- ***Template DNA.*** The template can be a fragment of DNA, a preparation of genomic DNA, a recombinant plasmid or bacteriophage λ, or any other DNA-containing sample. Template DNA is dissolved in 10 mM Tris-Cl (pH 7.6) containing a low concentration of EDTA (<0.1 mM).

- ***Thermostable DNA polymerase.*** *Taq* DNA polymerase is the standard and appropriate enzyme for the amplification stage of most forms of PCR. However, where elongation from 3′-mismatched primers is suspected, a thermostable DNA polymerase with 3′→5′ proofreading activity may be preferred (Chiang et al. 1993). Please see Thermostable DNA Polymerases (p. 8.6) and the information panel on ***TAQ* DNA POLYMERASE.**

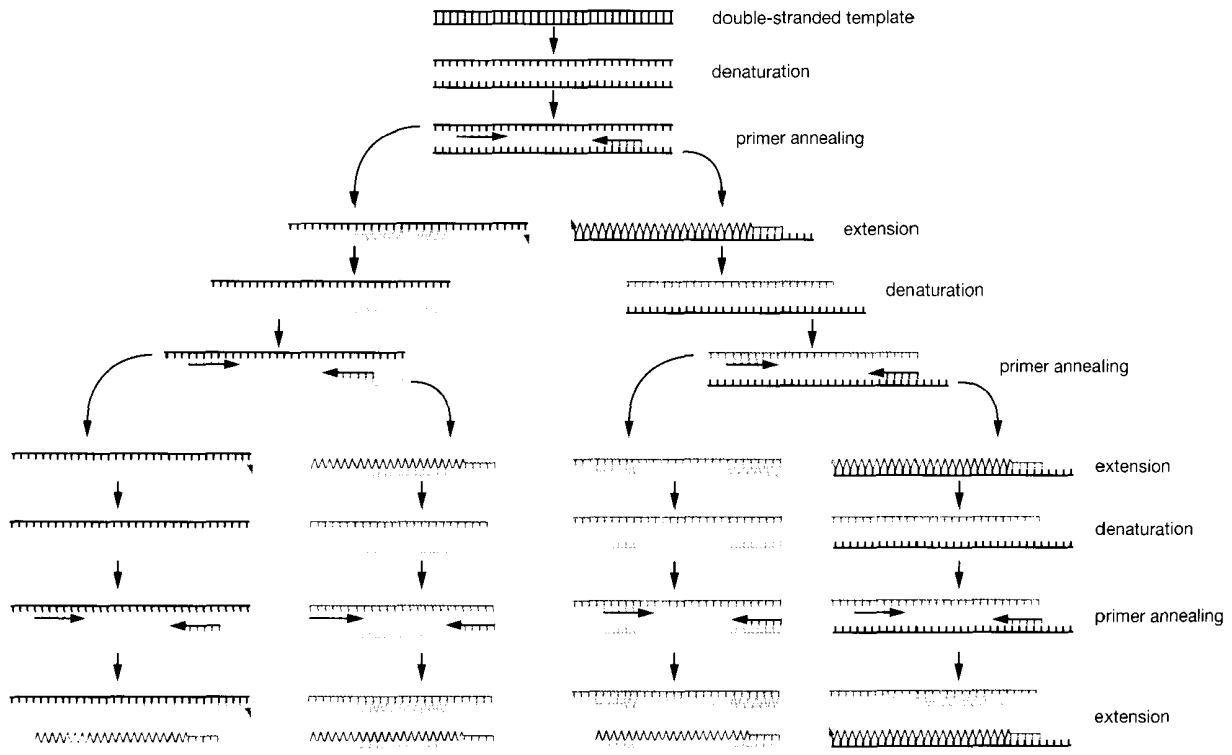

FIGURE 8-2 Sequence of Amplification in the PCR

The diagram shows the steps involved in the first few rounds of a PCR. The original template (*top line*) is double-stranded DNA and the leftward and rightward oligonucleotide primers are shown as ← and →, respectively. The products of the first few rounds of the amplification reaction are heterogeneous in size; however, the tract of DNA lying between the two primers is preferentially amplified and quickly becomes the dominant product of the amplification reaction.

Taq DNA polymerase is supplied in a storage buffer containing 50% glycerol. Because this solution is very viscous and difficult to pipette accurately, the best method is to centrifuge the tube containing the enzyme at maximum speed for 10 seconds at 4°C in a microfuge and then to withdraw the required amount of enzyme using a positive-displacement pipette.

