydroxyapatite columns in disposable 3-cc plastic syringes as follows:
   a. Remove the barrel from the syringe.
   b. Use the wide end of a Pasteur pipette to push a Whatman GF/C filter to the bottom of the syringe. The filter should completely cover the bottom of the syringe.
   c. Attach an 18-gauge hypodermic needle to the syringe.
   d. Insert the syringe through a Neoprene gasket in the apparatus shown in Figure A8-4.
   e. Use a Pasteur pipette to add enough of the slurry of hydroxyapatite to the syringe to form a column whose packed volume is 0.5–1.0 ml. Wash the column with several volumes of 0.01 M sodium phosphate (pH 6.8). The column will not be harmed if it runs dry; simply rewet before use.
   f. Seal the bottom of the column by sticking a small Neoprene stopper on the end of the hypodermic needle.
5. Load the sample containing the nucleic acid onto the column.

   The concentration of phosphate in the sample should be less than 0.08 M.

6. Remove the Neoprene stopper, and allow the sample to flow through the column.

   There is usually no need to collect and save the loading buffer that elutes from the column.

7. Wash the column with 3 ml of 0.01 M sodium phosphate.

8. Seal the bottom of the column with a Neoprene stopper, and add 1 column volume of SS buffer preheated to 60°C.
9. After 5 minutes, remove the Neoprene stopper and collect the eluate in microfuge tubes. No more than 0.5 ml should be collected in any one microfuge tube. Repeat Steps 8 and 9 two more times.
10. Seal the bottom of the column with a Neoprene stopper, and add 1 column volume of DS buffer preheated to 60°C.
11. After 5 minutes, remove the Neoprene stopper and collect the eluate in microfuge tubes. No more than 0.5 ml should be collected in any one microfuge tube. Repeat Steps 10 and 11 two more times.
12. Allow the eluates to cool to room temperature. DNA can then be extracted as follows:
    a. Add an equal volume of isobutanol to each of the tubes containing the desired nucleic acids.
    b. Mix the two phases by vortexing, and centrifuge the mixture at maximum speed for 20 seconds at room temperature in a microfuge.
    c. Discard the upper (organic) phase.
    d. Repeat the extraction with isobutanol until the volume of the aqueous phase is 100–125 µl.
    e. Remove salts from the DNA by chromatography on, or centrifugation through, a small column of Sephadex G-50 equilibrated in TE (pH 8.0).
    f. Recover the DNA by precipitation with 2 volumes of ethanol at 0°C.

NOTE

- In molecular cloning, nucleic acids fractionated by hydroxyapatite are usually radiolabeled, and the tubes containing the desired fractions can be easily identified by Cerenkov counting in a liquid scintillation counter.

FRAGMENTATION OF DNA

The fragmentation of DNA is often a necessary step preceding library construction or subcloning for DNA sequencing. Fragmentation is typically achieved by physical or enzymatic methods; the most commonly used of these are described in Table A8-6. Although each approach is reasonably successful for generating a range of fragments from a large contiguous segment of DNA, each has its particular limitations. Because they are independent of sequence composition, physical methods for shearing DNA typically result in more uniform and random disruption of the target DNA than enzymatic methods. In particular, methods involving hydrodynamic shearing due to physical stress induced by sonication or nebulization produce collections of appropriately random fragments. The variety in lengths of these fragments is quite large, however, and their use usually requires a subsequent size selection step to narrow the range of fragments that are acceptable for cloning or sequencing.

AUTOMATED SHEARING

During the last few years, a method for hydrodynamic shearing, initially based on the use of high-performance liquid chromatography (HPLC) and called the "point-sink" flow system, has become increasingly refined and, finally, automated (Oefner et al. 1996; Thorstenson et al. 1998). In the point-sink system, an HPLC pump is used to apply pressure to the DNA sample, thereby forcing it through tubing of very small diameter. In the automated process known as HydroShear (commercially available from Gene Machines), a sample of DNA is repeatedly passed through a small hole until the sample is fragmented to products of a certain size. The final size distribution is determined by both the flow rate of the sample and the size of the opening, parameters that are controlled and monitored by the automated system. At any given setting, DNA fragments larger than a certain length are broken, whereas shorter fragments are unaffected by passage through the opening. The resulting sheared products therefore have a narrow size distribution: Typically 90% of the sheared DNA falls within a twofold size range of the target length. It is reasonable to expect that libraries constructed from these DNA fragments are likely to be of higher quality than those made using one of the "old-fashioned" ways. They will certainly contain clones of more uniform size, and possibly may be more comprehensive in their coverage of the genome. However, libraries constructed from sonicated or hydrodynamically sheared DNA, although imperfect, are certainly workable. Perfectionists will feel that the machine is necessary; pragmatists will find it merely desirable.

TABLE A8-6 Hydrodynamic Shearing Methods Used to Fragment DNA

METHOD	PROS AND CONS	REFERENCES
Sonication	Requires relatively large amounts of DNA (10–100 μg); fragments of DNA distributed over a broad range of sizes; only a small fraction of the fragments are of a length suitable for cloning and sequencing; requires ligation of DNA before sonication and end-repair afterward; DNA may be damaged by hydroxyl radicals generated during cavitation (McKee et al. 1977).	Deininger (1983)
Nebulization	Easy and quick; requires only small amounts of DNA (0.5–5 μg) and large volumes of DNA solution; no preference for AT-rich regions; size of fragments easily controlled by altering the pressure of the gas blowing through the nebulizer; fragments of DNA distributed over a narrow range of sizes (700–1330 bp); requires ligation of DNA before nebulization and end-repair afterward.	Bodenteich et al. (1994); Hengen (1997)
Circulation through an HPLC pump	Requires expensive apparatus, ligation of DNA before sonication, and 1–100 μg of DNA; fragments of DNA distributed over a narrow range of sizes that can be adjusted by changing the flow rate; end-repair of fragments before cloning not necessary.	Oefner et al. (1996); Thorstenson et al. (1998)
Passage through the orifice of a 28-gauge hypodermic needle	Cheap, easy, and requires only small amounts of DNA; however, the fragments are a little larger (1.5–2.0 kb) than required for shotgun sequencing; requires ligation of DNA before cleavage and end-repair afterward.	Davidson (1959, 1960); Schriefer et al. (1990)

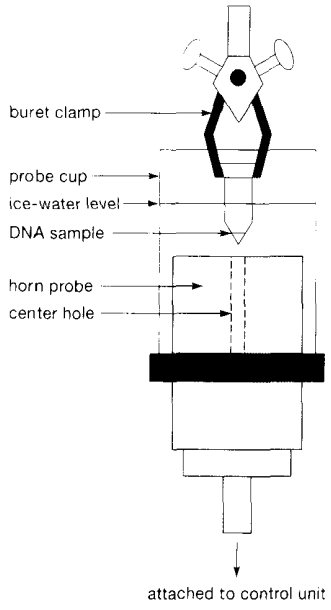

FIGURE 8-5 Cup Horn Sonicator for Random Fragmentation of DNA

The cup horn attachment for a Heat Systems sonicator is depicted with a sample tube in place. The cup horn unit, which contains a large horn probe, is attached to the sonicator control unit and filled with ice water before the sample is sonicated. Typically, the sample tube is held in place from above by using a buret clamp and a ring stand. Alternatively, a tube holder can be fabricated from 1/4-inch plastic and used to hold up to eight tubes for simultaneous processing. (Redrawn, with permission, from Birren et al. 1997.)

Sonication

DNA samples are subjected to hydrodynamic shearing by exposure to brief pulses of sonication. DNA that has been sonicated for excessive periods of time is extremely difficult to clone, perhaps because of damage caused by free radicals generated by cavitation. Most sonicators will not shear DNA to a size smaller than 300–500 bp, and it is tempting to continue sonication until the entire population of DNA fragments has been reduced to this size. However, the yield of subclones is usually greater if sonication is stopped when the fragments of target DNA first reach a size of ~700 bp.

Calibration of the Sonicator

1. Transfer 10 µg of bacteriophage λ DNA (or some other large DNA of defined molecular weight) to a microfuge tube. Add TE (pH 7.6) to a final volume of 150 µl. Distribute 25-µl aliquots of the DNA solution into five microfuge tubes. Store the remaining DNA in an ice bath.

2. Fill the cup horn of the sonicator (Figure A8-5) with a mixture of ice and H_2O. Clamp the five microfuge tubes containing the bacteriophage λ DNA just above the probe.

   If the temperature of the sample rises during sonication, the speed and vigor of fragmentation will increase. It is therefore important to mix the ice and H_2O after each burst of sonication and to add fresh ice when necessary.

3. Sonicate at maximum output and continuous power for bursts of 10 seconds. After each burst, remove one of the microfuge tubes from the sonicator and store it on ice.

4. After sonication is completed, analyze the size of the DNA fragments in each stored sample by electrophoresis through a 1.4% agarose gel. Use suitable standards for molecular-weight markers (please see Appendix 6, Figure A6-4).

5. Stain and photograph the gel, and then estimate the amount of sonication required to produce a reasonable yield of fragments of the desired size (500 bp to 2 kb).

   The times of sonication given in this method are for a cup horn sonicator with a nominal peak output energy of 475 W. Because the actual output of different sonicators varies widely, it is necessary to calibrate each instrument. A probe-type sonicator can be used with a microtip if the volume of the DNA sample is increased to ~250 µl to accommodate the probe. After sonication is completed, concentrate the DNA by precipitation with 2 volumes of ethanol and dissolve in 25 µl of TE (pH 7.6).

Sonication of Target DNA

6. Sonicate the chosen DNA sample for the length of time estimated to produce a reasonable yield of fragments of the desired size (500 bp to 1 kb). Confirm that the fragmentation has gone according to plan by analyzing an aliquot of the sample (~200 ng) by electrophoresis through a 1.4% agarose gel as described above.

Nebulization

Nebulization is performed by collecting the fine mist created by forcing DNA in solution through a small hole in the nebulizer unit. The size of the fragments is determined chiefly by the speed at which the DNA solution passes through the hole, the viscosity of the solution, and the temperature.

Modification of the Nebulizer

1. Modify a nebulizer model number CA-209 (available from CIS-US Inc., Bedford, Massachusetts) by sealing the mouthpiece hole in the top cover with a QS-T plastic cap. Connect a length of Nalgene tubing to the smaller hole. This tubing will be connected to a source of nitrogen gas.

Calibration of the Nebulizer

2. Prepare a sample containing 25 µg of bacteriophage λ DNA or other large DNA of defined size in 500 µl of TE (pH 7.6) containing 25% glycerol. Store the DNA solution in an ice bath for 5 minutes.
3. Place the DNA in the cup of a nebulizer connected to a nitrogen gas source and place the nebulizer in an ice-water bath.

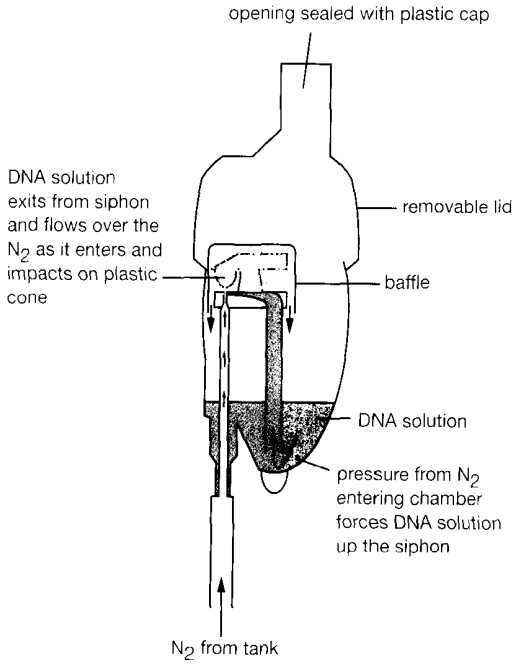

FIGURE A8-6 Nebulizer for Random Fragmentation of DNA

A DNA solution containing glycerol, for viscosity, is placed in the nebulizer. The nebulizer is attached to a nitrogen tank. Pressure from nitrogen entering the chamber siphons the DNA solution from the bottom of the chamber to the top. The solution exits the siphon and impacts on a small plastic cone suspended near the top of the chamber, thus shearing the DNA.

4. Nebulize the DNA sample at 10 psi (69 KPa) for 90 seconds.

   The nebulizer usually leaks a little.

5. After nebulization is completed, collect the DNA by placing the entire unit in a rotor bucket of a bench-top centrifuge fitted with pieces of Styrofoam to cushion. Centrifuge the nebulizer at 2500 rpm for 30 seconds. Analyze the size of the DNA fragments by electrophoresis through a 1.4% agarose gel with appropriate standards, e.g., the fragments generated by digestion of pUC18/19 DNA with *Sau*3AI. For detail of standards, please see Appendix 6, Table A6-4.

6. If the fragments are too large (>1.0 kb) repeat the procedure increasing either the pressure of the nitrogen gas (to 14 psi or 96.5 KPa) or the length of nebulization (2 minutes). Repeat the procedure until conditions are found that produce a reasonable yield of fragments of the desired size (500 bp to 1 kb).

Nebulization and Recovery of the Target DNA

7. Nebulize the target DNA to produce a reasonable yield of fragments of the desired size (500 bp to 1 kb).

8. Confirm that the fragmentation has gone according to plan by analyzing an aliquot of the sample (~200 ng) by electrophoresis through a 1.4% agarose gel as described above.

9. Distribute the remainder of the sample into two microfuge tubes and recover the DNA by precipitation with 3 volumes of ethanol in the presence of 2.5 M ammonium acetate.

10. Centrifuge the DNA sample at maximum speed for 5 minutes in a microfuge, wash the pellet with 0.5 ml of 70% ethanol at room temperature, and centrifuge again. Remove the ethanol and allow the DNA to dry in the air for a few minutes. Dissolve the pellet of DNA in 25 µl of TE (pH 7.6).

CENTRIFUGATION

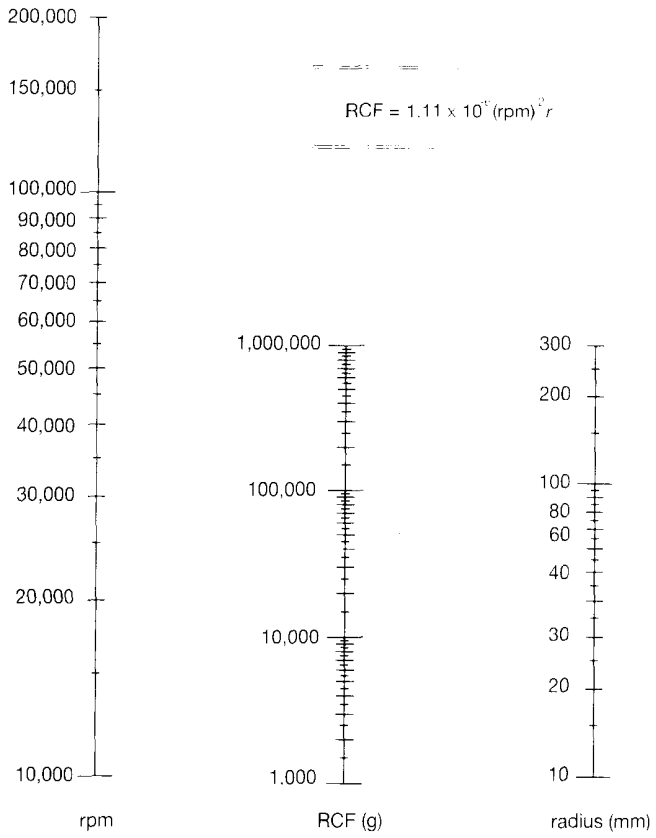

FIGURE A8-7 Nomogram for Conversion of Rotor Speed (rpm) and Relative Centrifugal Force (RCF)

The symbol r represents the radial distance from the center of the rotor to the point for which RCF is required. This is generally equivalent to r_{max} of the rotor. For the example marked, rotor speed = 80,000 rpm and r = 20 mm. RCF can be read as ~145,000g from the middle scale. Using the equation given above, RCF can be calculated as 142,080g. (Figure kindly provided by Siân Curtis.)

TABLE A8-7 Commonly Used Rotors

	R_{MAX}	G_{MAX}	MAX RPM
Sorvall Rotors			
GS3 Sorvall superspeed	151.3	13,700	9,000
GSA Sorvall super superspeed	145.6	27,400	13,000
HB6	146.3	27,617	13,000
AH629 Sorvall ultraspeed	161.0	151,000	29,000
SS-34 Sorvall	107.0	20,500	50,200
Beckman Rotors			
JA17 Beckman	123	17,000	39,800
JA20 Beckman	108	20,000	48,400
SW 28.1 Beckman	171.3	28,000	150,000
Type 50 Beckman	70.1	50,000	196,000
Vti50 Beckman	86.6	50,000	242,000

Type 70Ti Beckman	39.5	70,000	504,000

SDS-POLYACRYLAMIDE GEL ELECTROPHORESIS OF PROTEINS

Almost all analytical electrophoreses of proteins are carried out in polyacrylamide gels under conditions that ensure dissociation of the proteins into their individual polypeptide subunits and that minimize aggregation. Most commonly, the strongly anionic detergent SDS is used in combination with a reducing agent and heat to dissociate the proteins before they are loaded onto the gel. The denatured polypeptides bind SDS and become negatively charged. Because the amount of SDS bound is almost always proportional to the molecular weight of the polypeptide and is independent of its sequence, SDS-polypeptide complexes migrate through polyacrylamide gels in accordance with the size of the polypeptide. At saturation, ~1.4 g of detergent is bound per gram of polypeptide. By using markers of known molecular weight, it is possible to estimate the molecular weight of the polypeptide chain(s). Modifications to the polypeptide backbone, such as N- or O-linked glycosylation, however, have a significant impact on the apparent molecular weight. Thus, the apparent molecular weight of glycosylated proteins is not a true reflection of the mass of the polypeptide chain.

In most cases, SDS-polyacrylamide gel electrophoresis is carried out with a discontinuous buffer system in which the buffer in the reservoirs is of a pH and ionic strength different from that of the buffer used to cast the gel. The SDS-polypeptide complexes in the sample that is applied to the gel are swept along by a moving boundary created when an electric current is passed between the electrodes. After migrating through a stacking gel of high porosity, the complexes are deposited in a very thin zone (or stack) on the surface of the resolving gel. The ability of discontinuous buffer systems to concentrate all of the complexes in the sample into a very small volume greatly increases the resolution of SDS-polyacrylamide gels.

The discontinuous buffer system that is most widely used was originally devised by Ornstein (1964) and Davis (1964). The sample and the stacking gel contain Tris-Cl (pH 6.8), the upper and lower buffer reservoirs contain Tris-glycine (pH 8.3), and the resolving gel contains Tris-Cl (pH 8.8). All components of the system contain 0.1% SDS (Laemmli 1970). The chloride ions in the sample and stacking gel form the leading edge of the moving boundary, and the trailing edge is composed of glycine molecules. Between the leading and trailing edges of the moving boundary is a zone of lower conductivity and steeper voltage gradient, which sweeps the polypeptides from the sample and deposits them on the surface of the resolving gel. There the higher pH of the resolving gel favors the ionization of glycine, and the resulting glycine ions migrate through the stacked polypeptides and travel through the resolving gel immediately behind the chloride ions. Freed from the moving boundary, the SDS-polypeptide complexes move through the resolving gel in a zone of uniform voltage and pH and are separated according to size by sieving.

Polyacrylamide gels are composed of chains of polymerized acrylamide that are cross-linked by a bifunctional agent such as *N,N'*-methylene-bis-acrylamide (please see Figure A8-8).

The effective range of separation of SDS-polyacrylamide gels depends on the concentration of polyacrylamide used to cast the gel and on the amount of cross-linking. Polymerization of acrylamide in the absence of cross-linking agents generates viscous solutions that are of no practical use. Cross-links formed from bisacrylamide add rigidity and tensile strength to the gel and form pores through which the SDS-polypeptide complexes must pass. The size of these pores decreases as the bisacrylamide:acrylamide ratio increases, reaching a minimum when the ratio is ~1:20. Most SDS-polyacrylamide gels are cast with a molar ratio of bisacrylamide:acrylamide of 1:29, which has been shown empirically to be capable of resolving polypeptides that differ in size by as little as 3%.

The sieving properties of the gel are determined by the size of the pores, which is a function of the absolute concentrations of acrylamide and bisacrylamide used to cast the gel. Table A8-8 shows the linear range of separation of proteins obtained with gels cast with concentrations of acrylamide that range from 5% to 15%.

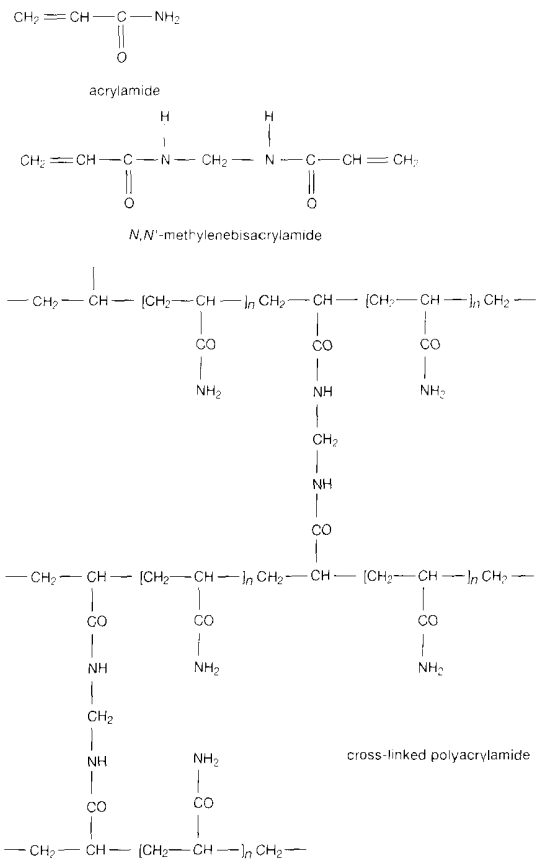

FIGURE A8-8 Chemical Structure of Polyacrylamide

Monomers of acrylamide are polymerized into long chains in a reaction initiated by free radicals. In the presence of *N,N'*-methylenebisacrylamide, these chains become cross-linked to form a gel. The porosity of the resulting gel is determined by the length of chains and degree of cross-linking that occurs during the polymerization reaction.

Reagents

- ***Acrylamide and* N,N′*-methylene-bis-acrylamide:*** Several manufacturers sell electrophoresis-grade acrylamide that is free of contaminating metal ions. A stock solution containing 29% (w/v) acrylamide and 1% (w/v) *N,N'*-methylene-bis-acrylamide should be prepared in deionized warm H_2O (to assist the dissolution of the bisacrylamide). Acrylamide and bisacrylamide are slowly converted during storage to acrylic acid and bisacrylic acid. This deamination reaction is catalyzed by light and alkali. Check that the pH of the solution is 7.0 or less, and store the solution in dark bottles at room temperature. Fresh solutions should be prepared every few months. Note that prepackaged, premixed stock solutions are commercially available (e.g., Life Technologies). These gel systems provide all the components except ammonium persulfate and are certainly convenient but perhaps a bit expensive.

- ***Sodium dodecyl sulfate (SDS):*** Several manufacturers sell special grades of SDS that are sufficiently pure for electrophoresis. Although any one of these will give reproducible results, they are not interchangeable. The pattern of migration of polypeptides may change quite drastically when one manufacturer's SDS is substituted for another's. We recommend exclusive use of one brand of SDS. A 10% (w/v) stock solution should be prepared in deionized H_2O and stored at room temperature. If proteins are to be eluted from the gel for sequencing, electrophoresis-grade SDS should be further purified as described by Hunkapiller et al. (1983).

TABLE A8-8 Effective Range of Separation of SDS-Polyacrylamide Gels

Acrylamide Concentration (%)	Linear Range of Separation (kD)
15	10–43
12	12–60
10	20–80
7.5	36–94
5.0	57–212

Molar ratio of bisacrylamide:acrylamide is 1:29.

- ***Tris buffers for the preparation of resolving and stacking gels:*** It is essential that these buffers be prepared with Tris base. After the Tris base has been dissolved in deionized H_2O, adjust the pH of the solution with HCl as described in Appendix 1. If Tris-Cl or Trizma is used to prepare buffers, the concentration of salt will be too high and polypeptides will migrate anomalously through the gel, yielding extremely diffuse bands.
- ***TEMED (N,N,N′,N′-tetramethylethylenediamine):*** TEMED accelerates the polymerization of acrylamide and bisacrylamide by catalyzing the formation of free radicals from ammonium persulfate. Use the electrophoresis grade sold by several manufacturers. Because TEMED works only as a free base, polymerization is inhibited at low pH.
- ***Ammonium persulfate:*** Ammonium persulfate provides the free radicals that drive polymerization of acrylamide and bisacrylamide. A small amount of a 10% (w/v) stock solution should be prepared in deionized H_2O and stored at 4°C. Ammonium persulfate decomposes slowly, and fresh solutions should be prepared weekly.
- ***Tris-glycine electrophoresis buffer:*** This buffer contains 25 mM Tris base, 250 mM glycine (electrophoresis grade) (pH 8.3), 0.1% SDS.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Acrylamide solutions <!>

Please see Table A8-9 for resolving gel recipes and Table A8-10 for stacking gel recipes.

Protein markers

Standard molecular-weight markers are commercially available (e.g., Life Technologies and Promega).

Protein samples

Samples to be resolved, for example, can be purified protein or cell lysates.

1x SDS gel-loading buffer

50 mM Tris-Cl (pH 6.8)
100 mM dithiothreitol
2% (w/v) SDS (electrophoresis grade)
0.1% bromophenol blue
10% (v/v) glycerol

Store 1x SDS gel-loading buffer lacking dithiothreitol at room temperature. Add dithiothreitol from a 1 M stock just before the buffer is used.

Modified from Harlow and Lane (1988).

1x Tris-glycine electrophoresis buffer

25 mM Tris

250 mM glycine (electrophoresis grade) (pH 8.3)

0.1% (w/v) SDS

Prepare a 5x stock of electrophoresis buffer by dissolving 15.1 g of Tris base and 94 g of glycine in 900 ml of deionized H_2O. Then add 50 ml of a 10% (w/v) stock solution of electrophoresis-grade SDS and adjust the volume to 1000 ml with H_2O.

Special Equipment

Power supply

A device capable of supplying up to 500 V and 200 mA is needed.

Vertical electrophoresis apparatus

The use of discontinuous buffer systems requires SDS-polyacrylamide electrophoresis to be carried out in vertical gels. Although the basic design of the electrophoresis tanks and plates has changed little since Studier (1973) introduced the system, many small improvements have been incorporated into the apparatuses. Standard vertical as well as minigel vertical electrophoresis systems for separation and blotting of proteins are now sold by many manufacturers (e.g., Life Technologies). Which of these systems to purchase is a matter of personal choice, but it is sensible for a laboratory to use only one type of apparatus. This type of standardization makes it easier to compare the results obtained by different investigators and allows parts of broken apparatuses to be scavenged and reused.

METHOD

Pouring SDS-polyacrylamide Gels

1. Assemble the glass plates according to the manufacturer's instructions.
2. Determine the volume of the gel mold (this information is usually provided by the manufacturer). In an Erlenmeyer flask or disposable plastic tube, prepare the appropriate volume of solution containing the desired concentration of acrylamide for the resolving gel, using the values given in Table A8-9. Mix the components in the order shown. Polymerization will begin as soon as the TEMED has been added. Without delay, swirl the mixture rapidly and proceed to the next step.

   The concentration of ammonium persulfate that we recommend is higher than that used by some investigators. This eliminates the need to rid the acrylamide solution of dissolved oxygen (which retards polymerization) by degassing.

3. Pour the acrylamide solution into the gap between the glass plates. Leave sufficient space for the stacking gel (the length of the teeth of the comb plus 1 cm). Use a Pasteur pipette to carefully overlay the acrylamide solution with 0.1% SDS (for gels containing ~8% acrylamide) or isobutanol (for gels containing ~10% acrylamide). Place the gel in a vertical position at room temperature.

   The overlay prevents oxygen from diffusing into the gel and inhibiting polymerization. Isobutanol dissolves the plastic of some minigel apparatuses.

4. After polymerization is complete (30 minutes), pour off the overlay and wash the top of the gel several times with deionized H_2O to remove any unpolymerized acrylamide. Drain as much fluid as possible from the top of the gel, and then remove any remaining H_2O with the edge of a paper towel.
5. Prepare the stacking gel as follows: In a disposable plastic tube, prepare the appropriate volume of solution containing the desired concentration of acrylamide, using the values given in

Table A8-10. Mix the components in the order shown. Polymerization will begin as soon as the TEMED has been added. Without delay, swirl the mixture rapidly and proceed to the next step.

The concentration of ammonium persulfate is higher than that used by some investigators. This eliminates the need to rid the acrylamide solution of dissolved oxygen (which retards polymerization) by degassing.

6. Pour the stacking gel solution directly onto the surface of the polymerized resolving gel. Immediately insert a clean Teflon comb into the stacking gel solution, being careful to avoid trapping air bubbles. Add more stacking gel solution to fill the spaces of the comb completely. Place the gel in a vertical position at room temperature.

Teflon combs should be cleaned with H_2O and dried with ethanol just before use.

Preparation of Samples and Running the Gel

7. While the stacking gel is polymerizing, prepare the samples in the appropriate volume of 1x SDS gel-loading buffer and heat them to 100°C for 3 minutes to denature the proteins.

Be sure to denature a sample containing marker proteins of known molecular weights. Mixtures of appropriately sized polypeptides are available from commercial sources.

Extremely hydrophobic proteins, such as those containing multiple transmembrane domains, may precipitate or multimerize when boiled for 3 minutes at 100°C. To avoid these pitfalls, heat the samples for 1 hour at a lower temperature (45–55°C) to effect denaturation.

8. After polymerization is complete (30 minutes), remove the Teflon comb carefully. Use a squirt bottle to wash the wells immediately with deionized H_2O to remove any unpolymerized acrylamide. If necessary, straighten the teeth of the stacking gel with a blunt hypodermic needle attached to a syringe. Mount the gel in the electrophoresis apparatus. Add Tris-glycine electrophoresis buffer to the top and bottom reservoirs. Remove any bubbles that become trapped at the bottom of the gel between the glass plates. This is best done with a bent hypodermic needle attached to a syringe.

▲ **IMPORTANT** Do not prerun the gel before loading the samples, since this procedure will destroy the discontinuity of the buffer systems.

9. Load up to 15 µl of each of the samples in a predetermined order into the bottom of the wells. This is best done with a Hamilton microliter syringe or a micropipettor equipped with gel-loading tips that is washed with buffer from the bottom reservoir after each sample is loaded. Load an equal volume of 1x SDS gel-loading buffer into any wells that are unused.

10. Attach the electrophoresis apparatus to an electric power supply (the positive electrode should be connected to the bottom buffer reservoir). Apply a voltage of 8 V/cm to the gel. After the dye front has moved into the resolving gel, increase the voltage to 15 V/cm and run the gel until the bromophenol blue reaches the bottom of the resolving gel (~4 hours). Then turn off the power supply.

11. Remove the glass plates from the electrophoresis apparatus and place them on a paper towel. Use an extra gel spacer to carefully pry the plates apart. Mark the orientation of the gel by cutting a corner from the bottom of the gel that is closest to the leftmost well (slot 1).

▲ **IMPORTANT** Do not cut the corner from gels that are to be used for immunoblotting.

12. At this stage, the gel can be fixed, stained with Coomassie Brilliant Blue or silver salts, fluorographed or autoradiographed, or used to establish an immunoblot, all as described on the following pages.

STAINING SDS-POLYACRYLAMIDE GELS

Unlabeled proteins separated by polyacrylamide gel electrophoresis typically are detected by staining, either with Coomassie Brilliant Blue or with silver salts. In a relatively rapid and straightforward reaction, Coomassie Brilliant Blue binds nonspecifically to proteins but not to the gel, thereby allowing visualization of the proteins as discreet blue bands within the translucent matrix of the gel (Wilson 1983). Silver staining, although somewhat more difficult to perform, is significantly more sensitive. The use of silver staining allows detection of proteins resolved by gel electrophoresis at concentrations nearly 100-fold lower than those detected by Coomassie Brilliant Blue staining (Switzer et al. 1979; Merril et al. 1984). The identification of proteins by silver staining is based on the differential reduction of silver ions, in a reaction similar to that used in photographic processes. Reagents for staining with Coomassie Brilliant Blue as well as kits (e.g., Blue Print Fast PAGE Stain, Life Technologies) are commercially available. Kits for silver staining are commercially available from Pierce and Bio-Rad.

HISTORICAL FOOTNOTE

Coomassie Brilliant Blue R-250 was first used as a laboratory reagent to stain proteins in 1963. Robert Webster, a graduate student in the laboratory of Stephen Fazekas de St. Groth at the Australian National University in Canberra, was searching for a way to locate influenza virus proteins that had been separated by electrophoresis on cellulose acetate strips. At that time, Australia had a thriving wool industry and government laboratories were intensely investigating the mechanism of action of various classes of dyes used for wool dying. Fazekas and Webster reasoned that these dyes must have a high affinity for proteins, and they obtained samples of a great many dyes from the Commonwealth Scientific and Industrial Organization. Included among them was Coomassie Brilliant Blue R-250, which had been used since the turn of the century in the textile dying industry. Webster soon found that Coomassie Brilliant Blue R-250 was a very sensitive stain for proteins, but he was frustrated by extreme day-to-day variation in the intensity of the staining. At home one night, he suddenly realized that the answer to the problem was to fix the protein before staining. He went back to the laboratory and fixed the separated influenza virus proteins with sulfosalicylic acid. After these results were published (Fazekas de St. Groth et al. 1963), the method was rapidly adapted to stain proteins separated by electrophoresis through polyacrylamide gels (Meyer and Lamberts 1965).

Because Coomassie Brilliant Blue R-250 is now a trademark of Imperial Chemical Industries PLC, the dye is generally listed in biochemical catalogs as Brilliant Blue. Two forms of the dye are available: Brilliant Blue G and Brilliant Blue R, which are given different numbers (42655 and 42660) in the Colour Index, a kind of dyer's Bible, in which dyes are classified and arranged according to color. Brilliant Blue G and Brilliant Blue R are, respectively, slightly soluble and insoluble in cold water, and soluble and slightly soluble in hot water and alcohols. Both dyes stain fixed proteins efficiently. They are used at a concentration of 0.05% in methanol:glacial acetic acid:water (50:10:40 v/v).

Staining SDS-Polyacrylamide Gels with Coomassie Brilliant Blue

Coomassie Brilliant Blue is an aminotriarylmethane dye that forms strong but not covalent complexes with proteins, most probably by a combination of van der Waals forces and electrostatic interactions with NH_3^+ groups. Coomassie Brilliant Blue is used to stain proteins after electrophoresis through polyacrylamide gels. The uptake of dye is approximately proportional to the amount of protein, following the Beer-Lambert law.

Polypeptides separated by SDS-polyacrylamide gels can be simultaneously fixed with methanol:glacial acetic acid and stained with Coomassie Brilliant Blue R-250, a triphenylmethane textile dye also known as Acid Blue 83. The gel is immersed for several hours in a concentrated methanol:acetic acid solution of the dye, and excess dye is then allowed to diffuse from the gel during a prolonged period of destaining.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Coomassie Brilliant Blue R-250

Methanol:acetic acid solution **<!>**

Combine 900 ml of methanol:H_2O (500 ml of methanol and 400 ml of H_2O) and 100 ml of glacial acetic acid.

Step 1 of this protocol requires the reagents listed on page A8.42.

METHOD

1. Separate proteins by electrophoresis through an SDS-polyacrylamide gel as described on page A8.40.
2. Prepare the staining solution by dissolving 0.25 g of Coomassie Brilliant Blue R-250 per 100 ml of methanol:acetic acid solution. Filter the solution through a Whatman No. 1 filter to remove any particulate matter.
3. Immerse the gel in at least 5 volumes of staining solution and place on a slowly rotating platform for a minimum of 4 hours at room temperature.
4. Remove the stain and save it for future use. Destain the gel by soaking it in the methanol:acetic acid solution without the dye on a slowly rocking platform for 4–8 hours, changing the destaining solution three or four times.

   The more thoroughly the gel is destained, the smaller the amount of protein detected by staining with Coomassie Brilliant Blue. Destaining for 24 hours usually allows as little as 0.1 μg of protein to be detected in a single band.

   A more rapid rate of destaining can be achieved by the following methods:

   - Destaining in 30% methanol, 10% acetic acid. If destaining is prolonged, there will be some loss in the intensity of staining of protein bands.
   - Destaining in the normal destaining buffer at higher temperatures (45°C).
   - Including a few grams of an anion exchange resin or a piece of sponge in the normal destaining buffer. These absorb the stain as it leaches from the gel.
   - Destaining electrophoretically in apparatuses that are sold commercially for this purpose.

5. After destaining, store the gels in H_2O in a sealed plastic bag.

   Gels may be stored indefinitely without any diminution in the intensity of staining; however, fixed polyacrylamide gels stored in H_2O will swell and may distort during storage. To avoid this problem, store fixed gels in H_2O containing 20% glycerol. Stained gels should not be stored in destaining buffer, because the stained protein bands will fade.

6. To make a permanent record, either photograph the stained gel (please see Chapter 5, Protocol 2) or dry the gel as described on p. A8.50.

Staining SDS-Polyacrylamide Gels With Silver Salts

A number of methods have been developed to stain polypeptides with silver salts after separation by SDS-polyacrylamide gel electrophoresis. In every case, the process relies on differential reduction of silver ions that are bound to the side chains of amino acids (Switzer et al. 1979; Oakley et al. 1980; Ochs et al. 1981; Sammons et al. 1981; Merril et al. 1984). These methods fall into two major classes: those that use ammoniacal silver solutions and those that use silver nitrate. Although both types of staining are ~100–1000-fold more sensitive than staining with Coomassie Brilliant Blue R-250 and are capable of detecting as little as 0.1–1.0 ng of polypeptide in a single band, silver nitrate solutions are easier to prepare and, by contrast to ammoniacal silver salts, do

not generate potentially explosive by-products. The method given below is a modification of the staining procedure originally devised by Sammons et al. (1981), which has since undergone several improvements (Schoenle et al. 1984). For further information, please see the discussion on silver staining in Appendix 9.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Acetic acid (1%) <!>

Developing solution

Prepare fresh for each use an aqueous solution of 2.5% sodium carbonate, 0.02% formaldehyde. <!>

Ethanol (30%)

Fixing solution

Ethanol:glacial acetic acid:H_2O (30:10:60) <!>

Photographic reducing solution (Switzer et al. 1979)

Optional, please see Step 10.

Prepare Solution A: Dissolve 37 g of NaCl and 37 g of $CuSO_4$ in 850 ml of deionized H_2O. Add concentrated NH_4OH <!> until a deep blue precipitate forms and then dissolves. Adjust the volume to 1 liter with H_2O.

Prepare Solution B: Dissolve 436 g of sodium thiosulfate in 900 ml of deionized H_2O. Adjust the volume to 1 liter with H_2O.

Mix equal volumes of Solution A and Solution B, dilute the mixture with 3 volumes of H_2O, and use the diluted mixture immediately.

Silver nitrate solution

Prepare fresh for each use, 0.1% solution of $AgNO_3$, <!> diluted from a 20% stock, stored in a tightly closed, brown glass bottle at room temperature.

Step 1 of this protocol requires the reagents listed on page A8.42

METHOD

▲ **IMPORTANT** Wear gloves and handle the gel gently because pressure and fingerprints produce staining artifacts. In addition, it is essential to use clean glassware and deionized H_2O because contaminants greatly reduce the sensitivity of silver staining.

1. Separate proteins by electrophoresis through an SDS-polyacrylamide gel as described on page A8.40.
2. Fix the proteins by incubating the gel for 4–12 hours at room temperature with gentle shaking in at least 5 gel volumes of fixing solution.
3. Discard the fixing solution, and add at least 5 gel volumes of 30% ethanol. Incubate the gel for 30 minutes at room temperature with gentle shaking.
4. Repeat Step 3.
5. Discard the ethanol and add 10 gel volumes of deionized H_2O. Incubate the gel for 10 minutes at room temperature with gentle shaking.
6. Repeat Step 5 twice.

   The gel will swell slightly during rehydration.
7. Discard the last of the H_2O washes, and, wearing gloves, add 5 gel volumes of silver nitrate solution. Incubate the gel for 30 minutes at room temperature with gentle shaking.

8. Discard the silver nitrate solution, and wash both sides of the gel (20 seconds each) under a stream of deionized H_2O.

   Allowing the surface of the gel to dry out will result in staining artifacts.

9. Add 5 gel volumes of fresh developing solution. Incubate the gel at room temperature with gentle agitation. Watch the gel carefully. Stained bands of protein should appear within a few minutes. Continue incubation until the desired contrast is obtained.

   Prolonged incubation leads to a high background of silver staining within the body of the gel.

10. Quench the reaction by washing the gel in 1% acetic acid for a few minutes. Then wash the gel several times with deionized H_2O (10 minutes per wash).

    A shiny gray film of silver sometimes forms on the surface of the gel. This can be removed by washing the gel for 2–3 seconds in a 1:4 dilution of photographic reducing solution. Rinse the treated gel extensively in deionized H_2O.

11. Preserve the gel by drying as described on the following pages.

DRYING SDS-POLYACRYLAMIDE GELS

SDS-polyacrylamide gels containing proteins radiolabeled with ^{35}S-labeled amino acids must be dried before autoradiographic images can be obtained. The major problems encountered when a gel is dried are (1) shrinkage and distortion and (2) cracking of the gel. The first of these problems can be minimized if the gel is attached to a piece of Whatman 3MM paper before it is dehydrated. (For nonradioactive gels, note that the preference may be to dry the gel between acetate sheets to allow transillumination and easy visualization of the dried gel.) However, there is no guaranteed solution to the second problem, which becomes more pronounced with thicker gels containing more polyacrylamide. Cracking generally occurs when the gel is removed from the drying apparatus before it is completely dehydrated. It is therefore essential to keep the drying apparatus in good condition, to use a reliable vacuum line that has few fluctuations in pressure, and to use the thinnest gel possible to achieve the desired purpose. An excellent alternative method is soaking the gel in 3% glycerol, followed by drying in air using a simple apparatus (available from AP Biotech or Owl Scientific).

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Fixing solution

Glacial acetic acid:methanol:H_2O (10:20:70 v/v/v) <!>

Gel dryer

Gel dryers are available from a number of commercial sources (e.g., Life Technologies and Promega). It is best to purchase the dryer from the manufacturer of the SDS-polyacrylamide gel electrophoresis tanks to ensure that the size of the dryer will be tailored to that of the gels and will accommodate several SDS-polyacrylamide gels simultaneously.

Methanol (20%) containing 3% glycerol <!>

Optional, please see Step 1.

Whatman 3MM paper

METHOD

1. Remove the gel from the electrophoresis apparatus and incubate it at room temperature in 5–10 volumes of fixing solution. The bromophenol blue will turn yellow as the acidic fixing solution diffuses into the gel. Continue fixation for 5 minutes after all of the blue color has disappeared, and then wash the gel briefly in deionized H_2O.

   If cracking of polyacrylamide gels during drying is a constant problem, soak the fixed gel in 20% methanol, 3% glycerol overnight before proceeding to Step 2.

2. On a piece of Saran Wrap slightly larger than the gel, arrange the gel with its cut corner on the lower right-hand side.

3. Place a piece of dry Whatman 3MM paper on the damp gel. The paper should be large enough to create a border (1–2 cm) around the gel and small enough to fit on the gel dryer. Do not attempt to move the 3MM paper once contact has been made with the gel.

4. Arrange another piece of dry 3MM paper on the drying surface of the gel dryer. This piece should be large enough to accommodate all of the gels that are to be dried at the same time.

5. Place the sandwich of 3MM paper/gel/Saran Wrap on the piece of 3MM paper on the gel dryer. The Saran Wrap should be uppermost.

6. Close the lid of the gel dryer, and apply suction so that the lid makes a tight seal around the gels. If the dryer is equipped with a heater, apply low heat (50–65°C) to speed up the drying process.
7. Dry the gel for the time recommended by the manufacturer (usually 2 hours for standard 0.75-mm gels). If heat was applied, turn off the heat for a few minutes before releasing the vacuum.
8. Remove the gel, which is now attached to a piece of 3MM paper, from the dryer.
9. Remove the piece of Saran Wrap and establish an autoradiograph as described in Appendix 9, or store the dehydrated gel as a record of the experiment.

IMMUNOBLOTTING

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Immunoblotting is used to identify and measure the size of macromolecular antigens (usually proteins) that react with a specific antibody (Towbin et al. 1979; Burnette 1981; for reviews, please see Towbin and Gordon 1984; Gershoni 1988; Stott 1989; Poxton 1990). The proteins are first separated by electrophoresis through SDS-polyacrylamide gels and then transferred electrophoretically from the gel to a solid support, such as a nitrocellulose, polyvinylidene difluoride (PVDF), or cationic nylon membrane. After the unreacted binding sites of the membrane are blocked to suppress nonspecific adsorption of antibodies, the immobilized proteins are reacted with a specific polyclonal or monoclonal antibody. Antigen-antibody complexes are finally located by radiographic, chromogenic, or chemiluminescent reactions.

Much mumbo-jumbo has been written about ways to avoid the problems that commonly arise in immunoblotting. These problems include inefficient transfer of proteins, loss of antigenic sites, low sensitivity, high background, and nonquantitative detection methods. Although no magic incantation can eliminate all of these undesirable difficulties for every antigen, a small amount of experimentation is usually sufficient to cure all but the most obdurate technical problems. Comprehensive reviews by Bjerrum and Schafer-Nielsen (1986), Bjerrum et al. (1988), and Stott (1989) provide catalogs of potential difficulties in immunoblotting and detailed suggestions for solving them.

Transfer of Proteins from Gel to Filter

Electrophoretic transfer of proteins from polyacrylamide gels to membranes is far more efficient and much quicker than capillary transfer. Transfer is carried out perpendicularly from the direction of travel of proteins through the separating gel, using electrodes and membranes that cover the entire area of the gel. Most commercial electrophoretic transfer devices use large electrodes made of graphite, platinum wire mesh, or stainless steel. In older devices, vertical electrodes were submerged in a tank of transfer buffer in a plastic cradle surrounding the gel and the membrane. The more modern devices use the efficient "semi-dry" method, in which Whatman 3MM paper saturated with transfer buffer is used as a reservoir. For transfer from SDS gels, the membrane is

TABLE A8-11 Buffers for Transfer of Proteins from Polyacrylamide Gels to Membranes

TYPE OF TRANSFER	BUFFER	REFERENCE
Semi-dry	24 mM Tris base 192 mM glycine 20% methanol <!>	Towbin et al. (1979)
Immersion	48 mM Tris base 39 mM glycine 20% methanol <!> 0.0375% SDS	Bjerrum and Schafer-Nielsen (1986)

Methanol minimizes swelling of the gel and increases the efficiency of binding of proteins to nitrocellulose membranes. The efficiency of transfer may be affected by the presence of SDS in the electrophoresis buffer, the pH of the transfer buffer, and whether the proteins were stained in the gel before transfer. To maximize transfer of protein to membranes, the concentration of SDS should be ≤0.1% and the pH should be ≥8.0. CAPS buffer should be used for transfer if the protein is to be sequenced on the membrane (Moos 1992). Glycine interferes with this procedure.

placed on the side of the gel facing the anode. The conditions used for transfer vary according to the design of the apparatus, and it is therefore best to follow the manufacturer's instructions at this stage.

Types of Membranes

Three types of membranes are used for immunoblotting: nitrocellulose, nylon, and polyvinylidene fluoride. Different proteins may bind with different efficiencies to these membranes, and particular antigenic epitope(s) may be better preserved in one case than another. It is therefore worthwhile wherever possible to test the efficiency with which the antigen of interest can be detected on various membranes, using several antibodies.

- ***Nitrocellulose*** (pore size 0.45 µm) remains a standard membrane used for immunoblotting, although membranes with a smaller pore size (0.22 µm or 0.1 µm) are recommended for immunoblotting of small proteins of M_r <14,000 (Burnette 1981; Lin and Kasamatsu 1983). The capacity of nitrocellulose to bind and retain proteins ranges from 80 µg/cm^2 to 250 µg/cm^2, depending on the protein. Proteins bind to nitrocellulose chiefly by hydrophobic interactions (van Oss et al. 1987), although hydrogen bonding between amino acid side chains and the nitro group of the membrane may also be involved. In any event, partial dehydration of the proteins by methanol or salt in the transfer buffer ensures a more lasting bond between the protein and the membrane. Even so, proteins may be lost from the membrane during processing, particularly if buffers containing nonionic detergents are used. Many investigators therefore fix the proteins to nitrocellulose membranes to reduce loss during washing and incubation with antibody (e.g., please see Gershoni and Palade 1982). However, it is important to check that the treatments used for fixation (glutaraldehyde, cross-linking, UV irradiation) do not destroy the antigenic epitope under study. These treatments can also increase the brittleness of nitrocellulose filters that are allowed to dry after transfer.

- ***Nylon and positively charged nylon membranes*** are tougher than nitrocellulose and bind proteins tightly by electrostatic interactions. Their capacity varies from one type of nylon to the next and from one protein to another but is usually in the range of 150 µg/cm^2 to 200 µg/cm^2. The advantage of nylon and charged nylon membranes over nitrocellulose is that they can be probed multiple times with different antibodies. However, nylon membranes have two potential disadvantages. First, as discussed below, no simple and sensitive procedure is available to stain proteins immobilized on nylon and charged nylon membranes. Second, because it is difficult to block all of the unoccupied sites on these membranes, antibodies tend to bind nonspecifically to the filter, resulting in a high background, especially when a highly sensitive detection method such as enhanced chemiluminescence (ECL) is used. In many cases, extended blocking in solutions containing 6% heat-treated casein and 1% polyvinylpyrrolidone (Gillespie and Hudspeth 1991) is required to achieve satisfactory results.

- ***Polyvinylidene fluoride*** (PVDF) (Pluskal et al. 1986) is mechanically strong and manifests a strong interfacial (hydrophobic) interaction with proteins. Before transfer, it is necessary to wet the hydrophobic surface of the membrane with methanol. The capacity of PVDF membranes is approximately equal to that of nylon membranes (~170 µg protein/cm^2). Proteins bind approximately sixfold more tightly to PVDF membranes than to nitrocellulose (van Oss et al. 1987) and are retained more efficiently during the subsequent detection steps. Proteins immobilized on PVDF can be visualized with standard stains such as Amido Black, India Ink, Ponceau S, and Coomassie Brilliant Blue.

Staining of Proteins during Immunoblotting

Separation of proteins in gels and transfer to membranes can be confirmed by staining. This is a simple procedure, but it requires careful choice of a stain that is sufficiently sensitive and appropriate for the type of membrane. Staining can be carried out at several stages in the immunoblotting procedure as outlined below.

- ***Staining gels before transfer to membranes.*** Proteins can be stained in polyacrylamide gels with conventional dyes such as Coomassie Brilliant Blue, destained, and then transferred electrophoretically to nitrocellulose or PVDF filters for immunoblotting (e.g., please see Thompson and Larson 1992). The chief advantage of this method is that proteins remain stained during immunodetection, thereby providing a set of internal markers. However, in some cases, staining of proteins in gels appears to reduce the efficiency of electroelution and/or to interfere with binding of antibody. (The use of prestained protein markers [Life Technologies] provides a set of internal markers during protein transfer without the need to stain the entire gel.)
- ***Staining proteins after transfer to membranes.*** The entire area of nitrocellulose and PVDF membranes can be stained with the removable but insensitive stain Ponceau S (Muilerman et al. 1982; Salinovitch and Montelaro 1986). When more permanent stains are used (e.g., India Ink [Hancock and Tsang 1983], Amido Black [Towbin et al. 1979; Wilson 1979], colloidal gold [Moeremans et al. 1985; Rohringer and Holden 1985], or silver [Yuen et al. 1982]), it is usually necessary to cut a reference lane from the membrane.

Brief exposure to alkali enhances staining with both India Ink and colloidal gold, perhaps by reducing loss of protein from the filter during washing (Sutherland and Skerritt 1986). Under these conditions, it is easily possible to detect a band containing as little as a few nanograms of protein. There is no satisfactory method to stain proteins immobilized on nylon or cationic nylon membranes. The high density of charge on these membranes causes dye molecules to bind indiscriminately to the surface, producing high backgrounds that obscure all but the strongest protein bands.

Blocking Agents

Traditional blocking agents such as 0.5% low-fat dry milk or 5% bovine serum albumin (Johnson et al. 1984; DenHollander and Befus 1989) are suitable for use with chromogenic detection systems based on horseradish peroxidase. However, these solutions are usually rich in residual alkaline phosphatase and should not be used in detection systems that employ this enzyme. This is particularly true with chemiluminescent systems, where the sensitivity is determined not by the strength of the emitted signal but by the efficiency of suppression of background. The best blocking solution for alkaline-phosphatase-based systems contains 6% casein, 1% polyvinylpyrrolidone, 10 mM EDTA in phosphate-buffered saline (Gillespie and Hudspeth 1991). The blocking solution should be heated to 65°C for 1 hour to inactivate residual alkaline phosphatase and then stored at 4°C in the presence of 3 mM sodium azide. For recipes, please see Appendix 1.

Probing and Detection

The antibody that reacts with the epitope of interest can be either polyclonal or monoclonal. In either case, it is not radiolabeled or conjugated to an enzyme but is merely diluted into an appropriate buffer for formation of antibody-antigen complexes. In general, backgrounds in immunoblotting are unacceptably high unless the primary antibody can be diluted at least 1:1000

when enzymatic methods of detection are used and at least 1:5000 when chemiluminescent methods are used. After washing, the bound antibody is detected by a radiolabeled or enzyme-conjugated secondary reagent, which recognizes common features of the primary antibody and carries a reporter enzyme or group. Secondary reagents include:

- ***Radioiodinated antibodies or* Staphylococcal *Protein A,*** which were used in the first immunoblots (e.g., please see Burnette 1981) and for a few years thereafter. However, radiolabeled secondary reagents have now been replaced by nonradioactive detection systems such as enhanced chemiluminscence, which are less hazardous and more sensitive. They remain the most accurate method for semi-quantitative immunoblotting.
- ***Antibodies conjugated to enzymes,*** such as horseradish peroxidase or alkaline phosphatase, for which a variety of chromogenic, fluorescent, and chemiluminescent substrates are available.
- ***Antibodies coupled to biotin,*** which can then be detected by labeled or conjugated streptavidin.

Images of radiolabeled reagents are captured on X-ray film or phosphorimagers, whereas the results of chromogenic and fluorogenic reactions are best recorded by conventional photography. Table A8-12 shows the approximate sensitivity with which the best of these methods can detect a standard antigen using antibodies of high titer and specificity. For more information about these detection methods, please see Appendix 9.

TABLE A8-12 Chromogenic and Chemiluminescent Methods of Detection of Immobilized Antigens

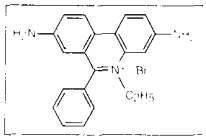
Enzyme	Reagent	Sensitivity	Comments	References
Chromogenic				
Horseradish peroxidase	4-chloro-1 naphthol/ H_2O_2	1 ng	The purple color of oxidized products fades rapidly on exposure to light.	Hawkes et al. (1982); Dresel and Schettler (1984)
	diaminobenzidine <!>/ H_2O_2	250 pg	Potentially carcinogenic. The diaminobenzidine reaction generates a brown precipitate, which is enhanced by the addition of cobalt, silver, and nickel salts.	de Blas and Cherwinski (1983); Gershoni (1988)
	3,3′,5,5′-tetramethylbenzidine	100 pg	Deep purple precipitate.	McKimm-Breschkin (1990)
Alkaline phosphatase	nitro blue tetrazolium/ 5-bromo-4-chloroindolyl phosphate	100 pg	Steel-blue precipitate.	Leary et al. (1983); Blake et al. (1984)
Chemiluminescent				
Horseradish peroxidase	luminol/4-iodo-phenol/ H_2O_2	300 pg	Oxidized luminol emits blue light that is captured on X-ray film. Luminescence generated by intense bands appears within a few seconds,whereas faint bands need at least 30 minutes to develop.	Schneppenheim and Rautenberg (1987); Harper and Murphy (1991); Schneppenheim et al. (1991)
Alkaline phosphatase	AMPPD 3-(4-methoxyspiro[1,2-dioxetane-3′2′-tricyclo-[3.3.1^{3,7}]decan]-4-yl)-phenylphosphate	1 pg	The enzymatically dephosphorylated product emits light. Because of its high turnover number, alkaline phosphatase rapidly generates a strong signal that provides an exquisitely sensitive method of immunodetection.	Gillespie and Hudspeth (1991)

Appendix 9

Detection Systems

STAINING NUCLEIC ACIDS

Ethidium Bromide



Ethidium bromide was synthesized in the 1950s in an effort to develop phenanthridine compounds as effective trypanocidal agents. Ethidium emerged from the screening program with flying colors. It was 10–50-fold more effective against trypanosomes than the parent compound, was no more toxic to mice, and, unlike earlier phenanthridines, did not induce photosensitization in cattle (Watkins and Wolfe 1952). Until recently, ethidium bromide was widely used for the treatment and prophylaxis of trypanomiasis in cattle in tropical and subtropical countries. The chemical structure of ethidium bromide is shown at the right.

Binding of Ethidium Bromide to Nucleic Acids

Ethidium bromide contains a planar tricyclic phenanthridine ring system that is able to intercalate between the stacked base pairs of double-stranded DNA. After insertion into the helix, the drug lies perpendicular to the helical axis and makes van der Waals contacts with the base pairs above and below. Whereas the planar ring system of the drug is buried, its peripheral phenyl and ethyl groups project into the major groove of the DNA helix. At saturation in solutions of high ionic strength, approximately one ethidium molecule is intercalated per 2.5 base pairs, independent of the base composition of the DNA. The geometry of the base pairs and their positioning with respect to the helix are unchanged except for their displacement by 3.4 Å along the helix axis (Waring 1965). This causes a 27% increase in the length of double-stranded DNA (Freifelder 1971) saturated with ethidium bromide.

Ethidium bromide also binds with highly variable stoichiometry to helical regions formed by intrastrand base pairing in RNA and heat-denatured or single-stranded DNA (Waring 1965, 1966; LePecq and Paoletti 1967). The fixed position of the planar group of ethidium bromide and its close proximity to the bases cause the bound dye to display a 20–25-fold increase in fluorescent yield compared to the dye in free solution. UV radiation at 254 nm is absorbed by the DNA and transmitted to the dye; radiation at 302 nm and 366 nm is absorbed by the dye itself. The energy is re-emitted with a quantum yield of 0.3 at 590 nm in the red-orange region of the visible spectrum (LePecq and Paoletti 1967; Tuma et al. 1999).

Most of the commercially available UV light sources emit UV light at 302 nm. The fluorescent yield of ethidium bromide–DNA complexes excited by irradiation is considerably greater at 302 nm than at 366 nm but is slightly less than at shorter wavelength (254 nm). However, the amount of photobleaching of the dye and nicking of the DNA is much less at 302 nm than at 254 nm (Brunk and Simpson 1977).

Staining DNA in Gels

Ethidium bromide is widely used to locate fragments of DNA in agarose gels (Aaij and Borst 1972; Sharp et al. 1973; please see the introduction to Chapter 5 and Protocol 2 in Chapter 5). The dye is usually incorporated into the gel and the electrophoresis buffer at a concentration of 0.5 µg/ml. Although the electrophoretic mobility of linear double-stranded DNA is reduced by ~15% in the presence of ethidium bromide, the ability to examine the gel directly under UV illumination is a great advantage. Since the fluorescent yield of ethidium bromide–DNA complexes is much greater than that of the unbound dye, small amounts of DNA (~10 ng/band) can be detected in

the presence of free ethidium bromide in gels (Sharp et al. 1973). Even smaller quantities of DNA can be detected if the DNA has previously been treated with chloroacetaldehyde, a chemical mutagen that reacts with adenine, cytosine, and guanine (Premaratne et al. 1993). A more practical way to enhance fluorescence is to destain the gel in a solution containing 10 mM Mg^{2+} before examining it under UV illumination (Sambrook et al. 1989).

Quantitating Double-stranded DNA

The formation of complexes between DNA and ethidium bromide can be observed with the naked eye because of the large metachromatic shift in the absorbtion spectrum of the drug that accompanies binding. The original maximum at 480 nm (yellow-orange) is shifted progressively to 520 nm (pink) with a characteristic isosbestic point at 510 nm. This provides a simple way to estimate the concentration of a sample of DNA by quantititive spectrophotometry (Waring 1965).

A faster and more sensitive method utilizes the UV-induced fluoresence emitted by intercalated ethidium bromide molecules. Because the amount of fluorescence is proportional to the total mass of DNA, the quantity of DNA can be estimated by comparing the light emitted by the sample at 590 nm with that of a series of standards (for more information on quantifying DNA with ethidium bromide, please see Appendix 8).

Improved Versions of Ethidium Bromide

Dimers of intercalating dyes bind to DNA with much greater affinity than the parent monomeric compound (Gaugain et al. 1978). Homodimers of ethidium bromide and heterodimers of acridine and ethidium are therefore much more sensitive reagents for detecting DNA than is monomeric ethidium bromide. For example, as little as 30 pg of DNA can be detected on a confocal fluorescence gel scanner (e.g., please see Glazer et al. 1990; Glazer and Rye 1992). However, the price for this increase in sensitivity is very steep; 1 mg of ethidium homodimer costs about ten times more than 1 g of ethidium bromide. Unsymmetric cyanine dyes unrelated to ethidium bromide are more sensitive detectors of DNA, but these dyes are also expensive (please see section on SYBR Dyes below). For information on disposal of ethidium bromide, please see Appendix 8.

Methylene Blue

Also known as Swiss Blue, in recognition of the nationality of Caro who first synthesized the dye in 1876, methylene blue (Fierz-David and Blangey 1949) is sometimes used as a stain for RNA that has been transferred to nitrocellulose filters or to certain types of nylon filters (Herrin and Schmidt 1988) (please see Chapter 7, Protocol 7).

Methylene blue may also be used to stain bands of DNA in agarose gels (please see the panel on **BRIEF PROTOCOL**). The aim is to avoid the use of ethidium bromide and to minimize the exposure of the DNA to UV irradiation, which can generate pyrimidine dimers and lower the biological activity of the DNA. This problem does not seem to be serious, but it is nevertheless a source of concern to some investigators.

Methylene blue has two absorbtion maxima (668 and 609 nm) in the visible spectrum, and is soluble in H_2O. For staining RNA immobilized on nylon or nitrocellulose, the dye is used at a concentration of 0.04% in 0.5 M sodium acetate (pH 5.2). Staining is reversible and can be carried out before hybridization.

BRIEF PROTOCOL

Staining DNA in Gels with Methylene Blue

1. Load and run a gel cast with GTG agarose in 1× TAE buffer.

   The smallest amount of DNA that can be reliably detected as a band by staining with methylene blue is ~40 ng. It is therefore necessary in most cases to load 2–3 times the normal quantity of DNA into the gel.

2. At the end of the electrophoretic run, place the gel in a glass dish containing 5 gel volumes of a solution containing 0.001–0.0025% methylene blue (available from Sigma) in 1 mM Tris-acetate (pH 7.4), 0.1 mM EDTA (pH 8.0).

3. Incubate the gel for 4 hours at room temperature, with gentle agitation on a rotary shaker.

4. Rinse the gel briefly in distilled H_2O and examine it on a light box of the kind used to illuminate X-ray films.

Silver Staining

Count Albert von Bollstadt (1193 or 1206–1280) is thrice famous. He was the teacher of St. Thomas Aquinas, he was an alchemist who described arsenic so clearly that he sometimes receives credit for the discovery of the element, and, of relevance to molecular cloning, he recorded that silver nitrate would stain human skin. Eight centuries later, silver staining has been refined into a highly sensitive technique for postelectrophoretic detection of DNA bands in polyacrylamide and agarose gels. At its best, silver staining can detect bands containing <1.0 ng of DNA. Described below are three general types of silver staining (Merril 1987, 1990; Mitchell et al. 1994).

- ***Photo development,*** like conventional photography and fluorography, uses photonic energy to reduce silver ions to the metallic element. Unfortunately, the simplicity and speed of the method cannot compensate for its lack of sensitivity, which is no better than can be achieved by conventional staining with ethidium bromide.

- ***Diammine staining*** methods use ammonium hydroxide to generate silver diammine complexes, which bind to the nucleic acid (Yuksel and Gracy 1985). Silver ions are then liberated from the complexes by decreasing the concentration of ammonium ions with citric acid. The liberated silver ions are finally reduced to metallic silver by formaldehyde. The basic method established by Johansson and Skoog (1987) is both rapid and reasonably sensitive (0.5–2 ng of DNA/band); greater sensitivity (0.1–1 ng DNA/band) can be achieved using the modifications described by Vari and Bell (1996). However, in our hands, it is difficult to achieve such high sensitivity on a regular basis. In addition, ammoniacal silver salts are potentially explosive and must be handled with great care.

- ***Nondiammine staining*** involves, for example, fixation of the DNA, sensitization of the DNA with glutaraldehyde, impregnation of the gel or membrane with silver nitrate at weakly acidic pH, and reduction of bound silver ions to metallic silver by alkaline formaldehyde. Many different variants of this technique have been published, but most of them suffer to a greater or lesser extent from the same problem: Bands of DNA stain gray or dog-yellow against a variable background of brownish surface staining (Vari and Bell 1996). This problem can be minimized, as in the protocol below, by carefully monitoring the gel during development so as to obtain the greatest discrimination between specific staining of the DNA and background staining of the gel. Differential reduction of silver ions can be improved by adding sodium thiosulfate to the alkaline formaldehyde solution (Bassam et al. 1991); thiosulfate removes silver ions from the gel surface by forming soluble complexes with silver salts. When working well, the nondiammine staining can detect bands of DNA containing 2–5 ng of DNA. A nondiammine silver staining is marketed by Promega as part of the Silver Sequence DNA sequencing kit. The

nondiammine staining method outlined below is simple and is sensitive enough to detect a band containing 2–5 ng of DNA in a polyacrylamide gel. The protocol was kindly provided by Dr. Sue Forrest (Victorian Clinical Genetics Service, Melbourne, Australia).

Silver Staining of DNA in Nondenaturing Polyacrylamide Gels

The volumes in the protocol are appropriate for staining a 150 x 150-mm polyacrylamide gel. Gels of this size are often used to analyze single-stranded DNA by SSCP (please see Chapter 13).

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Acetic acid (3% v/v) <!>

Developer

Dissolve 22.9 g of sodium carbonate in a final volume of 1 liter of distilled H_2O. Store the solution at room temperature away from direct light (e.g., in a closet).

Ethanol (10% v/v)

Ethanol/Glycerol (10% and 7% v/v, respectively)

Formaldehyde (37% v/v) <!>

Nitric acid (0.7% v/v) <!>

Silver nitrate (0.2% w/v), freshly prepared <!>

METHOD

1. After electrophoresis is complete, place the gel, still attached to one glass plate, in a plastic tray reserved for silver staining. Do not touch the surface of the gel at any time.

   Because pressure on the gel causes background staining, the various solutions used for silver staining are removed from the plastic tray with a pipette attached via a trap to a vacuum line.

2. Rinse the gel twice with distilled H_2O to remove electrophoresis buffer. During rinsing, the gel will float free and the glass plate can then be removed.

3. Fix the gel in 10% ethanol by gentle shaking for 10 minutes on a rocking platform. Remove the 10% ethanol by suction and repeat the process.

   If necessary, the gel can be left for several hours in the second batch of 10% ethanol.

4. Remove the ethanol by suction and add just enough 0.7% nitric acid to cover the gel. Shake the gel gently on a rocking platform for 6 minutes. Remove the nitric acid by suction and rinse the gel with two changes of distilled H_2O.

5. Add just enough 0.2% silver nitrate to cover the gel. Shake the gel gently on a rocking platform for 30 minutes. Rinse the gel and the staining tray three times with distilled H_2O.

   The silver nitrate solution may be reused but staining then may become unreliable.

6. To 100 ml of developer, add 125 µl of formaldehyde solution. Transfer the developer/formaldehyde solution to the staining tray and shake the tray gently in an indirect light (e.g., cover the container with aluminum foil). When the solution turns yellow or when a dark precipitate becomes noticeable, replace the developer/formaldehyde with a second batch of 100 ml of the same solution. Continue to shake the gel in indirect light. Monitor the appearance of bands and background. When the ratio of signal to noise is at its maximum, remove the second batch of developer/formaldehyde.

7. Add 250 ml of 3% acetic acid to the staining tray. Shake the gel gently for 5 minutes.
8. Remove the 3% acetic acid and wash the gel with 10% ethanol. Remove the ethanol and then store the gel for 2 minutes in a fresh batch of 10% ethanol.
9. Photograph the gel by transillumination on a white light box using Polaroid 667 film. The best photographs are obtained when the area around the gel is covered with black paper.
10. For long-term storage, either keep the gel in 10% ethanol/7% glycerol or dry it as follows:
    a. Lay a glass plate 2 cm longer and wider than the gel across the top of a beaker.
    b. Wet a piece of Saran Wrap approximately the same size as the glass plate. Lay the wet wrap on the glass plate, taking care to remove any air bubbles.
    c. Place the gel in the center of the piece of Saran Wrap and then cover it with another piece of pre-wet wrap, the same size as the first. Remove all wrinkles and air bubbles.
    d. Place gel spacers, ~1 cm thick on the Saran Wrap around the four edges of the gel. Use a series of bulldog clips to clamp the gel spacers to the glass plate.
    e. Allow the gel to dry for 24–48 hours, until the Saran Wrap feels crisp.

SYBR Dyes

The SYBR dyes are unsymmetric cyanine compounds, developed by Molecular Probes, that have some advantages as stains for DNA and RNA over phenanthridine dyes such as ethidium bromide. The information about SYBR dyes in the scientific literature is sparse. However, the Web Site of the manufacturer (http://www.probes.com) has much useful information, which is summarized below. For further details on the advantages and use of SYBR dyes, please see Chapter 5, Protocol 2.

Three SYBR dyes are used in molecular cloning: SYBR Green I and II and SYBR Gold. All three dyes are essentially nonfluorescent in free solution but, upon binding to nucleic acids, display greatly enhanced fluorescence and a high quantum yield. SYBR Green I, for example, has a quantum yield of 0.8 upon binding to double-stranded DNA, whereas SYBR Gold has a quantum yield of 0.7 and 1000-fold enhancement of fluorescence (Tuma et al. 1999). Because the SYBR dyes generate strong signals with very little background and have a high affinity for nucleic acids, they can be used in low concentrations and are more sensitive than conventional stains such as ethidium bromide. SYBR Green I and II, however, have some less desirable characteristics:

- These dyes are not optimally stimulated by standard transilluminators that emit UV radiation at 300 nm. The signal strength improves when illumination at 254 nm is used, but at this wavelength, damage to DNA is maximal.
- Both dyes penetrate agarose gels slowly. Postelectrophoretic staining can take 2 hours or more when the gels are thick or contain a high concentration of agarose.
- The dyes are not particularly photostable.
- SYBR Green I is only slightly more sensitive than ethidium bromide in detecting single-stranded DNA in agarose gels.

For these reasons, SYBR Green I and II are not commonly used to stain DNA in agarose gels. However, SYBR Green II detects RNA in denaturing agarose gels with fivefold greater sensitivity than ethidium bromide and does not interfere with northern transfer. The dye is therefore useful when analyzing quantities of RNA that are too small to be detected by ethidium bromide. SYBR

Green I, on the other hand, is used chiefly to quantify DNA in solution, for example, in real time polymerase chain reactions (please see the panel on **REAL TIME PCR** in Chapter 8, Protocol 15).

SYBR Gold, which has come onto the market more recently, is the best of the SYBR dyes. It is tenfold more sensitive than ethidium bromide, and its dynamic range is greater. Unlike SYBR Green I and II, SYBR Gold penetrates gels quickly and can therefore be used to stain DNA and RNA both in conventional neutral polyacrylamide and agarose gels and in gels containing denaturants such as urea, glyoxal, and formaldehyde. Because SYBR Gold most probably binds to the backbone of charged phosphate residues, the electrophoretic mobility of DNA stained with the dye is markedly retarded, and the bands of DNA are sometimes curved. For this reason, gels are stained with SYBR Gold after electrophoresis is complete. The level of background fluorescence is so low that no destaining is required. When excited by standard transillumination at 300 nm, nucleic acids stained with SYBR Gold generate bright gold fluorescent signals that can be captured on conventional black and white Polaroid film (type 667) or on charged couple device (CCD)-based image detection systems. The stained nucleic acids can be transferred directly to membranes for northern or Southern hybridization (Tuma et al. 1999).

Although many enzymatic reactions are not inhibited by SYBR Gold, polymerase chain reactions are sensitive to high concentrations of the dye. Inhibition can, however, be relieved by adjusting the concentration of Mg^{2+} (Tuma et al. 1999) or be avoided by removing SYBR Gold from the template DNA by standard ethanol precipitation.

SYBR Gold is supplied as a 10,000x concentrate in anhydrous dimethylsulfoxide (DMSO). The high cost of the dye precludes its use for routine staining of gels. However, the dye may be cost-effective as an alternative to radiolabeling or silver staining of DNA in techniques such as single-strand conformation polymorphism (SSCP) and denaturing gradient gel electrophoresis (DGGE).

AUTORADIOGRAPHY AND IMAGING

The first autoradiograph was obtained in 1867, when Niepce de St. Victor described the blackening of emulsions of silver chloride and iodide by uranium nitrate and tartrate. The blackening occurred even when the uranium salt was separated from the emulsion by sheets of colored glass. At that time, radioactivity had not been discovered and Niepce struggled unsuccessfully to explain his results in terms of luminescence.

Molecular cloning depends on techniques to map accurately the distribution of radioactive atoms on two-dimensional surfaces. For the last 20 years, autoradiographic images of Southern blots, northern hybridizations, DNA sequencing gels, and library screens have been the icons of the field. In autoradiography, a radioactive specimen emits radiation, generally in the form of β-particles whose image is recorded on photographic emulsion. A diagram of the events that occur during exposure of photographic emulsion to radioactivity is shown in Figure A9-1.

The emulsions used in autoradiography are suspensions of crystals (grains) of silver halide in gelatin. Exposure to radiation activates the halide crystals, producing a latent image that can be converted to a true image by development. Each β-particle emitted by the sample converts a number of silver ions to silver atoms, which are then withdrawn from the crystal lattice. The resulting latent image is unstable since the atoms of silver tend to lose their captured electrons and to resume their places in the lattice. At room temperature, this return reaction has a half-time of ~1 second. At –70°C, the rate of the return reaction is much slower, and there is little fading of the latent image.

During development, the activated nuclei of silver atoms catalyze the conversion of the entire silver halide grain into metallic silver. In most emulsions, it is necessary to activate between 5 and 10 silver atoms per crystal in order to obtain complete conversion of the crystal during development. Crystals with fewer activated silver atoms have a lower chance of development. This means that the intensity of the final image is not proportional to the intensity of the incident radiation. Low levels of radiation will generate developed images that are disproportionately faint. In photography, this phenomenon is known as low-intensity reciprocity failure.

Conversely, exposure to an intense source of light or β-particles can saturate all of the silver bromide crystals so that the emulsion becomes refractory to further radiation. The density of such burnt images is no longer proportional to the intensity of the incident radiation. Developed images whose absorbance at 545 nm exceeds 1.3 on a microdensitometer have saturated the film and cannot be used to quantitate the intensity of the original source of radiation.

The three isotopes most commonly used for autoradiography are ^{35}S, ^{33}P, and ^{32}P, all of which emit β-particles. The energies of these particles are different: ^{35}S emits a particle with a maximum energy of 0.167 MeV that can penetrate film emulsion only to a depth of 0.25 mm (see Figure A9-2). ^{33}P emissions are slightly stronger (0.249 MeV) with a maximum penetration depth of 0.6 mm. Although this depth is sufficient to allow the emitted β-particles to interact productively with silver

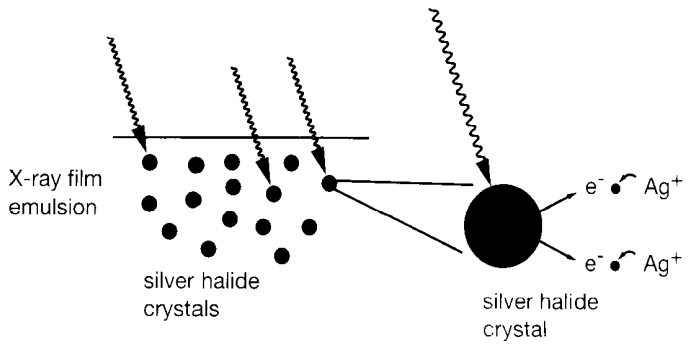


FIGURE A9-1 Events Leading to the Formation of an Autoradiographic Image

The diagram shows that particles entering the autoradiographic image cause ejection of electrons from silver halide crystals. These electrons attract positively charged silver ions, generating precipitates of silver atoms.

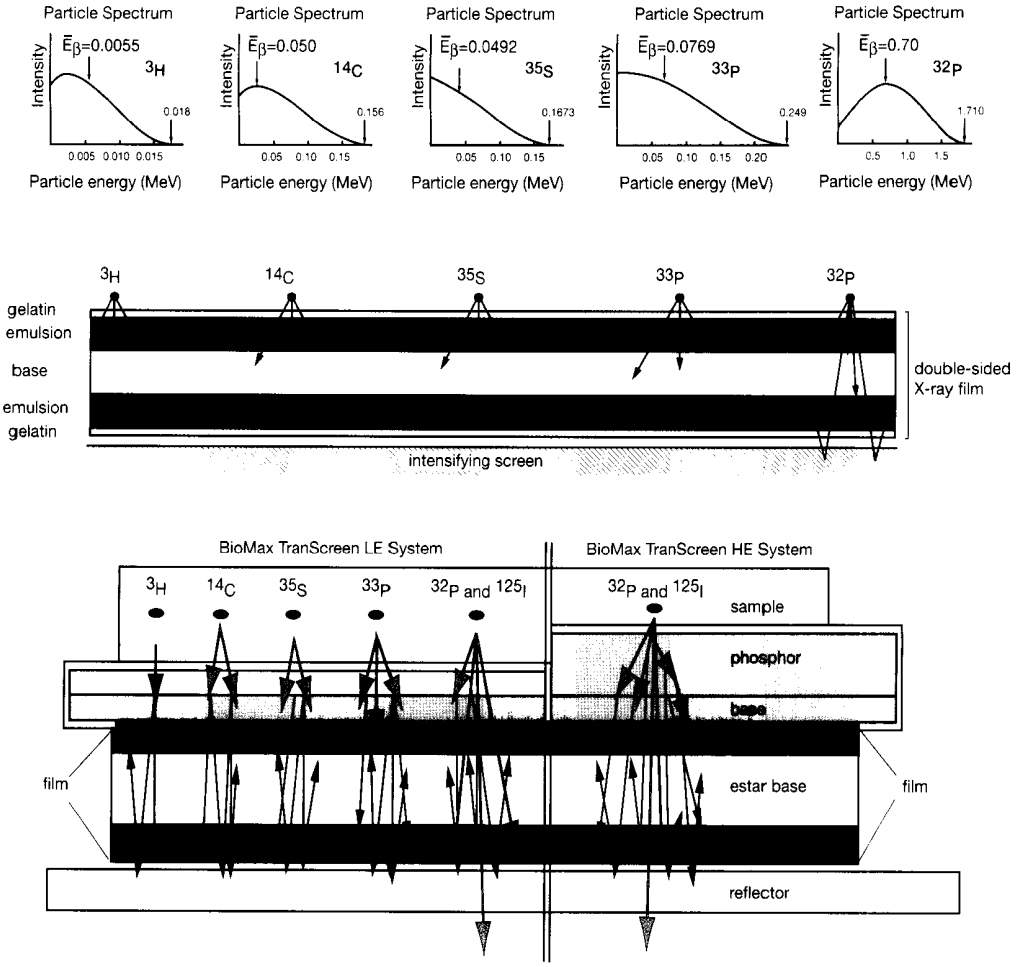

FIGURE A9-2 Energy of Radiation Emitted by Commonly Used Isotopes

(Top) Graphs show the spectra of energies carried by particles emitted by decaying radioactive isotopes. In each case, the arrow marks the average energy per particle. *(Middle)* Diagram showing the depth to which commonly used isotopes penetrate autoradiographic film. *(Bottom)* Principle of Kodak BioMax TranScreen Systems (Modified, with permission, from Eastman Kodak Company; Kodak, BioMax, and TranScreen are trademarks of Eastman Kodak Company.)

halide crystals in the emulsion, it is not enough to allow the particles to pass through barriers (e.g., Saran Wrap) that might be placed between the film and the source of the radiation. Thus, when establishing autoradiographs of ^{35}S- or ^{33}P-labeled material, it is essential that the film and the source of the radiation be directly apposed to one another. To reduce internal absorption of radiation, gels should be as thin as possible and should be fixed and dried before autoradiographs are taken. Nitrocellulose and nylon filters should be thoroughly dried, and care should be taken to ensure that the surface carrying the radioactivity is placed in contact with the film. (*Warning:* Damp gels and membranes stick tightly to the film and usually cannot be removed.)

^{32}P, by contrast to ^{35}S and ^{33}P, emits a β-particle with sufficient energy (1.709 MeV) to penetrate water or plastic to a depth of 6 mm and to pass completely through an X-ray film. Gels and filters therefore need not be completely dried (although the sharpness of the autoradiographic image is much improved if they are) and can be covered with Saran Wrap before they are exposed to the film. Radiation from ^{32}P is strong enough to require shielding by 1-cm Plexiglas, which blocks β-particles while minimizing production of Bremstrahlung.

AUTORADIOGRAPHY AND PHOSPHORIMAGING

Intensifying Screens

Strong β-particles, such as those emitted by decay of ^{32}P, can pass undetected through X-ray film. To increase the efficiency with which high-energy particles are detected, an intensifying screen may be placed behind the X-ray film. Radioactive particles that pass through the film hit the intensifying screen and cause it to emit photons that are captured by silver halide crystals in the emulsion. The efficiency of the intensifying screen is determined largely by the thickness of the phosphor layer. A thicker phosphor layer results in a "faster" screen because the thick layer absorbs more radiation than a thin layer. Thick screens are faster, but generate fuzzier images on film, due primarily to diffusion of light in the phosphor layer.

Most conventional intensifying screens are made of calcium tungstate, which emits blue light after capture of β-particles. Other screens contain rare earths such as lanthanum oxybromide (blue light) or gadolinium oxysulfide, which emits green light. Modern calcium tungstate screens such as Lightning Plus (Dupont, Cronex) enhance the intensity of an autoradiographic image by a factor of ~5 when the film is exposed at low temperature (−70°C) to retard the decay of the latent image (Koren et al. 1970; Swanstrom and Shank 1978). Intensifying screens are usually used in pairs, with double-sided X-ray film and the ^{32}P-labeled sample sandwiched between the two screens in a light-tight cassette.

Conventional intensifying screens do not improve the efficiency with which low-energy β-particles can be captured by X-ray film. It is therefore a waste of time to use these screens with samples that are labeled with ^{35}S, ^{33}P, ^{14}C, or ^{3}H (Laskey and Mills 1977; Sanger et al. 1977). However, specialized screens for use with these isotopes are available from Kodak. These screens are placed between the sample and the film. β-particles from the sample are captured by the screen and converted into photons, which are then detected by the film, as illustrated in Figure A9-2. The signal enhancement provided by TranScreen is generally equivalent to the sensitivity obtained using fluorography.

Preflashing

The spectral emission of some phosphors requires that an appropriately sensitized film be used or much of the light will be wasted. Accordingly, the efficiencies with which low levels of radioactivity can be detected are increased by a further twofold by preexposing the film to a short (~1 msec) flash of light emitted by a stroboscope or a photographic flash unit. This exposure generates stable pairs of silver atoms within each silver halide crystal and therefore increases the probability that an incoming particle of radiation will generate an activated crystal, which will be reduced to silver metal during the developing process. The distance of the light source from the film during preexposure should be determined empirically as follows (Laskey and Mills 1975, 1977). Note that preflashing is not recommended for high-sensitivity films such as BioMax (Kodak). Preflashing these films induces high levels of background.

1. Cover the stroboscope or flash unit with an orange filter (Kodak, Wratten 21 or 22A). This filter reduces the amount of incident blue light, to which X-ray film is very sensitive.
2. Working in total darkness, place the film perpendicular to the light source and at least 50 cm away from it. This prevents uneven illumination. Cover the film with a diffusing screen. If a suitable screen is not available, use a piece of Whatman No. 1 filter paper.

3. Expose a series of test films to the light source for different lengths of time and then develop the films. Cut the films into pieces that will fit neatly into the cuvette holder of a spectrophotometer. Measure the absorbance at 545 nm of the exposed films against a blank consisting of film that was not preexposed. Choose an exposure time that causes the absorbance to increase by 0.15.

Preflashed film has another advantage: The intensity of the image on the film becomes proportional to the amount of radioactivity in the sample (Laskey 1980). The intensity of autoradiographic images on preexposed film can therefore be quantitated by microdensitometry and be used to measure the amount of radioactivity in the original sample. By contrast, the silver halide crystals in film that is not preexposed to light are not fully activated and therefore respond in a sigmoidal fashion to increasing amounts of radioactivity (Laskey and Mills 1975, 1977). This relationship can complicate quantitation of autoradiographic images. The best types of films, for all types of autoradiography except fluorography, are Kodak X-Omat-R and Fuji RX. When preexposed, these films yield images whose absorbances are proportional to the intensity of the source of radioactivity over a range of 0.15–1.0. However, true linear responses are only obtained when (1) the background absorbance of the film at 545 nm is raised to an OD of 0.10–0.20 and (2) the presensitizing flash is brief (~1 msec).

Fluorography

The intensity of autoradiographic images of weak β-emitters such as ^{3}H, ^{14}C, and ^{35}S can be enhanced by impregnating the samples with chemicals that are fluorescent and emit many photons when they encounter a single quantum of radiation (Wilson 1958, 1960). Fluorography increases the sensitivity of detection of ^{14}C and ^{35}S approximately tenfold and permits detection of ^{3}H, which is otherwise virtually invisible to conventional autoradiography. Fluorography is therefore particularly useful for the detection of radiolabeled proteins and nucleic acids in polyacrylamide gels.

In the original methods (Bonner and Laskey 1974; Laskey and Mills 1975), aqueous gels containing the radioactive samples were equilibrated with DMSO, impregnated with the scintillant PPO (2,5-diphenyloxazole), soaked in H_2O to remove the DMSO, dried, and exposed to X-ray film at –70°C. These procedures were costly, tedious (requiring at least 5 hours of work), and irreproducible in inexperienced hands. The most frequent cause of difficulty was the failure to remove DMSO: Complete removal is essential to avoid sticky gels after drying. Because of these problems, a number of alternative solvents have been developed to deliver PPO to the sample. These include ethanol (Laskey 1980), glacial acetic acid (Skinner and Griswold 1983), and several other organic solvents (e.g., please see Shine et al. 1974; Southern 1975).