- ***Automatic pipetting devices.*** Automatic micropipetting devices equipped with barrier tips should be used to assemble the components of PCRs. Disposable barrier tips are fitted with a hydrophobic barrier to prevent the accidental passage of liquids into a micropipetting device. This arrangement reduces the potential for cross-contamination of PCRs and DNA samples. Barrier micropipette tips are sold by several commercial companies (e.g., ART Barrier tips from Molecular Bioproducts, Inc.).
- ***Positive-displacement pipette.*** Positive-displacement pipetting, in which the piston is in direct contact with the liquid, is used for accurate transfer of high-viscosity liquids.
- ***Microfuge tubes or microtiter plates.*** Thin-walled plastic tubes that fit snugly in the block of the thermal cycler are used for amplification. Their use facilitates heat transfer and greatly reduces much of the time lag in reaching programmed temperatures.
- ***Thermal cycler programmed with desired amplification protocol.*** A large number of programmable thermal cyclers marketed by different commercial companies are licensed by Perkin-Elmer for use in PCR. The choice among these instruments depends on the investiga-

tor's inclination, the available budget, and the range of uses to which the machine will be put. Before purchasing a thermal cycler, we recommend soliciting as many opinions as possible to find out the pros and cons of different machines. If the machine is not licensed for use in PCR, investigators must negotiate their own financial arrangements with Perkin-Elmer. *The Scientist* profiles thermal cyclers every year (www.the-scientist.com).

MATERIALS

▲ **IMPORTANT** To reduce the chance of contamination with exogenous DNAs, prepare and use a special set of reagents and solutions for PCR only. Bake all glassware for 6 hours at 15°C and autoclave all plasticware. For more information, please see the panel on **CONTAMINATION IN PCR** in the introduction to this chapter.

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

10x Amplification buffer

Chloroform **<!>**

dNTP solution (20 mM) containing all four dNTPs (pH 8.0)

Enzymes and Buffers

Thermostable DNA polymerase

Gels

Polyacrylamide **<!>** *or agarose gel*

Please see Step 4.

Nucleic Acids and Oligonucleotides

Bystander DNA

Please see the panel to Step 1.

Forward primer (20 μM) in H_2O and Reverse primer (20 μM) in H_2O

Please see the discussion on Primers in the protocol introduction.

> Use the following formula to calculate the molecular weight of the oligonucleotides:
>
> $$M_r = (C \times 289) + (A \times 313) + (T \times 304) + (G \times 329)$$
>
> where *C* is the number of C residues in the oligonucleotide, *A* is the number of A residues, *T* is the number of T residues, and *G* is the number of G residues. The molecular mass of a 20-mer will be ~6000 daltons; 100 pmoles of the oligonucleotide will be equivalent to ~0.6 μg.

Template DNA

Dissolve template DNA in 10 mM Tris-Cl (pH 7.6) containing a low concentration of EDTA (<0.1 mM) at the following concentrations: mammalian genomic DNA, 100 μg/ml; yeast genomic DNA, 1 μg/ml; bacterial genomic DNA, 0.1 μg/ml; and plasmid DNA, 1–5 ng/ml.

Special Equipment

Barrier tips for automatic micropipetting device

Microfuge tubes (0.5 ml, thin-walled for amplification reactions) or Microtiter plates

Positive-displacement pipette

Thermal cycler programmed with desired amplification protocol

If the thermal cycler is not equipped with a heated lid, use either mineral oil or paraffin wax to prevent evaporation of liquid from the reaction mixture during PCR. Paraffin wax not only prevents evaporation, but also maintains separation between components (e.g., primer and template) until the reaction mixture is heated. This separation prevents nonspecific binding of primers during the initial phase of the reaction (please see the information panel on **HOT START PCR**).

Additional Reagents

Step 4 of this protocol may require the reagents listed in Chapter 6, Protocol 10, and/or Chapter 12, Protocol 6.

METHOD

1. In a sterile 0.5-ml microfuge tube, amplification tube, or the well of a sterile microtiter plate, mix in the following order:

10x amplification buffer	5 µl
20 mM solution of four dNTPs (pH 8.0)	1 µl
20 µM forward primer	2.5 µl
20 µM reverse primer	2.5 µl
1–5 units/µl thermostable DNA polymerase	1–2 units
H_2O	28–33 µl
template DNA	5–10 µl
Total volume	50 µl

The table below provides standard reaction conditions for PCR.

Mg^{2+}	KCl	dNTPs	Primers	DNA polymerase	Template DNA
1.5 mM	50 mM	200 µM	1 µM	1–5 units	1 pg to 1 µg

The pH of the reaction buffer should be 8.3 when measured at 25°C. Because of the high temperature dependence of the p*K*a of Tris, the pH of the reaction will drop to ~7.2 at 72°C (Good et al. 1966; Ferguson et al. 1980). The amount of template DNA required varies according to the complexity of its sequence. In the case of mammalian DNA, up to 1.0 µg is used per reaction. Typical amounts of yeast, bacterial, and plasmid DNAs used per reaction are 10 ng, 1 ng, and 10 pg, respectively.

Each set of PCRs must always include positive and negative controls. Positive controls are required to monitor the efficiency of the PCR, whereas negative controls are required to detect contamination with DNAs that contain the target sequence.

	Bystander DNA[a]	Template DNA[b]	Target DNA[c]	Specific Primers[d]
Positive Controls				
1	+	–	+	+
2	–	–	+	+
Negative Controls				
3	–	–	–	+
4	+	–	–	+

[a]Bystander DNA does not contain target sequences. It should resemble the template DNA in all other respects: complexity, size, and concentration.