Despite these improvements, PPO has now largely been replaced as a scintillant by sodium salicylate (Chamberlain 1979) or by commercial scintillants (see below). With sodium salicylate, the level of enhancement is approximately equal to that obtained with organic scintillants, although the bands are slightly more diffuse. Commercially available aqueous scintillants such as En^{3}Hance, Enlightning, or Entensify (NEN Life Science Products) and Amplify (Amersham) are supplied in liquid and spray-on form and, if used in accordance with the manufacturer's instructions, give results every bit as good as those obtained with PPO, with far less work. However, they are exceedingly expensive.

The types of X-ray film used for fluorography should match the fluorescence spectrum of the scintillant. Sodium salicylate emits at 409 nm, whereas PPO emits at 375 nm. Commercial enhancers emit either blue or UV light. Films that are sensitive in this region of the spectrum are called "screen-type" X-ray films and include Kodak BioMax MS, Amersham Hyperfilm-MP, and Fuji RX.

TABLE A9-1 Sensitivity of Autoradiographic Methods for Detection of Radioisotopes

Isotope	Method	Sensitivity (dpm/mm^2)
^{35}S	no enhancement	30–60
	fluorography	2–3
	TranScreen LE (Kodak)	0.8–1.2
^{32}P	direct	2–5
	intensifying screen	0.5
	TranScreen HE (Kodak)	0.05–0.1
^{33}P	direct	15–30
	intensifying screen	1–1.5
	TranScreen LE (Kodak)	0.4–0.6
^{14}C	fluorography	2
	TranScreen LE (Kodak)	0.8–1.2
^{125}I	intensifying screen	1–2
^{3}H	fluorography	10–20
	TranScreen LE (Kodak)	74–110

Sensitivity of Different Autoradiographic Methods

Table A9-1 shows the sensitivities of different autoradiographic methods for the detection of radioisotopes, with and without various enhancements. The amounts of radioactivity shown in the table are those required to obtain a detectable image (A_{545} = 0.02) on preflashed film that is exposed to the sample for 24 hours. Much longer exposure times may be necessary to obtain publishable images.

Setting up Autoradiographs

1. Prepare gels for autoradiography in one of the following ways:
   a. Fix the SDS-polyacrylamide gels containing ^{33}P or ^{35}S, ^{14}C, or ^{3}H as described in Chapter 5, Protocol 11. Use a commercial gel dryer to dry the gels onto Whatman 3MM paper.
   b. Fix the sequencing gels containing ^{33}P or ^{35}S as described in Chapter 12, Protocol 12. Use a commercial gel dryer to dry the gels onto Whatman 3MM paper.
   c. For maximal sensitivity and resolution, fix, dry, and mount the polyacrylamide gels containing ^{32}P on backing paper.

      Satisfactory images of wet, unfixed gels can also be obtained as long as the gels are sealed in a plastic bag or wrapped in Saran Wrap before they are exposed to the film (please see Chapter 5, Protocol 11). ^{32}P-labeled nucleic acids in agarose gels can be detected by exposing the wet gel (wrapped in Saran Wrap) to X-ray film. However, for maximal sensitivity and resolution, transfer the radiolabeled nucleic acids to a solid support (nitrocellulose or nylon membrane) as described in Chapter 6, Protocol 8. Dry the solid supports and cover with Saran Wrap to prevent contamination of intensifying screens and film holders.

2. Place pieces of tape marked with radioactive ink around the edge of the sample on the backing paper or Saran Wrap. Cover the pieces of tape with Scotch Tape. This arrangement prevents contamination of the film holder or intensifying screen with the radioactive ink.

   Alternatively, attach luminescent labels to the paper or Saran Wrap. These may be purchased from several manufacturers (e.g., Stratagene).

3. In a darkroom, place the sample in a light-tight X-ray film holder and cover it with a sheet of X-ray film. If preflashed film is used, the preexposed side should face the sample; if an intensifying screen is used, the preexposed side should face the intensifying screen.
4. Expose the film for an appropriate length of time (see Table A9-1). When conventional intensifying screens or fluorography is used, the film must be exposed at –70°C. The low temperature stabilizes the silver atoms and ions that form the latent image of the radioactive source.
5. Remove the film holder from storage (use gloves to handle holders stored at –70°C). In a darkroom, remove the film as quickly as possible and allow it to warm up to room temperature before developing.

   If it is necessary to obtain another autoradiograph, apply another film immediately and return the film holder and screens to the freezer as rapidly as possible. If condensation forms before the new film can be applied, allow the sample and screens to reach room temperature and wipe away all condensation before applying the new film.
6. Develop the X-ray film either in an automatic X-ray film processor or by hand as follows:

   X-ray developer
   5 minutes

   3% acetic acid stop bath or water bath
   1 minute

   rapid fixer
   5 minutes

   running water
   15 minutes

   The temperatures of all solutions should be 18–20°C.
7. Use the images of the radioactive or luminescent markers to align the autoradiograph with the sample.

Phosphorimaging

Autoradiography has been the mainstay of molecular cloning for many years. Recently, however, two types of phosphorimaging devices have become available that create images of radiation sources on computer screens rather than on conventional photographic film. One type of device (area detector) scans the gel or filter in small windows with a Geiger counter, compiling a contour map of the number of radioactive disintegrations per unit area. The other device uses plates coated with a light-responsive phosphor. The film or filter is directly exposed to the plates, and the energy emitted is stored in a europium-based coating. The plates are then scanned by a laser, releasing photons that are collected to form an image. Both devices present the image on a computer screen. These instruments are more expensive than those required for conventional autoradiography and the images have a lower resolution. However, the images can be detected in ~10–20% of the time required by conventional autoradiography and a darkroom is not required. In addition, the linear range of imaging instruments extends over about five orders of magnitude, an improvement of at least 100-fold over conventional X-ray film. Densitometric analysis of images is therefore more accurate and far simpler. Details of phosphorimaging methodology will vary with the device used and manufacturers' instructions should be followed. The images are captured electronically and can be stored and prepared for publication using programs such as Adobe Photoshop (Adobe Systems Incorporated).

Isotopic Data

TABLE A9-2 Isotopic Data

^{3}H		^{35}S		^{32}P	
Time (Years)	% Activity Remaining	Time (Days)	% Activity Remaining	Time (Days)	% Activity Remaining
1	94.5	2	98.4	1	95.3
2	89.3	5	96.1	2	90.8
3	84.4	10	92.3	3	86.5

60	50.0				

One Curie (Ci) is equivalent to the amount of an isotope undergoing 3.7×10^{10} nuclear disintegrations/second (2.22×10^{12} disintegrations/minute). 1 Ci = 3.7×10^{10} becquerels (Bq).

1 Bq = 2.7×10^{-11} Ci
1 μCi = 37×10^{3} Bq = 37 kBq = 2.22×10^{6} dpm
1 mCi = 37×10^{6} Bq = 37 MBq = 2.22×10^{9} dpm
1 Ci = 37×10^{9} Bq = 37 GBq = 2.22×10^{12} dpm

CHEMILUMINESCENCE

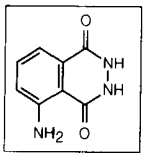
Larry J. Kricka
Department of Pathology and Laboratory Medicine, University of Pennsylvania, Philadelphia

Radioactive reagents have been gradually replaced by nonisotopic reagents for some tasks in molecular biology. Concern over laboratory safety and the economic and environmental aspects of radioactive waste disposal have been key factors in this change. Generally, the new nonisotopic systems have improved in terms of analytical sensitivity and the time required to obtain a result. The most prominent nonisotopic analytical methods exploit chemiluminescence. This technique has been particularly effective when used in combination with an enzyme label, so that the amplifying properties of an enzyme label and the high sensitivity of a chemiluminescent detection reaction are combined to produce an ultrasensitive assay (e.g., chemiluminescent detection of peroxidase- and alkaline-phosphatase-labeled proteins and nucleic acid probes). In all of the commonly used applications in molecular biology, the analytical performance of the chemiluminescent systems approaches that of ^{125}I- or ^{32}P-based systems. Chemiluminescent systems also avoid the lengthy signal detection times required with ^{32}P-based methods, yielding results in minutes rather than days. In addition, chemiluminescent probes can be easily stripped from membranes, allowing the membranes to be reprobed many times without significant loss of resolution. Experimental protocols for directly attaching nonisotopic labels to nucleic acids and indirect labeling methods based on biotin, fluorescein, and digoxigenin labels are now well established. The ancillary reagents (e.g., avidin, streptavidin, antidigoxigenin, and antifluorescein enzyme conjugates) required for the indirect methods are widely available. In addition, several companies have developed complete kits of labeling and detection reagents to simplify and facilitate the application of the chemiluminescent assays.

Chemiluminescence is the light emission produced in certain chemical reactions as a result of the decay of chemi-excited intermediates to the electronic ground state. Most chemiluminescent reactions are oxidation reactions because the production of visible light requires highly energetic reactions (63.5 kcal/mole for visible light at 450 nm) (please see the panel on **CHEMILUMINESCENT REACTIONS**).

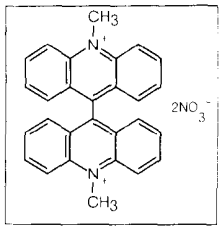
CHEMILUMINESCENT REACTIONS

Acridinium ester + peroxide + base
Adamantyl 1,2-dioxetane aryl phosphate + alkaline phosphatase
Lucigenin + peroxide + base
Luminol + peroxide + base
Nitric oxide + ozone
bis(2,4,6-trichlorophenyl)oxalate + peroxide + fluorescer



Generally, chemiluminescent reactions are inefficient, especially in aqueous environments, and the chemiluminescent quantum yields are typically <10%. Despite such inefficiency, this type of reaction is analytically useful and there are many highly sensitive assays based on compounds with quantum yields of only 1% (e.g., luminol [5-amino-2,3-dihydro-1,4-phthalazinedione]; the chemical structure of luminol is shown at the left).

Chemiluminescence has a long history (for a review, please see Campbell 1988) and some of the compounds in routine use today have been known for a long time. Luminol was first synthesized in 1853 (its chemiluminescent properties were not recognized until 1928), and lucigenin



(bis-*N*-methylacridinium nitrate; the chemical structure of lucigenin is shown at the right) was synthesized in 1935. Chemiluminescent reactions are known in the gas phase (reaction of nitric oxide and ozone), liquid phase (e.g., luminol oxidation reaction), and solid phase (e.g., phosphorous oxidation reaction) (Gundermann and McCapra 1987; Campbell 1988; Van Dyke and Van Dyke 1990).

There are numerous applications for chemiluminescent reactions ranging from the familiar emergency lighting that exploits the fluoresence-sensitized peroxyoxalate oxidation reaction (Cyalume Lightsticks) to the study of phagocytosis using lucigenin or luminol to enhance weak cellular chemiluminescence (Allen and Loose 1976). In molecular biology, chemiluminescent compounds are used as labels in nucleic acid probe and protein blotting applications (e.g., Southern and western blotting), and as reagents to detect enzyme-labeled nucleic acids and proteins (Tables A9-3 and A9-4) (Kricka 1992; Nozaki et al. 1992). Specific advantages of chemiluminescent assays and protocols are improved sensitivity over conventional radiometric, colorimetric, and fluorometric detection systems, hazard-free reagents, rapid results, and versatile assay formats (e.g., solution- and membrane-based assays).

Chemiluminescent Labels

Acridinium Esters and Related Compounds

Light emission from an acridinium-ester-labeled antigen or antibody, prepared using an activated label (2′,6′-dimethyl-4′-[*N*-succinimidyloxycarbonyl]phenyl 10-methylacridinium-9-carboxylate), is triggered by simply adding a mixture of sodium hydroxide and hydrogen peroxide. The light is emitted as a rapid flash lasting <5 seconds, and this time scale imposes certain constraints on the initiation of light production and its measurement (Weeks et al. 1983; Law et al. 1989). Usually, the light emission is measured by injecting the reagents into the assay tube positioned directly in front of a photodetector in the light-tight measuring chamber of the luminometer. Acridinium esters and the acridinium carboxamide analogs (acridinium-9-[*N*-sulfonyl]carboxamide) (Kinkel et al. 1989; Mattingly 1991) are the principal chemiluminescent labels used in immunoassay (available from Assay Designs Inc, Athens, GA; Behringwerke AG, Marburg, Germany; Ciba Corning Diagnostics, Medfield, MA, and Molecular Light Technology Research Ltd, Cardiff, UK). The detection limit for this type of label is ~0.5 attomole (0.5×10^{-18} moles).

Nonseparation DNA probe assays based on hybridization protection have been devised (Arnold et al. 1989). This type of assay does not require the separation of bound from unbound labeled species and so can be conveniently performed in a single step. The hybridization protection assay format exploits the millionfold difference in the hydrolysis rate of an acridinium-ester-

TABLE A9-3 Chemiluminescent Assays for Immunoassay and Nucleic Acid Hybridization Labels

Enzyme	Substrate	Detection Limit (Zeptomoles)
Acridinium ester	NaOH + peroxide	500
Alkaline phosphatase	AMPPD	1
β-D-galactosidase	AMPGD	30
Horseradish peroxidase	luminol + perborate + 4-iodophenol	5,000
Isoluminol	microperoxidase + peroxide	50,000
Xanthine oxidase	luminol + Fe EDTA	3,000

labeled probe that is hybridized to complementary target DNA and labeled probe free in solution. Hydrolysis using a pH 7.6 borate buffer destroys the chemiluminescent property of the label, and the light emission produced after the hydrolysis step is due solely to the hybridized labeled probe (available from Gen-Probe, San Diego, CA).

Luminol and Its Analogs

Luminol was the first chemiluminescent compound to be used as an immunoassay label (Schroeder et al. 1978). Light emission is triggered by adding an oxidant (e.g., hydrogen peroxide) in the presence of a suitable catalyst (horseradish peroxidase, microperoxidase, ferricyanide). However, labeling via the 5-amino group of luminol reduced light emission by a factor of 10. Isoluminol, the 6-amino isomer of luminol, is less efficient than luminol (quantum yield 0.1%), but labeling at the 6-position increases the light emission by a factor of 10, and thus this compound, and its amino-substituted analogs, such as *N*-(4-aminobutyl)-*N*-ethylisoluminol (ABEI), have become the favored labels for immunoassay applications (Kohen et al. 1979; Pazzagli et al. 1982).

Pyridopyridazines represent a separate class of chemiluminescent compounds. Early data indicate that these compounds, particularly the 8-amino-5-chloro-7-phenyl and 8-hydroxy-7-phenyl derivatives, will be useful as labels and co-substrates for detection of peroxidase labels. Compared to luminol, these compounds have a much more intense chemiluminescence (~50-fold) (Masuya et al. 1992).

Chemiluminescent Enzyme Assays

Alkaline Phosphatase

Adamantyl 1,2-dioxetane aryl phosphates (e.g., AMPPD; disodium 3-(4-methoxyspiro[1,2-dioxetane-3,2′-tricyclo[3.3.1^{3,7}]decan]-4-yl)-phenylphosphate) and the 5-substituted analogs (e.g., 5-chloro: CSPD; available from Tropix Inc.) have become extremely popular as chemiluminescent substrates for alkaline phosphatase labels (Bronstein et al. 1989, 1990, 1991; Schaap et al. 1989). The detection limit for the enzyme is 1 zeptomole (10^{-21} moles) and the light emission is long-lived (>1 hour), thus making this an ideal system for use with membrane-based assays. The light emission from this reaction can be enhanced by a nylon membrane surface and by certain polymers, for example, polyvinylbenzyl(benzyldimethylammonium) chloride. In the case of nylon, the enhancement is due to sequestering of the dephosphorylated intermediate in hydrophobic domains; these stabilize and minimize nonluminescent decomposition of the intermediate. Chemiluminescent assays for alkaline phosphatase labels are now used widely for blotting and DNA sequencing (Beck and Köster 1990; Tizard et al. 1990).

β-galactosidase

Adamantyl 1,2-dioxetane aryl galactoside substrates (AMPGD) for this enzyme are increasing in popularity. The enzyme cleaves the galactoside group from the 3-position of the aromatic ring to produce a phenoxide intermediate, and this compound decomposes to produce light. The detection limit for the enzyme using this assay is 30 zeptomoles.

Horseradish Peroxidase

Luminol and other cyclic diacylhydrazides serve as chemiluminescent cosubstrates for horseradish peroxidase. The basic isoenzyme of horseradish peroxidase can be assayed in amounts <5 attomoles (5×10^{-18} moles) using an assay reagent comprising luminol, hydrogen peroxide, and an enhancer (e.g., 4-iodophenol or 4-hydroxycinnamic acid) (Whitehead et al. 1983; Thorpe et al. 1985; Thorpe and Kricka 1986). Enhancement of the acidic isoenzymes of peroxidase is much less effective. The role of the enhancer is to increase the intensity of the light emission and reduce background light emission due to oxidation of luminol by peroxide or other oxidants. This dual effect has dramatic impact on the detection of peroxidase activity and increases the ratio of signal to background by several thousandfold (the enhanced chemiluminescent assay reagents are available from Amersham). This sensitive assay for peroxidase (>10-fold more sensitive than a colorimetric assay) has been combined effectively with the catalyzed reporter deposition (CARD) protocol (Wigle et al. 1993). In this amplification scheme, a peroxidase label reacts with a biotin tyramine substrate to produce highly reactive radical products that react with the label and any protein in the immediate vicinity of the label. Next, deposited biotin groups are reacted with streptavidin-peroxidase (in this way, the original peroxidase label is amplified manyfold), and bound peroxidase is detected using the enhanced chemiluminescent assay. Significant improvements in sensitivity were achieved using the combination of CARD and chemiluminescent detection as opposed to colorimetric detection of the deposited peroxidase.

Xanthine Oxidase

This enzyme can be assayed using a mixture of luminol and an iron EDTA complex (Baret et al. 1990; Baret and Fert 1990). The assay is sensitive (detection limit 3 attomoles), and one notable advantage is that the light emission from the xanthine-oxidase-catalyzed chemiluminescent reaction is very long-lived (>96 hours).

Glucose Oxidase

Several chemiluminescent assays for glucose oxidase have been developed. Isoluminol or luminol in the presence of a microperoxidase catalyst can be used to assay peroxide produced by the action of glucose oxidase on glucose (Sekiya et al. 1991); alternatively, the peroxide can be measured using the chemiluminescent fluorophore-sensitized bis(2,4,6-trichlorophenyl) oxalate reaction (Arakawa et al. 1982).

Commercial Reagents, Kits, and Luminometers

Comprehensive surveys of available chemiluminescent reagents and kits and luminometers for the measurement of light emission have been published (please see Stanley 1992, 1993). Also available are a series of compilations of references to current developments in both the fundamental and applied aspects of chemiluminescence (please see Kricka and Stanley 1992; Kricka et al. 1993; Wilkinson 1998). Chemiluminescence can be detected using a range of measuring devices, including a photomultiplier tube (in photon counting or less sensitive photon current mode) or silicon photodiode, or it can be imaged using a CCD camera (Wick 1989) or photographic film (Kricka and Thorpe 1986). CCD cameras are gaining in popularity because they are a convenient and sensitive means of detecting light emission from a two-dimensional source such as a membrane or a 96-well microplate. In addition, the kinetics of light emission are easily monitored, and image enhancement and background subtraction improve the quality of the results.

BIOLUMINESCENCE

Bioluminescent organisms generate light from chemical reactions that are catalyzed by enzymes called luciferases. Many of these reactions are extremely efficient and produce about one photon per luciferase cycle. In the laboratory, light generated by the action of luciferases can be captured, amplified, and measured in a luminometer. A sensitive instrument can detect the light produced by the activity of 2×10^4 luciferase molecules (10^{-20} moles), a level that is several orders of magnitude more sensitive than any non-light-producing enzymatic reaction. Because assays for luciferases are simple to perform, luciferase genes have become widely used as reporters which, when linked to appropriate regulatory elements, provide accurate measurements of the level of gene expression. In the short space of 3 or 4 years, luciferases have replaced chloramphenicol acetyltransferase (CAT) as the reporter system of choice. Assays for luciferase are more sensitive, faster, and less expensive than CAT assays; they do not require the use of radiolabeled compounds and may not involve the destruction of the host cells.

Luciferases are widely distributed in nature and are diverse in structure. The best studied are those of the common North American firefly *Photinus pyralis* (*Photinus* luciferin 4-mono-oxygenase) and the marine microorganism *Vibrio harveyi* (alkanal, reduced-FMN:oxido oxidoreductase). The properties and substrate specificities of these two luciferases are very different.

Firefly Luciferase

Firefly luciferase catalyzes the oxidative decarboxylation of D(−) luciferin in the presence of ATP-Mg^{2+} to generate oxyluciferin and light:

$$\text{luciferin} + \text{ATP-Mg}^{2+} + \text{luciferase} \rightarrow \text{luciferase:luciferyl-AMP} + PP_i$$

$$\text{luciferase:luciferyl-AMP} + O_2 \rightarrow \text{luciferase} + \text{oxyluciferin} + CO_2 + \text{AMP} + h\nu\ (562\ \text{nm})$$

Luciferin is a generic term for substrates that generate light during oxidation catalyzed by luciferases. Firefly luciferin, 6-hydroxybenzothiazole [D-(−)-(6′hydroxy-2′benzothiazolyl)D^2-thiazoline-4-carboxylic acid] was first isolated in pure form from fireflies in 1957 by Bitler and McElroy; 9 mg of pure luciferin was obtained from 15,000 fireflies. Nowadays, luciferin is synthesized chemically.

Properties of Firefly Luciferase

Firefly luciferase is a 521-amino-acid protein with a predicted molecular weight of 57,000 (de Wet et al. 1987) that is targeted to peroxisomes in all organisms in which the protein is expressed (Keller et al. 1987; for review, please see Gould and Subramani 1988). The membrane-bound nature of peroxisomes undoubtedly limits access of substrates (luciferin and ATP) to the enzyme and may account for the low level of light produced when firefly luciferase is assayed in intact mammalian cells (de Wet et al. 1987; Gould and Subramani 1988). Deletion or mutation of the three carboxy-terminal amino acid residues generates cytosolic forms of the enzyme. Several of these cytoplasmic mutants appear to retain full enzymatic activity (Gould and Subramani 1988), but it is not yet known whether they are more accessible to substrates that are added to the extracellular medium.

In addition to tolerating changes at its carboxyl terminus, firefly luciferase will accept alterations to its amino terminus. The enzyme has been expressed in *E. coli* (1) as a fusion protein that lacks the first six amino acids of luciferase and contains eight amino-terminal residues encoded by the expression vector and the synthetic oligonucleotide used for cloning (de Wet et al. 1985) and (2) as a 92-kD fusion with a modified *Staphylococcus aureus* A protein (Subramani and

DeLuca 1988). A series of eukaryotic expression vectors for measuring promoter strength has been developed by Promega. A particularly useful version, the Dual Luciferase Reporter Assay System (DRL), encodes two luciferases, one from the firefly and the other from the sea pansy (*Renilla reniformis*). This dual reporter assay provides a convenient internal standard for normalization of gene expression measurements.

Firefly luciferase, isolated either from fireflies or from *E. coli* expressing a cloned copy of the luciferase gene, is available commercially (Boehringer Mannheim, Sigma, and Promega). A solution of purified firefly luciferase (1 mg/ml) has an absorbance at 280 nm of 0.75 (DeLuca and McElroy 1978).

Assays for Firefly Luciferase

Luminometry. Addition of ATP and luciferin to preparations of firefly luciferase generates a flash of light that peaks 0.3 second later and lasts for a few seconds. Within 1 minute after mixing substrate and enzyme, the intensity of the emitted light falls to ~10% of peak values and then declines more slowly over a period of several minutes. The decay in light emission is caused by slow turnover of the enzyme and product inhibition by pyrophosphate (DeLuca and McElroy 1978). Dissociation of the enzyme-product complex occurs more efficiently in the presence of acetyl–coenzyme A (CoA) (Wood 1991) and nonionic detergents such as Triton X-100 (Kricka and DeLuca 1982). The concentration of ATP in the assay affects the intensity of light produced in the two phases of the reaction. Firefly luciferase has two distinct, catalytically active ATP-binding sites. One site is responsible for the initial flash, whereas the second, which has a higher affinity for ATP, is involved in the continuous production of light of lower intensity (DeLuca and McElroy 1984). Assays for luciferase generally contain concentrations of ATP that are sufficient to saturate both sites of the enzyme. Under these conditions, the amount of light emitted during the initial flash is proportional to the amount of enzyme in the reaction mixture over five orders of magnitude. Because of the short duration of the initial flash, most assays for luciferase require special luminometers that are designed to allow injection and rapid mixing of reagents and immediate analysis of the emitted light. A moderately priced luminometer can detect as little as 0.03–0.10 pg of luciferase.

An improved luciferase assay system is available from Promega. The system generates a burst of light whose intensity remains nearly constant for ~20 seconds and then decays slowly with a half-time of 5–10 minutes. These more favorable kinetics are achieved by including Triton X-100 and acetyl-CoA in the assay system. Luciferin is oxidized more efficiently by luciferyl-CoA than by luciferyl-AMP (Wood 1991). The emitted light can be measured either in a luminometer or in a liquid scintillation counter.

Liquid scintillation spectroscopy. If a luminometer is not available, firefly luciferase can be assayed in a conventional liquid scintillation counter. Reaction conditions have been reported that minimize the intensity of the initial flash and optimize the long-lasting emission of low-intensity light by firefly luciferase (Nguyen et al. 1988). The reactions are carried out in microfuge tubes or 96-well plates (Schwartz et al. 1990), and the emitted light is measured in a channel of a scintillation counter that detects chemiluminescence. Collection of data begins a few seconds after the reagents have been mixed and continues for 3–5 minutes. Under optimal conditions, measurement of long-lasting emission of light in a scintillation counter is as sensitive an assay for firefly luciferase as luminometry.

Some scintillation counters are not equipped with a preset channel for detection of chemiluminescence. However, the standard channels used for counting of atomic disintegration can be used for assay of luciferase provided the coincidence circuit is turned off. The counts per minute are then proportional to the intensity of luminescence. If the coincidence circuit cannot be turned

off, the intensity of luminescence will be proportional to the square root of the counts per minute after background has been subtracted.

Photographic and X-ray film. Firefly luciferase can be detected by exposing the light-emitting reaction to X-ray or photographic films (de Wet et al. 1986; Wood and DeLuca 1987). This method is useful for preliminary screening of samples for the presence or absence of firefly luciferase (e.g., screening tissue extracts of transgenic animals or estimating the relative efficiencies of a series of mutant promoters).

Firefly Luciferase as a Reporter Molecule

The use of luciferase as a reporter gene follows the same basic strategy developed for other reporter gene systems. In brief, a segment of DNA containing putative regulatory *cis*-acting elements is inserted into a plasmid upstream of a cloned copy of luciferase cDNA. The chimeric construct is used to transfect cultured cells of the appropriate type, and luciferase activity is assayed some time later in extracts of the transfected cells. When the assay is carried out in the presence of excess substrates, the amount of luminescence is proportional to the concentration of newly synthesized enzyme. Because extracts are likely to contain ATP, whose concentration is unknown, luciferase is generally measured by adding luciferin as the last substrate. Promoterless expression vectors for luciferase have been described by Nordeen (1988). Another suitable plasmid, pGEM-*luc*, sold by Promega, contains the firefly luciferase gene positioned in the center of the multiple cloning region of pGEM-11Zf(−).

Cultures of mammalian cells (2×10^5 cells) transfected by the calcium phosphate method with a reporter construct in which expression of firefly luciferase is driven by a moderately strong promoter produce ~15–50 ng of luciferase. Luciferase activity is stable for several weeks in extracts of cells stored at 4°C.

Luciferase was first used in 1988 as a reporter for promoter activity in transgenic mice (DiLella et al. 1988). Since then, it has been used sucessfully as a reporter to measure the tissue specificity, developmental expression, and strength of more than a dozen different promoters in transgenic animals. Luciferase is commonly used as a reporter to locate and analyze regulatory elements in mammalian genes (e.g., please see van Zonneveld et al. 1988; Economou et al. 1989; Hudson et al. 1989). In addition, luciferase has been used (1) to identify proteins that influence gene transcription (Waterman et al. 1988; Mellon et al. 1989), (2) to investigate the effects of mRNA structure on protein synthesis (Baughman and Howell 1988; Malone et al. 1989), and (3) to measure rates of intracellular protein recycling (Nguyen et al. 1989). Luminometric measurements can detect ~5×10^5 molecules of luciferase in 10 mg of protein in a crude tissue extract, which is a fivefold increase in sensitivity over assays for CAT activity in tissue extracts (Robinson et al. 1989).

Bacterial Luciferase

Luciferase of *Vibrio harveyi* is a heterodimer whose α and β subunits (355 and 324 amino acids, respectively) are encoded by the bacterial *luxA* and *luxB* genes. These genes, which are part of an operon (Belas et al. 1982; for review, please see Ziegler and Baldwin 1981), have been cloned, sequenced, and expressed, first in *E. coli* (Baldwin et al. 1984; Cohn et al. 1985; Johnston et al. 1986) and then in plants, where the *luxA* and *luxB* cistrons were placed downstream from two separate promoter elements (Koncz et al. 1987). The termination codon of *luxA* and the short intercistronic distance separating *luxA* and *luxB* have been replaced by sequences encoding polypeptide linkers (Boylan et al. 1989; Kirchner et al. 1989). The resulting fused *luxA* and *luxB* genes express highly active luciferase that can be assayed in yeast, *E. coli*, and plant cells. This abil-

ity to express bacterial luciferase as a single polypeptide removes a major obstacle to its use as a reporter molecule in mammalian cells. Bacterial luciferase catalyzes the oxidation of long-chain aldehydes into carboxylic acids using $FMNH_2$ as a cofactor, producing photons as one of the reaction products:

$$RCHO + O_2 + FMNH_2 \rightarrow RCOOH + FMN + H_2O + h\nu\ (490\ nm)$$

where R is an aliphatic moiety containing at least seven carbon atoms; FMN is a flavin mononucleotide; and $FMNH_2$ is a reduced flavin mononucleotide. Bacteria contain enough $FMNH_2$ to drive this reaction, and light emission can therefore be measured directly from intact cells, allowing gene expression to be assayed in real time (e.g., please see Legocki et al. 1986). In yeasts, the intracellular concentration of $FMNH_2$ is much lower, and the intensity of in vivo luminescence is therefore far lower than in intact bacteria. However, the level of light produced in intact yeast cells expressing the bacterial *lux* genes is still 1000-fold over background and significantly above that reported for firefly luciferase (Tatsumi et al. 1988). Intact cells of higher eukaryotes do not contain enough $FMNH_2$ to drive the reaction catalyzed by the fused *luxAB* genes. However, addition to cell extracts of $FMNH_2$ and an $FMNH_2$-generating system (e.g., NAD[P]H:FMN reductase; available from Boehringer Mannheim) generates high levels of luminescence.

Although side-by-side comparisons of efficiency have not been reported, a *luxAB* fusion has two theoretical advantages over firefly luciferase as a reporter molecule: *luxAB* is a cytosolic molecule, and its substrate, the aldehyde decanal, penetrates membranes easily. Although the quantum yield of the photochemical reaction catalyzed by *luxAB* is less than that of firefly luciferase, *luxAB* may turn out to be the more sensitive reporter in intact cells. For a summary of chromogenic and luminescent methods of detection of immobilized antigens, please see Appendix 8, Table A8-12.

Green Fluorescent Protein

The bioluminescent jellyfish, *Aequorea victoria* emits a characteristic green fluorescence, which is due to the interaction of two proteins, the calcium-binding photoprotein aequorin, and the green fluorescent protein (GFP). The emission spectrum of GFP peaks at 508 nm (Johnson et al. 1962), a wavelength close to that of living *Aequorea* tissue, but distinct from the chemiluminescence of pure aequorin, which is blue and peaks near 470 nm. With the initial purification and crystallization of GFP, it was discovered that calcium-activated aequorin could efficiently transfer its luminescent energy to GFP when the two were co-adsorbed onto a cationic support (Morise et al. 1974). Green light is produced when energy is transferred by a Föster-type mechanism from Ca^{2+}-activated aequorin to GFP. Blue light emitted by activated aequorin is captured by a hexapeptide chromophore (beginning at residue 64 of GFP) that contains a cyclic structure (4-[*p*-hydroxybenzylidene]imidazolidin-5-one) attached to the peptide backbone through the 1-position and 2-position of the ring (Shimomura 1979). Interestingly, this structure appears to be conserved among fluorescent proteins, even those from nonbioluminescent organisms (Matz et al. 1999).

The GFP gene was cloned in 1992 (Prasher et al. 1992) and is now used as a reporter in a wide range of organisms (e.g., please see Chalfie et al. 1994; Wang and Hazelrigg 1994; Marshall et al. 1995; Yeh et al. 1995; Chiu et al. 1996; Niedenthal et al. 1996; Misteli et al. 1997). Expression levels of GFP can be measured accurately using a fluorometer. Fluorescence is measured directly in intact living cells in 96-well plates and expression is assessed on an individual cell basis using fluorescence microscopy. Engineered variants of GFPs that fluoresce at different wavelengths and with different intensities have been developed and are available from various commercial sources (e.g., Research Genetics and CLONTECH). For more information on GFP and its applications in molecular biology, please see the information panel in Chapter 17.

ANTIBODIES

Antibodies are used for several major purposes in molecular cloning:

- to screen cDNA libraries for clones that express a specific protein
- to purify fusion proteins that are tagged with a specific epitope
- to detect and quantify foreign protein expressed by recombinant DNA techniques
- to confirm that a cloned gene encodes a protein of interest
- to detect probes labeled with biotin or digoxygenin
- to detect mRNAs by immunohistochemical analysis

Antibodies come in a variety of classes, affinities, and idiotypes. They can be polyclonal or monoclonal, engineered or natural, and raised in animals or generated in vitro. However, as far as molecular cloning is concerned, the specificity of the antibody is far more important than its provenance. Antibodies can be divided into three groups according to how they react with their target proteins.

- ***Antibodies that react with the foreign protein independently of its conformation.*** Antibodies of this type are particularly useful for measuring the total amount of the target protein in crude preparations or in cell extracts. They are usually polyclonal in nature and are prepared by immunizing animals with partially denatured protein or with a peptide whose sequence corresponds to part of the intact protein. However, monoclonal antibodies that are pan-specific are not uncommon.
- ***Antibodies that react only with epitopes specific to the native form of the target protein.*** Antibodies of this type are typically monoclonal, have been raised against native protein, and recognize a given sequence of amino acids only when it occurs in its native three-dimensional configuration. These antibodies are useful for testing whether mutated forms of proteins that have been generated by in vitro mutagenesis are folded correctly or whether a wild-type protein expressed in heterologous cells is assembled into a correct three-dimensional configuration.
- ***Antibodies that react only with denatured forms of the target protein.*** These antibodies are raised against fully denatured antigens and can be either monoclonal or polyclonal. Antibodies of this type are useful for western blotting and for immunological screening of cDNA libraries.

Although there is no way to guarantee the production of particular types of antibodies, it is nevertheless possible to choose an immunization regimen that will favor the production of antibodies with the desired characteristics. However, it is always necessary to screen several independent antisera or a series of monoclonal antibodies to identify those suited to the tasks at hand.

Purification of Antibodies

For many purposes, antisera need not be fractionated before use. However, if the antisera are to be radiolabeled or conjugated to enzymes such as horseradish peroxidase (HRP) or alkaline phosphatase, it is necessary to purify the IgG fraction or, in some cases, to purify the antibody of interest by binding it to its cognate antigen.

Although many techniques have been developed to purify IgG molecules, the method of choice is adsorption to, and elution from, beads coated with protein A, a component of the cell wall of *S. aureus* (Hjelm et al. 1972). For reasons that are not known, this protein (M_r = 42,000)

binds strongly to sites in the second and third constant regions of the Fc portion of the immunoglobulin heavy chain (Deisenhofer 1981). Each IgG molecule therefore contains two binding sites for protein A. Because protein A itself has five potential sites for binding to IgG (Sjödahl 1977), it is possible to form multimeric complexes of the two types of proteins.

Not all immunoglobulins bind to protein A with the same affinity. Antibodies from humans, rabbits, and guinea pigs bind most tightly, followed in decreasing order of affinity by those from pigs, mice, horses, and cows (Kronvall et al. 1970a,b; Goudswaard et al. 1978). Immunoglobulins from goats, rats, chickens, and hamsters bind in a much weaker fashion, and a "bridging" antibody is usually required to purify them by adsorption to protein A.

Within any one species, different classes of immunoglobulins vary in the sequences of their Fc regions and consequently bind to protein A with different affinities. Of the major classes of human IgG, for example, three (IgG1, 2, and 4) bind with high affinity and one (IgG3) binds very weakly, if at all. Similarly, mouse IgG2a binds with high affinity, IgG2b and IgG3 bind tolerably well, and IgG1 binds poorly (Ey et al. 1978). These differences are generally unimportant when dealing with polyclonal sera, where antibodies against the target antigen are distributed throughout all of the major subclasses of IgG. Consequently, purification of polyclonal immunoglobulins raised in rabbits, humans, and mice by binding to protein A may alter the distribution of subclasses of IgG, but it rarely changes the specificity or avidity of the final preparation. However, monoclonal antibodies secreted from hybridomas carry only one subclass of heavy chain. Before attempting to purify a given monoclonal antibody, it is essential to determine the subclass of its heavy chain using commercially available immunological reagents directed against isotypes of the Fc region. If the monoclonal antibody falls into a class that binds poorly to protein A (e.g., by binding to protein G or to human IgG3 or mouse IgG1), it should be purified by another method (e.g., ammonium sulfate precipitation, followed by chromatography on DEAE-cellulose). Alternatively, a bridging antibody can be used to attach the monoclonal antibody to protein A.

Protein A coupled to a solid support by cyanogen bromide is supplied by several manufacturers (e.g., protein A–Sepharose CL-4B; Pharmacia). Each milliliter of swollen gel can bind ~10–20 mg of IgG (equivalent to 1–2 ml of antiserum). Antibodies bind to protein A chiefly by hydrophobic interactions (Deisenhofer 1981) that can be disrupted at low pH. Protein A is remarkably resilient and withstands repeated cycles of exposure to low pH extremely well; it can also be treated with high concentrations of denaturing agents such as urea, guanidine hydrochloride, or potassium isothiocyanate without permanent damage. Most antibodies can withstand transient exposure to low pH, and this treatment is now the standard method to release them in an active form from protein A–Sepharose beads. For additional information on protein A, protein G, and protein L, please see the information panel on **IMMUNOGLOBULIN-BINDING PROTEINS: PROTEINS A, G, AND L** at the end of this appendix.

Although hyperimmune antisera raised in experimental animals contain very high concentrations of immunoglobulin directed against the target antigen, such antisera also always contain antibodies directed against other antigens. In addition, the immunoglobulins in antisera may bind with low avidity to molecules that are not true target antigens. For these and other reasons, antisera can manifest a level of background reactivity that is unacceptably high. There are three ways to deal with this problem:

- ***Use an innocuous blocking agent (e.g., bovine serum albumin, normal serum, or BLOTTO)*** to compete with the immunoglobulin for nonspecific binding sites. Blocking agents are routinely included in solutions used, for example, in immunological screening of expression libraries constructed in plasmid or bacteriophage λ vectors.

- ***Remove antibodies that are directed against specific contaminating antigens by adsorption.*** Methods to remove antibodies directed against bacterial antigens are discussed in Chapter 14,

Protocol 4. Antibodies that cross-react with components in eukaryotic cells can be adsorbed with acetone extracts of a cell line or tissue that are known not to express the true target antigen. If such a line cannot be identified with certainty, use an acetone extract of commercially available dried yeast (Sambrook et al. 1989). Alternatively, unwanted antibodies can be adsorbed to antigens immobilized on nitrocellulose or PVDF membranes.

- ***Separate antibodies directed against the target antigen from contaminating antibodies by affinity purification.*** In some cases (e.g., when the antigen is a protein), the antigen may be coupled to a matrix such as cyanogen-bromide-activated Sepharose. Antibodies directed against epitopes displayed by the protein will be retained by the column; all other immunoglobulins will pass through. The bound antibody is then released from the column by agents that disrupt the antigen-antibody complex (e.g., potassium isothiocyanate and low-pH buffers). Details of the methods used to prepare antibodies by immunochromatography vary from antigen to antigen and from antibody to antibody. However, the general principles are well-described in a number of reviews (e.g., please see Hurn and Chantler 1980; Harlow and Lane 1988, 1999). When using these methods, it is essential to use highly purified antigen and to avoid the batch of antigen that was used to raise the antibody in the experimental animals. Furthermore, it is important to remember that antibodies with different affinities for the antigen will show different patterns of elution from the column; those that bind loosely to the antigen will elute first, and those that bind most tightly will elute last. In fact, antibodies with the highest avidity may be denatured by the elution buffer before they dissociate from the antigen. Thus, there is a tendency during immunopurification to select for antibodies that are specific for the antigen but that bind with low affinity.

Antibodies may be purified on a small scale by adsorption to, and elution from, protein antigens that are immobilized on diazotized paper (Olmsted 1981), or nitrocellulose filters (Burke et al. 1982; Smith and Fisher 1984; Earnshaw and Rothfield 1985), after electrophoresis through SDS-polyacrylamide gels. Antibodies prepared by this method are especially useful for confirming the identity of cDNA clones isolated from expression libraries constructed in bacteriophage λ or plasmid expression vectors. For example, many false-positive clones can be eliminated by purifying antibodies from crude sera by virtue of their ability to bind to a fusion protein partly encoded by the cloned cDNA and testing the ability of these purified antibodies to precipitate the target protein or to react with it on a western blot. However, this method works well only when the antibodies react with epitopes that are displayed on denatured proteins. Typically, ~50 ng of immunopurified antibody is recovered per microgram of target protein loaded on the original SDS-polyacrylamide gel. Because of the idiosyncratic nature of the interactions between antibodies and their target proteins, it is not possible to give conditions for binding and elution that are universally applicable. For example, most antibodies can be eluted from their immobilized antigens with glycine buffer (pH 2.8). However, Earnshaw and Rothfield (1985) found that antibodies to human centromeric proteins could be eluted only with a solution containing 3 M potassium thiocyanate and 0.5 M NH_4OH. Investigators who wish to use this potentially powerful technique should be prepared to invest some effort in defining the optimal conditions for binding and release of their particular antibodies from their target proteins.

Immunological Assays

Antibodies are used in a wide variety of assays, both qualitative and quantitative, to detect and measure the amount of target antigens. These assays include western blotting, immunoprecipitation, and solid-phase radioimmunoassay (RIA).

Western Blotting

Western blotting (Towbin et al. 1979; Burnette 1981; Towbin and Gordon 1984) is to proteins what Southern blotting is to DNA. In both techniques, electrophoretically separated components are transferred from a gel to a solid support and probed with reagents that are specific for particular sequences of amino acids (western blotting) or nucleotides (Southern hybridization). In the case of proteins, the probes usually are antibodies that react specifically with antigenic epitopes displayed by the target protein attached to the solid support. Western blotting is therefore extremely useful for the identification and quantitation of specific proteins in complex mixtures of proteins that are not radiolabeled. The technique is almost as sensitive as standard solid-phase radioimmunoassays and, unlike immunoprecipitation, does not require that the target protein be radiolabeled. Furthermore, because electrophoretic separation of proteins is almost always carried out under denaturing conditions, any problems of solubilization, aggregation, and coprecipitation of the target protein with adventitious proteins are eliminated.

The critical difference between Southern and western blotting lies in the nature of the probes. Whereas nucleic acid probes hybridize with a specificity and rate that can be predicted by simple equations, antibodies behave in a much more idiosyncratic manner. As discussed earlier, an individual immunoglobulin may preferentially recognize a particular conformation of its target epitope (e.g., denatured or native). Consequently, not all monoclonal antibodies are suitable for use as probes in western blots, where the target proteins are denatured. Polyclonal antisera, on the other hand, are undefined mixtures of individual immunoglobulins, whose specificity, affinity, and concentration are often unknown. It is therefore not possible to predict the efficiency with which a given polyclonal antiserum will detect different antigenic epitopes of an immobilized, denatured target protein.

Although there is an obvious danger in using undefined reagents to assay a target protein that may also be poorly characterized, most problems that arise with western blotting in practice can be solved by designing adequate controls. These include the use of (1) antibodies (i.e., preimmune sera, normal sera, or irrelevant monoclonal antibodies) that should not react with the target protein and (2) control preparations that either contain known amounts of target antigen or lack it altogether.

Often, there is little choice of immunological reagents for western blotting — it is simply necessary to work with whatever antibodies are at hand. However, if a choice is available, either a high-titer polyclonal antiserum or a mixture of monoclonal antibodies raised against the denatured protein should be used. Reliance on a single monoclonal antibody is hazardous because of the high frequency of spurious cross-reactions with irrelevant proteins. If, as is usually the case, monoclonal and polyclonal antibodies have been raised against native target protein, it will be necessary to verify that they react with epitopes that either (1) resist denaturation with SDS and reducing agents or (2) are created by such treatment. This test can be done by using denatured target antigen in a solid-phase radioimmunoassay or in western dot blots.

In western blotting, the samples to be assayed are solubilized with detergents and reducing agents, separated by SDS-polyacrylamide gel electrophoresis, and transferred to a solid support (usually a nitrocellulose or PVDF filter), which may then be stained (e.g., with Ponceau S). The filter is subsequently exposed to unlabeled antibodies specific for the target protein. Finally, the bound antibody is detected by one of several secondary immunological reagents (e.g., ^{125}I-labeled or anti-immunoglobulin, or anti-immunoglobulin or protein A coupled to horseradish peroxidase or alkaline phosphatase), followed by autoradiography, enhanced chemiluminescence, or enzymatic production of a colored precipitate. As little as 1–5 ng of an average-sized protein can be detected by western blotting. For more information on western blotting, please see Appendix 8.

Immunoprecipitation

Immunoprecipitation is used to detect and quantitate target antigens in mixtures of proteins. The power of the technique lies in its selectivity: The specificity of the immunoglobulin for its ligand is so high that the resulting antigen-antibody complexes can be purified from contaminating proteins. Furthermore, immunoprecipitation is extremely sensitive and is capable of detecting as little as 100 pg of radiolabeled protein. When coupled with SDS-polyacrylamide gel electrophoresis, the technique is ideal for analysis of the synthesis and processing of foreign antigens expressed in prokaryotic and eukaryotic hosts or in in vitro systems.

The target protein is usually immunoprecipitated from extracts of cells that have been radiolabeled. However, immunoprecipitation can also be used to analyze unlabeled proteins as long as sufficiently sensitive methods are available to detect the target protein after it has been dissociated from the antibody. Such methods include enzymatic activity, binding of radioactive ligands, and western blotting.

Solid-phase Radioimmunoassay

The solid-phase radioimmunoassay (RIA) is a quantitative method that is capable of detecting as little as 1 pg of target antigen. This means that RIAs are sufficiently sensitive to measure, for example, the amount of foreign protein produced by transfected mammalian cell cultures. There are many different kinds of RIAs, which fall into four basic designs:

- ***Competition RIAs:*** In this method, the unlabeled target protein in the test sample competes with a constant amount of radiolabeled protein for binding sites on the antibody. The amount of radioactivity present in the unbound or bound target protein is then measured. This type of assay can be extremely sensitive but requires that target protein be available (preferably in a pure form) to serve both as a competitor and as a standard.
- ***Immobilized antigen RIAs:*** In this method, unlabeled antigen is attached to a solid support and exposed to radiolabeled antibody. Comparison of the amount of radioactivity that binds specifically to the samples under test with the amount that binds to a known amount of immobilized antigen allows the antigen in the test samples to be quantitated. Although used occasionally, this type of assay is not particularly useful for quantitation of small amounts of foreign protein in complex mixtures (e.g., in cell lysates); most of the binding sites on the solid support become occupied by proteins other than the target protein, so that the sensitivity of the assay is comparatively low.
- ***Immobilized antibody RIAs:*** In this method, a single antibody bound to a solid support is exposed to radiolabeled antigen. The amount of antigen in the test sample can be determined by the amount of radioactivity that binds to the antibody. This assay is not useful for quantitating the amount of foreign protein in many different samples, chiefly because of the practical difficulty of radiolabeling the protein either in vivo or in vitro.
- ***Double-antibody RIAs:*** In this method, one antibody bound to a solid support is exposed to the unlabeled target protein. After washing, the target protein bound to the immobilized antibody is quantitated with an excess of a second radiolabeled antibody. This assay is extremely sensitive and specific because the target protein is essentially purified and concentrated by immunoadsorption. Furthermore, many test samples can be processed simultaneously. However, the method requires that the first and second antibodies recognize nonoverlapping epitopes on the target protein. Ideally, the first antibody is monoclonal, whereas the second can be either a polyclonal antibody or a monoclonal antibody of different specificity. However, in

some cases, it may be possible to use the same polyclonal antibody for both parts of the assay. If suitable antibodies are available, this is the method of choice for quantitation of target proteins in complex mixtures.

Radiolabeling of Antibodies

Of the several methods that are available to radioiodinate antibodies, the most commonly used is a reaction in which an electrophilic iodine species is generated by oxidation of $Na^{125}I$ with chloramine-T (*N*-chlorobenzenesulfonamide). The positively charged iodine then reacts with the side chains of tyrosyl, and to a lesser extent, histidyl residues (for review, please see Seevers and Counsell 1982). Iodination by chloramine-T was devised as a method to label small amounts of polypeptide hormones to very high specific activity (Hunter and Greenwood 1962; Greenwood et al. 1963). However, the reaction conditions are so severe as to cause extensive denaturation of proteins that are sensitive to oxidation. The modified procedure devised by McConahey and Dixon (1966, 1980), which uses lower concentrations of chloramine-T and longer reaction times, yields native proteins without a significant loss in the efficiency of radiolabeling. Nowadays, most investigators prefer to use chloramine-T covalently coupled to nonporous polystyrene beads (Iodobeads, Pierce) (Markwell 1982). This has several benefits: It reduces the amount of radiolabeled molecular iodine generated in the reaction and simplifies measurements of the time course and overall efficiency of radioiodination (Cheng and Rudick 1991). In addition, because there is very little contact between the protein and the oxidizing agent, oxidative damage to the protein is minimized. Finally, when iodination is carried out according to standard protocols, no more than one atom of ^{125}I is incorporated per protein molecule. Conformational distortions caused by the introduction of a bulky iodine atom are therefore kept to a minimum.

An alternative to chloramine-T is Iodogen (1,3,4,6-tetrachloro-3α,6α-diphenylglycouril), an oxidizing reagent resembling a fourfold chloramine-T (Fraker and Speck 1978). Iodogen is sparingly soluble in water and forms a thin coating on the wall of the tube used for radioiodination. Solid-phase reagents such as Iodogen and Iodobeads (available from Pierce) give radiochemical yields that are equal to those obtained with free chloramine-T (Woltanski et al. 1990) while significantly reducing the potential for exposure of laboratory workers to volatile forms of radioiodine.

Radioiodination with chloramine-T and similar compounds will not work with proteins and peptides that lack accessible tyrosines or are extremely susceptible to damage by oxidation. These proteins should be labeled by the Bolton-Hunter reagent (Bolton and Hunter 1973). The *N*-succinamidyl group of this reagent (*N*-succinamidyl 3-[4-hydroxy 5-[^{125}I]iodophenyl]propionate) condenses with free amino groups and with imino groups in lysyl side chains to give a derivative in which the radioiodinated phenyl group is linked via an amide bond to the target protein (for more details, please see Langone 1980; Harlow and Lane 1988).

Antipeptide Antibodies

If the sequence of a protein is known or can be deduced from the nucleic acid sequence, specific antisera can be raised by immunizing animals with a synthetic peptide corresponding in sequence to a segment of the native protein (for review, please see Lerner 1984). If information about the primary sequence of the target protein is limited, there may be little or no choice in the peptide sequence used as an immunogen. However, there is a good chance that peptides chosen at random will be at least partially buried in the native protein and they may be too hydrophobic to be

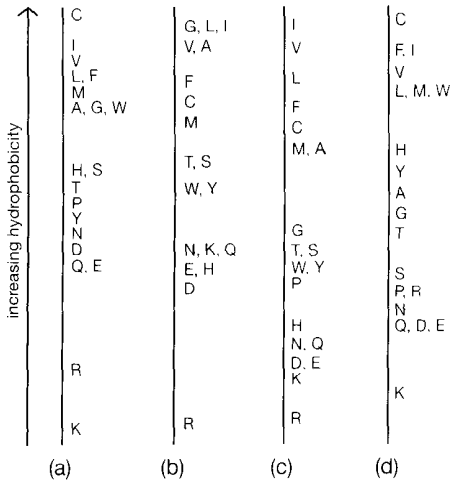

FIGURE A9-3 Hydrophobicity Scales

Several hydrophobicity scales, approximately normalized to each other and increasing from bottom to top. Data from (*a*) Janin (1979); (*b*) Wolfenden et al. (1981); (*c*) Kyte and Doolittle (1982); and (*d*) Rose et al. (1985). Please also see Figure A7-2 in Appendix 7. (Reprinted, with permission, from Richardson and Richardson 1989 [©Kluwer Academic/Plenum Publishers].)

efficient immunogens. Antibodies directed against these peptides may be of low titer and/or may react only with denatured protein.

Hydrophilic peptides that contain charged residues are much better immunogens and also have a high probability of occupying a surface location on the native protein. Antipeptide antibodies raised against conformationally flexible surface features of proteins such as turns and β-loops are likely to be of high titer and may react efficiently with the native protein. Most of the computing packages that are commonly used to analyze DNA sequences contain programs to search protein sequences for surface peptides that are likely to be good antigens. The goal of these programs is to choose a sequence of 11–15 amino acids that contains a preponderance of polar residues and no more than four adjacent hydrophobic residues. Such peptides are likely to be soluble in aqueous solvents and therefore easy to couple to carrier proteins.

Several scales of hydrophobicity and hydrophilicity have been proposed for amino acids (please see Figure A9-3) (Janin 1979; Wolfenden et al. 1981; Kyte and Doolittle 1982; Rose et al. 1985). Although these scales are in good general agreement, they differ slightly in the order of amino acids and in the relative hydrophobicity values assigned to them. This variability arises because the hydrophobicity of an amino acid residue is the product of several different factors, including electrostatic charge, hydrogen-bonding capability, and surface area. In addition, the hydrophobicity of an amino acid can be assessed experimentally by partitioning into solvents of various types. The variation in hydrophobicity scales of amino acids reflects the particular weightings that different investigators have attached to these and other factors.

Computer programs to predict strongly antigenic sites in proteins rely on hydrophobicity scales alone or in combination with programs that predict secondary structure. The strongest antigenic sites are predicted in regions of the protein surface that are high in charge and low in hydrophobicity. Rarely found in ordered structures such as helices or sheets, such regions usually map to turns and loops that are rich in residues with H-bonding potential.

Highly charged regions also often occur at the amino and carboxyl termini of proteins, which tend to be regions of high flexiblility. However, if the protein of interest is a secretory or transmembrane protein, or is located in organelles such as mitochondria or chloroplasts, it is better not to use peptides derived from the terminal regions. The amino-terminal peptide is likely to be part of a signal or leader sequence that will be cleaved during posttranslational processing. The carboxy-terminal region of transmembrane proteins may be located on the cytoplasmic side of the membrane and may only be accessible to antibodies after cells are permeabilized, fixed, or lysed.

GUIDELINES FOR CHOOSING AN IMMUNOGENIC PEPTIDE

An immunogenic peptide should have:

- a sequence 11–15 amino acids long
- no more than six hydrophobic residues
- no more than four adjacent hydrophobic residues
- no consensus sites for *N*-glycosylation* (N-X-S/T)
- no basic residues if glutaraldehyde is to be used as a cross-linker
- no internal or cysteine residues if m-maleimidobenzoic acid *N*-hydroxysuccinimide ester (MBS) is to be used as a cross-linker
- a tyrosine residue because the peptide can then easily be radiolabeled with ^{125}I

*Oligosaccharide groups added to secretory and plasma membrane proteins can shield the underlying amino acid residues from interacting with antibodies and other ligands. Antibodies generated against a synthetic peptide may therefore not recognize the glycosylated target protein even though the immunogen and the target share amino acid sequences. When raising antibodies against secretory and plasma membrane proteins, it is best to avoid regions that contain consensus sites for glycosylation.

Usually, the synthetic peptide is coupled to a carrier protein such as keyhole limpet hemocyanin through an amino- or carboxy-terminal cysteine residue. Ideally, therefore, the sequence of the peptide should end with a "natural" cysteine that is present in the cognate sequence of the target protein. If this is not possible, choose a peptide that has no cysteine at all. Chemical synthesis of the peptide, which proceeds from the carboxyl terminus to the amino terminus, is then initiated from an "artificial" cysteine that has no counterpart in the natural cognate sequence. This terminal cysteine is used as a linker to couple the synthetic peptide to the carrier protein. Alternatively, multiple copies of a pepide can be linked to each other. Other methods of coupling peptides to carriers are available but are rarely used. These include:

- ***Glutaraldehyde-mediated cross-linking of basic residues in the peptide and a carrier protein.*** Because glutaraldehyde reacts with $-NH_2$ groups to form Schiff's bases, peptides containing lysine residues can be efficiently cross-linked to a protein such as keyhole limpet hemocyanin, whose surface is rich in basic residues. However, lysines, if present in the peptide, are likely to be important contributors to its antigenicity. Modifying them may reduce the antigenicity of the peptide and/or generate antibodies that efficiently recognize the modified residues but do not interact with the unmodified cognate sequence in the target protein.
- ***Use of peptide-resin as the immunogen.*** Novabiochem sells a polymethylacrylamide/Keiselguhr composite derived using ethylene diamine. Antigenic peptides can be synthesized directly on the free amino group of the base resin and remain attached to the support by a covalent bond. After deprotection of the peptide with trifluoroacetic acid and homogenization of the inorganic Keiselguhr, the peptide-polyamide complex can be emulsified with adjuvant and injected into animals.

Immunization with the carrier-peptide complexes will generate a mixture of antibodies of various affinities and specificities. Some antibodies will be directed toward the carrier (protein or resin) or the cross-linking groups; others will react with both peptide and carrier. However, as long as the synthetic protein is at least 11 residues in length, a proportion of the antibodies will be specific for amino acid sequences that are shared by the peptide and its cognate protein. Usually, there is no need to remove antibodies directed against the linking groups and the carrier protein, since these do not interfere with antibodies directed against the target protein.

However, antibodies that cross-react with the carrier protein can, if necessary, be removed by immunoabsorption with resin or by immunoaffinity chromatography on Sepharose columns containing immobilized carrier protein.

Conjugated Antibodies

Antibodies can be conjugated to a wide variety of substances without significant erosion of avidity and specificity. These substances include biotin, fluorochromes of various colors, and enzymes such as alkaline phosphatase, horseradish peroxidase, and urease. Antibodies conjugated to different substances allow simultaneous detection of more than one antigen and generate strong signals that can be further amplified through the use of secondary antibodies and avidin-conjugated enzymes.

- ***Biotinylated antibodies*** are used chiefly to detect antigens by enzyme-linked immunosorbent assay (ELISA), for antibody screening of expression libraries, and for western blotting.

  The labeled avidin-biotin (LAB) technique uses an avidin-enzyme conjugate to detect a biotinylated primary or secondary antibody.

  The bridged avidin-biotin (BRAB) assay, as its name implies, uses avidin as a bridge between a biotinylated primary or secondary antibody and a biotin-enzyme conjugate.

  The avidin-biotin complex (ABC) assay is the most sensitive of these three assays. The biotinylated enzyme is preincubated with avidin, forming large complexes that are then used to detect biotinylated primary or secondary antibodies.

  Biotinylated secondary antibodies are available from several manufacturers (e.g., Pierce and Vector).

- ***Fluorochrome-labeled antibodies*** are used chiefly for immunohistochemistry. Wherever possible, it is best to use fluorochrome-labeled, affinity-purified, anti-immunoglobulins or fluorochromes conjugated to avidin or streptavidin. These reagents, which are commercially available, have lower background and less nonspecific fluorescence than fluorescent antiserum or immunoglobulin fractions. The choice among fluorochromes is usually dictated by the types of filters that are available for the fluorescence microscope. Fluorescein has a lower background than rhodamine, but bleaches more rapidly. Texas Red emits strongly and is resistant to photobleaching. Phycoerythrin, a phycobiliprotein whose fluorescent yield is 30–50 times greater than that of fluorescein and rhodamine, is used when extreme sensitivity is required (Oi et al. 1982). Table A9-5 summarizes the excitation and emission wavelengths of various fluorochromes.

TABLE A9-5 Excitation and Emission Wavelengths of Fluorochromes

FLUOROCHROME	EXCITATION WAVELENGTH (nm)	EMISSION WAVELENGTH (nm)
Fluorescein	495 blue	524 greenish-yellow
Rhodamine	540 green, visible	575 orange-red
Texas Red	595 orange-red, visible	620 red
Oregon Green	496 blue	524 greenish-yellow
R-phycoerythrin	480, 545, 565 green, visible	574 orange-red

- ***Enzyme-conjugated antibodies.*** Antibodies coupled to horseradish peroxidase, alkaline phosphatase, β-galactosidase, and urease are available commercially. These can be used as secondary reagents for the enzymatic detection of primary antibody-antigen complexes. For both immunoscreening and western blotting, enzymatic methods are more sensitive and give lower backgrounds than radiolabeled antibodies or protein A. Enzyme-conjugated antibodies are particularly useful for screening expression libraries because signals develop directly on the nitrocellulose filter (rather than on a sheet of X-ray film or a phosphorimager), so that positive plaques can be located more accurately.

Conjugated enzymes catalyze the formation of insoluble colored precipitates on the surface of a nitrocellulose filter at the site of an antibody-antigen complex (Towbin et al. 1979; Hawkes et al. 1982; Blake et al. 1984; Knecht and Dimond 1984; Towbin and Gordon 1984; Hawkes 1986). Alkaline phosphatase and horseradish peroxidase are the most commonly used conjugated enzymes. Alkaline phosphatase remains active for several hours, during which the end-product of the reaction — a dark blue precipitate of diformazan (McGadey 1970) — continues to accumulate and intensify in color. By contrast, horseradish peroxidase is inactivated within a short period of time by its substrate, peroxide, which may account for the lower sensitivity of horseradish-peroxidase-conjugated antibodies in detecting antibody-antigen complexes on nitrocellulose filters (Mierendorf et al. 1987). Furthermore, some protocols using horseradish peroxidase antibodies employ a carcinogenic chromogen, *o*-dianisidine, which requires special handling and disposal. For a summary of chromogenic and luminescent methods of detection of immobilized antigens, please see Table A8-12 in Appendix 8.

HORSERADISH PEROXIDASE

Horseradish peroxidase (HRP), a heme-containing protein, is generally isolated from wild horseradish roots as a mixture of several isozymes. The classical preparation (Shannon et al. 1966) is predominantly a mixture of two forms (isozymes B and C), each with a M_r ~40,000. HRP catalyzes the transfer of two electrons from a substrate to hydrogen peroxide, to generate H_2O and an oxidized donor. When 3,3′-diaminobenzidine (DAB) is used as the substrate (Graham and Karnovsky 1966), the oxidized product polymerizes to form an intense brown residue that is insoluble in both H_2O and ethanol. In the presence of transition elements, such as cobalt and nickel, the residue is a slatey blue-black. These reactions form the basis of sensitive chromogenic assays for peroxidase that have been used for many years in electron microscopy (Robbins et al. 1971), immunocytochemistry (Nakane and Pierce 1967), various enzyme-linked immunosorbent assays and western blotting (see Figure A9-4). However, diaminobenzidine has some disadvantages as a substrate: It is possibly carcinogenic (Garner 1975; Weisburger et al. 1978), and it is not as sensitive a detector of HRP activity as more recently developed compounds such as 3,3′,5,5′-tetramethylbenzidine (TMB) (e.g., please see Roberts et al. 1991). The oxidation products of TMB are normally soluble but can be "captured" by pretreating blots with dextran sulfate (McKimm-Breschkin 1990) or by using a particulate form of TMB that is available commercially. With these modifications, TMB is suitable for detection of HRP-antibody conjugates that are directed against proteins (including antibodies of another species) or ligands that can be attached to nucleic acid probes.

In addition to DAB and TMB, other HRP substrates that can be oxidized to insoluble chromogenic products include 4-chloro-1-naphthol (purple precipitate) and 3-amino-4-ethylcarbazole (red precipitate). Neither of these substrates is as sensitive a detector of HRP activity as diaminobenzidine. In addition, a number of chromogenic substrates for HRP are available that yield attractively colored, soluble oxidation products. In addition to TMB, these include *O*-phenylenediamine dihydrochloride (OPD) (tangerine orange) (Wolters et al. 1976), and 2,2′-azino-di(3-ethylbenzthiazoline-6-sulphonic acid) (ABTS) (green) (Engvall 1980). The best fluorogenic substrate is 3-(*p*-hydroxyphenyl) propionic acid (HPPA) (violet) (Roberts et al. 1991).

In the presence of hydogen peroxide, HRP can also be used to trigger a cyclical chemiluminescent reaction that results in the oxidation of luminol to an excited form of 3-aminophthalate (Isaacson and Wettermark 1974; Roswell and White 1978; Durrant 1990; Stone and Durrant 1991) (please see Figure A9-5). As this compound returns to ground state, blue light is emitted at 428 nm. However, because the efficiency of this reaction is low, various *para*-substituted phenol-based compounds are used to increase the quantity and duration of the light emitted by the reaction (Whitehead et al. 1983; Hodgson and Jones 1989). In the presence of *p*-iodophenol, for example, the light emitted by the reaction may be increased by >1000-fold and the emission may be sustained for several hours. In addition, enhancers reduce the background by inhibiting chemical oxidation of luminol. Enhancers are thought to achieve these effects by eliminating the rate-limiting step in the reaction cycle by (1) reacting with HRP and (2) forming enhancer radicals that in turn react with luminol to form luminol radicals (please see Figure A9-5). The net result is an increase in the efficiency and speed, but not the characteristics, of the light-producing reaction. Light emitted from the reaction can be captured on X-ray film, phosphorimagers, or CCD cameras.

HRP can be directly coupled to single-stranded nucleic acid probes (Renz and Kurz 1984; Stone and Durrant 1991) or it can be conjugated to an antibody specific for ligands such as biotin or digoxygenin that can be incorporated into nucleic acid probes by standard enzymological techniques. In either case, the HRP/luminol reaction is sufficiently sensitive for nonradioactive detection of nucleic acids in Southern and northern hybridizations (Thorpe and Kricka 1986). Under ideal conditions, the limit of detection of nucleic acid probes is ~5×10^{-17} moles (Urdea et al. 1988). However, the HRP/luminol reaction is considerably less sensitive than chemiluminescent reactions involving cleavage of 1,2-dioxetanes by alkaline phosphatase (please see the information panel on **AMPPD**). In addition, to achieve maximal sensitivity, the HRP/luminol reaction may require extensive optimization of its various components. For these reasons, HRP is now used less than alkaline phosphatase for the chemiluminescent detection of nucleic acids and proteins.

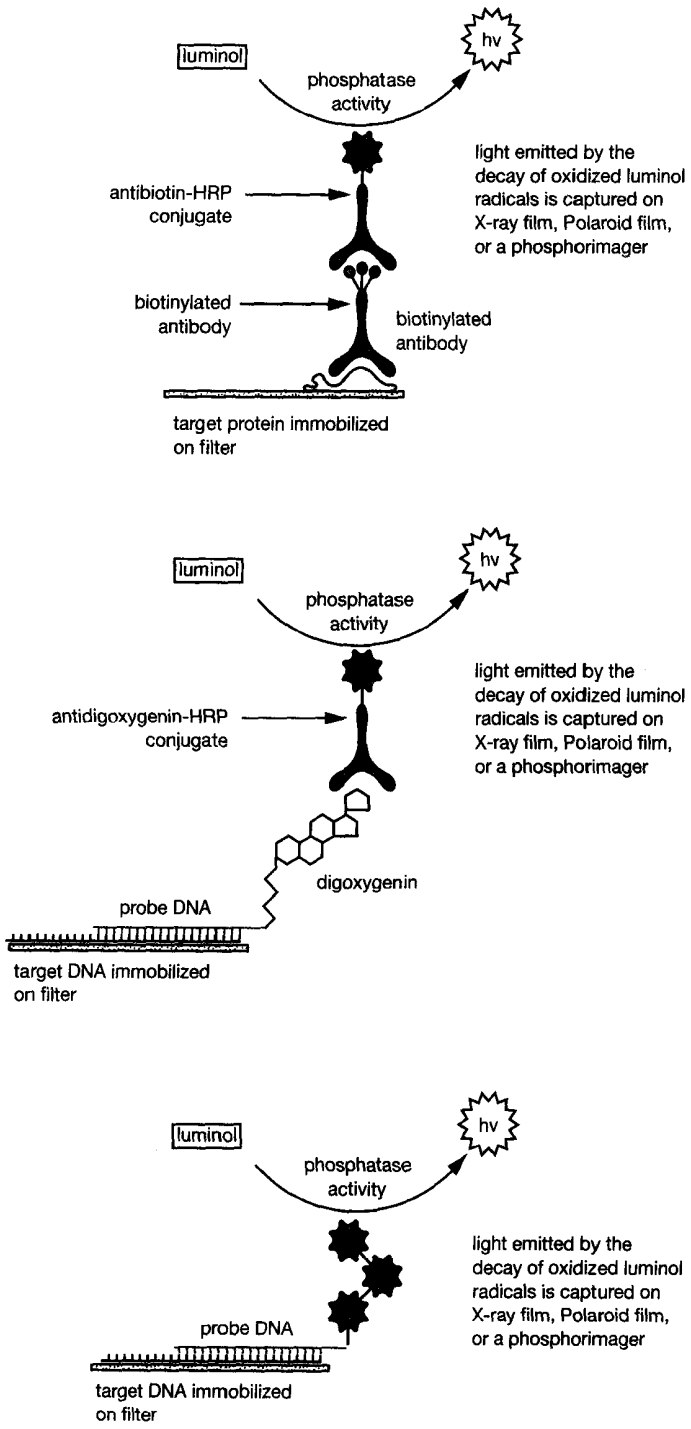

FIGURE A9-4 Experimental Formats for Detection of Immobilized Nucleic Acids and Proteins with Horseradish Peroxidase (HRP)

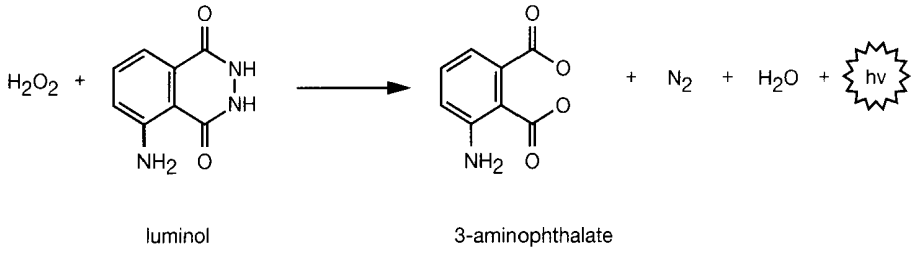
Light emitted by the decay of oxidized luminol radicals is captured on X-ray film or by a CCD camera.



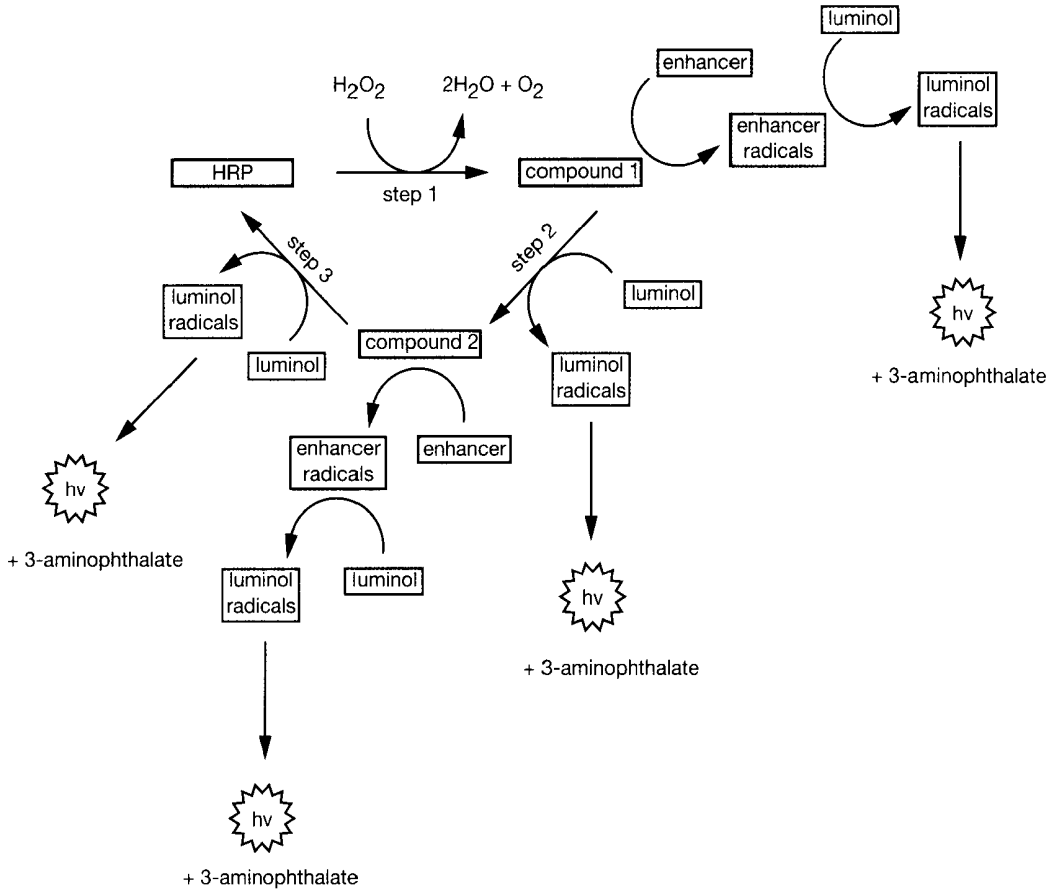


FIGURE A9-5 Proposed Cyclic Reaction for the Generation of Light by Oxidation of Luminol by HRP

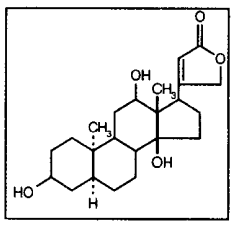
DIGOXYGENIN



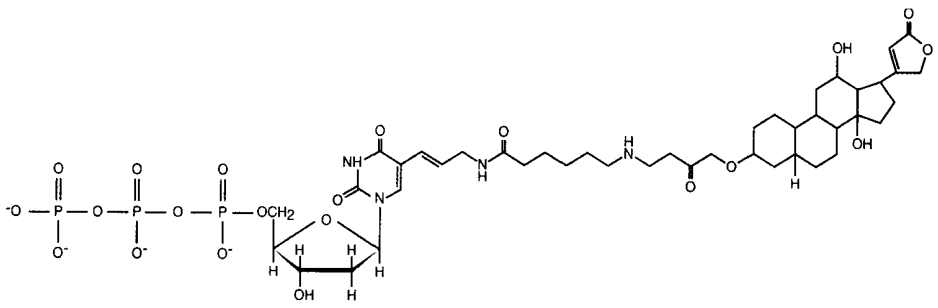
The cardenolide digoxygenin (M_r = 390.53) can be derived by chemical or enzymatic removal of four sugar residues from desacetylanatoside C isolated from *Digitalis purpurea* (Reichstein 1962) or it can be extracted directly from *D. orientalisi* and *D. lanata* L. *Scrophulariaceae* (Maanich and Schneider 1941; Hegenauer 1971). The chemical structure of digoxygenin (Cardwell and Smith 1953, 1954; Pataki et al. 1953) is shown in the box at the right.

In molecular cloning, digoxygenin is used as a ligand that can be incorporated into DNA and RNA probes and detected after hybridization with an anti-digoxygenin-antibody enzyme conjugate (Kessler et al. 1989; Kessler 1991) (please see Figure A9-6). Digoxygenin-labeled probes can therefore be used in Southern, northern, and dot-blot hybridizations. They also have considerable advantages for in situ hybridization, in part because the hapten digoxygenin is not present in animal cells (e.g., please see Tautz and Pfeifle 1989; Hemmati-Brivanlou et al. 1990). This absence eliminates background contributed by endogenous molecules. Such is not always the case with biotin-labeled probes. Digoxygenin-labeled nucleic acid probes can be stripped from nylon filters by heating the filters to 37°C for 20–30 minutes in a large volume of 0.1% SDS, 2 mM EDTA (pH 8.0) (Church and Kieffer-Higgins 1988). After washing, the filters can be reprobed without significant loss of efficiency or sensitivity.

Note that after several cycles of probing, stripping, and reprobing, the background of chemiluminescence may increase significantly due to the accumulation of alkaline phosphatase residue on the filter. This problem can be avoided by treating the filter with proteinase K and formamide between every second and third probing (Dubitsky et al. 1992).

Labeling Nucleic Acids with Digoxygenin

For labeling of nucleic acids, digoxygenin is supplied by the manufacturer (Boehringer Mannheim) in two forms: digoxygenin-11-dUTP (DIG-11-dUTP) and digoxygenin-11-UTP (DIG-11-UTP). In each form, digoxygenin is coupled by an alkali-stable linkage and a spacer arm to deoxyuridine triphosphate and uridine triphosphate, respectively.



- DIG-11-dUTP is a substrate for *E. coli* DNA polymerase, the Klenow fragment of DNA polymerase I, thermostable polymerases such as *Taq*, reverse transcriptase, and terminal transferase. Digoxygenin can therefore be introduced into DNA by a variety of standard reactions including random priming, nick translation, amplification, end-filling, and 3′-tailing.
- DIG-11-UTP is incorporated into RNA during in vitro transcription of DNA templates by bacteriophage-encoded DNA-dependent RNA polymerases (T3, T7 and SP6 RNA polymerases) (please see Table A9-6).

Oligonucleotides that have been 5′-aminated during synthesis can be labeled with digoxygenin by reaction with NHS-digoxygenin (digoxygenin-3-*O*-methylcarbonyl-ε-aminocaproic acid-*N*-hydroxysuccinamide ester; Boehringer Mannheim) (Richterich and Church 1993).

TABLE A9-6 Methods of Labeling Nucleic Acids with Digoxygenin

Method of Labeling	Enzyme	Number of Digoxygenin Molecules Incorporated	Reference
Random priming	Klenow fragment	1 per 25–36 nucleotides	Kessler et al. (1990)
Nick translation	*E. coli* DNA polymerase I	1 per 25–36 nucleotides	Höltke et al. (1990)
Tailing	Terminal transferase	1 per 12 nucleotides	Schmitz et al. (1991)
Amplification by PCR	*Taq* and other thermostable polymerases	1 per 25 nucleotides	Seibl et al. (1990)
Transcription	T3, T7, and SP6 RNA polymerases	1 per 25–36 nucleotides	Höltke and Kessler (1990)
cDNA synthesis	Reverse transcriptase	1 per 25–36 nucleotides	McCracken (1989)

For review, please see Kessler (1991).

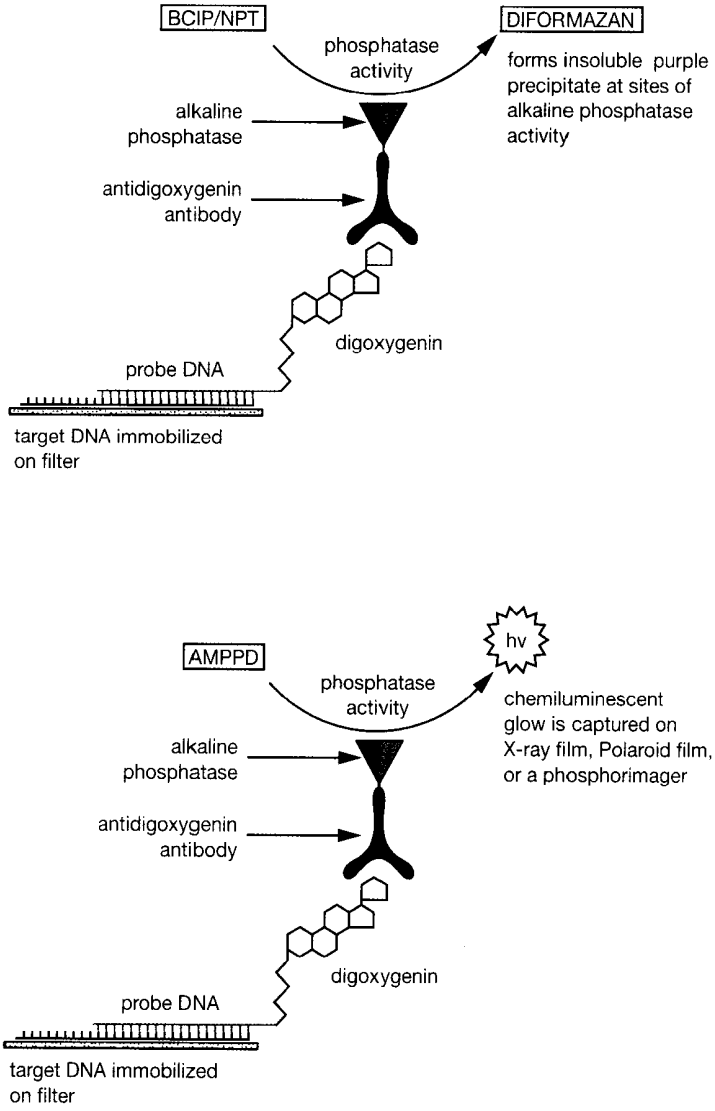


FIGURE A9-6 Detection of Digoxygenin-labeled Nucleic Acid Probes with BCIP/NBT or AMPPD

Digoxygenin-specific Antibodies Coupled to Reporter Enzymes

High-affinity digoxygenin-specific antibody is raised in sheep immunized with the digoxygenin-coated proteins edestin or bovine serum albumin. The most versatile of the immunological reagents available for detection of digoxygenin-labeled probes are FAB fragments of antidigoxygenin immunoglobulin that have been coupled to alkaline phosphatase (Boehringer Mannheim). The best chromogenic substrates for immunolocalized alkaline phosphatase are the binary reagents 5-bromo-4-chloro-3-indolyl phosphate (BCIP) and 4-nitroblue tetrazolium chloride (NBT). For more information on these reagents, please see the information panel on **BCIP**.

Under optimal conditions, where high concentrations (50–100 ng/ml) of digoxygenin-labeled probe are used in the hybridization step and the color reactions are incubated for extended times (16–24 hours), it is possible to detect <1 pg of target DNA in a dot-blot assay (e.g., please see Kerkhof 1992). However, far greater sensitivity and a more linear response are obtained with the soluble chemiluminescent substrate adamantyl 1,2-dioxetane phosphate (AMPPD; Tropix, Inc.; Roche) (Kerkhof 1992; Bronstein et al. 1993). In AMPPD luminescent systems, which have gained rapidly in popularity in recent years, removal of the phosphate residue by alkaline phosphatase stimulates the substrate to emit chemiluminescence at 477 nm, which can be measured using a luminometer. The light occurs as a glow that persists for several hours in solution and for considerably longer on nylon surfaces (Tizard et al. 1990). Images of blots can be captured on X-ray film, on Polaroid instant black and white film (Kricka and Thorpe 1986), on a phosphorimager, or on a CCD camera (Karger et al. 1993). At its best, chemiluminescent detection of digoxygenin-labeled probes is highly sensitive (0.03 pg of target DNA or RNA) and rapid (<30 minutes exposure). The method is therefore ~10-fold more sensitive and 50-fold faster than autoradiographic detection of ^{32}P-labeled nucleic acid probes. In addition, reprobing is simplified since stripping of the filter may not be required (Allefs et al. 1990). As a consequence of these advantages, chemiluminescent assays for alkaline phosphatase labels are used for detection of immobilized nucleic acid sequences in a wide variety of techniques involving blotting and DNA sequencing. For more information on AMPPD systems, please see the information panel on **AMPPD**.

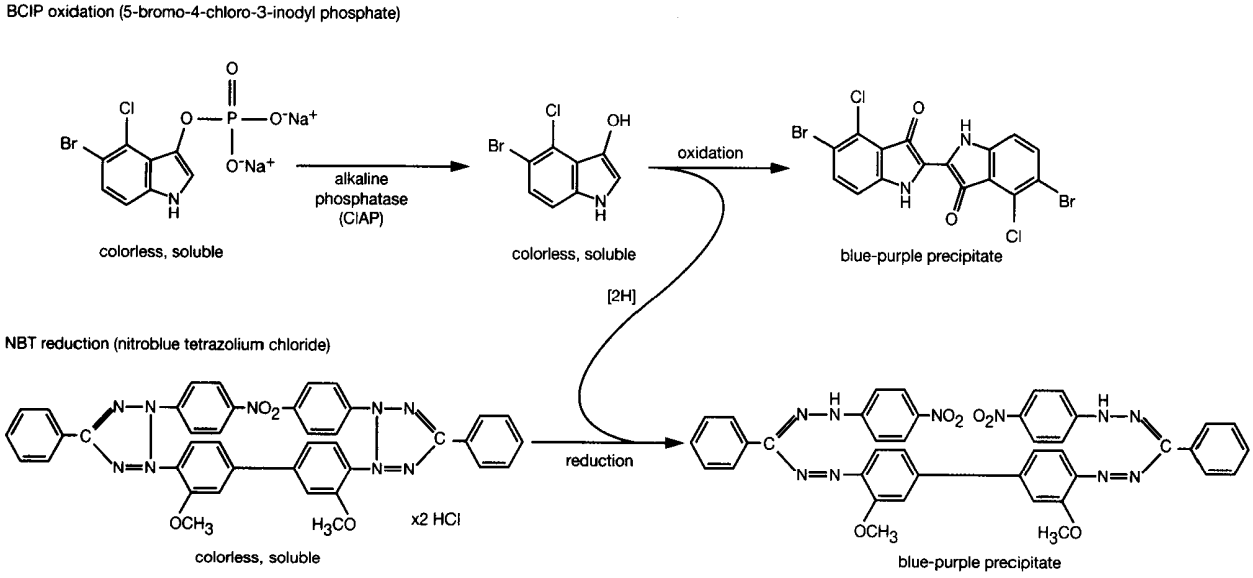

FIGURE A9-7 Oxidation of BCIP and Reduction of NBT in the BCIP/NPT Indicator Reaction

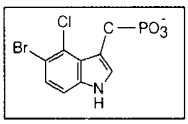
(Reprinted, with permission, from Kessler 1991 [Copyright 1991 ©Academic Press London].)

BCIP



BCIP (5-bromo-4-chloro-3-indolyl phosphate, F.W. 370.4, [disodium salt]; F.W. 433.6 [toluidine salt]) is used in combination with nitroblue-tetrazolium salt (NPT) to detect alkaline phosphatase in situ. The binary reagent forms insoluble precipitates at sites of alkaline phosphatase activity and is the most sensitive indicator system available for chromogenic detection of alkaline phosphatase conjugates. In this reaction (Figure A9-7), alkaline phosphatase catalyzes the removal of the phosphate group from BCIP, generating 5-bromo-4-chloro-3-indolyl hydroxide, which dimerizes to the insoluble blue compound, 5,5′-dibromo-4,4′-dichloroindigo. The two reducing equivalents produced during the dimerization reaction reduce one molecule of nitroblue tetrazolium to the insoluble, intensely purple dye, diformazan (McGadey 1970; Franci and Vidal 1988). Color development occurs over several hours, but the time required to produce maximum signal varies considerably, depending on the amount of antibody bound to the target molecule.