[b]Template DNA is the DNA under test.

[c]Target DNA contains the target sequence. It can be a recombinant DNA clone, a purified DNA fragment, or a sample of genomic DNA. It should be added to the positive control at concentrations equivalent to those expected in the template DNA. It is often necessary to set up a series of positive controls containing different amounts of target DNA spanning the amount predicted in the template DNA. An appropriate dilution of the target sequence should be prepared ahead of time in an area of the laboratory different from that used for the preparation of other PCR reagents. This precaution reduces the risk of contaminating equipment and plasticware in the area of the laboratory set aside for PCRs.

[d]Specific Primers are oligonucleotide primers specific for the segment of target DNA.

2. If the thermal cycler is not fitted with a heated lid, overlay the reaction mixtures with 1 drop (~50 µl) of light mineral oil to prevent evaporation of the samples during repeated cycles of heating and cooling. Alternatively, place a bead of wax into the tube if using a hot start protocol. Place the tubes or the microtiter plate in the thermal cycler.

3. Amplify the nucleic acids using the denaturation, annealing, and polymerization times and temperatures listed below.

Cycle Number	Denaturation	Annealing	Polymerization
30 cycles	30 sec at 94°C	30 sec at 55°C	1 min at 72°C
Last cycle	1 min at 94°C	30 sec at 55°C	1 min at 72°C

These times are suitable for 50-µl reactions assembled in thin-walled 0.5-ml tubes and incubated in thermal cyclers such as the Perkin-Elmer 9600 or 9700, Master Cycler (Eppendorf), and PTC 100 (MJ Research). Times and temperatures may need to be adapted to suit other types of equipment and reaction volumes.

Polymerization should be carried out for 1 minute for every 1000 bp of length of the target DNA.

Most thermal cyclers have an end routine in which the amplified samples are incubated at 4°C until they are removed from the machine. Samples can be left overnight at this temperature, but should be stored thereafter at –20°C.

4. Withdraw a sample (5–10 µl) from the test reaction mixture and the four control reactions and analyze them by electrophoresis through an agarose or polyacrylamide gel. Be sure to include DNA markers of an appropriate size. Stain the gel with ethidium bromide or SYBR Gold to visualize the DNA.

A successful amplification reaction should yield a readily visible DNA fragment of the expected size. The identity of the band can be confirmed by DNA sequencing (please see Chapter 12, Protocol 6), Southern hybridization (please see Chapter 6, Protocol 10), and/or restriction mapping.

If all has gone well, lanes of the gel containing samples of the two positive controls (Tubes 1 and 2) and the template DNA under test should contain a prominent band of DNA of the appropriate molecular weight. This band should be absent from the lanes containing samples of the negative controls (Tubes 3 and 4). If, on the other hand, all is not well, please see Tables 8-4 and 8-5.

5. If mineral oil was used to overlay the reaction (Step 2), remove the oil from the sample by extraction with 150 µl of chloroform.

The aqueous phase, which contains the amplified DNA, will form a micelle near the meniscus. The micelle can be transferred to a fresh tube with an automatic micropipette.

For many purposes, e.g., purification of the amplified DNA using a Centricon microconcentrator or cloning amplification products, it is desirable to remove the oil from the sample before proceeding.

▲ **IMPORTANT** Do not attempt chloroform extractions in microtiter plates. The plastic used in these plates is not resistant to organic solvents.

OPTIMIZATION OF PCRs

When setting up PCRs for first time with new template DNA, new primers, or a new preparation of thermostable DNA polymerase enzyme, amplification will generally be less than optimal. Fine tuning of the reaction is usually required to suppress nonspecific amplification and/or to enhance the yield of the desired DNA product. Table 8-4 lists some commonly observed problems and suggests ways in which the reaction can be optimized.

TABLE 8-4 Troubleshooting Amplifications

PROBLEM	EXPLANATION	SUGGESTED REMEDY
Bands of the desired product are sharp but very faint in both positive controls *and* test PCR. Bands of the desired product smear into the portion of the gel containing lower-molecular-weight DNAs.	Inefficient priming or inefficient extension.	Set up a series of PCRs containing different concentrations of the two primers. Find the optimal concentration and then set up a series of touchdown PCRs containing different concentrations of Mg^{2+} to find the optimal concentration. Include GC-Melt (CLONTECH) in the reaction mixture Use the minimum possible temperature during the annealing step. Consider adding adjuvants such as BSA (0.2–0.6 mg/ml), DMSO (5%), or glycerol (5%) to the reaction mixture.
Bands of the desired product are very faint in the test sample and in positive control 2. The band in positive control 1 is much stronger.	Dirty template DNA.	Repurify the template DNA by extraction (twice) with phenol:chloroform and ethanol precipitation. Dissolve the purified DNA in H_2O (no EDTA).
Bands in the negative controls.	Contamination of solutions or plasticware with template DNA.	Please see the panel on **CONTAMINATION IN PCR** (Introduction) and then make up new reagents.
Distinct band(s) of the wrong molecular weight.	