BCIP/NBT is a sensitive detector of alkaline phosphatase activity but is not quantitative. Quantitative assays of the enzyme are carried out using the chromogenic substate *p*-nitrophenyl phosphate (McComb and Bowers 1972; Brickman and Beckwith 1975; Michaelis et al. 1983). This substrate is sold by Sigma under

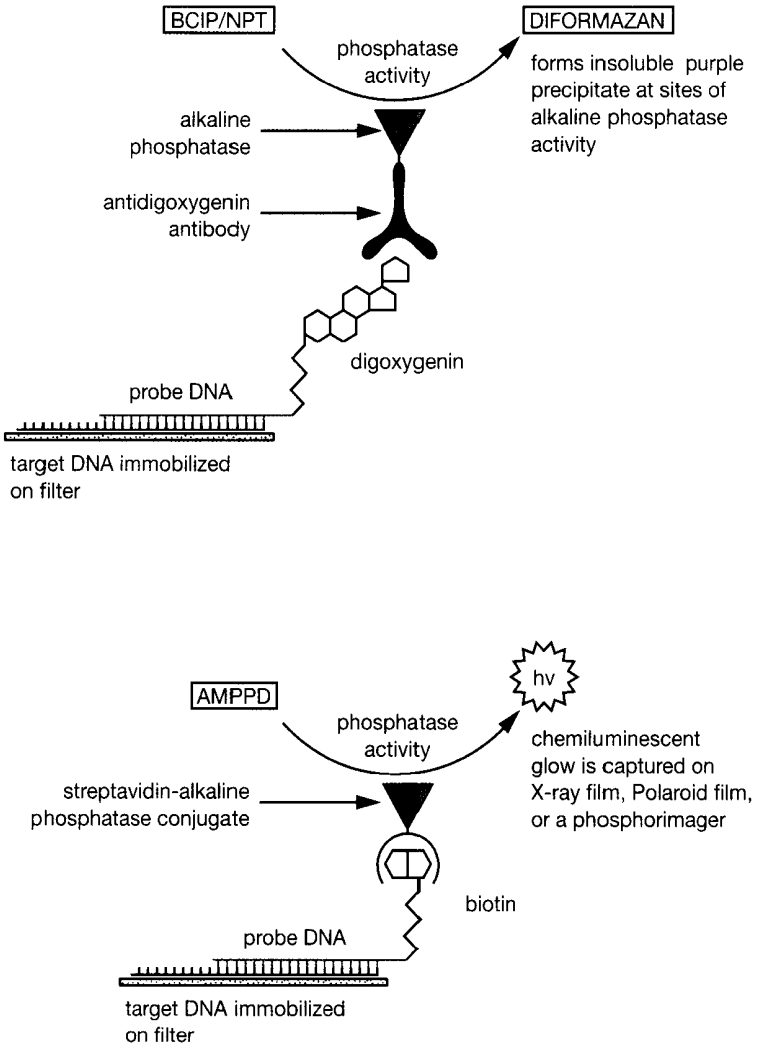


FIGURE A9-8 Detection of Digoxygenin- and Biotin-labeled Nucleic Acid Probes with BCIP/NPT

the name "Sigma No. 104 phosphatase substrate." Hydrolysis of Sigma 104 generates *p*-nitrophenol, which in aqueous solution absorbs strongly at 420 nm. A more sensitive bioluminescence-based assay has also been described (Miska and Geiger 1987) in which D-luciferin-*O*-phosphate is used as a substrate. The amount of luciferin released by hydrolysis of the substrate is titrated using luciferase, and light impulses are then measured in a luminometer.

In molecular cloning, BCIP/NPT is widely used as an indicator in nonradioactive systems to detect nucleic acids or proteins. Almost always, these systems consist of several components that are used in sequence. When working at its best, the BCIP/NPT indicator system is sensitive enough to detect single copies of genes in Southern hybridization of total mammalian DNA. Typical arrangements are shown in Figure A9-8.

Southern, northern, and dot blots can be rehybridized by stripping the precipitate of formazan from charged nylon filters with *N,N*-dimethylformamide. Note that *N,N*-dimethylformamide's vapor is irritating to skin and mucous membranes and should therefore be used only in a well-ventilated chemical fume hood. Digoxygenin-labeled oligonucleotide probes can be removed from membranes by *N,N*-dimethylformamide at room temperature or by heating to 70–75°C in a buffer containing high concentrations of SDS (Richterich and Church 1993). The membranes then can be reprobed.

Chromogenic detection of alkaline phosphatase is far less sensitive than the luminescent method using the soluble 1,2-dioxetane substrate AMPPD (Schaap et al. 1987). In this system, the sensitivity in dot blots is increased from 0.2 pg in 16 hours to 1 fg in 1 hour. In Southern hybridizations, using AMPPD as an indicator, the sensitivity is ~70 fg in 1 hour (e.g., please see Allefs et al. 1990).

In addition to its use as an indicator for alkaline phosphatase conjugates, BCIP/NBT has also been used to detect alkaline phosphatase expressed in sections of vertebrate tissues (Fields-Berry et al. 1992) and to identify bacterial colonies that express BAP (Brickman and Beckwith 1975; for review, please see Manoil et al. 1990).

BCIP is sold as a disodium salt or a toluidine salt. The toluidine salt of BCIP is suitable for use with the commercially available nonradioactive detection systems for nucleic acids and proteins.

AMPPD

AMPPD (adamantyl-1,2-dioxetane phosphate also known as -[2′spiroadamantane]-4-methoxy-3-[3′′-(phosphoryl)phenyl]1,2,-dioxetane *or* disodium 3-(4-methoxyspiro[1,2-dioxetane-3,2′-tricyclo-[3.3.1.^{3,7}]decan]-4-yl)-phenylphosphate) is a substrate used in alkaline-phosphatase-triggered chemiluminescence for the detection of biopolymers immobilized on nylon or PVDF membranes (Bronstein and McGrath 1989; Bronstein et al. 1990; Tizard et al. 1990; Gillespie and Hudspeth 1991). Figure A9-9 shows a typical format used for the detection of proteins in western blotting and for hybridization of immobilized nucleic acids.

The sensitivity of chemiluminescent detection of DNA, RNA, and proteins using AMPPD is superior to available colorimetric, bioluminescent, or fluorimetric methods and is at least equal to the traditional autoradiographic techniques that have dominated molecular cloning for the last 20 years (e.g, please see Beck and Köster 1990; Bronstein et al. 1990; Carlson et al. 1990; Pollard-Knight et al. 1990). In solution, the light output from the activity of fewer than 1000 molecules (1 zmole or 10^{-21} moles) of alkaline phosphatase may be measured (Schaap et al. 1989). Less than 0.1 pg of RNA or DNA may be detected in standard Southern and northern hybridizations (e.g, please see Beck et al. 1989), whereas <1 pg of a target protein may be detected in western blots of total cell proteins (Gillespie and Hudspeth 1991).

Figure A9-10 shows the events triggered by dephosphorylation of AMPPD that leads to the production of light. Alkaline phosphatase catalyzes the removal of the single phosphate residue of AMPPD, generating a moderately stable dioxetane anion that fragments into adamantanone and the excited state of a methyl-*meta*oxybenzoate anion. On return to ground state, the anion emits visible, yellow-green light (Bronstein et al. 1989). The dephosphorylation of dioxetanes by alkaline phosphatase is quite efficient with a turnover rate of ~4.0×10^3 molecules s^{-1} (Schaap, cited in Beck and Köster 1990). However, the half-life of the excited 1,2 dioxetane anion is comparatively long, varying from 2 minutes to several hours, depending on the

local environment (Bronstein 1990). Thus, when the dephosphorylation reaction is carried out in the presence of excess AMPPD, the dioxetane anion is initially produced more rapidly than it decays. This behavior explains why chemiluminescence is emitted in the form of a "glow" that increases in intensity for several minutes and then persists for several hours (Figure A9-11). On nylon membranes, the kinetics are even slower because the excited dioxetane anion is stabilized by hydrophobic pockets in the membrane (Tizard et al. 1990). The hydrophobic interactions between the nylon and the anion also cause a "blue shift" of ~10 nm in the emitted light, i.e., from 477 nm to 466 nm (Beck and Köster 1990; Bronstein 1990).

In most experimental situations, the extended kinetics of chemiluminescence on nylon filters are advantageous because they allow time to make capture images at several exposures. However, the slow kinetics may be of practical importance when alkaline-phosphatase-triggered chemiluminescence is used to detect extremely low concentrations of DNA, RNA, or protein, for example, when the target band of DNA on a filter is expected to contain $<10^{-18}$ moles. In such cases, CSPD, a halogen-substituted derivative of AMPPD, may be a better choice. The addition of a chlorine atom to the 5-position of the adamantyl group

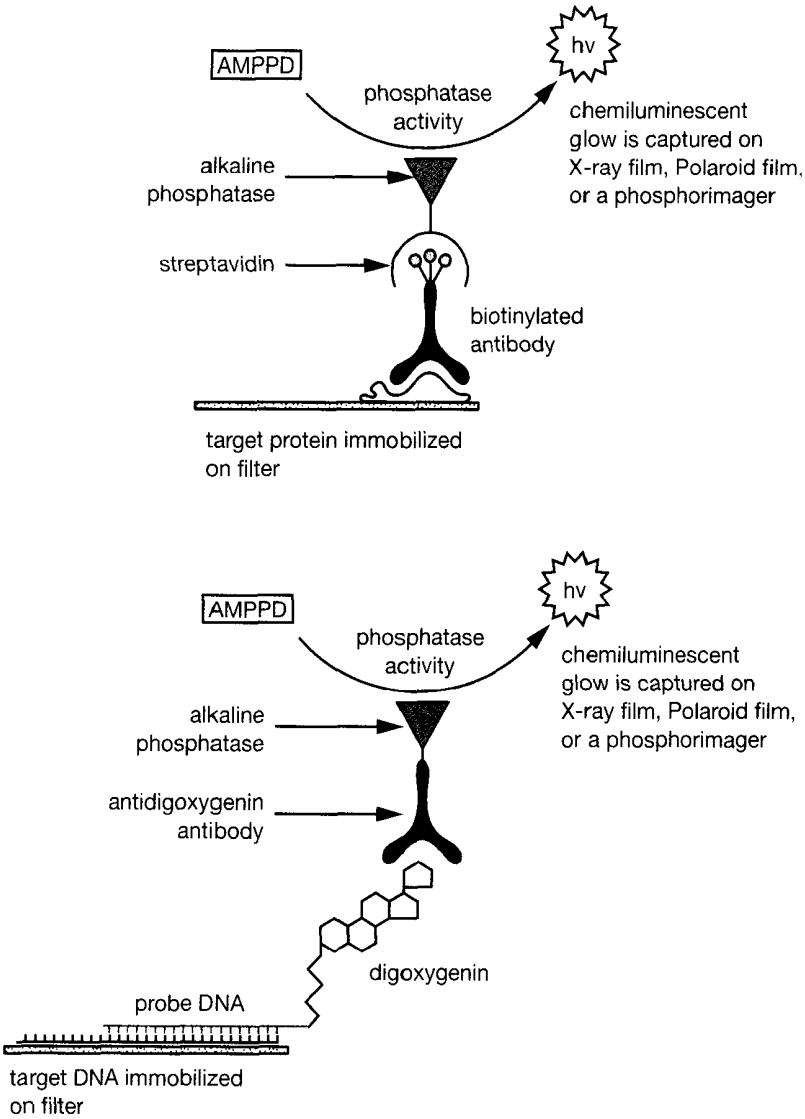

FIGURE A9-9 Detection of Immobilized Nucleic Acids and Proteins with AMPPD

(*Top*) Detection of target protein by western blotting; (*bottom*) detection of nucleic acid sequence in Southern or northern blotting.

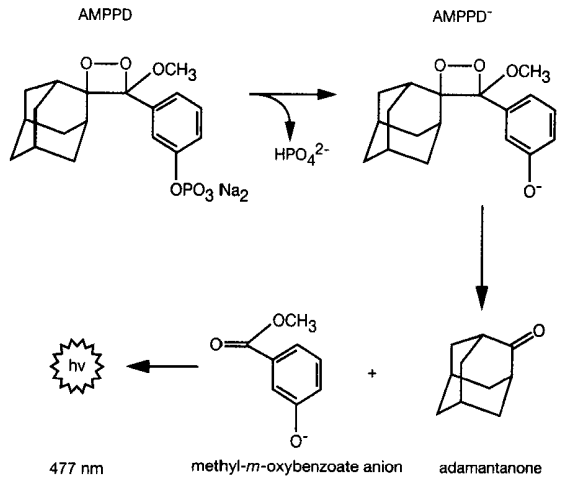

FIGURE A9-10 Chemiluminescent Generation of Light by Dephosphorylation of AMPPD

diminishes the tendency of the 1,2 dioxetane to self-aggregate and restricts its interactions with nylon filters. With this compound, the time to reach maximum light emission is markedly reduced so that very small quantities of target molecules can be detected rapidly (e.g., please see Martin et al. 1991).

CDP-*Star*, a third 1,2-dioxetane substrate, follows a decomposition pathway similar to that of AMPPD and CSPD, but it produces a signal several times brighter. The CDP-*Star* signal also peaks earlier in the reaction and persists for longer (up to several days) than that of its rivals (source: Tropix Web Site www.tropix.com).

Nitrocellulose filters lack the appropriate hydrophobic surfaces and are therefore not recommended for use with either AMPPD, CSPD, or CDP-*Star*; however, PVDF can be used with all three.

AMPPD is an extremely stable compound: The activation energy for its thermal decomposition in H_2O is 21.5 kcal/mole and its half-life at 25°C is ~20 years. Since nonenzymatic hydrolysis is very slow, the background of chemiluminescence on blots is minimal. In fact, the sensitivity of chemiluminescent detection of proteins and nucleic acids is generally limited, not by spontaneous decay of AMPPD, but by the presence of trace amounts in buffers of alkaline phosphatase of bacterial origin (Bronstein et al. 1990).

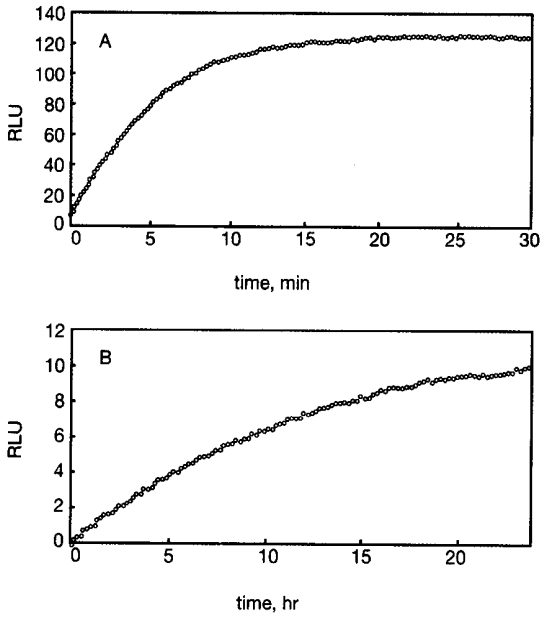

FIGURE A9-11 Kinetics of Chemiluminescence of AMPPD

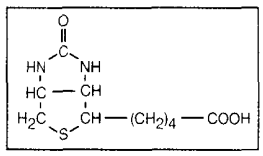
Shown are the kinetics of chemiluminescence of alkaline-phosphatase-catalyzed decomposition of AMPPD in (*A*) 0.05 M bicarbonate/carbonate/1 mM $MgCl_2$ (pH 9.5) or (*B*) on a Biodye A membrane. Luminescent rates are expressed as relative light units (RLU). (Reprinted, with permission, from Tizard et al. 1990.)

AVIDIN AND BIOTIN



Biotin (vitamin H, coenzyme R; F.W. 244.3) is a water-soluble vitamin that binds with high affinity to avidin (M_r = 66,000), a tetrameric, basic glycoprotein, abundant in raw egg white (for review, please see Green 1975). Because each subunit of avidin can bind one biotin molecule, 1 mg of avidin can bind ~14.8 µg of biotin. The dissociation constant of the complex is ~1.0×10^{-15} M, which corresponds to a free energy of association of 21 kcal/mole. With such a tight association, the off-rate is extremely slow and the half-life of the complex is 200 days at pH 7.0 (Green and Toms 1973). For all practical purposes, therefore, the interaction between avidin and biotin is essentially irreversible. In addition, the avidin-biotin complex is resistant to chaotropic agents (3 M guanidine hydrochloride) and to extremes of pH and ionic strength (Green and Toms 1972). The strength of the interaction between biotin and avidin provides a bridging system to bring molecules with no natural affinity for one another into close contact.

Biotin can be attached to a variety of proteins and nucleic acids, often without altering their properties. Similarly, avidin (or streptavidin, its nonglycosylated prokaryotic equivalent) can be joined to reporter enzymes whose activity can be used to locate and/or quantitate avidin-biotin-target complexes. For example, in enzyme immunoassays, a biotinylated antibody bound to an immobilized antigen or primary antibody is often assayed by an enzyme, such as horseradish peroxidase or alkaline phosphatase, that has been coupled to avidin (Young et al. 1985; French et al. 1986). In addition, in nucleic acid hybridization, biotinylated probes can be detected by avidin-conjugated enzymes or fluorochromes. Derivatives of biotin are used to biotinylate proteins, peptides, and other molecules (for review and references, please see Wilchek and Bayer 1990).

The disadvantage of egg white avidin is the relatively high background of nonspecific binding caused by the presence of oligosaccharide groups. This problem can be reduced by using streptavidin, a tetrameric nonglycosylated 58,000-dalton protein secreted by *Streptomyces avidini* that binds biotin with approximately the same affinity as egg-white avidin.

For more information on biotin, please see the information panel on **BIOTIN** in Chapter 11. Much useful information about avidin-biotin chemistry and avidin-biotin techniques is available in a handbook entitled *Avidin-Biotin Chemistry: A Handbook*, published and sold by Pierce.

IMMUNOGLOBULIN-BINDING PROTEINS: PROTEINS A, G, AND L

Protein A

Protein A, a cell wall component of *Staphylococcus aureus*, binds to the Fc region of immunoglobulins (IgG) of many mammalian species and thereby helps the bacterium escape the immune response of the host (Forsgren and Sjöquist 1966; for review, please see Langone 1982; Boyle and Reis 1987; Boyle 1990; Bouvet 1994) (please see Table A9-7). The interaction of protein A with the Fc portion of IgG molecules does not block the ability of the antibody to combine with its antigen (Figure A9-13). Protein A has been used extensively for both qualitative and quantitative analysis of immunochemical reactions (Goding 1978; Harlow and Lane 1988, 1999).

[a]Protein LA combines the immunoglobulin-binding domains of protein A and protein L.

- ***When coupled to a radioactive, enzymatic, or fluorescent tag,*** protein A is an excellent reagent to detect and quantitate antibodies with high affinity for the protein. Protein A chemically coupled to particles of colloidal gold can be used to locate IgGs by electron microscopy.
- ***Protein A immobilized on a solid support*** can be used to purify antibodies and to collect immune complexes, antigens, and whole cells (please see Figure A9-14).
- ***Using ELISA-like sandwich techniques, DNA fragments can be purified*** and detected using purified protein A or engineered fusion proteins containing the IgG-binding domains of protein A domains (e.g., please see Lindbladh et al. 1987; Peterhans et al. 1987; Werstuck and Capone 1989; for review, please see Stahl et al. 1993).

Chimeric proteins containing two independent ligand-binding domains have also been explored as adhesive immunological reagents. For example:

- ***Molecules labeled with digoxygenin*** may be labeled with a fusion protein containing an IgG-binding domain of protein A and an antigen-binding site of an antidigoxygenin antibody. The label may then be detected with any antibody that binds to protein A (Tai et al. 1990).
- ***Streptavidin-protein A chimeras*** may be used for indirect labeling of antibodies with enzymes (Sano and Cantor 1991).
- ***Protein A-maltose binding protein chimeras*** may be used as bifunctional reagents for binding antibodies to a solid matrix (Xue et al. 1995).
- ***Protein A*** can be used as an affinity tag to purify fusion proteins synthesized in pro- and eukaryotic cells (e.g., please see Kobatake et al. 1995; Nilsson et al. 1985; for reviews, please see Nilsson and Abrahmsén 1990; Uhlén and Moks 1990; Uhlén et al. 1992; Stahl et al. 1993). The simplest protocol involves purifying fusion proteins containing the Fc-binding domains of protein A by affinity chromatography with an IgG resin (Uhlén et al. 1983; Nilsson et al. 1985).

The gene for protein A (Uhlén et al. 1984) encodes a preprotein of 509 amino acids that consists of a signal sequence, which is removed during secretion: five homologous, independent IgG-binding domains, each of 58 amino acids; and a repetitive carboxy-terminal anchor (region X), of 180 amino acids. Crystallographic analysis of cocrystals of a single IgG-binding domain of protein A bound to human Fc shows that the IgG-binding domain contains two α-helices that form extensive hydrophobic interactions with the second and third constant regions of the Fc domain (Deisenhofer 1981).

Protein G

Protein G was first isolated from streptococcal strains belonging to groups C and G (Björck and Kronvall 1984). Protein G, like staphylococcal protein A, has a high affinity for the Fc region of mammalian antibodies. However, the two proteins are quite different in structure and have different affinities for antibodies (please see Table A9-8) (Åkerström et al. 1985). Whereas protein A is rich in α-helices and forms hydrophobic interactions with immunoglobulins, protein G has a large content of β-sheet structures (Olsson et al. 1987; Gronenborn et al. 1991). Protein G binds to the first constant domain of IgG (Erntell et al. 1985) and the interaction between the two molecules involves alignment of β strands to form a continuous β-sheet across the interacting surfaces (Derrick and Wigley 1992). The structures recognized by protein G and protein A are closely related (Stone et al. 1989). However, many species and subclasses of IgGs that do not bind well to protein A bind with high efficiency to protein G. For example, protein G is able to bind efficiently to human immunoglobulins of the IgG3 subclass, whereas protein A cannot (Sjöbring et al. 1991). Chimeric proteins, containing ligand-binding domains of proteins A and G exhibit the combined specificities of the parental proteins (Eliasson et al. 1988, 1989).

One potential disadvantage of protein G as a reagent to collect immune complexes and to purify IgGs is that it binds strongly to bovine serum albumin (Björck et al. 1987). However, the IgG-binding site and the serum albumin-binding site are structurally distinct (Nygren et al. 1988; Sjöbring et al. 1989) and engineered versions of protein G lacking the albumin-binding site are commercially available. The serum albumin domains of protein G have been used as purification tags in fusion proteins (Nygren et al. 1988, 1991; Sjölander et al. 1993).

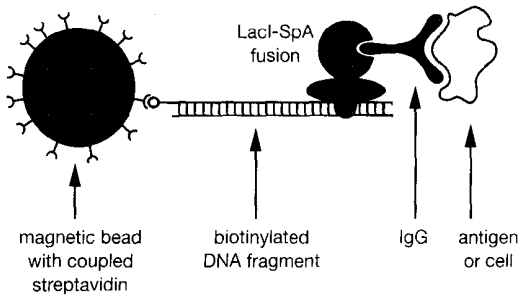

FIGURE A9-14 Isolation of Antigens or Whole Cells Using a LacI-SpA Fusion Protein

The figure illustrates the use of a *lac* repressor (LacI-SpA) fusion protein for reversible recovery of protein antigens or whole cells using magnetic beads with a coupled DNA fragment containing the lac operator (*lac*O) sequence.

Protein L

Protein L (M_r ~76,000) (Åkerström and Björck 1989) is a cell-wall component of the anaerobic bacterium *Peptostreptococcus magnus* (Björck 1988), which binds with high affinity to the κ light chains of immunoglobulins. This interaction does not interfere with the antigen-binding sites of the antibody (Åkerstrom and Björck 1989). Protein L binds to a wide range of Ig subclasses including human, mouse, rat, rabbit, and chicken (please see Table A9-8), but it does not bind to bovine, goat, or sheep Ig. These species-specific binding characteristics make protein L a useful tool for antibody purification, in particular for the purification of monoclonal antibodies from media supplemented with fetal bovine serum or bovine serum albumin and the purification of humanized antibodies from transgenic animals. Protein L is available commercially (e.g., CLONTECH and Pierce).

Appendix 10

DNA Array Technology

Vivek Mittal
Cold Spring Harbor Laboratory

INTRODUCTION

With the growing abundance of sequencing data from such diverse organisms as yeast, bacteria, fruit fly, several plants, and humans comes a pressing need for developing and applying technologies to perform comprehensive functional analyses. DNA microarrays have been developed in response to the need for simultaneous analysis of the patterns of expression of thousands of genes. Microarrays therefore offer tremendous advantages over traditional "single-gene" methods such as northern hybrization, reverse transcriptase–polymerase chain reaction (RT-PCR), and nuclease protection.

The Process

In a typical application, high-density nucleic acid samples, usually cDNAs or oligonucleotides, are delivered (or printed) by a robotic system onto very small, discrete areas of coated substrates (or chips) usually microscopic glass slides or membrane filters, and then immobilized to the substrate. The resulting microarray is then hybridized with a complex mixture of fluorescently labeled nucleic acids (probe) derived from a desired source. Following hybridization, the fluorescent markers are detected using a high-resolution laser scanner. A pattern of gene expression is obtained by analyzing the signal emitted from each spot with digital imaging software. The pattern of gene expression of the experimental sample can then be compared with that of a control for differential analyses. The use of terms varies in the literature; however, in this discussion, probe refers to the mixture of labeled nucleic acids and target denotes the immobilized array of nucleic acid samples.

Applications

Two chief applications of DNA microarray technology are described briefly below. Other applications include gene discovery, genotyping, and pathway analysis.

Analysis of Gene Expression

Gene expression patterns are biologically informative and provide direct clues to function. Correlating changes in gene expression with specific changes in physiology can provide mechanistic insights into the dynamics of various biological processes in an organism. Microarray technology may be used, for example, for simultaneously detecting expression of many genes in different tissues or at different developmental stages; for comparing genes expressed in normal and diseased states; and for analyzing the response of cells exposed to drugs or different physiological conditions. The value of microarrays for identifying patterns of gene expression has been demonstrated clearly in organisms such as yeast, fruit flies, mice, and humans. In yeast, for example, gene expression patterns obtained using cDNA arrays correlate very well with changes in the yeast cell cycle (yeast data sets and analysis tools are available at cmgm.stanford.edu/pbrown/). In explorations of human cancer, expression arrays have aided in the molecular classification of B-cell lymphomas and leukemias. These studies are likely to help us to understand the pathophysiology of cancer and to define targets for therapeutic intervention.

Monitoring Changes in Genomic DNA

Cancer cells typically exhibit genomic instability, including gain-of-function mutations of oncogenes often marked by gene amplifications or translocations and loss-of-function mutations in

tumor suppressor genes often marked by point mutations and subsequent loss of heterozygosity or by homozygous deletions. Three laboratories are now using microarrays for high-resolution analysis of genomic DNA:

- The Brown laboratory (cmgm.stanford.edu/pbrown) uses cDNA microarrays.
- The Gray laboratory (cc.ucsf.edu/gray/) uses microarrays of genomic DNA cloned in BAC vectors.
- The Wigler laboratory (nucleus.cshl.org/wigler/) uses microarrays derived from low-complexity representations of genomic DNA.

Which method or combination of methods will be successful in measuring changes in copy number of nonabundant sequences with high statistical confidence in clinical samples remains to be determined.

Mutations and polymorphisms, in particular single nucleotide polymorphisms (SNPs), can be studied within and among species using high-density oligonucleotide arrays. These so-called mutation detection arrays consist of oligonucleotides representing all known sequence variants of a gene or a collection of genes. Because hybridization to oligonucleotides is sensitive enough to detect single-nucleotide mismatches, an homologous gene carrying an unknown sequence variation can be screened rapidly for a large number of changes. Examples of mutation detection arrays include a p53 gene chip, an HIV gene chip, and a breast cancer BRCA-1 gene chip.

The remainder of this discussion focuses on the technological aspects of DNA microarrays, with little further emphasis on applications. It is imperative to remember that DNA microarrays represent a developing technology and that there remain substantial obstacles in the design and analysis of these microarrays.

OVERVIEW AND SCHEMA OF DNA MICROARRAYS

There are six basic steps in performing a DNA microarray experiment (please see Figure A10-1):

1. Processing cDNA clones to generate print-ready material.
2. Printing cDNA clones (or oligonucleotides) onto a substrate.
3. Sample RNA isolation (either total RNA or mRNA).
4. Preparation of the probe (e.g., cDNA synthesis and labeling).
5. Hybridization of the labeled probe DNA to the DNA arrayed on the substrate.
6. Image acquisition of hybridization results and image analysis.

Clone Sources and Their Description

The initial resources required to design and fabricate gene expression microarrays include genomic or cDNA sequence data, cDNA clones, or both. Traditional approaches to gene discovery, such as cloning, have identified only a small subset of genes in an organism. More recent approaches, for example, large-scale sequencing of expressed sequence tags (ESTs), have greatly enhanced the rate of gene discovery. GenBank now has a collection of >1 million human ESTs. EST sequences are deposited into the databank dbEST (www.ncbi.nlm.nih.gov/dbEST/index.html), a division of GenBank. Sequences stored in dbEST are subjected to an automated

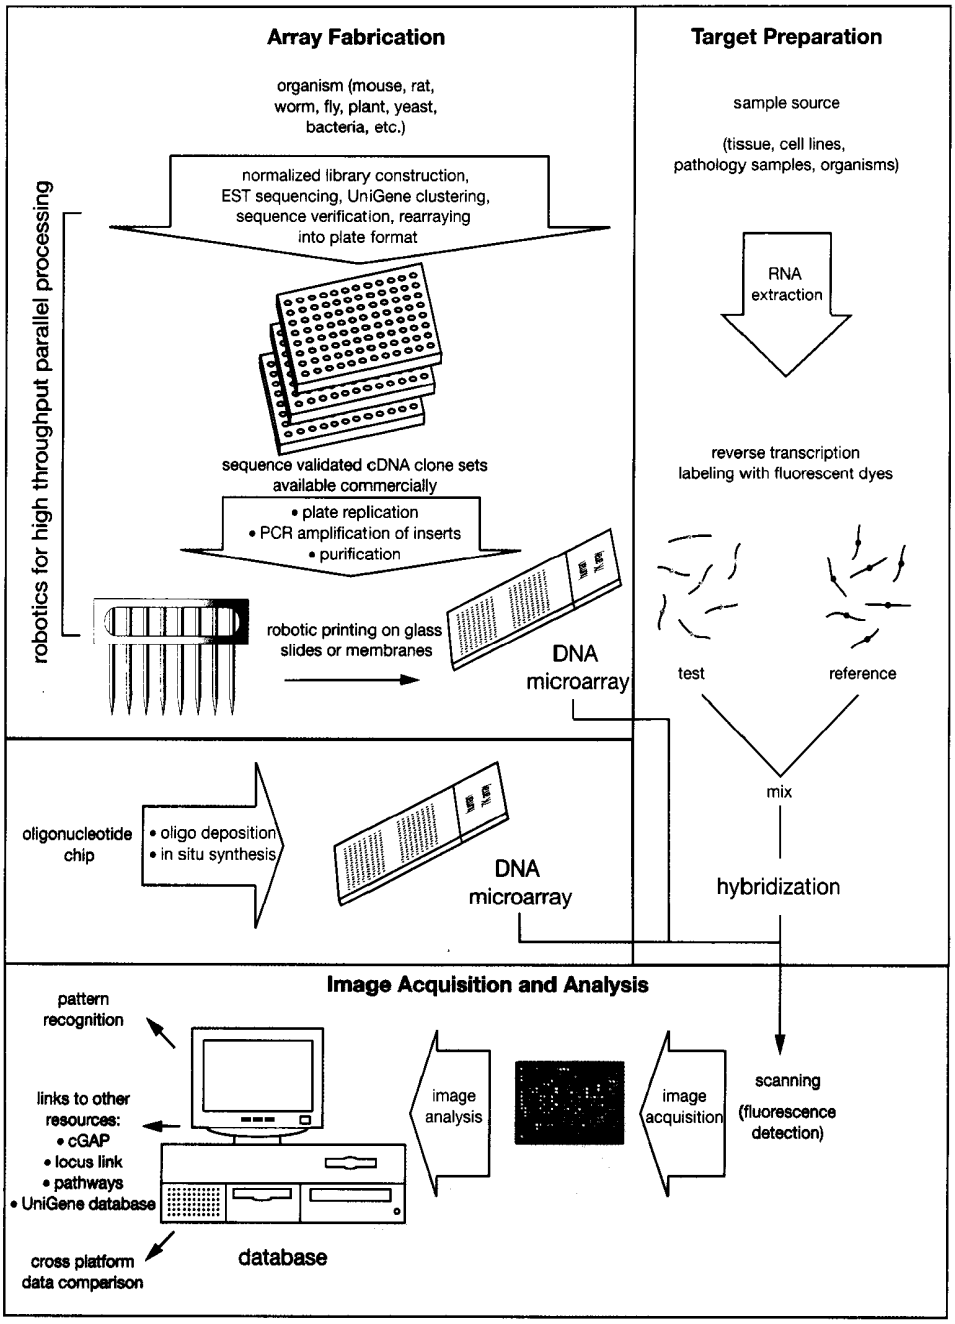

FIGURE A10-1 Flowchart: Performing a Microarray Experiment

process called UniGene that compares ESTs and assembles overlapping sequences into clusters (www.ncbi.nlm.nih.gov/UniGene/index.html). Clone sets, comprising the largest single representative of each cluster, are sequence-verified and then made available to the public through licensed vendors (http://image.llnl.gov/image/html/idistributors.shtml).

The current UniGene collection of human and mouse cDNA sequences (~40,000 and 10,000 sequence-validated clones, respectively) is available for purchase through official vendors such as Research Genetics (www.resgen.com) and Incyte Genomics (gem.incyte.com/gem/products/unigemv2.shtml). The UniGene collection is likely to expand proportionally with progress in

the various genome sequencing projects. Another resource for the human cDNA collection is the German Human Genome Project (http://www.rzpd.de/general/html/glossary/unigene.shtml). A comprehensive, sequence-validated full-length mouse cDNA collection is also available from Riken Genomic Sciences Center, Japan (http://hgp.gsc.riken.go.jp/) and from the National Institute of Aging (http://lgsun.grc.nia.nih.gov/). Table A10-1 presents genomic resources for organisms other than human and mouse that are available for microarray fabrication.

Robotics for High-throughput Processing

Considering the enormous size of clone sets derived from eukaryotic genomes, some degree of automation is typically required to obtain print-ready material with a high degree of accuracy and reproducibility. Two robotic systems, designed for high-throughput parallel processing, encompassing fully automated or semi-automated liquid-dispensing and plate-handling systems are the Robbins Hydra Work Station (www.robsci.com), which uses high-precision Teflon-coated capillaries, and the Beckman Coulter Multimek (www.beckmancoulter.com), which uses disposable tips. In addition to accurate volumetric handling of liquids to and from standard 96-well or 384-well plates, these robotic systems also have reformatting capabilities, allowing the transfer of material between 96- and 384-well plates on the same work surface. Each robotic unit can be integrated with other automated systems. Robots with analogous capabilities are the Qiagen BioRobot (www.qiagen.com/automation/), Tecan AG GENESIS sample processor (www.tecan.com), Packard MultiPROBE (www.packardinst.com), and Tomtec Quadra (www.tomtec.com).

Solid Support and Surface Chemistry

The development of novel solid supports and efficient chemistries for the manufacture of spatially resolved microscopic DNA arrays is essential if the potential of DNA chip technology is to be fully realized. A good substrate must bind DNA efficiently and uniformly, and leave the surface-bound DNA both functional and accessible. The density of DNA attached to the substrate must be high, the bound array must be stable, and the substrate must be chemically inert and have ultra-low intrinsic fluorescence while providing strong signal intensity and a broad dynamic range. Two basic substrates commonly used are glass and membrane filters.

Chemically treated microscope glass slides are the most widely used support. Glass is optically superior, durable under high temperatures of hybridization, and nonporous, thus keeping hybridization volumes to a minimum; it has low autofluorescence and good geometry and is amenable to high-density array fabrication. The major disadvantages of glass are that its planar surface has low loading capacity, the array on a glass support is not reusable, and an efficient chemistry for linking DNA to glass is lacking.

Glass slides coated with amine or aldehyde surface chemistry are available from Corning Microarray Technology (CMT) (http://www.cmt.corning.com/), Cel (www.cel-1.com/bio-molecular_products.htm), and TeleChem International (www.Arrayit.com). It is also possible to attach DNA covalently to glass slides. SurModics' 3D-Link Activated Slides are coated with a three-dimensional matrix that covalently binds amine-terminated DNA (PCR products or oligonucleotides) through endpoint attachment (www.surmodics.com). A common method for making amine-coated glass slides in-house is to treat them with polylysine. Details on the chemistry and instructions for preparing polylysine slides are available on the Brown laboratory Web Site (http://cmgm.stanford.edu/pbrown/index.html).

A major effort is now under way to explore the use of porous materials (such as nitrocellulose, nylon, and acrylamide) as substrates for attachment of nucleic acids. Porous substrates per-

TABLE A10-1 Genomic Resources for Microarrays

ORGANISM	MATERIAL	COMMENTS	RESOURCE
Rat	6000 cDNA clones	1500 sequence-validated clones are available.	Research Genetics (www.resgen.com)
Yeast (*S. cerevisiae*)	ORF-specific primer pairs	These primers are designed to amplify complete coding regions including start and stop codons from genomic DNA (possible because very few yeast genes contain introns). mit the immobilization of large amounts of target molecules due to greatly enhanced surface area, providing enhanced sensitivity compared to planar substrates. Porous substrates based on polymer matrices provide a three-dimensional hydrophilic environment similar to free solution for biomolecular interactions. The utility of nitrocellulose-coated glass surfaces for microarrays has been demonstrated. The high binding capacity of nitrocellulose combined with low background

fluorescence makes these membrane-coated slides a superior substrate for microarrays. They are available from Schleicher & Schuell (www.s-und-s.de/).

Microarray Production

Microarrays may be produced using one of the methods described below. Alternatively, prefabricated microarrays from many sources are available commercially. Microarray fabrication technologies are of two kinds: in situ synthesis of nucleic acids and exogenous deposition of prepared materials on solid substrates. Three types of advanced technologies have emerged as early favorites in automated microarray production.

Contact Printing

In this approach, DNA fragments are directly deposited onto a glass support using a precision robot. The DNA sample is loaded into a spotting pin by capillary action and small volumes are transferred to a solid surface, such as a microscope slide, by direct physical contact between the pin and the solid substrate. After the first spotting cycle, the pin is washed and a second sample is then transferred to an adjacent address. A robotic control system and multiplexed print heads allow automated microarray fabrication. One of the crucial factors affecting array fabrication using the contact printing method is the reproducibility and durability of the spotting pins (also called quills or tips). Custom, machine-made high-precision pins can be obtained from Telechem International (www.arrayit.com), Majer Precision Engineering (http://www.majerprecision.com/), and Die-Tech (San Francisco).

The first contact printing arrayer was designed and built in the laboratory of Patrick Brown at Stanford University. An arrayer based largely on the Stanford prototype was subsequently fabricated in the National Human Genome Research Institute (NHGRI, www.nhgri.nih.gov/DIR/LCG/15K/HTML) and at the Albert Einstein College of Medicine (http://sequence.aecom.yu.edu/bioinf/microarray/printer.html). For the "do-it-yourself" approach, detailed instructions for assembling a contact printing arrayer, including a description of the necessary parts, can be found at http://cmgm.stanford.edu/pbrown/mguide/. Commercial robotic systems for making arrays by contact printing are offered by

- Cartesian Technology (www.cartesiantech.com/pixsyspa.htm)
- GeneMachines' OmniGrid (www.genemachines.com)
- Genomic Solutions (www.genomicsolutions.com)
- BioRobotics (www.biorobotics.co.uk)
- Genetix (www.genetix.co.uk/Microarraying.htm)
- Intelligent Bio-Instruments (www.intelligentbio.com)
- Genepak (www.genpakdna.com)
- Amersham Pharmacia Biotech (www.apbiotech.com/application/microarray/)

A less expensive alternative to robotic spotting of samples onto substrates is to use a handheld 384-pin arraying device, available from V & P Scientific, Inc. (www.vp-scientific.com/). This vendor offers pin tools for 96-, 384-, and 1536-well plates, as well as registration accessories that allow the creation of high-density arrays of up to 3456 samples per array.

Photolithography

Developed by Affymetrix (www.affymetrix.com), this method combines photolithography technology from the semiconductor industry with DNA synthetic chemistry to permit the manufacture of high-density oligonucleotide microarrays. A solid support is derivatized with a covalent linker terminated with a photolabile protecting group. A photomask is used to determine which positions react with light. Exposure to light causes dissociation of the protecting group at the exposed site. A chemical coupling reaction is then used to add a specific nucleotide to the new deprotected site, and the process is repeated using a different mask. The end result is a precision-made array, containing many oligonucleotides of known sequence. The Affymetrix method for making arrays demands a technical sophistication that generally cannot be imported to academic laboratory settings.

Pin and Ring

A "pin and ring" device is used for sample spotting by a noncontact mechanism. The ring holds a droplet of solution picked up from the well of a microtiter plate, and the pin punches a smaller droplet from this reservoir onto the substrate. The main advantage of this technology is the ability to generate consistent delivery from a variety of solvents with DNA, proteins, and small molecules on virtually any substrates. The technology as it currently stands has a high degree of precision but lacks the desired robustness. This technology was developed at Genetic Microsystems, now wholly owned by Affymetrix (www.affymetrix.com).

Commercial Arrays and Integrated Array Services

The formidable task of generating microarrays is time-consuming and frequently cost-prohibitive for many laboratories. Some commercial ventures have fabricated microarrays on membranes (nylon and nitrocellulose) and/or glass, and these are available commercially (please see Table A10-2). Commercial arrays are also available from Hyseq (www.hyseq.com) and Stratagene (www.stratagene.com/gc/gene.htm).

Choice of an Array System

The choice of a DNA array for a particular experiment requires consideration of the expense, desired density of DNA on the array, reproducibility among chips, and type of DNA to be immobilized on the surface. The first decision is whether the chips should contain immobilized cDNAs or shorter oligonucleotide sequences. cDNA samples must be spotted onto the chips as complete molecules, whereas oligonucleotides can be either spotted or synthesized on the surface of a chip with high fidelity. Another important decision is whether the user will make the arrays or purchase the chips. The advantages and disadvantages for each of these issues for each approach are presented in Table A10-3.

TABLE A10-2 Commercial Arrays

PRODUCTS	SOURCE	DESCRIPTION	COMMENTS
GeneChip product line (includes high-density DNA arrays for human, murine, yeast, and plant genomes)	Affymetrix www.affymetrix.com	GeneChip expression arrays use ~20 pairs of matched and mismatched oligonucleotides to interrogate each transcript. GeneChips designed for clinical settings include: *p53 GeneChip* to detect single-nucleotide polymorphisms of the p53 tumor-suppressor gene. *HIV GeneChip* to detect mutations in the HIV-1 protease and viral reverse transcriptase genes. *P450 GeneChip*, which focuses on mutations of key liver enzymes that metabolize drugs.	This oligonucleotide-pairing strategy helps identify and minimize the effects of nonspecific hybridization and background signal (a major concern in array experiments) to permit sensitive and accurate recognition of low-intensity hybridization patterns from mRNAs. In addition to expression monitoring, Affymetrix chips are also used for sequence analysis, genotyping, and SNP mapping. An integrated platform comprising an automated hybridization station, array scanner, and software for image analysis is mandatory for Affymetrix DNA chip users. A Pathways analysis software package from the same source is available for image analysis of the GeneFilters.
GeneFilters microarrays (for human, murine, and yeast)	Research Genetics www.resgen.com	The human cDNA arrays consist of 30,000 nonredundant sequence-validated I.M.A.G.E clones (on six different membranes) chosen from the UniGene set. The tissue-specific GeneFilters are gene expression arrays that contain sequences enriched for expression in prostate, ovary, breast, and colon tissues. Membranes carrying 6144 yeast ORFs and 10,000 sequence-validated rat cDNAs are also available.	
Atlas cDNA arrays	CLONTECH www.clontech.com	Arrays on nylon membranes or glass are available for a range of mammalian genes involved in cellular pathways such as oncogenesis, apoptosis, and cell cycle regulation. The arrays contain human, mouse, or rat cDNA and are usually spotted in duplicate. The Atlas human 1.0 cDNA array (on glass) represents 1081 known genes, covering a broad range of biologically significant genes and pathways.	All of the immobilized cDNAs have been tested for optimal performance and minimal cross hybridization. An integrated Expression Array platform, including a total RNA purification/labeling system, image analysis software, and bioinformatics database, is available.
Membrane Expression arrays	Incyte Genomics www.incyte.com/expression/argem1.html	The human array represents 20,000 I.M.A.G.E cDNA clones of human ESTs. The plant array contains clones representing 7900 *Arabidopsis thaliana* genes from all major tissue categories (roots, rosettes, and inflorescence).	Arrays carrying proprietary Incyte sequences are available only to Incyte subscribers. The data analysis is done in-house.
Membrane arrays for human and mouse	Super Array Inc. www.superarray.com	Super Array Incorporated provides pathway-specific gene expression membrane arrays.	Custom arrays are also available.
Expression microarrays	Genometrix Inc. www.genometrix.com	Microarrays are available in membrane format or on microscope slides for analyzing cancer-related human gene expression and mouse gene expression. Arrays for risk and toxicity assessments are also available.	A BioScanner for high-density imaging accompanied by GeneView software for image analysis is available.
Genomic microarray	Vysis Inc. www.vysis.com	The array contains >58 different gene targets, reported to be amplified in various human cancers or cancer cell lines, including HER-2/neu, cyclin D1, and Myc. The array contains large fragments (80–150 kb) of genomic DNA spotted onto chromium-coated glass slides.	The Vysis array is currently the only commercial source of a genomic array for assessing gene copy number. The array can be used to detect amplifications of threefold or greater.
discoveryARRAY Gene Display	Display Systems Biotech www.displaysystems.com	The unique human and mouse discoveryARRAY Gene Display slides are made using the company's proprietary restriction fragment differential display (RFDD-PCR) technology, which identifies and isolates nonredundant expressed cDNA sequences. Tissue-specific sequence arrays for eight different human tissues (liver, brain, kidney, heart, prostrate, lung, mammary, and spleen) are also available.	Display Systems Biotech allows users to discover and characterize completely novel genes by analyzing differential expression patterns of various biological samples. The clones identified by RFDD-PCR are completely independent of expression level or preexisting cDNA libraries or sequence databases.
Arrays carrying covalently bound oligonucleotides	Operon Technologies www.operon.com	Oligonucleotides, 70 nucleotides in length, are each optimized for sequence specificity and melting temperature. The human collage array represents 320 genes from eight functional categories: apoptosis, cancer, cell cycle, transcription factors, neuron/axon guidance, heat shock/stress, blood/inflammation, and aging. The apoptosis array contains 374 genes.	Operon also offers "array-ready" DNA products, normalized for concentration and ready to print. Customized 70 mers are also available.
Micromax	NEN Life Sciences www.nen.com/products/micromax/prod_serv	Two unique arrays are available, one containing a collection of 294 human transcription factors and the other containing a mixture of 196 human kinase and 96 phosphatase genes.	

TABLE A10-3 Choice of an Array System

Array Type	Advantages	Disadvantages
cDNA arrays	• Availability of large nonredundant, sequence-validated clone sets from different organisms. • Because prior sequence information is not required, cDNA arrays are an excellent choice for gene discovery. • cDNA size is optimal for specific hybridization. • Technology for spotting DNA on glass and membranes is readily available.	• Processing clones to generate print-ready material is cumbersome. • Density of printed cDNA is lower than for in-situ-synthesized oligonucleotides. • cDNA sequences may contain repetitive sequences such as *Alu* in human 3′ UTRs or B elements in rodent 3′ UTRs, resulting in cross-hybridization. • Clone authentication can be a problem.
Oligonucleotide chips	• High-density chips can be fabricated. • In situ synthesis on the chip generates consistent and uniform geometry of spots. • Oligonucleotide arrays may be used for genotyping as well as for gene expression analysis. • Maintaining large collections of cloned DNA molecules is not essential. • Because oligonucleotides are relatively short and can be designed for any gene region, oligonucleotide chips can be used for sequencing, identification of polymorphisms, and potentially for identification of different transcript splice variants.	• There is an absolute sequence data requirement for designing oligonucleotides. • Oligonucleotide selection rules are not well defined. • Short sequences are not the best targets for hybridization and, therefore, appropriate controls must be included. • Oligonucleotide chips are extremely expensive and the current manufacturing process is inherently inflexible.
Homemade systems	• Technology for array fabrication is readily available and well suited to laboratory setting. • Once the infrastructure is established, it is a less expensive way of making arrays. • Unlimited number of arrays can be generated as required (quite useful considering microarray experiments are performed with a large number of arrays). • Most flexible and versatile way to study any available genes. New genes can be added easily. • User has complete control over the research and is less dependent on commercial companies.	• User must learn to design and build chips. • Not the system of choice if only a small number of arrays are needed or a limited number of experiments are performed because capital costs run high. (This cost can be circumvented by establishing core facilities and shared resources.) • Tracking of clones and print material can be cumbersome and error-prone.
Commercial systems	• Uniformity in chip quality. • Burden of production and quality control is on the manufacturers. • User has access to proprietary technologies and private clone resources. • Integrated packages are available for array hybridization and downstream informatics.	• Limited flexibility. • Chip costs are extremely high. • User is totally dependent on outsourced production of chips.

IMAGING AND ANALYSIS OF THE ARRAY

Sample Processing and Hybridization

Once the array has been printed or purchased, the next step is to hybridize a labeled probe to the immobilized DNAs on the array. Typically, the probes for arrays are labeled representations of cellular mRNA pools isolated from various biological resources, such as cell cultures, tissues of model organisms, clinical biopsies, and histological samples. Detailed protocols for preparing the probe samples (including isolation of RNA, synthesis of cDNA, and incorporation of fluorescent dyes) and hybridizing the probe molecules to the immobilized DNA arrays are available on the following Web Sites:

Stanford University	www.cmgm.stanford.edu/pbrown/
Albert Einstein College of Medicine	www.sequence.aecom.yu.edu/bioinf/microarray/protocol.html
NHGRI	www.nhgri.nih.gov/DIR/LCG/15K/HTML/protocol.html
Cold Spring Harbor Laboratory	www.nucleus.cshl.org/wigler/
Collection of protocols	www.protocol-online.net/molbio/DNA/dna_microarray.htm
TIGR protocols	www.tigr.org/tdb/microarray

Detection of the Hybridization Signal

After hybridization, the DNA microarray is scanned to monitor the fluorescence of each probe that was successfully hybridized to the target. Most microarrays utilize two fluorophores, typically, the most commonly used fluorophores are Cy3 (green channel excitation) and Cy5 (red channel excitation). To generate a complete microarray image, it is necessary to acquire an image for each of these fluorophores. In general, two different scanning approaches are used: (1) sequential scanning acquires one image at a time and then builds the ratio image after acquisition is completed, and (2) simultaneous scanning acquires both images at the same time. Although a range of scanners is available, it is difficult to judge their relative performances at this time. A listing of scanners and their notable features is presented in Table A10-4.

TABLE A10-4 Scanning Systems

Scanning System	Source	Description
GenePix 4000	Axon Instruments, Inc. www.axon.com	This highly compact scanner has 10-μm resolution and simultaneous dual wave length scanning. Its main strengths are a very short scan time and perfect pixel-to-pixel registration of the images in both channels. (Keeping the pixels in register between channels is a problem often associated with dual-wavelength scanners.) It also includes elaborate image analysis software. The Axon scanner is currently limited to using only two fluorophores.
ScanArray 5000	General Scanning, Inc. www.gsilumonics.com/products_frame/datashts/scanarray/sa5000.htm	This microarray scanner utilizes a confocal laser with a resolution of 10 μm and includes advanced software for image acquisition, image analysis, and data mining. The distinguishing feature is the use of 4 different excitation lasers and 10 emission filters, providing users with the flexibility of many different fluorescent dyes (emission spectra between 500 and 700 nm) for sample labeling. This setup permits more than two differently labeled samples to be used for probing each microarray.
GeneTAC 1000	Genomic Solutions www.genomicsolutions.com/products/bio/img.htm	GeneTAC 1000 uses a CCD camera and a highly sensitive detector capable of detecting up to four fluorophores per experiment. It also has an automated sample holder, with provisions for loading and scanning 24 slides at one time.
HP GeneArray Scanner	Hewlett-Packard www.affymetrix.com/products/ins_array.html	The HP GeneArray Scanner is a high-resolution (3-μm) scanner designed to read Affymetrix GeneChip probe arrays.
The Storm system	Molecular Dynamics www.mdyn.com/arrays/gen.htm	This system combines phosphorimager autoradiography technology with two nonradioactive fluorescent-labeling techniques: direct fluorescence and chemifluorescence. The Storm system scans storage phosphor screens plus fluorescent gels and chemifluorescent blots in a 35 x 43-cm scanning area and is thus well-suited for scanning membrane arrays.
GMS 418 Array Scanner	Genetic Microsystems www.affymetrix.com	This system is a scanning laser confocal imaging epifluorescence microscope with a 10-μm resolution.

Image Analysis

The objective of microarray image analysis is to extract hybridization signals from each probe. Signals are measured as absolute intensities for a given target (essentially for arrays hybridized to a single sample) or as ratios of two probes with different fluorescent labels, representing two separate treatments to be compared with one probe as an internal control. The ratio of two signals provides relative response ratios rather than an estimate of an absolute signal. A typical color image is shown in Figure A10-2.

Once images are obtained in digitized form, they are subjected to further analyses using a variety of software programs. These programs provide a more accurate quantification of the intensity ratio. Undesired features of the data such as uneven spots, dust on the slides, and nonspecific hybridizations are flagged as inadequate and are not considered for further analysis. Background fluorescence, such as autofluorescence of the solid support or nonspecific binding of sample to the array, can also be subtracted from the intensity of a feature. Subsequently, the mean,

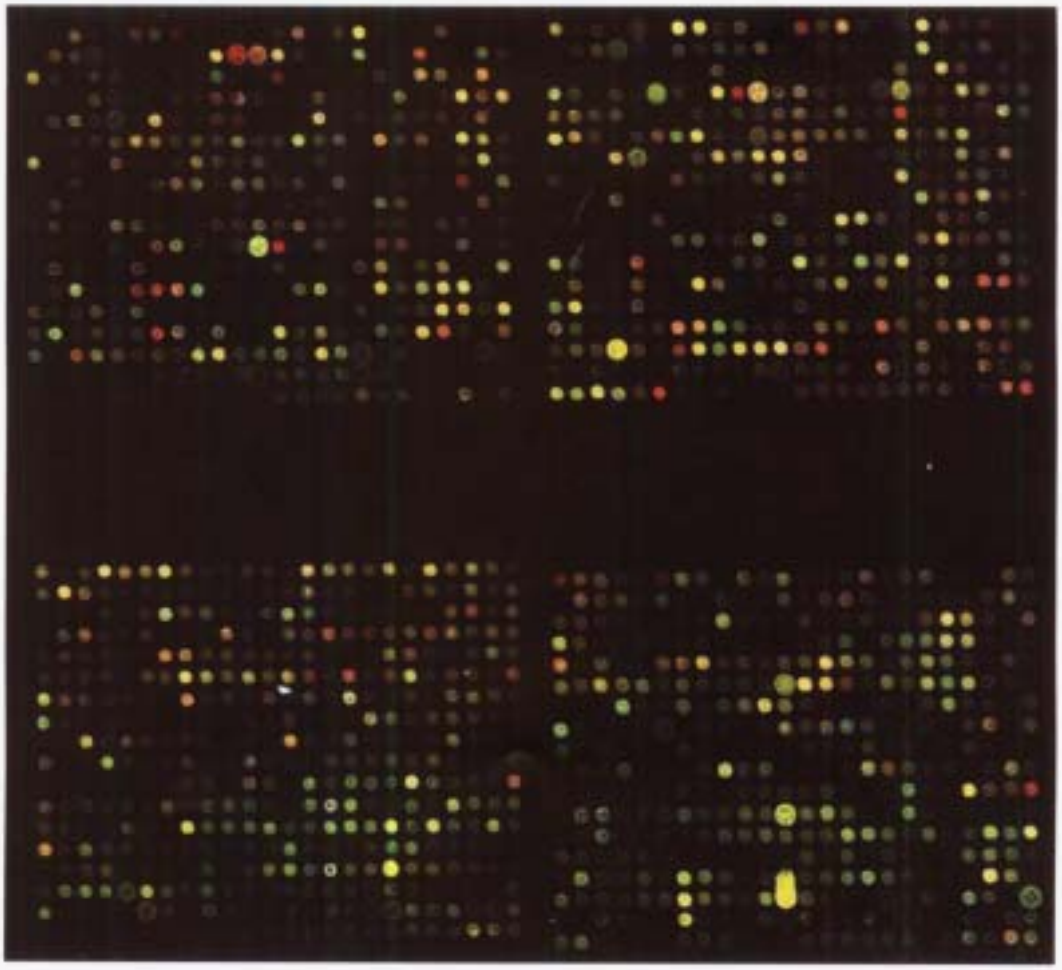

FIGURE A10-2 Expression Patterns in a Human cDNA Array (from cells induced with the human tumor suppressor PTEN, protein tyrosine phosphatase, and tensin homolog)

A portion of a human cDNA array hybridized with a red fluor-tagged experimental probe and a green fluor-tagged reference (uninduced) probe. The measured intensities from the two fluorescent reporters have been false-colored red and green and overlaid. Yellow signals (red plus green) indicate roughly equal amounts of bound cDNA from each sample and therefore have equal intensities in the red and green channels. Spots containing mRNA present at a higher level in one or the other sample show up as predominantly red or green. (Image provided by Vivek Mittal and Michael Wigler, Cold Spring Harbor Laboratory.)

median, and standard deviation of pixel intensities in each feature is determined and subjected to further detailed analysis. The following image analysis programs are commonly used:

- ***GenePix Pro*** is a program for scanning and analyzing microarray slides using the GenePix 4000 Scanner. It can also be used to analyze images acquired with other scanners. GenePix Pro automatically aligns the blocks of feature indicators on an image and aligns feature indicators within the blocks with features on the image. It is fully integrated with the Web in such a way that the gene names or their accession numbers can be linked to any database. It can be purchased directly from Axon (www.axon.com).
- ***ScanAlyze,*** a program similar to GenePix Pro, was developed by Michael Eisen at Stanford University and is freely available from http://rana.stanford.edu/software/.

Other image analysis programs include ArrayVision (from Imaging Research Inc.: http://imaging.brocku.ca/products/); deArray (from NHGRI: www.nhgri.nih.gov/DIR/LCG/15K/HTML); ImaGene (from BioDiscovery: http://www.biodiscovery.com/products/ImaGene/imagene.html); TIGR Spotfinder (from TIGR: www.tigr.org/softlab/); MicroArray Suite (from Scanalytics: www.scanalytics.com/sos/product/hts/microarray.html); GenExplore (from Applied Maths: www.applied-maths.com/ge/ge.htm); GeneData AG (from Basel: www.genedata.com/prod-exp.html); Partek Pro 2000 (from Partek Inc.: www.partek.com/); and Spotfire.net (from Spotfire: www.spotfire.com).

Some Considerations in Performing a Microarray Experiment

Because microarray experiments are miniaturized and of a high-throughput nature, they are sensitive to both external and internal fluctuations, for example, during delivery of the target DNAs onto the substrate and during hybridization. Approximately 7–8% of the variation in the data is estimated to be due to background noise. It is therefore imperative to follow proper averaging and normalization procedures, both to minimize these variables and to ensure that the extracted data are reliable and meaningful. It is also important to note that, as of this writing, there are no globally accepted rules or standards for performing controlled microarray experiments. Furthermore, the platforms as well as the methods for data extraction and analysis are subject to great variability. The following are general recommendations for performing experiments on homemade arrays and should be used as guidelines only.

- ***Replicate each experiment on multiple arrays.*** Averaging the normalized ratios for the same controls to compensate for array-to-array variation.
- ***Perform experiments using color reversal to account for variations in dye incorporation.*** The purpose of reversing the label for the two replicates is to reduce variability in signals that can occur due to differential incorporation of fluorescent labels by reverse transcriptase or other associated technical variability. False positive results can be substantially reduced using this strategy.
- ***Randomize the address of arrayed DNAs on the surface of the substrate*** to control for variation in hybridization that may occur at different locations on the array.
- ***Include a large number of controls on every array*** to verify the success of the probe synthesis, labeling, and hybridization. Some recommended controls include:

  Doping/spiking RNA controls, where mRNAs synthesized from cDNA clones by in vitro transcription are added to each labeling reaction. Ideally, these mRNAs are derived from genes that are not homologous to the organism under study (e.g., nonhomologous plant mRNAs are used on the human expression array). The cognate genes for these mRNAs

are represented on the array. These controls are useful for determining variations in differential labeling of samples, for assaying the stringency of the hybridization, and for calibrating the ratios for comparisons among experiments.

Intensity series clones, where clones from the organism under study that represent high, medium, and low expression are represented on the array. These are useful for estimating sensitivity of detection and measuring relative saturation and scanning effects.

Blocking controls. Most array hybridization experiments require the addition of cold DNA (e.g., human C_0t1 DNA and polyadenylic acid for human cDNA expression arrays) to block nonspecific annealing including hybridization due to repetitive elements. Inclusion of human C_0t1 DNA or oligo(dA) spots on human expression arrays should have little or no hybridization signal if repetitive elements have been successfully blocked.

Background hybridization controls. It is often useful to include blank salt spots and spots of DNA from another organism whose mRNA is not represented in the sample. These controls give an estimate of the nonspecific component of the hybridization and are useful for subtracting background from feature values.

Contamination controls. DNA samples that are used multiple times for printing arrays may become contaminated with bacteria or yeast. Total genomic DNA or cDNA clones of common contaminants such as *E. coli* and yeast are represented in the array to monitor for spurious hybridizations.

cDNA synthesis and RNA label quality control. Hybridization intensity is often dictated by the size of the labeled sample. This variable can be monitored with appropriate quality control elements. For example, DNA fragments, encompassing 100–200 bp tiled across an entire gene, can be spotted on arrays. Labeled cDNA probes of high integrity will hybridize efficiently to all spots, whereas cDNAs of lesser quality will generate proportionately weaker signals with fragments that map to the 5′ end of the gene.

- ***Control of geometric artifacts.*** The use of standard floating coverslips for DNA array hybridization sometimes results in uneven distribution of the probe DNA on the array, which compromises the hybridization. This situation occurs because the hybridization volume under a coverslip is small, which results in inefficient mixing of the hybridization fluid and generation of localized temperature gradients. The compromise is manifest by geometrical distortions in the image due to variations in hybridization at different locations within the array. One way to circumvent this variable is to use custom-made raised-edge coverslips (also referred to as "lifters"; available from www.eriesci.com/). These coverslips provide separation and ensure even dispersal of hybridization solution between the array and the coverslip. Another solution is to use larger hybridization volumes within specially designed hybridization chambers. These ensure efficient mixing of the hybridization fluid, which brings more probe molecules into contact with the cognate target in the array, thus increasing the number of productive events. Hybridization chambers are available from Schleicher & Schuell (www.s-und-s.de/) and CLONTECH (www.clontech.com).

MICROARRAY DATA MINING, ANALYSIS, AND MANAGEMENT

Because microarray analysis is a high-throughput technology, the amount of data being generated is expanding at a tremendous rate. The handling and analyses of these data therefore require elaborate databases, query tools, and data-visualization software. A brief description of some of these databases and analysis software follows:

- ***Another MicroArray Database.*** AMAD is a flat file, Web-driven database system written entirely in PERL and javascript, and intended for use with microarray data. AMAD supports both ScanAlyze and GenePix image analysis software. Further multivariate statistical analyses are performed on the values obtained from the data analysis program by using Mike Eisen's Cluster analysis and TreeView; both are freely available from www.rana.Stanford.edu/software/. AMAD, developed by a group of experienced scientists originally from Stanford University, is the only free database (available from www.microarrays.org) and provides a reliable analysis and data storage tool for investigators with little or no experience in handling enormous amounts of microarray data.
- ***Resolver (Rosetta Inpharmatics).*** Resolver is a comprehensive storage, visualization, and analysis tool for high-volume gene expression data obtained using cDNA microarrays, oligonucleotide arrays, and other technologies. It is interlaced with a powerful discovery tool for pathway interrogation, functional gene assignment, and compound analysis. Multi-experiment analyses are possible through correlation plots, cluster trees, and BLAST-like searches that can be conducted within the database. This feature enables the user to perform ranked similarity searches across entire data sets containing tens of thousands of gene expression profiles. More information about Resolver is available at www.rii.com/prodserv/resolver/index.htm.
- ***GeneSpring (Silicon Genetics)*** is a powerful analysis and visualization software suite available for genomic expression experiments. It is capable of handling and analyzing enormous data sets from any organism. Clustering, pathway determination, regulatory sequence detection, Eigenmode analysis, and a variety of data visualization tools are principal features of GeneSpring. A copy of a free demonstration version and software for purchase are available at www.sigenetics.com.
- ***IPLab MicroArray Suite for Macintosh (Scanalytics)*** is image analysis software capable of performing basic routines for extracting and visualizing microarray data generated from virtually any scanning device. Originally developed by researchers at the National Institute for Human Genome Research (NHGRI), this software is now a completely supported product available from Scanalytics Inc. (www.scanalytics.com/sos/product/hts/microarray.html).

A DNA microarray database can be linked to a reference database, for example, the UniGene database, to allow access to information about particular genes. Each UniGene entry corresponds to a single human or rodent gene and provides a direct link to GenBank gene and EST entries, to SWISS-PROT entries, and to literature entries through PubMed. Several groups have begun to assemble comprehensively curated gene databases for mammals. Such databases will facilitate rapid retrieval of information concerning functional and biochemical pathways. Some of the databases under development are:

Kyoto Encyclopedia of Genes and Genomes (KEGG)	http://www.genome.ad.jp/kegg/
Locus Link	www.ncbi.nlm.nih.gov/LocusLink/
WIT	wit.mcs.anl.gov/WIT2/
SPAD Signaling pathway Database	www.grt.kyushu-u.ac.jp/spad/
Genecards	http://bioinformatics.weizmann.ac.il/cards/
BRITE	www.genome.ad.jp/brite_old/
EGAD	www.tigr.org/docs/tigr-scripts/egad_scripts/role_report.spl
Stanford genome resources	http://genome-www4.stanford.edu/cgi-bin/SMD/source/sourceSearch
Database of transcribed sequences	www.cbil.upenn.edu/DOTS
South African National Bioinformatics STACK database	www.sanbi.ac.za.Dbases.html
TIGR Gene Indices	www.tigr.org/tdb/tgi.shtml

The large-scale data sets normally obtained from related microarray experiments are subjected to pattern recognition analysis to identify groups of genes that are regulated in a similar manner across many experiments. Pattern recognition is performed using a variety of multivariate analytical algorithms, such as hierarchial clustering, k-means clustering, and self-organizing maps. Typically, the interpreted array analysis highlights a relatively smaller number of spots representing differentially expressed mRNAs whose cognate genes are further validated by resequencing and whose patterns of expression are confirmed by other more reliable but low-throughput methods such as northern blotting, nuclease protection, or RT-PCR (for details of these protocols, please see Chapter 7, Protocols 8 and 10, and Chapter 8, Protocol 8).

As large-scale gene expression data accumulate over time, public access to these data becomes an important issue. In its current format, the data are widely dispersed and lack uniform structure and retrieval modalities. Efforts to establish some type of standardized data format for storing and communicating microarray-based gene expression data are in progress, largely due to efforts of the European Bioinformatics Institute (www.ebi.ac.uk/microarray/MGED/). The main objectives of this effort are (1) to ensure reproducibility and verifiability of results, (2) to identify controlled vocabularies for annotating the samples and experiments, and (3) to define the data communication standards. The development of standards for cross-platform data comparison and normalization is also under way.

EMERGING TECHNOLOGIES

The field of microarray technology presents a tremendous technical challenge for both academic institutions and industry. Commercial companies are vying with one another to establish market dominance. Novel platforms are being developed that promise higher throughput and better reproducibility; but which technology will emerge as the system of choice remains to be determined. This discussion surveys some of the emerging technologies that are likely to have a significant impact on the future of microarray research.

Novel Microarray Fabrication Methods

- ***Piezoelectric Printing*** uses technology analogous to that employed in ink-jet printers. The sample is loaded into a miniature nozzle equipped with a piezoelectric element around the nozzle. An electric current is applied to the piezoelectric element, which causes the nozzle to expel a precise amount of liquid from the jet onto the substrate. After the first step, the jet is washed and the second sample is loaded and deposited to an adjacent address. This method allows high-density gridding of virtually any molecule of interest, including DNA, antibodies, and small molecules, onto the substrate of choice. Arrays can be produced on nonporous (glass), porous (filters), and three-dimensional (Hydro-gel) substrates. The piezoelectric technology is not currently as robust as photolithography or microspotting. The BioChip Arrayer from Packard Instrument Co. uses piezoelectric "drop-on-demand" tips to provide noncontact dispensing (www.packardinst.com).
- ***Bubble Jet Technology*** uses the ink-ejecting mechanism used in printing devices. A Bubble Jet ink-jet device is used to eject 5′-terminal-thiolated oligonucleotides onto glass surfaces. The printing head (which is similar to conventional piezoelectric devices) consists of a heater that generates a bubble of fluid in a nozzle. The bubble pressure then ejects a microdroplet of material from the aperture.

Alternate approaches for fabrication of high-density in-situ-synthesized oligonucleotide arrays are under way. The Digital Optical Chemistry (DOC) system developed by Skip Garner and colleagues at the University of Texas Southwestern Medical Center (www.pompous.swmed.edu/) consists of three parts: a Digital Micromirror Device that selectively focuses ultraviolet light onto a glass substrate where chemistry is done, a fluidics system that delivers the chemical reagents in the proper sequence, and a computer program that controls both the Digital Micromirror Device and fluidics system according to the desired sequence pattern. This system alleviates the need for expensive photolithographic masks (using instead a "virtual" digital mask) and generates unique chips very rapidly. Another benefit of using DOC is that the machine is a benchtop unit that can be manufactured for use in any laboratory. In a similar technological direction, Xiaolian Gao at the University of Houston (www.zeiram.chem.uh.edu/gao/) uses a digital photolithographic system and new oligonucleotide deprotection chemistry using photogenerated acids and newly developed synthesis microreactors. These technological improvements should in the future permit chips of any design to be made in regular research laboratories at an affordable cost and with improved quality.

Resequencing

Also known as sequencing by hybridization (SBH), resequencing uses a set of oligonucleotides comprising all possible combinations of sequences in a given length that are synthesized and immobilized on a chip. The DNA fragment to be sequenced is broken down into smaller pieces, fluorescently labeled, and hybridized to the chip. The sequence of the DNA emerges from the pattern of fluorescence bound to the nested sequence. Since the chip contains all possible sequences, this system has the distinct advantage of being able to sequence DNA from any source. Fragments containing nonrandom sequences such as direct and inverted repeats presently limit this technique. The technology is being developed by Hyseq Inc., in collaboration with PE Corporation (www.hyseq.com).

Specific, High-throughput Genotyping by Primer Extension on Microarrays

A system to genotype SNPs and point mutations by a DNA-polymerase-assisted primer extension reaction using a microarray format is being developed by Ann-Christine Syvanen at Uppsala University in Sweden. Miniaturized reaction chambers formed on microscope slides allow analysis of 80 individual samples for hundreds of SNPs, potentially allowing the generation of >20,000 genotypes per slide. Minisequencing single-base extensions from one primer per SNP with dideoxynucleotides labeled with four fluorophores, or alternatively, extension of two allele-specific primers per SNP with one fluorescent deoxynucleotide, may be used. The genotypes of the samples at each SNP are determined by measuring the slides in a fluorescence array scanner.

Direct Identical-by-descent Mapping Using DNA Arrays

This mapping method is being developed in both the Brown (www.cmgm.stanford.edu/pbrown/) and the Cheung (www. w95vcl.neuro.chop.edu/vcheung/) laboratories and facilitates the isolation and physical mapping of DNA fragments shared identical-by-descent (IBD) between individuals. IBD mapping is a combination of two techniques: genomic mismatch scanning (GMS), a method for genetic linkage mapping, and DNA microarray technology. In this method, specialized enzymes are used to isolate DNA fragments shared IBD between two individuals. The isolated DNA fragments are mapped at high resolution by hybridization to a DNA array representing physically ordered genomic segments. Compared to traditional genotyping methods, direct IBD

mapping allows the entire genome to be analyzed in one step without laborious locus-by-locus genotyping. Microarray-based genetic linkage mapping will be useful in mapping genes that underlie complex genetic traits in yeast and in the distribution of meiotic recombination events across the entire genome. Parallel work is directed at adapting the GMS methodology to the human genome. In a demonstration of the feasibility of this technique, a gene for congenital hyperinsulinemia has been mapped by the Cheung lab.

Protein Microarrays

As a complementary approach to gene expression profiling on cDNA microarrays, microarrays of specific antibodies are being developed to measure the abundance of thousands of different proteins in samples from cells, or in biological fluids, such as serum or urine. Preactivated surfaces are used for the covalent immobilization of antibodies. Proteins from experimental and reference samples are differentially labeled with fluorescent dyes and hybridized to the array. Evaluation of the various applications of protein microarrays in detecting and diagnosing disease is under way. Because this application would not be restricted to antigen-antibody systems, protein microarrays should provide a general resource for high-throughput screens of gene expression, receptor-ligand interactions, and protein-protein interactions. Information on the development of protein arrays is available at www.molgen.mpg.de/~proteingroup/LuekingetalPub.html.

Tissue Microarrays

This array-based high-throughput technique facilitates gene expression and copy-number surveys of very large numbers of tissue specimens. For example, as many as 1000 cylindrical tissue biopsies from individual tumors can be distributed in a single tumor tissue microarray. Sections of the microarray provide targets for parallel in situ detection of DNA, RNA, and protein targets in each specimen on the array, and consecutive sections allow the rapid analysis of hundreds of molecular markers in the same set of specimens. Tissue microarrays were developed in the Olli-P. Kallioniemi laboratory at the National Human Genome Research Institute (www.nhgri.nih.gov/DIR/CGB/TMA/about.html). A machine to make tissue microarrays is available from Beecher Instruments (www.beecherinstruments.com).

Use of Arrays to Detect DNA-Protein Interactions

The potential of DNA microarrays for high-throughput screening of DNA-protein interactions is being exploited in several laboratories. One of the major interests is the detection of transcription-factor-binding sites in the genome under different physiological conditions. The general approach uses construction of an array containing both the intergenic and the coding region of the genome. Next, the total DNA and protein content of a cell is cross-linked in vivo, and a chromatin immunoprecipitation (ChIP) experiment using antibody specific to a transcription factor is performed. The DNA component of the immunoprecipitate (DNA–protein–antibody complex) is labeled with fluorescent dyes by PCR and hybridized to the array. A positive spot on the array is likely to be the target of the protein. This approach is feasible for organisms whose complete genomic sequence is known. Methods to analyze genome-wide protein-DNA interactions in yeast are being developed by Iyer and Brown at Stanford University.

Using a more general approach, the Church laboratory (http://arep.med.harvard.edu/gmc/) has generated arrays of single-stranded DNA oligonucleotides (all possible sequence combinations) carrying a constant sequence region at one end. The single-stranded arrays are converted to a double-stranded array by annealing and enzymatically extending a complementary primer.

Arrays containing all possible permutations of a site at each position will facilitate exploration of the spectrum of sequence-specific protein-binding sites in genomes.

Barcode Chip

In an effort to assign a function to every gene in the yeast genome, a novel high-throughput method is under development at Stanford University. The project is described on the Web Site http://sequence-www.stanford.edu/group/yeast_deletion_project/deletions3.html.

A library of yeast strains, harboring a deletion in each gene, is generated. Each of the deletions is tagged with a unique 20-mer DNA sequence that acts as a molecular barcode for individual deletions. The mixture of all such tag strains then allows for the analysis of the entire genome with the manipulation of a single sample. During growth under a variety of conditions, the loss of a tag indicates the loss of a corresponding deletion from the population. The concentration of each tag is determined by PCR amplification of the mixture and hybridization to a chip that contains tag complements at defined positions. Thus, phenotypes of individual strains can be analyzed in parallel. This approach has prospects for use in other organisms as well.

Bioelectronic Chips

A number of companies are focusing on creating microchips using microelectronics. Nanogen-chips (www.nanogen.com/) contain probes that can be electrically activated individually. A sample is applied to the chip, and the spot is electrically activated, which allows the sample to be concentrated and bound efficiently. The chip is then washed and another sample applied. Thus, multiplex hybridizations can be performed to the same chip. This technology has potential applications in a number of other analyses, including antigen-antibody, enzyme-substrate, cell-receptor, and cell separation techniques.

Orchid Biocomputer (Princeton, NJ; www.orchid.com) is designing a microfluidics chip that has precise control over the flow of process chemicals and temperature integration. This chip is used for screening SNPs. Both of these technologies have implications in drug screening and clinical diagnostics.

SUMMARY

From providing detailed profiles of the differential expression of literally thousands of genes to exploiting protein microarrays to build a resource of protein interactions, the applications of array technology are likely to produce an explosion of information on many biological fronts. The final challenge, beyond the emerging technological developments, may well lie in developing effective means for storing, sharing, and analyzing the information.

Appendix 11

Bioinformatics

David Mount, *University of Arizona, Tucson*
Judy Cuddihy, *Cold Spring Harbor Laboratory*

The following tables present widely used software for analyzing DNA, RNA, and protein sequences, as well as databases and types of searches that can be performed for DNA, RNA, and protein structure and function. The organization for Table A11-1 is outlined below:

- DNA
  - Sequence Submission
  - Sequence Alignments (Pairwise and Multiple)
  - Scoring Matrices
  - Motifs and Patterns
  - Genes, Exons, and Introns
  - Promoters, Transcription-factor-binding Sites
  - Other Regulatory Sites
- RNA
  - Secondary Structure
  - RNA-specifying Genes, Motifs
- Protein
  - Sequence Alignment
  - Motifs, Patterns, and Profiles

Because of the ever-changing nature of software and World Wide Web sites, it is worth the effort to consult the relevant Web or FTP sites for more information and the latest versions of software and databases. In most instances, a license is needed if the programs or databases are used for commercial purposes; see each site for further information. Commercial programs have not been included in this survey. For more information on these options, refer to the Web Sites of the relevant companies.

In addition to the specific sites for software and databases, there are several "gateway" Web pages that offer access to many of the sites listed in the tables, as well as to additional sites. The following Web pages offer a good starting place for many searches:

National Center for Biotechnology Information (NCBI)
Web Site: http://www.ncbi.nlm.nih.gov

This site offers a wide range of databases and searches via Web-based interactive forms, including GenBank, PubMed, BLAST, genome biology resources and databases, cancer resources and databases, and many other resources. These resources are integrated by Entrez, a search and retrieval system that also includes cross-referenced information. Submission to the GenBank database can be made here.

Baylor College of Medicine Search Launcher
Web Site: http://www.hgsc.bcm.tmc.edu/SearchLauncher

Web-based interactive forms and links are provided for many types of searches, including nucleic acid, protein sequence and pattern, species-specific protein, sequence alignments, gene features, and protein secondary structure, as well as for many sequence utilities.

The Sanger Centre
Web Site: http://www.sanger.ac.uk

Web-based interactive forms and links are provided to a wide range of databases and software utilities, including the many genome sequencing projects.

EBI-European Bioinformatics Institute, EMBL Outstation
Web Site: http://www.ebi.ac.uk

Web-based interactive forms and links to databases and software utilities are given. Submissions to EMBL Data Libraries can be made here.

ExPASy Molecular Biology Server-Expert Protein Analysis System, Swiss Institute of Bioinformatics
Web Site: http://www.expasy.ch

This protein-specific site provides a wide range of links to database and software utility resouces for analysis of protein structure and function.

For more extensive information on the mathematical and statistical underpinnings of bioinformatics software, as well as methods for database searching and analysis of DNA, RNA, and protein sequence, please see Mount (2001).

TABLE A11-1 Bioinformatics Software

Program Name	Web Site/FTP Site	Description/Platforms	Input Format	Interpretation/Results
Sequence Submission				
BankIt	http://www.ncbi.nlm.nih.gov/BankIt	Web-based sequence submission tool for direct submission to GenBank; submitted sequence must be DNA/RNA sequence that has been sequenced by the submitter. This tool is for one or a few submissions with uncomplicated sequence annotation.	FASTA	Returned by e-mail are: preliminary GenBank flat file; GenBank accession number; completed GenBank flatfile.
Sequin (formerly called Authorin)	http://www.ncbi.nlm.nih.gov/Sequin/index.html *FTP:* www.ncbi.nlm.nih.gov/sequin	Submission and update of sequence submission to GenBank, EMBL, and DDJB. Handles simple and complex submissions; automatically performs functions that need to be done manually in other submission programs. Has powerful sequence annotation tools, built-in validation functions; graphical and sequence views. Runs on UNIX and PC; has NetworkAware mode to exchange information with NCBI.	FASTA for sequence files; also PHYLIP, NEXUS, MACAW, FASTAGAP for population, phylogenetic, and mutation studies.	GenBank flat file; GenBank accession number.
Webin	http://www.ebi.ac.uk/Tools/index.html	Web-based interface preferred for EMBL sequence submission. Data can be modified and viewed before submission; has bulk submission procedure for 25 or more related sequences; also EBI vector screening software.	EMBL Data Libraries accession number.	Local alignment.
Sequence Alignments (methods for aligning two sequences at a time; for database searches that give pairwise alignments, see Table A11-2)				
BLAST (*B*asic *A*lignment *S*earch *T*ool) (Altschul et al. 1990; Karlin and Altschul 1990, 1993; Tatusova and Madden 1999)	http://www.ncbi.nlm.nih.gov/gorf/bl2.html	The BLAST algorithm is primarily used for similarity searches in sequence databases, but it may also be used for aligning a pair of sequences. The BLAST Web Site also provides a page for aligning two sequences by first searching for conserved words and using these to seed an alignment.	FASTA or Accession/Genbank index number (web site)	Local alignment of sequences based on word "seeds" and graphical representation of alignment.
FASTA programs				
FASTA (Pearson and Lipman 1988)	http://fasta.bioch.virginia.edu *FTP:* ftp.virginia.edu, dir /pub/fasta	FASTA is used primarily for similarity searches in sequence databases, but it may also be used for aligning a pair of DNA sequences or a pair of protein sequences. Web-based interactive form or downloadable software. Permission needed for commercial use. FASTA may be established on a variety of computer platforms, including Macintosh and PC Windows, but without a graphical interface.	FASTA or Accession/Genbank index number (web site)	Single, local (Smith-Waterman) alignment between two sequences.

(Continued on following pages.)

TABLE A11-1 (*Continued*)

Program Name	Web Site/FTP Site	Description/Platforms	Input Format	Interpretation/Results
LFASTA	http://fasta.bioch.virginia.edu	Compares two protein or DNA sequences for local similarity; uses the FASTA word search method to locate regions of similarity and then performs and scores a local (Smith Waterman) alignment. BLOSUM50 scoring matrix used by default but other matrices can also be specified; gap penalties can also be designated. Use LALIGN or SIM instead.	FASTA	Local sequence alignment.
FASTX/FASTY	http://fasta.bioch.virginia.edu	Compares translated DNA sequence to protein sequence database.	FASTA	Translates DNA sequence in 3 forward and 3 reverse frames; allows frameshifts.
LALIGN, LALIGN0, PLALIGN (see Huang et al. 1990; Huang and Miller 1991)	http://fasta.bioch.virginia.edu	Compares 2 DNA or 2 protein sequences to identify regions of sequence similarity; default scoring matrix is BLOSUM50 but others can be specified; optional gap penalties; uses sim algorithm to provide a local (Smith-Waterman) alignment; provides *n* different alignments with the same two residues never aligned more than once using the SIM method; can identify internal repeats. LALIGN scores penalties for gaps at the ends of the alignment; LALIGN0 does not penalize end gaps. PLALIGN produces a graphical plot of the alignment much like a dot matrix.	FASTA	Reports several sequence alignments if there are similar regions as well as similarity scores. Web site reports significance of alignment score based on PRSS analysis (see next entry).
PRSS (see Huang et al. 1990; Huang and Miller 1991)	http://fasta.bioch.virginia.edu	Evaluates the significance of pairwise similarity scores of 2 DNA or 2 protein sequences; uses BLOSUM50 matrix and standard gap penalties as default for proteins, but others may be used; second sequence is scrambled (at level of individual characters or of words) many times and each scrambled sequence is aligned with first sequence to give a range of unrelated sequence scores. From these scores, an Expect value for the original alignment score is calculated, i.e., the number of alignments between unrelated sequences that can achieve such a score.	FASTA	Reports similarity scores for 2 sequences; the second sequence is then shuffled a specified number of times compared with the first sequence.
Bayes Block Aligner (primarily used for sequence alignments but also has been used for similarity searching in sequence databases) (Zhu et al. 1997, 1998)	www.wadsworth.org/resnres/bioinfo	Finds all possible blocks (short ungapped alignments between a pair of sequences up to a specified number of blocks), then generates all possible alignments of the sequences that includes compatible sets of these blocks. There is no gap penalty; unmatched sequence regions between blocks are neither aligned nor scored. Scores alignments with a series of log odds scoring matrices to provide an odds score for	FASTA	Most probable sequence alignments according to different sampling criteria; probability that a given pair of residues is aligned; probability of each scoring matrix and each choice for number of blocks, and Bayesian probability that sequences are related.

		each alignment and matrix combination. The sum of all of these scores is calculated and the contribution of each alignment, block number, and scoring matrix to this sum is used to calculate posterior probabilities for the alignment, scoring matrix, etc., using conditional probability calculations (Bayesian statistics). Sequence characters aligned most often regardless of other variables may be determined. Download and compile software for Sun Solaris or SGI Irix or as C source code. PC Windows version also available with no graphic interface. Licensing agreement needed.		
SIM (Huang et al. 1990; Huang and Miller 1991)	http://www.expasy.ch/tools/sim-prot.html	Like LALIGN, finds *n* alignments by a local (Smith-Waterman) alignment algorithm with much increased speed of calculation.	FASTA	Reports *or* local alignments in order of similarity score.
Scoring Matrices				
BLOSUM scoring matrices (see also BLOCKS database) (Henikoff and Henikoff 1992, 1993, 1994; Henikoff et al. 1995)	http://www.blocks.fhcrc.org	Examines multiple alignments of related protein regions, in order to produce a matrix of amino acid substitutions scores, rather than extrapolating from scores of divergent but closely related sequences (as do the PAM scoring matrices). Most alike proteins in the alignment may be clustered to reduce the frequency of changes among the more commonly represented amino acids (e.g., for BLOSUM62, sequences that are 62% or more identical are clustered). There is no specific evolutionary model for these matrices as there is for PAM matrices; all sequences are considered just as likely to be the ancestor of the others (a star phylogeny).		Detection of similarity between protein sequences as evidence of evolutionary homology.
DNA PAM matrices	http://blast.wustl.edu/, see "Improved sensitivity of nucleic acid database searches using application-specific scoring matrices."	Assumes Markov model of change in DNA sequences (see PAM matrices below).		Prediction of evolutionary distance between DNA sequences.
PAM (*P*ercent *A*ccepted *M*utation or mutations that survive natural selection) (Dayhoff et al. 1978; Schwartz and Dayhoff 1978; for more recent versions, please see Gonnett et al. 1992; Jones et al. 1992)	FTP: ftp://ncbi.nlm.nih.gov, directory/blast/matrices	Predicts the expected amount of substitution in protein sequences that have had a given amount of evolutionary time to diverge from a common ancestor sequence. Assumes a Markov model of change (no site-to-site variation and no change in composition) and forward and reverse changes equally as likely. Matrix values give log odds scores for matches or mismatches. Best odds score for alignment is found when scoring matrix that matches number of mismatches in the alignment is used.		When used with alignment program, provides measure of similarity between 2 sequences being characterized by evolutionary distance. 1 PAM corresponds to the average change in 1% of all amino acid positions.

(Continued on following pages.)

TABLE A11-1 (*Continued*)

Program Name	Web Site/FTP Site	Description/Platforms	Input Format	Interpretation/Results
DNA Sequence Alignment: Multiple Sequence Alignment				
MSA (Lipman et al. 1989)	http://www.psc.edu/general/software/packages/msa/msa.html *Interactive Web forms at:* http://www.ibc.wustl.edu/service/msa/index.html (other programs also available on this site)	Aligns several nucleic acid or protein sequences globally; uses dynamic programming to produce optimal alignment of all sequences at the same time; sequences are weighted in accord with their similarity to other sequences in the group. Uses sum of pairs score for evaluating columns in the alignment; normally limited to 3 sequences because it requires large amounts of computer time and memory. Three versions allow alignment of >3 sequences; up to 50 sequences where each sequence has <150 residues; up to 25 sequences where each sequence has <500 residues; up to 10 sequences where each sequence has <1000 residues. Interactive Web-based form; UNIX.	FASTA, GCG, PIR and other formats recognized by the READSEQ program.	Initially shows heuristic alignment based on a progressive pairwise alignment; this alignment is used to limit the search space for an optimal alignment; an optimal alignment is then shown; calculation of alignment costs; divergence values for each pairwise alignment; maximum score of optimal alignment.
CLUSTALW (Higgins and Sharp 1988; Higgins et al. 1992; Thompson et al. 1994)	*Interactive Web-based form at:* http://www.ibc.wustl.edu/ibc/msa.html http://dot.imgen.bcm.tmc.edu:9331/multi-align/multi-align.html http://www.infobiogen.fr/ docs/ClustalW/clustalw.html *FTP:* ftp.ebi.ac.ukdir/pub/software/unix/clustalw.tar.Z	Performs multiple alignments on a set of DNA or protein sequences or adds new sequences to an existing alignment; uses a progressive alignment of sequence pairs and groups using as a guide of similarity a neighbor-joining phylogenetic tree initially made by pairwise alignments of the sequences. The contribution of individual sequences to the alignment is weighted in accord with the amount of divergence from the other sequences (different from MSA). Uses position-dependent gap penalties depending on the estimated divergence in each region of the aligned sequences. Excellent method for sequences that are not very divergent; can make errors in the initial alignments of most-alike sequences that becomes more possible with increasing divergence. Matrices that may be used are BLOSUM80,62, 45,30; Gonnett80,120,160,250,350; PAM20,60, 120,350. CLUSTALW (weighted alignments) is a major update and rewrite of CLUSTALV. Interactive Web-based form; ANSI-C version for UNIX and VMS or any machine with ANSI-C compiler; executables for major platforms MAC, PC. Clustal X provides a graphic interface for an X windows environment.	FASTA; also GCG/MSF, NBRF/PIR, EMBL/Swiss Prot, GDE flat file, CLUSTAL, and GCG9-RSF formats. All sequences to be aligned must be in one file. Formats recognized by REASEQ program may be used.	Output formatted in CLUSTAL (shows sequence aligned in blocks), NBRF/PIR, GCG/MSF for input into GCG software; PHYLIP for input into Phylip, GDE flatfiles. For graphical views of the phylogenetic trees calculated after sequence alignment, other software, such as Phylip, must be used.
PIMA (Pattern-induced Multiple Alignment) (Smith and Smith 1990, 1992)	*Interactive Web-based form at:* http://dot.imgen.bcm.tmc.edu:9331/multi-align/multi-align.html *FTP:* ftp.ebi.ac.ukdir/pub/software/unix	Constructs multiple sequence alignments by first performing pairwise alignments between the sequences and clustering the sequences into one or more families based on the scores.	See previous entry.	Multiple sequence alignment.

		Common patterns are located in each family and the set of sequences is then aligned using these patterns as starting points; uses constraints to determine gap locations. Interactive Web-based form; UNIX.		
MACAW (*M*ultiple *A*lignment *C*onstruction and *A*nalysis *W*orkbench) (Schuler et al. 1991)	*FTP:* ncbi.nlm.nih.govdir/pub/macaw	Locates, analyzes, and edits blocks of localized sequence similarity among multiple sequences; constructs multiple alignments by analyzing, editing, and combining blocks of aligned sequence segments. Sequence blocks are located using a sum of pairs scoring system to produce a local multiple sequence alignment or the Gibbs sampler (see Gibbs sampler, below), a statistical method, is used. The user interface allows the editing and linking of blocks. PC, NT, Mac.	FASTA	Multiple sequence alignment based on blocks; statistical evaluation of block similarity
SAM (*S*equence *A*lignment and *M*odeling System) (Haussler et al. 1992; Hughey and Krogh 1995, 1996)	http://www.cse.ucsd.edu/research/compbio/sam.html *FTP:* ftp.cse.ucsc.edudir/pub/protein/sam1.01.tar.Z.crypt	Uses a hidden Markov model to represent a multiple sequence alignment of a set of full sequences or partial sequences. The HMM allows matches, insertions, and deletions in the alignment. A model is produced for each sequence set by training the model with a family of related sequences. A large number of sequences (>50) are required to produce a representative model, and the larger the set, the better the model produced. A multiple sequence alignment may be used as input. The trained HMM will produce a multiple sequence alignment of the training sequences, and may also be used to search for new family members in sequence databases. HMMs have the advantage of offering a well-defined probabilistic model of sequence alignments. Conversion programs for HMMER formats are included. Encrypted source code; UNIX, Mas-Par.	DNA, RNA, and protein alphabets; user-defined alphabets, most common formats such as FASTA, GenBank, NBRF, EMBL, GCG, DNA Strider, Phylip, GCG/MSF, PAUP NEXUS, PIR CODATA; can be given a predetermined multiple sequence alignment. Uses READSEQ program to recognize sequence formats.	Hidden Markov model-based multiple sequence alignment; database search for new family members.
HMMER (Haussler et al. 1992; Hughey and Krogh 1995, 1996)	http://genome.wustl.edu/eddy/hmmer.html *FTP:* genome.wustl.edudir/pub/eddy	Uses hidden Markov models to produce multiple sequence alignment of DNA, RNA, or protein sequences (see also SAM entry). Uses hidden Markov models to search databases for homologs of the query sequence family. UNIX and ANSI-C versions.	FASTA, GenBank, EMBL, Swiss-Prot, GCG/MSF, SELEX	Hidden Markov model-based multiple sequence alignment. Smith-Waterman local alignments found by database searching. Global Needleman Wunsch alignments found by database searching.
SAGA (*S*equence *A*lignment by *G*enetic *A*lgorithm) (Notredame and Higgins 1996)	http://www.ebi.ac.uk/~cedric	Creates multiple sequence alignments using genetic algorithms (developed as computer science tool) and user-defined objective functions (descriptors of multiple alignment quality). Software evolves population of alignments in	See program notes.	Globally optimal multiple sequence alignment.

(Continued on following pages.)

TABLE A11-1 *(Continued)*

Program Name	Web Site/FTP Site	Description/Platforms	Input Format	Interpretation/Results
		quasi-evolutionary manner; improves the fitness of the population using the objective functions. The software can align <20 sequences that are <400 residues long. A related program, COFFEE (Notredame et al. 1998; available at same site), can be used to optimize the multiple sequence alignment obtained. ANSI-C and UNIX versions.		
DIALIGN segment alignment (Morgenstern et al. 1996)	http://www.gsf.de/biodv/dialign.html	Compares whole segments of sequences instead of single residues. Constructs pairwise and multiple sequence alignments from gap-free pairs of equal-length segments, called diagonals. Especially useful for detecting local similarities in otherwise unrelated sequence. Download executables for DEC, SUN, HP, SG, CONVEX, and LINUS. (For commercial use, contact genomatix@gsf.de. DIALIGN2 offers a Web-based interactive form.	EMBL, FASTA, GCG/RSF, GenBank.DNA/protein sequences <1 Mb.	Alignment of input sequence; graphical representation of degree of local similarity between aligned sequences; sequence tree showing degrees of similarity.
MultAlin (Corpet 1988)	http://protein.toulouse.inra.fr/multalin.html	Web-based interactive form for multiple sequence alignment. Alignment parameters can be set; consensus level options can be chosen for output.	Multi-Alin FASTA; EMBL-SwissProt; GenBank	Multiple sequence alignment output as colored image, plain text, or HTML.
PRRP progressive global alignment (randomly or doubly-nested) (Gotoh 1995)	ftp.genome.ad.jp/pub/genome/saitama-cc	Iterative method of multiple sequence alignment based on a profile method in which groups of sequences are repeatedly aligned, guided by a tree until best score is obtained. Avoids errors made by progressive alignment methods when sequences are divergent.	Special format (see program notes).	Best alignment after repeated trials.
DNA: Motifs and Patterns				
MEME (*M*ultiple *E*xpectation *M*aximization for *M*otif *E*licitation) (Bailey and Elkan 1994, 1995; Bailey 1995)	http://www.sdsc.edu/MEME/meme/website/intro.html *Interactive Web-based form at:* www.sdsc.edu/MEME/website/meme.html	Detects motifs (conserved sequence patterns of the same length; no gaps; no covariations between positions) in groups of related DNA or protein sequences. The software uses a statistical technique (the expectation maximization or EM algorithm) to locate motifs of a given length range, of which there may be 0, 1, or more in an individual sequence, as specified by the user. The output is a PSSM (a position-specific-scoring-matrix) of each motif found with columns that represent motif positions and rows that represent the distribution of residues in each column in a log-odds format. The matrix may be used to search sequence		Results are e-mailed to user, including: PSSMs, which represent the distribution of residues in each column of the motifs found; diagram showing the information content of each column (represents degree of conservation at each motif position), multilevel consensus sequence, examples of motifs found, and location in input sequences; motif also output in BLOCKS format. PSSM may be subsequently

		databases using MAST. License needed for commercial use. Interactive Web-based form; ANSI source code.		used for database searches using MAST.
Meta-MEME (Grundy et al. 1997)	*FTP:* metameme.sdsc.edu *Interactive Web-based form at:* http://www.sdsc.edu/MEME/meme/website/intro.html	Combines DNA or protein motif patterns from MEME into a hidden Markov model (HMM) that represents an alignment of the sequences through alignments of the conserved motifs. The HMM may then be used to search sequence databases for other family members. Interactive Web-based form; ANSI-C source code and program binaries for selected platform.	Set of similar DNA or protein sequences in variety of formats (e.g., FASTA) or a set of motif models previously determined using MEME.	Motif-based multiple sequence alignment of query set of sequences for use in searching sequence databases for additional family members. Computes Viterbi score or total probability score for homology detection reported as log-odds scores
ASSET (*A*ligned *S*egment *S*tatistical *E*valuation *T*ool) (Neuwald and Green 1994)	*FTP:* ncbi.nlm.nih.gov Dir:/pub/asset	Performs a depth-first search for conserved sequence patterns to create a multiple sequence alignment by maximizing the log likelihood ratio statistic. Available as C code for UNIX system.	FASTA	Patterns found are reported as motifs with score and locations in sequences.
BLOCKS server (see also Table A11-2) (Smith et al. 1990; Henikoff and Henikoff 1991; Henikoff et al. 1999a,b)	http://www.blocks.fhcrc.org	Blocks are conserved patterns of amino acid sequences of the same length (no gaps) found in members of a protein family. The BLOCKS resource will create blocks from a multiple sequence alignment or locate them in unaligned sequences by either a pattern-searching method or statistical method (Gibbs sampling). BLOCKS server is used to produce position-specific scoring matrices (PSSMs) and a consensus (cobbler) sequence that may in turn be used to scan additional proteins in sequence databases for presence of block. An input sequence may also be scanned against blocks databases. Blocks have been calibrated for specificity against the Prosite and Swiss-Prot databases.	Input sequences in FASTA format on alignment (see description).	Blocks found are reported in their own (blocks) format. PSSMs and a cobbler (consensus) are also given for further database searching. Output can be used to predict PCR primers using CODEHOPS.
BLIMPS–BLOCKS Improved Searcher (Henikoff and Henikoff 1991; Wallace and Henikoff 1992)	http://blocks.fhcrc.org *FTP:* ncbi.nlm.nih.gov Dir:/repository/blocks/unix/blimps *FTP:* howard.fhcrc.org Dir:/blimps/	Alignment search software that scores sequence against BLOCKS database or blocks against sequence. (See also BLOCKS database in DNA: Motifs and Patterns.)	See BLOCKS server.	See BLOCKS server.
emotif (Exploring the *Motif* Universe (Nevill-Manning et al. 1998)	http://dna.stanford.edu/emotif/simple.html	Forms motifs or subsets of aligned sequences. Interactive Web-based form.	Aligned sequence.	List of retrieved motifs.
MAST (*M*otif *A*lignment and *S*earch *T*ool) (Bailey and Gribskov 1998)	http://www.sdsc.edu/MEME/meme/website/mast.html	Searches databases for sequences that contain one or more motifs. (Motifs are defined on this site as conserved sequence patterns of the same length that occur one or more times in a related set of sequences.) Motifs are identified by searching through a set of related sequences with the MEME or	One or more motifs in MEME output or any file an an appropriate format (GCG profile file, concatenated GCG profile files, motif file format). The individual motifs cannot contain gaps.	Retrieved motifs; maximum of 50 matches returned. Output consists of names of high-scoring sequences, motif diagrams showing order and spacing of motifs (PSSM that describes score of each possi-

(Continued on following pages.)

TABLE A11-1 (*Continued*)

PROGRAM NAME	WEB SITE/FTP SITE	DESCRIPTION/PLATFORMS	INPUT FORMAT	INTERPRETATION/RESULTS
		BLOCKS servers; each are represented by a PSSM (position-specific scoring matrix) showing the variation in each column of the aligned motifs as a log odds score. Each PSSM is moved across each database sequence to identify high-scoring matches. Sequences with highest-scoring matches are identified. Web-based interactive form.		ble letter at each position in the pattern), detailed annotation of sequence; sequences shown with the location and scores for each motif found, and a combined probability score that these matches would have occurred by chance is also shown. HTML or ASCII format.
Gibbs sampler (Gibbs Sampling Strategy for Multiple Alignment) (Lawrence et al. 1993)	*FTP:* ncbi.nlm.nih.gov Dir:/pub/gibbs	Finds conserved patterns of sequence of the same length in a set of related sequences (no gaps, no correlations between positions) by a Gibbs sampling strategy. This method repeatedly rescans individual sequences in the set with a trial PSSM (position-specific scoring matrix) to find conserved patterns, using a probabilistic approach for choosing a matching location in the sequence, and then updates the matrix. Eventually, common patterns will be recruited to the matrix. May require initial estimate of pattern length (see also BLOCKS Web Site and MACAW).	FASTA	Location of conserved pattern in the sequences.
DNA: Genes, Exons, Introns				
Genie (Kulp et al. 1996; Reese et al. 1997)	http://www.fruitfly.org/seq_tools/genie.html	Finds potential genes in *Drosophila* genomic sequences using a hidden Markov model trained on known *Drosophila* genes, including a neural network trained on *Drosophila* splice sites. Tries to find one gene match on each strand of each sequence submitted; multiple sequences can be submitted. Software has been trained on human genes, but claims to give good results for other vertebrate sequences, *Drosophila*, other invertebrates.	DNA sequence in FASTA or multiple-FASTA; maximum DNA sequence length is 90,000 bases.	Highest-scoring gene location on each input DNA strand.
GeneMark (Borodovsky and McInich 1993)	http://genemark.biology.gatech.edu/GeneMark/gm_info.html *e-mail service:* genemark@amberbiology.gatech.edu ***OR*** genemark@embl-ebi.ac.uk	Identifies protein-coding regions in prokaryotic or eukaryotic genomic DNA sequences. Uses inhomogeneous Markov chain models, each trained on known genes of each organism. Analyzes EST sequences; predicts long exons; can be used for designed RT-PCR primers. Web-based interactive form; e-mail server. License required for use of local version. GeneMark.hmm algorithm (Lukashin and Borodovsky 1998) is an extension of GeneMark used for more accurate finding of 5′ ends in bacterial, human, and *C. elegans* genes.	DNA sequence in GCG, FASTA, EMBL, GenBank, PIR, NBRF, Phylip, text formats.	Coding signals for putative genes shown in graphical format (PSGRAPH). Text output for ORF predictions; possible frameshifts; right and left end of ORFs; orientation and frame of region; mean probability function; internal exon predictions.

Grail II (Gene Recognition and Analysis Internet Link) (Uberbacher and Mural 1991)	http://compbio.ornl.gov/Grail-1.3/	Predicts exons in human genomic sequences. Uses neural networks trained on intron length, GC-composition, codon usage, 6-mer preference scores, splice junction scores, and other features. These scores are weighted in the neural network so as to give the best overall prediction of the training sequences. For new sequences, a sliding sequence window is moved across the sequence and a prediction (exon score) is made for each window.	Several formats.	List of best candidate exons and most probable gene structure.
GeneParser (Snyder and Stormo 1993, 1995)	*FTP:* beagle.colorado.edu/pub/GeneParser	Predicts gene structure in genomic DNA sequences. Uses sequence indicators found in known exons, introns, and splice junctions (see Grail) to evaluate likelihood that a sequence interval represents an exon or intron. Applies dynamic programming algorithm to find the exon/intron combination that maximizes the likelihood function for predicting a gene structure. Neural network used to adjust weights to sequence indicators for best fit to known genes.	See documentation.	List of best candidate exons and most probable gene structures.
GENSCAN (Burge and Karlin 1997)	http://CCR-081.mit.edu/GENSCAN.html Web servers also at Stanford University, DKFZ/EMBnet. Heidelberg, Pasteur Institute e-mail server at Pasteur Institute	Predicts genes in genomic DNA based on probabilistic models in gene structure in various organisms. Executables available for UNIX; license needed for commercial use.	DNA sequence, one-letter code.	Most probable gene structures.
NetGene (Brunak et al. 1991)	http://130.225.67.199/services/NetGene/index.html *e-mail service:* netgene@cbs.dtu.dk	Predicts splice sites in vertebrate genes. Uses neural networks trained to recognize differences in sequence features between exon and nonexon sequences (see Grail).	FASTA	Produces list of most strongly predicted exons.
FGENES (V.V. Solovyev, unpubl.)	http://genomic.sanger.ac.uk/gf/gf.html	Predicts genes and exons by using pattern-based structure prediction. Algorithm based on pattern recognition of different types of exons, promoters, and poly(A) signals; dynamic programming finds optimal combinations and then constructs set of gene models. Interactive Web-based form. FGENESH+ (A.A. Salamov and V.V. Solovyev, unpubl.) predicts multiple genes in genomic DNA sequence using a hidden Markov model of genes and similarity with known protein. FGENES-M produces pattern-based human multiple variants of gene structure prediction.	FASTA, plain sequence.	Text output: number of predicted genes, number of predicted exons, positions of predicted genes and exons.
MZEF (Michael Zhang's Exon Finder) (Zhang 1997)	http://sciclio.cshl.org/genefinder *FTP:* phage.cshl.org Dir:/pub/science/mzef	Predicts internal coding exons. Based on prediction algorithm using quadratic discriminant function for multivariate statistical pattern recognition (best discriminates between exon and nonexon sequences using sequence features similar to those described for Grail). Software for SUN, DEC Alpha. Need site license for commercial use.	FASTA; maximum of 200 kb.	Exon boundaries in base pairs, posterior probability, frame preference score, ORF ordinator, acceptor score, coding preference score, donor score.

(Continued on following pages.)

TABLE A11-1 (*Continued*)

Program Name	Web Site/FTP Site	Description/Platforms	Input Format	Interpretation/Results
DNA: Promoters, Transcription-factor Binding Sites				
Transfac (Heinemeyer et al. 1999)	http://transfac.gbf.de/TRANSFAC *FTP:* transfac.gbf.de	Transfac is a relational database of transcription factor *cis*-acting binding sites and transcription factors from many organisms, and also includes PSSMs (position-specific scoring matrices) representing the observed variation in each column of the aligned binding sites for one factor. (Some matrices may not be specific so that false positive matches are common.) Download is flat ASCII files. Software is for noncommercial use only. Programs include Coinspector, MatInspector, MatInd.	See web site.	Predicted location of TF binding sites.
CorePromoter (Zhang 1998)	http://sciclio.cshl.org/ genefinder/ CPROMOTER	Predicts transcriptional start sites and localizes them into 50–100-bp core-promoter regions. Uses quadratic discrimination analysis to distinguish sequence features (e.g., conserved sequence words) characteristic of promoter sequences. Web-based interactive form. License needed for commercial use.	FASTA; DNA sequence must be <2 kb.	N-profile position scores; strand; prior probability; QDA data; maximum number of predictions.
NNPP (*P*romoter *P*rediction by *N*eural *N*etwork) (Reese 1994; Reese and Eeckman 1995; Reese et al. 1996)	http://www.fruitfly.org/ seq_tools/ promoter-instrucs.html	Finds eukaryotic and prokaryotic promoters in DNA sequence. Uses time-delay neural networks (TDNN) that recognize features such as the TATA box, the GC box, the CAAT box, and the initiator region that spans the transcription start site (TSS). TDNN is repeatedly trained and re-trained until it recognizes the most important features of each element as a scoring matrix. Predictions for each element are then combined so that elements can be found even when their spacing varies.	FASTA	Transcription start sites most likely to be promoters. For eukaryotes, list of the 51 bases spanning –40 to +11 where +1 is the predicted transcription start site. For prokaryotes, 46 bases spanning from –41 to + 5 where +1 is the predicted transcription start site.
TESS (*T*ranscription *E*lement *S*earch *S*ystem) (Schug and Overton 1997)	http://www.cbil.upenn.edu/tess	Finds potential transcription-factor-binding sites in DNA sequence (see Transfac). Has Web-based interactive forms for combined search query, browsing Transfac, string-based searching, filtered string-based searching. Options for filtering, setting thresholds, attributes, and scoring schemes.	DNA sequence	Predicted sites.
TFBIND (Tsunoda and Takagi 1999)	http://tfbind.ims.u-tokyo.ac.jp	Searches for transcription-factor-binding sites, including TATA boxes, GC boxes, CCAAT boxes, and transcription start sites.	FASTA	Predicted sites.

		Uses weight matrix in Transfac database and cut off values (see Transfac). Web-based interactive form.		
TSSG (V.V. Solovyev et al., unpubl. [see http://dot.imgen.bcm.tmc.edu:9331/gene-finder/gf.html])	http://genomic.sanger.ac.uk/gf/Help/tssg.html for information *e-mail service:* service@theory.bchs.uh.edu Put tssg in subject line of message.	Recognizes human PolII promoter region and transcription start site. Uses a linear discriminant function that combines characteristics of functional motifs and oligonucleotide composition of transcription start sites.	DNA sequence	Promoter region, including sequence name, LDF threshold and length of sequence, number of predicted promoter regions, positions of predicted sites, TATA box positions, transcription start site positions, functonal motifs for each predicted region.
TSSW (V.V. Solovyev et al., unpubl. [see http://dot.imgen.bcm.tmc.edu:9331/gene-finder/gf.html])	http://genomic.sanger.ac.uk/gf/Help/tssw.html-for information *e-mail service:* service@bchs.uh.edu *OR* services@bioinformatics.weizmann.ac.il Put tssw in subject line of message.	Recognizes human PolII promoter region and transcription start site. Uses linear discriminant function for prediction; combines characteristics describing functional motifs and oligonucleotide composition of the sites.	Name of sequence; sequence letters. Maximum line length is 79 characters.	Name of sequence; linear discriminant function threshold and length of sequence; number of predicted promoter regions; positions of predicted sites, TATA box, and transcription start site positions; functional motifs for each predicted region.
MAR-Finder (Kramer et al. 1996; Singh et al. 1997)	http://www.ncgr.org/ MarFinder/about.html	Deduces presence of matrix-associated regions (MARs) in DNA sequence. (Matrix-associated regions are the regions at which the chromatin fiber attaches to the nuclear matrix and are necessary for transcriptional regulation.) Method used is statistical inference and a Boolean logic network; 18 motifs known to occur in the neighborhood of MARs are used in the analysis. Web-based interactive form; registration necessary.	FASTA	High-scoring regions in base pairs, including average and integrated strengths; graphical output showing output of relative positions of potential MARs.
GenomeInspector (Quandt et al. 1996a,b)	http://www.gsf.de/biodv/genomeinspector.html	Detects distance correlation between open reading frames and transcription binding sites on megabases of nucleotide sequence; uses large-scale correlation analysis. Download executables for DEC Alpha, SUN, HP, Silicon Graphics, CONVEX; UNIX and X-windows. License needed for commercial use.	Many formats including database annotation, GCG, ConsInspector, MatInspector.	Graphical display showing correlation of ORFs and ARS-binding factor 1 binding sites.
DNA: Other Regulatory Sites				
consensus and wconsensus (Hertz and Stormo 1999)	FTP:beagle.colorado.edu/pub/consensus	A sliding window from each sequence is scanned against windows of the remaining sequences to find the most alike regions. The combined alignments of two or more windows are then used to recruit additional matching regions from other sequences. The algorithm is greedy in the sense that the first sequences to be matched determine the ultimate alignment of all sites found. Thus,	Set of input sequences.	Aligned sites in input sequences and position-specific scoring matrices for these sites.

(*Continued on following pages.*)

TABLE A11-1 (*Continued*)

PROGRAM NAME	WEB SITE/FTP SITE	DESCRIPTION/PLATFORMS	INPUT FORMAT	INTERPRETATION/RESULTS
		multiple cycles of matching are necessary. In consensus, window width is user-specified, and in wconsensus, it is not specified since the method can recruit flanking sequence if informative. The object is to maximize the information content (highest conservation of bases in each column) of a PSSM (position-specific scoring matrix). Includes important statistical evaluation of the PSSM. Note that there is no accounting for covariation within the sites as in palindromic regulatory sites, but methods to locate such regions have been described (Hertz and Stormo 1995). Available for implementation on UNIX platforms.		
polyadq (Zhang 1997)	http://sciclio.cshl.org/mzhanglab/tabaska/polyadq/polyadq_form.html	Decides if a given AATAA or ATTAAA hexamer is a true poly(A) signal. Algorithm uses quadratic discriminant analysis (see MZEF) Web-based interactive form.	FASTA. Can set cut-off score by four methods.	Prediction for each AATAA or ATTAAA found in the query sequence. Output is head, plus or minus prediction, site, sequence, and score.
Pol3scan (Pavesi et al. 1994)	http://irisbioc.bio.unipr.it/pol3scan.html	Searches eukaryotic DNA sequence for PolIII intergenic control regions; can discriminate between tRNA genes and related class III elements. Algorithmic method based on analysis of 231 eukaryotic tRNA promoter regions; weight (position-specific scoring) matrices and weight vectors used for scoring. Web-based interactive form.	ReadSeq; also all common formats including FASTA, GenBank, EMBL, GCG, etc.	Predictions of class III intragenic region and presence of transcription termination sites.
RNA: Secondary Structure				
MFOLD (Jaeger et al. 1989; Zuker 1989; Walter et al. 1994)	http://bioweb.pasteur.fr/seqanal/interfaces/mfold.html	Predicts RNA secondary structure; computes number of folds, 5′ base number (start), and 3′ base number (stop). Uses energy minimization method of Zuker. A maximum of 1400 bases can be folded. Web-based interactive form. Can be implemented on a local UNIX host with graphic interface for exploring alternative structural models in given energy range.	RNA and DNA 1-nucleotide sequence in most common formats, including FASTA, IG, GenBank, NBRF, EMBL, etc.	Energy matrices that determine the optimal and suboptimal secondary structure; computed folding has energy within given range of computed minimum free energy. Matrices are written to an output file. Plotfold software is used to read the file and display a representative set of optimal and suboptimal secondary structures.
Vienna RNA package (Shapiro 1988; McCaskill 1990; Shapiro and Zhang	http://www.tbi.univie.ac.at/~ivo/RNA	Calculates predictions of RNA structures with minimum free energies as well as equilibrium partition functions and base-pairing probabil-	RNA sequence; HIT representation for structure representation	RNAfold produces plots and dot plot of minimum free energy structure and base pair

1990; Bonhoeffer et al. 1993; Fontana et al. 1993; Hofacker et al. 1994; Wuchty et al. 1999)		ities. Web-based interactive form for moderate sized RNAs. RNAfold calculates secondary RNA structure. RNAeval calculates energy of RNA sequence on given structure. RNAheat calculates specific heat of RNA. RNAinverse finds an RNA sequence with a given secondary structure. RNAdistance calculates the distance of RNA secondary structure. RNApbdist calculates the distance of thermodynamic RNA secondary structure groups. RNAsubopt calculates suboptimal secondary structure. Download source codes (C code library) or stand-alone programs for UNIX, LINUX.		probabilities. RNAeval gives energy in Kcal/mole; RNA heat, temperature in degrees C, specific heat in Kcal/(mole*K). RNAinverse, found sequence, Hamming distance to start sequence. RNAdistance, base pair distribution. RNApbdist, partition function and matrix of base-pairing probabilities, dot plots. RNAsubopt, structure in bracket notation and energy in Kcal/mole.

RNA: RNA-specifying Genes, Motifs

tRNAscan-SE (Fichant and Burks 1991; Eddy and Durbin 1994; Pavesi et al. 1994; Lowe and Eddy 1997)	http://www.genetics.wustl.edu/eddy/tRNAscan-SE	Searches for tRNA genes in genomic DNA or RNA sequence. Candidate tRNAs are identified and analyzed by a highly selective tRNA covariance model (sequence variation that occurs at two separated sites to conserve base pairing in regions of RNA secondary structure); searches are done at 30,000 bp/sec. The method also searches for eukaryotic PolIII sites and RNA promoters. Web-based interactive form.UNIX source code can also be accessed from the Web page.	Raw sequence, FASTA, GenBank, EMBL, GCG, IG. Searches are best as one sequence at a time, each sequence under 100,000 nucleotides.	Candidate tRNA genes.
snoRNA (Lowe and Eddy 1999)	http://rna.wustl.edu/snoRNAdb	Searches prescreened sections of genomic sequence with characteristic sequence patterns for 2′-*O*-ribose methylation guide snoRNA genes (sno, small nucleolar). The algorithm uses probabilistic methods similar to those used in speech recognition and computational liguistics. SCFG models (stochastic, context-free grammars) are used to recognize regions with a particular pattern of sequence covariation in separated regions of sequence that corresponds to sequences that base pair to form dsRNA secondary structure.		

Protein: Sequence Alignment

FASTA, SSEARCH, Baves block aligner	Please see DNA sequence alignment section.			

(Continued on following pages.)

TABLE A11-1 *(Continued)*

Program Name	Web Site/FTP Site	Description/Platforms	Input Format	Interpretation/Results
Proteins: Motifs, Patterns, Profiles				
emotif, ProfileMaker, Psi-BLAST, Phi-BLAST, PowerBLAST, Blast 2, Bayes block aligner, LAMA, BLOCKS	Please see DNA motifs, patterns, profiles section.			
PowerBLAST	http://www.ncbi.nlm.nih.gov/Kuehl/prefinished/powblast.html	Provides added functionality over the traditional BLAST programs. Allows masking of a sequence against human repetitive elements, comparison of masked sequence against multiple databases simultaneously. Allows rapid examination of ESTs, STSs, and gene hits in the context of their spatial relationships to one another. User can set additional parameters, filter BLAST hits by organism, and choose multiple output options. Web-based interactive form.	FASTA	Text, HTML, or ASN.1 output. A file is output for each sequence in the query. The out put can be viewed with a mask. Sequin can be used to annotate the BLAST hits.
PfScan (ProfileScan) (Swiss Institute of Bioinformatics [see www site])	http://www.isrec.isb-sib.ch/software/PFSCAN_form.html	Scans protein or DNA sequence against profiles from the PROSITE catalog. PROSITE contains amino acid patterns found in families of functionally related proteins, e.g., representing active site of protein kinases. The patterns are given as regular expressions that provide a list of the sequential amino acids found in the sites showing conserved, variable, amino acids not found and skipped amino acid positions. Also scans profiles against Swiss-Prot protein sequence database. Can search against the Pfam database. Web-based interactive form.	FASTA	Optimal alignment scores for profiles—PROSITE profiles N score; Pfam-A Nscore; Gribskov Z score; PROSITE patterns.
Pfam (Sonnhammer et al. 1997, 1998; Bateman et al. 1999, 2000)	http://www.sanger.ac.uk/Software/Pfam *Sweden:* www.cgr.ki.se/Pfam *USA:* pfam.wustl.edu	Enables rapid and automatic classification of predicted proteins into protein domain families; considers domain organization of proteins. Annotates protein using hidden Markov model software (see HMMER) that represents highly suitable probabilistic models of protein families, predicts genes, and annotates DNA sequence using the Wise2 package. The database contains 2128 families matching 65% of the proteins in Swiss-Prot. Genomic DNA can be directly searched against the Pfam library. This software was used to annotate the *C. elegans* genome.	FASTA	Graphical representation of domain structure. Name of domain in Pfam; start and end points of domain; statistical score of match in bits and *E* values; alignment of matching section of query sequence to relevant hidden Markov model. Provides functional annotation, literature references, and database links for each family. The output can be linked to the SCOP database to determine if the domain's structure has been solved.

ScanProsite (Swiss Institute of Bio informatics - see WWW site)	http://www.expasy.ch/tools/scnpsite.html	Scans sequence against patterns in PROSITE or a pattern against Swiss Prot. Web based interactive form.		
PPSEARCH (European Bioinformatics Institute, Hinxton, UK)	http://www2.ebi.ac.uk/ppsearch	Scans sequence against patterns in PROSITE.		Graphical output.
PROSITE (Klaus Harmuth, University of Vienna; Manfred D. Zorn, Lawrence Berkeley Laboratory)	http://pbil.ibcp.fr/cgi-bin/npsa_automat.pl?page=npsa_prosite.html *FTP*: genome.lbl.gov Dir:/pub/prosite File: ProSite.shar.Z	Scans sequence against patterns from PROSITE; can define level of mismatches. Web-based interactive form. Download UNIX C code. Also available commercially. Many other programs that use PROSITE are listed at www.expasy.ch/cgi-bin/lists/prosite.org	Swiss-Prot, FASTA, ASCII	ASCII. Positions of patterns shown under sequence; complete PROSITE pattern; position pattern of pattern occurrences for each pattern.
BEAUTY (BLAST Enhanced Alignment Utility) (Worley et al. 1995, 1998)	http://gc.bcm.tmc.edu:8088/searchlauncher/launcher.html	An enhanced version of NCBI BLAST that facilitates identification of functions of matched sequences. Integrates protein families, conserved regions, annotated regions, alignment displays, and WWW resources. Includes new databases of conserved regions and functional domains for protein sequences in NCBI Entrez. An updated version of BEAUTY-X provides enhanced output for DNA queries, ability to search any protein database, and more domain information. Web-based interactive form.	FASTA and other formats.	Schematic display compares relative locations of conserved regions, annotated domains and sites, locally aligned regions matched in a BLAST search, and WWW links to external databases for additional functional information.

TABLE A11-2 Database Similarity Search Software

Program Name	Web Site/FTP Site	Description/Platforms	Input Format	Interpretation/Results
BLAST (*Basic Alignment Search Tool*) (Altschul et al. 1990; Karlin and Altschul 1990, 1993; Tatusova and Madden 1999)	http://www.ncbi.nlm.nih.gov/BLAST	Sequence similarity search tool for analysis of nucleotide (DNA) and protein databases; uses heuristic algorithm that seeks high-scoring words and then uses these to produce gapped local alignments; filters out low-complexity regions from the search (optional); assigns scores with well-defined statistical interpretation so that real matches can be distinguished from random background hits. Default scoring matrix is BLOSUM62. The significances of the matches are given an Expect (*E*) score, the expected number of alignments between a random query sequence and a database of random sequences of the same "effective" length and number that will score as well. Available as interactive Web-based interface, stable URL, e-mail server, network BLAST with downloadable client for AIX, UNIX (see Web Site for details). Subprograms include: *blastn*–compares nucleotide query sequence against nucleotide sequence database *blastp*–compares amino acid query sequence against protein sequence database *blastx*–compares 6-frame conceptual translation products of nucleotide query sequence (both strands) against protein sequence database *tblastn*–compares protein query sequence against nucleotide sequence database dynamically translating all 6 reading frames *tblastx*–compares 6-frame translations of nucleotide query sequence against 6-frame translations of nucleotide sequence database A stand-alone BLAST system can be established locally on many computer platforms, including PC Windows 32, by FTP from ncbi.nlm.nih.gov/blast/executables.	FASTA or Accession/ GenBank index no.	Mouse-clickable histogram of matches; list of high-scoring database sequences; gapped, local alignment of query sequence with matching data base sequences with statistical evaluation; list of parameters used and statistical calculations made during search.
PHI-BLAST (*Position Hit Initiated BLAST*) (Zhang et al. 1998)	http://www.ncbi.nlm.nih.gov/BLAST	Finds protein sequences that share an amino acid pattern, entered using PROSITE syntax (a regular expression). Program is integrated with PSI-BLAST so that query results can be used to start one or more rounds of PSI-BLAST searching using Web-based interactive form.	FASTA or Accession/ GenBank index no.	Statistical significance of sequences that contain patterns are reported using *E* values. Multiple sequence alignment (a position-specific scoring matrix of the matching sequences) can then be used for additional rounds (iterations) of database searching using PSI-BLAST.
PSI-BLAST (*Position-specific BLAST*) (Altschul et al. 1997)	http://www.ncbi.nlm.nih.gov/BLAST	Search for similar protein sequences using a multiple sequence alignment as the query, thus allowing searches for new combinations of residues found in the alignment. Starts with a regular BLAST search, but as new matching sequences are found, these are added to the alignment and an iteration of the search can then be performed; multiple iterations are possible until no more matching sequences are found. Web-based interactive form.	FASTA or Accession/ GenBank index no.	A multiple sequence alignment (a position-specific scoring matrix of the matching sequences) replaces the initial pattern and may be used for additional rounds (iterations) of database searching until no more matching sequences are found.

BLAST2 - Gapped BLAST (*Altschul et al. 1997*).	http://www.ncbi.nlm.nih.gov/BLAST	The newer version 2 of BLAST returns a local (Smith Waterman) alignment from BLAST searches and uses the statistical significance of the alignment scores to identify the *most alike sequences; this is the default condition* for the BLAST2 program. Earlier versions of BLAST identified high-scoring regions, and used the sum of these scores to evaluate the signifi cance of the sequence similarity.	FASTA or Accession/ GenBank index no.	
BLAST-Genome Sequences	http://www.ncbi.nlm.nih.gov/genome/seq	Searches a query sequence against the human genome data base (or any other genomic sequence database). Interactive Web-based form.	FASTA or Accession/ GenBank index no.	Match of sequence by chromosome number.
WU-BLAST (Washington University *BLAST*) (Altschul et al. 1990; Gish and States 1993; Karlin and Altschul 1993; Altschul and Gish 1996; W. Gish *unpubl.*)	*http://blast.wustl.edu*	Performs similarity searches of proteins and nucleotide sequence databases; similar to NCBI BLAST but developed independently and can produce different results. WU-BLAST2 uses gapped alignments to identify matching sequences; produces a gapped local (Smith-Waterman) alignment; calculates statistical significance based on the combined scores of high-scoring regions (the sum statistics method as *in earlier pre-version 2 versions of* NCBI BLAST). BLASTN, BLASTP, TBLASTN, BLASTX and TBLASTX programs are available (see NCBI BLAST); includes improvements for identifying coding regions and uses DNA scoring matrices for more significant alignment of nucleic acids. *Contains enhancements for optimized execution,* reduced virtual memory requirements, support for parallel processing, and eXtended Database Format (XDF). Software is downloadable from Web Site: License is free for academic and nonprofit use; fee for commercial use.	FASTA or Accession/ GenBank index no.	Mouse-clickable map of matching sequences, lists of matching sequences *with sum-statistics* scores, gapped alignments with potentially multiple regions of similarity; can be used to show all exons in multi-exon sequence; all complete on par-tial copies of repetitive ele ment in genomic sequence.
FASTA Programs				
FASTA (Pearson and Lipman 1988)	http://fasta.bioch.virginia.edu *FTP:* ftp.virginia.edudir /pub/.fasta	The FASTA package includes a suite of programs for data base similarity searching and for pair-wise sequence align ment. Compares DNA sequence to another DNA sequence or to a DNA sequence database (designated library by the programs), or a protein sequence to another protein sequence or to a protein sequence database; also compares protein sequence to translated DNA sequence or DNA sequence database (library). FASTA3 (version 3) returns matches based on a normalized *Z score,the number of standard deviations* above a mean of 50 and standard deviation of 10 for matching all unrelated sequences of the same length in the database. The *E* (expect) value of the *Z* score, the number of unrelated sequences in the database that are expected to score as well, *is given.* Can search individual genomes; databases listed on Web form. Web-based interactive form, or down-loadable software. Permission needed for commercial use. FASTA may be established on a variety computer platforms, including Macintosh and PC Windows, but without a graphical interface.	FASTA or Accession/ GenBank index no.	*Provides a graphical display of the range* of alignment scores found between the query sequence and each database sequence, with a fit of the scores with unrelated proteins to the extreme value distribution. A list of high-scoring sequences is then given followed by gapped alignments of the query and matched data base sequences. Normalized *Z* scores are used to describe the relationship of the alignment score between related sequences to that found for unrelated sequences in the *same length* range (mean 50, standard deviation 10). The *E* value of these high *Z* scores is the expected number of unrelated sequence alignments with *Z* scores as high as that found with the *matched sequence.*

(Continued on following pages.)

TABLE A11-2 (*Continued*)

Program Name	Web Site/FTP Site	Description/Platforms	Input Format	Interpretation/Results
TFASTX/TFASTY FASTX, FASTY (Chao et al. 1992)	http://fasta.bioch.virginia.edu	Compares protein sequence to translated DNA sequence or DNA sequence database (TFASTX/TFASTY) or translated DNA sequence against protein sequence database (FASTX/FASTY); designed to accommodate high error rate in EST sequences by allowing frameshifts and substitutions.	FASTA or Accession/Genbank index no.	Single alignment between 2 sequences; DNA sequence is translated in 3 forward and 3 reverse frames; protein query is compared to each of the 6 derived protein sequences. DNA sequence is translated from one end to the other and intervening sequences are not edited out; termination codons are translated into unknown amino acids.
FASTS/TFASTS FASTF/TFASTF	http://fasta.bioch.virginia.edu	Compares sequence of peptide fragments (mass-spectrophotometric analysis) (FASTS) or an ordered peptide mixture (FASTF) against a protein (FASTS) or DNA (tFASTS) data base.	See Web site	Similar to FASTA, includes list of matching sequences in the database.

TABLE A11-3 Bioinformatics Databases

Database	WWW Address	Description
DNA		
GenBank	www.ncbi.nlm.nih.gov/Genbank/GenbankSearch.html	DNA sequence database maintained by National Center for Biotechnology Information (NCBI); member of International DNA Databases.
EMBL (Baker et al. 2000)	www.ebi.ac.uk/embl/	DNA sequence database maintained by European Bioinformatics Institute (EBI); member of International DNA databases.
DDBJ	www.ddbj.nig.ac.uk	DNA sequence database maintained by DNA Data Bank of Japan; member of International DNA Databases.
DNA: Motifs, Patterns

DATABASE	WWW ADDRESS	DESCRIPTION
Protein: Structural Coordinates		
PDB (*P*rotein *D*ata *B*ank) (Berman et al. 2000)	http://www.rcsb.org/pdb	Three-dimensional macromolecular structure data determined mainly by X-ray crystallography and nuclear magnetic resonance; also contains atomic coordinates, reference citations, and primary and secondary structure information. Operated by the Research Collaboration for Structural Bioinformatics, Rutgers.

This survey of databases lists the principal databases as well as some of the more specialized databases for DNA, protein, and RNA. There are several Web pages that list and provide links to the large array of databases. Among these are:

Gabriel's Hot List
http://www.bmm.icnet.uk/useful/usefulz.html
Extensive lists of links to sequence and structure databases and to specialized databases.

A List of Databases, Rockefeller University
http://linkage.rockefeller.edu/wli/gene/databases.html
Links to DNA, protein, and genome databases.

Bioinformatics Resouces, Bioinformatics Group, University of Waterloo, Canada
http://wh.math.umaterloo.ca/bioinfo_res.html
Links to DNA, protein, and genome databases.

The RNA World
http://www.imb-jena.de/RNA.html
Links to RNA-specific databases.

Amos' WWW Links
http://www.expasy.ch/alinks.html
Extensive lists of links to protein databases and resources.

and also see
http://www.bioinformaticsonline.com, a Web Site for Mount D. *Bioinformatics: Sequence and genome analysis* (Cold Spring Harbor Laboratory Press 2001)

Appendix 12

Cautions

GENERAL CAUTIONS

The following general cautions should always be observed.

- Become **completely familiar** with the properties of all substances used before beginning the procedure.
- **The absence of a warning** does not necessarily mean that the material is safe, since information may not always be complete or available.
- If **exposed** to toxic substances, contact the local safety office immediately for instructions.
- **Use proper disposal procedures** for all chemical, biological, and radioactive waste.
- For specific guidelines on **appropriate gloves**, consult the local safety office.
- Handle **concentrated acids and bases** with great care. Wear goggles and appropriate gloves, as well as a face shield if handling large quantities.

  Do not mix strong acids with organic solvents as they may react. Sulfuric acid and nitric acid especially may react highly exothermically and cause fires and explosions.

  Do not mix strong bases with halogenated solvent as they may form reactive carbenes which can lead to explosions.

  When preparing diluted solutions of acids from concentrated stocks, add acid to water ("If you do what you oughta, add acid to wata").

- Never **pipette** solutions using mouth suction. This method is not sterile and can be dangerous. Always use a pipette aid or bulb.
- Keep **halogenated and nonhalogenated** solvents separately (e.g., mixing chloroform and acetone can cause unexpected reactions in the presence of bases). Halogenated solvents are organic solvents such as chloroform, dichloromethane, trichlorotrifluoroethane, and dichloroethane. Some nonhalogenated solvents are pentane, heptane, ethanol, methanol, benzene, toluene, *N*,*N*-dimethylformamide (DMF), dimethylsulfoxide (DMSO), and acetonitrile.
- **Laser radiation**, visible or invisible, can cause severe damage to the eyes and skin. Take proper precautions to prevent exposure to direct and reflected beams. Always follow manufacturers safety guidelines and consult the local safety office. For more detailed information, see caution below.
- **Flash lamps**, due to their light intensity, can be harmful to the eyes and may explode on occasion. Wear appropriate eye protection and follow the manufacturer's guidelines.
- **Photographic fixatives and developers** contain harmful chemicals. Handle them with care and follow manufacturer's directions.

- **Power supplies and electrophoresis equipment** pose serious fire hazard and electrical shock hazards if not used properly.
- **Microwave ovens and autoclaves** in the lab require certain precautions. If the screw top on the bottle is not loose enough, and there is not enough space for the steam to vent, the bottle can explode when the containers are removed from the microwave or autoclave. Always loosen bottle caps before microwaving or autoclaving.
- Use extreme caution when handling **cutting devices** such as microtome blades, scalpels, razor blades, or needles. Microtome blades are extremely sharp! If unfamiliar with their use, have an experienced person demonstrate proper procedures. For proper disposal, use a "sharps" disposal container in the lab. Discard used needles unshielded, with the syringe still attached. This method prevents injuries (and possible infections) while manipulating used needles since many accidents occur while trying to replace the needle shield. Injuries may also be caused by broken Pasteur pipettes, coverslips, or slides.

GENERAL PROPERTIES OF COMMON CHEMICALS

The hazardous materials list can be summarized in the following categories:

- Inorganic acids, such as hydrochloric, sulfuric, nitric, or phosphoric, are colorless liquids with stinging vapors. Avoid spills on skin or clothing. Dilute spills with large amounts of water. The concentrated forms of these acids can destroy paper, textiles, and skin as well as cause serious injury to the eyes.
- Salts of heavy metals are usually colored powdered solids that dissolve in water. Many of them are potent enzyme inhibitors and therefore toxic to humans and to the environment (e.g., fish and algae).
- Most organic solvents are flammable volatile liquids. Breathing their vapors can cause nausea or dizziness. Also avoid skin contact.
- Other organic compounds, including organosulphur compounds such as mercaptoethanol or organic amines, have very unpleasant odors. Others are highly reactive and must be handled with appropriate care.
- If improperly handled, dyes and their solutions can stain not only the sample, but also skin and clothing. Some of them are also mutagenic (e.g., ethidium bromide), carcinogenic, and toxic.
- Nearly all names ending with "ase" (e.g., catalase, β-glucuronidase, or zymolase) refer to enzymes. There are also other enzymes with nonsystematic names like pepsin. Many of them are provided by manufacturers in preparations containing buffering substances, etc. Be aware of the individual properties of materials contained in these substances.
- Toxic compounds often used to manipulate cells (e.g., cycloheximide, actinomycin D, and rifampicin) can be dangerous and should be handled appropriately.

HAZARDOUS MATERIALS

Acetic acid (concentrated) must be handled with great care. It may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and goggles. Use in a chemical fume hood.

Acetonitrile is very volatile and extremely flammable. It is an irritant and a chemical asphyxiant that can exert its effects by inhalation, ingestion, or skin absorption. Treat cases of severe exposure as cyanide poisoning. Wear appropriate gloves and safety glasses. Use only in a chemical fume hood. Keep away from heat, sparks, and open flame.

Acrylamide (unpolymerized) is a potent neurotoxin and is absorbed through the skin (effects are cumulative). Avoid breathing the dust. Wear appropriate gloves and a face mask when weighing powdered acrylamide and methylene-bisacrylamide. Use in a chemical fume hood. Polyacrylamide is considered to be nontoxic, but it should be handled with care because it might contain small quantities of unpolymerized acrylamide.

Actinomycin D is a teratogen and a carcinogen. It is highly toxic and may be fatal if inhaled, ingested, or absorbed through the skin. It may also cause irritation. Avoid breathing the dust. Wear appropriate gloves and safety glasses. Always use in a chemical fume hood. Solutions of actinomycin D are light-sensitive.

$AgNO_3$, *see* **Silver nitrate**

α-Amanitin is highly toxic and may be fatal by inhalation, ingestion, or skin absorption. Symptoms may be delayed for as long as 6–24 hours. Wear appropriate gloves and safety glasses. Always use in a chemical fume hood.

Aminobenzoic acid may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses.

Ammonium acetate, $H_3CCOONH_4$, may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses. Use in a chemical fume hood.

Ammonium chloride, NH_4Cl, may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses. Use in a chemical fume hood.

Ammonium formate, *see* **Formic acid**

Ammonium hydroxide, NH_4OH, is a solution of ammonia in water. It is caustic and should be handled with great care. As ammonia vapors escape from the solution, they are corrosive, toxic, and can be explosive. Use only with mechanical exhaust. Wear appropriate gloves. Use only in a chemical fume hood.

Ammonium molybdate, $(NH_4)_6Mo_7O_{24}{\cdot}4H_2$) (or its **tetrahydrate**) may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses. Use in a chemical fume hood.

Ammonium persulfate, $(NH_4)_2S_2O_8$, is extremely destructive to tissue of the mucous membranes and upper respiratory tract, eyes, and skin. Inhalation may be fatal. Wear appropriate gloves, safety glasses, and protective clothing. Always use in a chemical fume hood. Wash thoroughly after handling.

Ammonium sulfate, $(NH_4)_2SO_4$, may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses.

Ampicillin may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses. Use in a chemical fume hood.

Aprotinin may be harmful by inhalation, ingestion, or skin absorption. It may also cause allergic reactions. Exposure may cause gastrointestinal effects, muscle pain, blood pressure changes, or bronchospasm. Wear appropriate gloves and safety glasses. Do not breathe the dust. Use only in a chemical fume hood.

Arc lamps are potentially explosive. Follow manufacturer's guidelines. When turning on arc lamps, make sure nearby computers are turned off to avoid damage from electromagnetic wave components. Computers may be restarted once the arc lamps are in operation.

Aspartic acid is a possible mutagen and poses a risk of irreversible effects. It may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses. Use in a chemical fume hood. Do not breathe the dust.

Bacterial strains (shipping of): The Department of Health, Education, and Welfare (HEW) has classified various bacteria into different categories with regard to shipping requirements (please see Sanderson and Zeigler, *Methods Enzymol. 204:* 248–264 [1991] or the instruction brochure by Alexander and Brandon (*Packaging and Shipping of Biological Materials at ATCC* [1986] available from the American Type Culture Collection [ATCC], Rockville, Maryland). Nonpathogenic strains of *Escherichia coli* (such as K-12) and *Bacillus subtilis* are in Class 1 and are considered to present no or minimal hazard under normal shipping conditions. However, *Salmonella, Haemophilus*, and certain strains of *Streptomyces* and *Pseudomonas* are in Class 2. Class 2 bacteria are "Agents of ordinary potential hazard: agents which produce disease of varying degrees of severity...but which are contained by ordinary laboratory techniques."

BCIG, *see* **5-Bromo-4-chloro-3-indolyl-β-D-galactopyranoside**

Biotin may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses. Use in a chemical fume hood.

Bisacrylamide is a potent neurotoxin and is absorbed through the skin (the effects are cumulative). Avoid breathing the dust. Wear appropriate gloves and a face mask when weighing powdered acrylamide and methylene-bisacrylamide.

Blood (human) and blood products and Epstein-Barr virus. Human blood, blood products, and tissues may contain occult infectious materials such as hepatitis B virus and HIV that may result in laboratory-acquired infections. Investigators working with EBV-transformed lymphoblast cell lines are also at risk of EBV infection. Any human blood, blood products, or tissues should be considered a biohazard and be handled accordingly. Wear disposable appropriate gloves, use mechanical pipetting devices, work in a biological safety cabinet, protect against aerosol generation, and disinfect all waste materials before disposal. Autoclave contaminated plasticware before disposal; autoclave contaminated liquids or treat with bleach (10% [v/v] final concentration) for at least 30 minutes before disposal. Consult the local institutional safety officer for specific handling and disposal procedures.

Boric acid, H_3BO_3, may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and goggles.

5-Bromo-4-chloro-3-indolyl-β-D-galactopyranoside (BCIG; X-gal) is toxic to the eyes and skin and may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety goggles.

Bromophenol blue may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses. Use in a chemical fume hood.

***n*-Butanol** is irritating to the mucous membranes, upper respiratory tract, skin, and especially the eyes. Avoid breathing the vapors. Wear appropriate gloves and safety glasses. Use in a chemical fume hood. *n*-Butanol is also highly flammable. Keep away from heat, sparks, and open flame.

Cacodylate contains arsenic, is highly toxic, and may be fatal if inhaled, ingested, or absorbed through the skin. It is a possible carcinogen and may be mutagenic. Wear appropriate gloves and safety glasses. Use in a chemical fume hood.

Cacodylic acid is toxic and a possible carcinogen. It may be mutagenic and is harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses. Use only in a chemical fume hood. Do not breathe the dust.

Carbenicillin may cause sensitization by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses.

Carbon dioxide, CO_2, in all forms may be fatal by inhalation, ingestion, or skin absorption. In high concentrations, it can paralyze the respiratory center and cause suffocation. Use only in well-ventilated areas. In the form of dry ice, contact with carbon dioxide can also cause frostbite. Do not place large quantities of dry ice in enclosed areas such as cold rooms. Wear appropriate gloves and safety goggles.

Cesium chloride, CsCl, may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses.

Cetylpyridinium bromide (CPB) causes severe irritation to the eyes, skin, and respiratory tract. Wear appropriate gloves and safety glasses. Use in a chemical fume hood.

Cetyltrimethylammonium bromide (CTAB) is toxic and an irritant and may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses. Avoid breathing the dust.

CH_3CH_2OH, *see* **Ethanol**

$C_6H_5CH_2SO_2F$, *see* **Phenylmethylsulfonyl fluoride**

$CHCl_3$, *see* **Chloroform**

$C_7H_7FO_2S$, *see* **Phenylmethylsulfonyl fluoride**

Chloramphenicol may be harmful by inhalation, ingestion, or skin absorption and is a carcinogen. Wear appropriate gloves and safety glasses. Use in a chemical fume hood.

Chloroform, $CHCl_3$, is irritating to the skin, eyes, mucous membranes, and respiratory tract. It is a carcinogen and may damage the liver and kidneys. It is also volatile. Avoid breathing the vapors. Wear appropriate gloves and safety glasses. Always use in a chemical fume hood.

Citric acid is an irritant and may be harmful by inhalation, ingestion, or skin absorption. It poses a risk of serious damage to the eyes. Wear appropriate gloves and safety goggles. Do not breathe the dust.

CO_2, *see* **Carbon dioxide**

Cobalt chloride, $CoCl_2$, may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses.

$CoCl_2$, *see* **Cobalt chloride**

Coomassie Brilliant Blue may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses.

Copper sulfate, $CuSO_4$, may be harmful by inhalation or ingestion. Wear appropriate gloves and safety glasses.

CPB, *see* **Cetylpyridinium bromide**

***m*-Cresol** may be fatal if inhaled, ingested, or absorbed through the skin. It may also cause burns and is extremely destructive to the eyes, skin, mucus membranes, and upper respiratory tract. Wear appropriate gloves and safety glasses. Use in a chemical fume hood.

CsCl, *see* **Cesium chloride**

CTAB, *see* **Cetyltrimethylammonium bromide**

$CuSO_4$, *see* **Copper sulfate**

Cysteine is an irritant to the eyes, skin, and respiratory tract. It may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses. Do not breathe the dust.

DEAE, *see* **Diethylaminoethanol**

DEPC, *see* **Diethyl pyrocarbonate**

Dichloromethylsilane, *see* **Dichlorosilane**

Dichlorosilane is highly flammable and toxic and may be fatal if inhaled. It is harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety goggles. Use only in a chemical fume hood. It reacts violently with water. Keep away from heat, sparks, and open flame. Take precautionary measures against static discharges.

Diethylamine, $NH(C_2H_5)_2$, is corrosive, toxic, and extremely flammable. It may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses. Use only in a chemical fume hood. Keep away from heat, sparks, and open flame.

Diethylaminoethanol (DEAE) may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses. Use in a chemical fume hood.

Diethyl ether, Et_2O or **$(C_2H_5)_2O$,** is extremely volatile and flammable. It is irritating to the eyes, mucous membranes, and skin. It is also a CNS depressant with anesthetic effects. It may be harmful by inhalation, ingestion, or skin absorption. Avoid breathing the vapors. Wear appropriate gloves and safety glasses. Always use in a chemical fume hood. Explosive peroxides can form during storage or on exposure to air or direct sunlight. Keep away from heat, sparks, and open flame.

Diethyl pyrocarbonate (DEPC) is a potent protein denaturant and is a suspected carcinogen. Aim bottle away from you when opening it; internal pressure can lead to splattering. Wear appropriate gloves and lab coat. Use in a chemical fume hood.

Diethyl sulfate (DES), $(C_2H_5)_2SO_4$, is a mutagen and suspected carcinogen. It is also volatile. Avoid breathing the vapors. Wear appropriate gloves. Use in a chemical fume hood. Use screw-cap tubes for all DES-treated cultures and mechanical pipettors to manipulate DES solutions. Dispose of all DES-treated cultures in bleach.

***N,N*-Dimethylformamide (DMF), $HCON(CH_3)_2$,** is irritating to the eyes, skin, and mucous membranes. It can exert its toxic effects through inhalation, ingestion, or skin absorption. Chronic inhalation can cause liver and kidney damage. Wear appropriate gloves and safety glasses. Use in a chemical fume hood.

Dimethylsulfate (DMS), $(CH_3)_2\ SO_4$, is extremely toxic and is a carcinogen. Avoid breathing the vapors. Wear appropriate gloves and safety glasses. Use only in a chemical fume hood. Dispose of solutions containing dimethylsulfate by pouring them slowly into a solution of sodium hydroxide or ammonium hydroxide and allowing them to sit overnight in the chemical fume hood. Contact the local safety office before re-entering the lab to clean up a spill.

Dimethylsulfoxide (DMSO) may be harmful by inhalation or skin absorption. Wear appropriate gloves and safety glasses. Use in a chemical fume hood. DMSO is also combustible. Store in a tightly closed container. Keep away from heat, sparks, and open flame.

Dinitrophenol (DNP) may be fatal by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses. Use only in a chemical fume hood.

Diphenyloxazole (PPO) may be carcinogenic. It may be harmful by inhalation, ingestion, or skin absorption.Wear appropriate gloves and safety glasses. Consult the local institutional safety officer for specific handling and disposal procedures.

Disodium citrate, *see* **Citric acid**

Dithiothreitol (DTT) is a strong reducing agent that emits a foul odor. It may be harmful by inhalation, ingestion, or skin absorption. When working with the solid form or highly concentrated stocks, wear appropriate gloves and safety glasses. Use in a chemical fume hood.

DMF, *see* ***N,N*-Dimethylformamide**

DMS, *see* **Dimethylsulfate**

DMSO, *see* **Dimethylsulfoxide**

DNP, *see* **Dinitrophenol**

Dry ice, *see* **Carbon dioxide**

DTT, *see* **Dithiothreitol**

EDC, *see* ***N*-Ethyl-*N*′-(dimethylaminopropyl)-carbodiimide**

EMS, *see* **Ethyl methane sulfonate**

Ethanol (EtOH), CH_3CH_2OH, may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses.

Ethanolamine, $HOCH_2CH_2NH_2$, is toxic and harmful by inhalation, ingestion, or skin absorption. Handle with care and avoid any contact with the skin. Wear appropriate gloves and goggles. Use in a chemical fume hood. Ethanolamine is highly corrosive and reacts violently with acids.

Ether, *see* **Diethyl ether**

Ethidium bromide is a powerful mutagen and is toxic. Consult the local institutional safety officer for specific handling and disposal procedures. Avoid breathing the dust. Wear appropriate gloves when working with solutions that contain this dye.

Ethyl acetate may be fatal by ingestion and harmful by inhalation or skin absorption. Wear appropriate gloves and safety goggles. Do not breathe the dust. Use in a well-ventilated area.

***N*-Ethyl-*N*′-(dimethylaminopropyl)-carbodiimide (EDC)** is irritating to the mucus membranes and upper respiratory tract. It may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses. Handle with care.

Ethyl methane sulfonate (EMS) is a volatile organic solvent that is a mutagen and carcinogen. It is harmful if inhaled, ingested. or absorbed through the skin. Discard supernatants and washes containing EMS in a beaker containing 50% sodium thiosulfate. Decontaminate all material that has come in contact with EMS by treatment in a large volume of 10% (w/v) sodium thiosulfate. Use extreme caution when handling. When using undiluted EMS, wear protective appropriate gloves and use in a chemical fume hood. Store EMS in the cold. DO NOT mouth pipette EMS. Pipettes used with undiluted EMS should not be too warm; chill them in the refrigerator before use to minimize the volatility of EMS. All glassware coming in contact with EMS should be immersed in a large beaker of 1 N NaOH or laboratory bleach before recycling or disposal.

EtOH, *see* **Ethanol**

$FeCl_3$, *see* **Ferric chloride**

Ferric chloride, $FeCl_3$, may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses. Use only in a chemical fume hood.

Formaldehyde, HCOH, is highly toxic and volatile. It is also a carcinogen. It is readily absorbed through the skin and is irritating or destructive to the skin, eyes, mucous membranes, and upper respiratory tract. Avoid breathing the vapors. Wear appropriate gloves and safety glasses. Always use in a chemical fume hood. Keep away from heat, sparks, and open flame.

Formamide is teratogenic. The vapor is irritating to the eyes, skin, mucous membranes, and upper respiratory tract. It may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses. Always use in a chemical fume hood when working with concentrated solutions of formamide. Keep working solutions covered as much as possible.

Formic acid, HCOOH, is highly toxic and extremely destructive to tissue of the mucous membranes, upper respiratory tract, eyes, and skin. It may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses (or face shield) and use in a chemical fume hood.

β-Galactosidase is an irritant and may cause allergic reactions. It may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses.

Giemsa may be fatal or cause blindness by ingestion and is toxic by inhalation and skin absorption. There is a possible risk of irreversible effects. Wear appropriate gloves and safety goggles. Use only in a chemical fume hood. Do not breathe the dust.

Glassware, pressurized must be used with extreme caution. Handle glassware under vacuum, such as desiccators, vacuum traps, drying equipment, or a reactor for working under argon atmosphere, with appropriate caution. Always wear safety glasses.

Glass wool may be harmful by inhalation and may cause skin irritation. Wear appropriate gloves and mask.

Glutaraldehyde is toxic. It is readily absorbed through the skin and is irritating or destructive to the skin, eyes, mucous membranes, and upper respiratory tract. Wear appropriate gloves and safety glasses. Always use in a chemical fume hood.

Glycine may be harmful by inhalation, ingestion, or skin absorption. Wear gloves and safety glasses. Avoid breathing the dust.

Guanidine hydrochloride is irritating to the mucous membranes, upper respiratory tract, skin, and eyes. It may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses. Avoid breathing the dust.

Guanidine thiocyanate may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses.

Guanidinium hydrochloride, *see* **Guanidine hydrochloride**

Guanidinium isothiocyanate, *see* **Guanidine thiocyanate**

Guanidinium thiocyanate, *see* **Guanidine thiocyanate**

H_3BO_3, *see* **Boric acid**

$H_3CCOONH_4$, *see* **Ammonium acetate**

HCl, *see* **Hydrochloric acid**

HCOH, *see* **Formaldehyde**

H_3COH, *see* **Methanol**

$HCON(CH_3)_2$, *see* **Dimethylformamide**

HCOOH, *see* **Formic acid**

Heptane may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses. It is extremely flammable. Keep away from heat, sparks, and open flame.

HNO_3, *see* **Nitric acid**

H_2O_2, *see* **Hydrogen peroxide**

$HOCH_2CH_2NH_2$, *see* **Ethanolamine**

$HOCH_2CH_2SH$, *see* **β-Mercaptoethanol**

H_3PO_2, *see* **Hypophosphorous acid**

H_3PO_4, *see* **Phosphoric acid (concentrated)**

H_2S, *see* **Hydrogen sulfide**

H_2SO_4, *see* **Sulfuric acid**

Hydrazine, N_2H_4, is highly toxic and explosive in the anhydrous state. It may be harmful by inhalation, ingestion, or skin absorption. Avoid breathing the vapors. Wear appropriate gloves, goggles, and protective clothing. Use only in a chemical fume hood. Dispose of solutions containing hydrazine in accordance with MSDS recommendations. Keep away from heat, sparks, and open flame.

Hydrochloric acid, HCl, is volatile and may be fatal if inhaled, ingested, or absorbed through the skin. It is extremely destructive to mucous membranes, upper respiratory tract, eyes, and skin. Wear appropriate gloves and safety glasses. Use with great care in a chemical fume hood. Wear goggles when handling large quantities.

Hydrogen peroxide, H_2O_2, is corrosive, toxic, and extremely damaging to the skin. It may be harmful by inhalation, ingestion, and skin absorption. Wear appropriate gloves and safety glasses. Use only in a chemical fume hood.

Hydrogen sulfide, H_2S, is an extremely toxic gas that causes paralysis of the respiratory center. It is irritating and corrosive to tissues and may cause olfactory fatigue. Do not rely on odor to detect its presence. Take great care when handling it. Keep H_2S tanks in a chemical fume hood or in a room equipped with appropriate ventilation. Wear appropriate gloves and safety glasses. It is also very flammable. Keep away from heat, sparks, and open flame.

***N*-Hydroxysuccinimide** is an irritant and may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses.

Hygromycin B is highly toxic and may be fatal if inhaled, ingested, or absorbed through the skin. Wear appropriate gloves and safety goggles. Use only in a chemical fume hood. Do not breathe the dust.

Hypophosphorous acid, H_3PO_2, is usually supplied as a 50% solution, which is corrosive and should be handled with care. It should be freshly diluted immediately before use. Wear appropriate gloves and safety glasses. Use in a chemical fume hood.

Inositol may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses.

IPTG, *see* **Isopropyl-β-D-thiogalactopyranoside**

Isoamyl alcohol may be harmful by inhalation, ingestion, or skin absorption and presents a risk of serious damage to the eyes. Wear appropriate gloves and safety goggles. Keep away from heat, sparks, and open flame.

Isobutanol, *see* **Isobutyl alcohol**

Isobutyl alcohol (Isobutanol) is extremely flammable and may be harmful by inhalation or ingestion. Wear appropriate gloves and safety glasses. Keep away from heat, sparks, and open flame.

Isopropanol is irritating and may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses. Do not breathe the vapor. Keep away from heat, sparks, and open flame.

Isopropyl-β-D-thiogalactopyranoside (IPTG) may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses.

Isotope ^{125}I accumulates in the thyroid and is a potential health hazard. Consult the local radiation safety office for further guidance in the appropriate use and disposal of radioactive materials. Wear appropriate gloves when handling radioactive substances. The $^{125}I_2$ formed during oxidation of $Na^{125}I$ is volatile. Work in an approved chemical fume hood with a charcoal filter when exposing the $Na^{125}I$ to oxidizing reagents such as chloramine-T, IODO-GEN, or acids. Because the oxidation proceeds very rapidly and releases large amounts of volatile $^{125}I_2$ when chloramine-T is used, it is important to be well prepared for each step of the reaction, so that the danger of contamination from volatile radiation can be minimized. Shield all forms of the isotope with lead. When handling the isotope, wear one or two pairs of appropriate gloves, depending on the amount of isotope being used and the difficulty of the manipulation required.

KCl, *see* **Potassium chloride**

$K_3Fe(CN)_6$, *see* **Potassium ferricyanide**

$K_4Fe(CN)_6 \cdot 3H_2O$, *see* **Potassium ferrocyanide**

$KH_2PO_4/K_2HPO_4/K_3PO_4$, *see* **Potassium phosphate**

$KMnO_4$, *see* **Potassium permanganate**

KOH, *see* **Potassium hydroxide**

Laser radiation, both visible and invisible, can be seriously harmful to the eyes and skin and may generate airborne contaminants, depending on the class of laser used. High-power lasers produce perma-

nent eye damage, can burn exposed skin, ignite flammable materials, and activate toxic chemicals that release hazardous by-products. Avoid eye or skin exposure to direct or scattered radiation. Do not stare at the laser and do not point the laser at someone else. Wear appropriate eye protection and use suitable shields that are designed to offer protection for the specific type of wavelength, mode of operation (continuous wave or pulsed), and power output (watts) of the laser being used. Avoid wearing jewelry or other objects that may reflect or scatter the beam. Some non-beam hazards include electrocution, fire, and asphyxiation. Entry to the area in which the laser is being used must be controlled and posted with warning signs that indicate when the laser is in use. Always follow suggested safety guidelines that accompany the equipment and contact your local safety office for further information.

LiCl, *see* **Lithium chloride**

Liquid nitrogen can cause severe damage due to extreme temperature. Handle frozen samples with extreme caution. Do not breathe the vapors. Seepage of liquid nitrogen into frozen vials can result in an exploding tube upon removal from liquid nitrogen. Use vials with O-rings when possible. Wear cryo-mitts and a face mask.

Lithium chloride, LiCl, is an irritant to the eyes, skin, mucous membranes, and upper respiratory tract. It may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety goggles. Use in a chemical fume hood. Do not breathe the dust.

Lysozyme is caustic to mucus membranes. Wear appropriate gloves and safety glasses.

Magnesium chloride, $MgCl_2$, may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses. Use in a chemical fume hood.

Magnesium sulfate, $MgSO_4$, may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses. Use in a chemical fume hood.

Manganese chloride, $MnCl_2$, may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses. Use in a chemical fume hood.

MeOH or H_3COH, *see* **Methanol**

β-Mercaptoethanol (2-Mercaptoethanol), $HOCH_2CH_2SH$, may be fatal if inhaled or absorbed through the skin and is harmful if ingested. High concentrations are extremely destructive to the mucous membranes, upper respiratory tract, skin, and eyes. β-Mercaptoethanol has a very foul odor. Wear appropriate gloves and safety glasses. Always use in a chemical fume hood.

MES, *see* **2-[*N*-morpholino]ethanesulfonic acid**

Methanol, MeOH or **H_3COH,** is poisonous and can cause blindness. It may be harmful by inhalation, ingestion, or skin absorption. Adequate ventilation is necessary to limit exposure to vapors. Avoid inhaling these vapors. Wear appropriate gloves and goggles. Use only in a chemical fume hood.

Methotrexate (MTX) is a carcinogen and a teratogen. It may be harmful by inhalation, ingestion, or skin absorption. Exposure may cause gastrointestinal effects, bone marrow suppression, liver or kidney damage. It may also cause irritation. Avoid breathing the vapors. Wear appropriate gloves and safety glasses. Always use in a chemical fume hood.

***N,N′*-Methylenebisacrylamide** is a poison and may effect the central nervous system. It may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses. Do not breathe the dust.

Methylene blue is irritating to the eyes and skin. It may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses.

Methylmercuric hydroxide is extremely toxic and may be harmful by inhalation, ingestion, or skin absorption. It is also volatile. Therefore, carry out all manipulations of solutions containing concentrations of methylmercuric hydroxide in excess of 10^{-2} M in a chemical fume hood and wear appropriate gloves when handling such solutions. Treat all solid and liquid wastes as toxic materials and dispose of in accordance with MSDS recommendations.

$MgCl_2$, *see* **Magnesium chloride**

$MgSO_4$, *see* **Magnesium sulfate**

2-[*N*-morpholino]ethanesulfonic acid (MES) may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses.

3-(*N*-Morpholino)-propanesulfonic acid (MOPS) may be harmful by inhalation, ingestion, or skin absorption. It is irritating to mucous membranes and upper respiratory tract. Wear appropriate gloves and safety glasses. Use in a chemical fume hood.

$MnCl_2$, *see* **Manganese chloride**

MOPS, *see* **3-(*N*-Morpholino)-propanesulfonic acid**

MTX, *see* **Methotrexate**

NaF, *see* **Sodium fluoride**

Na_2HPO_4, *see* **Sodium hydrogen phosphate**

NaN_3, *see* **Sodium azide**

$NaNO_3$, *see* **Sodium nitrate**

NaOH, *see* **Sodium hydroxide**

N_2H_4, *see* **Hydrazine**

NH_4Cl, *see* **Ammonium chloride**

$(NH_4)_6Mo_7O_{24}{\cdot}4H_2O$, *see* **Ammonium molybdate**

NH_4OH, *see* **Ammonium hydroxide**

$(NH_4)_2SO_4$, *see* **Ammonium sulfate**

$(NH_4)_2S_2O_8$, *see* **Ammonium persulfate**

Nickel sulfate, $NiSO_4$, is a carcinogen and may cause heritable genetic damage. It is a skin irritant and may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses. Use in a chemical fume hood. Do not breathe the dust.

$NiSO_4$, *see* **Nickel sulfate**

Nitric acid, HNO_3, is volatile and must be handled with great care. It is toxic by inhalation, ingestion, and skin absorption. Wear appropriate gloves and safety goggles. Use in a chemical fume hood. Do not breathe the vapors. Keep away from heat, sparks, and open flame.

PEG, *see* **Polyethyleneglycol**

Perchloric acid may be fatal by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses. Use only in a chemical fume hood.

Phenol is extremely toxic, highly corrosive, and can cause severe burns. It may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves, goggles, and protective clothing. Always use in a chemical fume hood. Rinse any areas of skin that come in contact with phenol with a large volume of water and wash with soap and water; do not use ethanol!

Phenylmethylsulfonyl fluoride (PMSF), $C_7H_7FO_2S$ or **$C_6H_5CH_2SO_2F$,** is a highly toxic cholinesterase inhibitor. It is extremely destructive to the mucous membranes of the respiratory tract, eyes, and skin. It may be fatal by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses. Always use in a chemical fume hood. In case of contact, immediately flush eyes or skin with copious amounts of water and discard contaminated clothing.

Phosphoric acid, H_3PO_4, is highly corrosive and may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses.

Piperidine is highly toxic and is corrosive to the eyes, skin, respiratory tract, and gastrointestinal tract. It reacts violently with acids and oxidizing agents and may be harmful by inhalation, ingestion, or skin absorption. Do not breathe the vapors. Keep away from heat, sparks, and open flame. Wear appropriate gloves and safety glasses. Use in a chemical fume hood.

PMSF, *see* **Phenylmethylsulfonyl fluoride**

Polyacrylamide is considered to be nontoxic, but it should be treated with care because it may contain small quantities of unpolymerized material (*see* **Acrylamide**).

Polyethyleneglycol (PEG) may be harmful by inhalation, ingestion, or skin absorption. Avoid inhalation of powder. Wear appropriate gloves and safety glasses.

Polyvinylpyrrolidone may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses. Use in a chemical fume hood.

Potassium cacodylate, *see* **Cacodylate**

Potassium chloride, KCl, may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses.

Potassium ferricyanide, $K_3Fe(CN)_6$, may be fatal by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses. Always use with extreme care in a chemical fume hood. Keep away from strong acids.

Potassium ferrocyanide, $K_4Fe(CN)_6 \cdot 3H_2O$, may be fatal by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses. Always use with extreme care in a chemical fume hood. Keep away from strong acids.

Potassium hydroxide, KOH and KOH/methanol, can be highly toxic. It may be harmful by inhalation, ingestion, or skin absorption. Solutions are caustic and should be handled with great care. Wear appropriate gloves.

Potassium permanganate, $KMnO_4$, is an irritant and a strong oxidant. It may form explosive mixtures when mixed with organics. Use all solutions in a chemical fume hood. Do not mix with hydrochloric acid.

Potassium phosphate, $KH_2PO_4/K_2HPO_4/K_3PO_4$, may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses. Do not breathe the dust. $K_2HPO_4 \cdot 3H_2O$ is *dibasic* and KH_2PO_4 is *monobasic*.

PPO, *see* **Diphenyloxazole**

Probe DNA or RNA, *see* **Radioactive substances**

Proteinase K is an irritant and may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses.

Putrescine is flammable and corrosive and may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses. Keep away from heat, sparks, and open flame.

Radioactive substances: When planning an experiment that involves the use of radioactivity, consider the physico-chemical properties of the isotope (half-life, emission type, and energy), the chemical form of the radioactivity, its radioactive concentration (specific activity), total amount, and its chemical concentration. Order and use only as much as needed. Always wear appropriate gloves, lab coat, and safety goggles when handling radioactive material. **X-rays** and **gamma rays** are electromagnetic waves of very short wavelengths either generated by technical devices or emitted by radioactive materials. They might be emitted isotropically from the source or may be focused into a beam. Their potential dangers depend on the time period of exposure, the intensity experienced, and the wavelengths used. Be aware that appropriate shielding is usually made of lead or other similar material. The thickness of the shielding is determined by the energy(s) of the X-rays or gamma rays. Consult the local safety office for further guidance in the appropriate use and disposal of radioactive materials. Always

monitor thoroughly after using radioisotopes. A convenient calculator to perform routine radioactivity calculations can be found at:

http://www.graphpad.com/calculators/radcalc.cfm

S-Adenosylmethionine is toxic and may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses. Use in a chemical fume hood. Do not breathe the dust.

SDS, *see* **Sodium dodecyl sulfate**

Silane may be harmful by inhalation, ingestion, or skin absorption. It is extremely flammable. Keep away from heat, sparks, and open flame. The vapor is irritating to the eyes, skin, mucous membranes, and upper respiratory tract. Wear appropriate gloves and safety glasses. Always use in a chemical fume hood.

Silica is an irritant and may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses. Do not breathe the dust.

Silver nitrate, $AgNO_3$, is a strong oxidizing agent and should be handled with care. It may be harmful by inhalation, ingestion, or skin absorption. Avoid contact with skin. Wear appropriate gloves and safety glasses. It can cause explosions upon contact with other materials.

Sodium acetate, *see* **Acetic acid**

Sodium azide, NaN_3, is highly poisonous. It blocks the cytochrome electron transport system. Solutions containing sodium azide should be clearly marked. It may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety goggles and handle it with great care.

Sodium cacodylate may be carcinogenic and contains arsenic. It is highly toxic and may be fatal by inhalation, ingestion, or skin absorption. It also may cause harm to the unborn child. Effects of contact or inhalation may be delayed. Do not breathe the dust. Wear appropriate gloves and safety goggles. Use only in a chemical fume hood. *See also* **Cacodylate.**

Sodium citrate, *see* **Citric acid**

Sodium dodecyl sulfate (SDS) is toxic, an irritant, and poses a risk of severe damage to the eyes. It may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety goggles. Do not breathe the dust.

Sodium fluoride, NaF, is highly toxic and causes severe irritation. It may be fatal by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses. Use only in a chemical fume hood.

Sodium hydrogen phosphate, Na_2HPO_4, (sodium phosphate, dibasic) may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses. Use in a chemical fume hood.

Sodium hydroxide, NaOH, and solutions containing NaOH are highly toxic and caustic and should be handled with great care. Wear appropriate gloves and a face mask. All concentrated bases should be handled in a similar manner.

Sodium nitrate, $NaNO_2$, is irritating to the eyes, mucous membranes, upper repiratory tract, and skin. It may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses and always use in a chemical fume hood. Keep away from acids.

Sodium nitrate, $NaNO_3$, may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses. Use in a chemical fume hood.

Sodium pyrophosphate is an irritant and may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses. Do not breathe the dust.

Sodium salicylate is an irritant and may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses. Do not breathe the dust.

Spermidine may be corrosive and harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses. Use in a chemical fume hood.

Streptomycin is toxic and a suspected carcinogen and mutagen. It may cause allergic reactions. It may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses.

Sulfuric acid, H_2SO_4, is highly toxic and extremely destructive to tissue of the mucous membranes and upper respiratory tract, eyes, and skin. It causes burns and contact with other materials (e.g., paper) may cause fire. Wear appropriate gloves, safety glasses, and lab coat. Use in a chemical fume hood.

SYBR Green I/Gold is supplied by the manufacturer as a 10,000-fold concentrate in DMSO which transports chemicals across the skin and other tissues. Wear appropriate gloves and safety glasses and decontaminate according to Safety Office guidelines. *See* **DMSO**.

TCA, *see* **Trichloroacetic acid**

TEMED, *see* ***N,N,N′,N′*-Tetramethylethylenediamine**

Tetracycline may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses and use in a chemical fume hood. Solutions of tetracycline are sensitive to light.

***N,N,N′,N′*-Tetramethylethylenediamine (TEMED)** is extremely destructive to tissues of the mucous membranes and upper respiratory tract, eyes, and skin. Inhalation may be fatal. Prolonged contact can cause severe irritation or burns. Wear appropriate gloves, safety glasses, and other protective clothing. Use only in a chemical fume hood. Wash thoroughly after handling. Flammable: Vapor may travel a considerable distance to source of ignition and flash back. Keep away from heat, sparks, and open flame.

TFA, *see* **Trifluoroacetic acid**

Thiourea may be carcinogenic and may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses. Use in a chemical fume hood.

Tissues (human), *see* **Blood (human) and blood products**

Trichloroacetic acid (TCA) is highly caustic. Wear appropriate gloves and safety goggles.

Trichlorotrifluoroethane may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety goggles. Use in a chemical fume hood. Keep away from heat, sparks, and open flame.

Trifluoroacetic acid (TFA) (concentrated) may be harmful by inhalation, ingestion, or skin absorption. Concentrated acids must be handled with great care. Decomposition causes toxic fumes. Wear appropriate gloves and a face mask. Use in a chemical fume hood.

Tris may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses.

Triton X-100 causes severe eye irritation and burns. It may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety goggles.

Trypan blue may be a carcinogen and may be harmful by inhalation, ingestion, or skin absorption. Do not breathe the dust. Wear appropriate gloves and safety glasses.

Tryptophan may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses.

Urea may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses.

UV light and/or **UV radiation** is dangerous and can damage the retina of the eyes. Never look at an unshielded UV light source with naked eyes. Examples of UV light sources that are common in the laboratory include hand-held lamps and transilluminators. View only through a filter or safety glasses that absorb harmful wavelengths. UV radiation is also mutagenic and carcinogenic. To minimize exposure, make sure that the UV light source is adequately shielded. Wear protective appropriate gloves when holding materials under the UV light source.

Valine may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses.

X-gal may be toxic to the eyes and skin. Observe general cautions when handling the powder. Note that stock solutions of X-gal are prepared in DMF, an organic solvent. For details, see ***N,N*-dimethylformamide.** See also **5-Bromo-4-chloro-3-indolyl-β-D-galactopyranoside (BCIG)**.

X-rays, *see* **Radioactive substances**

Xylene is flammable and may be narcotic at high concentrations. It may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses. Use only in a chemical fume hood. Keep away from heat, sparks, and open flame.

Xylene cyanol, *see* **Xylene**

Zinc chloride, $ZnCl_2$, is corrosive and poses possible risk to the unborn child. It may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses. Do not breathe the dust.

$ZNCl_2$, *see* **Zinc chloride**

Zymolase may be harmful by inhalation, ingestion, or skin absorption. Wear appropriate gloves and safety glasses.

Appendix 13

Suppliers

Commercial sources and products have been included in the text for the user's convenience and should not necessarily be construed as an endorsement by the authors. With the exception of those suppliers listed in the text with their addresses, all suppliers mentioned in this manual can be found in the *BioSupplyNet Source Book* and on the Web Site at:

http://www.biosupplynet.com

If a copy of *BioSupplyNet Source Book* was not included with this manual, a free copy can be ordered by using any of the following methods:

- Complete the Free *Source Book* Request Form found at the "Get the *Source Book*" link on the Web Site:

  http://www.biosupplynet.com

- E-mail a request to info@biosupplynet.com
- Fax a request to 631-370-8808

Appendix 14

Trademarks

Products mentioned in this book that may be trademarked or registered-trademarked are listed on the www.MolecularCloning.com Web Site for informational purposes only. Any trademarks or names being used are for editorial purposes only, with no intention of infringing upon that trademark. CSHL Press has provided and will continue to provide, to the best of our ability, accurate and up-to-date information on its Web Site. However, all registered trademarks and servicemarks are the property of their respective owners, and are listed on the Web Site solely for identification or description of the applicable goods and services. Therefore, please consult individual manufacturers and other resources for current and specific product information.

We shall not cease from exploration
And the end of all our exploring
Will be to arrive where we started
And know the place for the first time.
T.S. ELIOT

When I look at the flight of the leaves

When I look at the flight of the leaves in
their floating down on to the paving of cobbles
and see them swept up as if by an
artist who has finished his picture at last

I think how (already nobody likes either
the way I stand, or my thoughtful face)
a manifestly yellow, decidedly
rusty leaf – has been left behind on the tree.

MARINA TSVETAEVA
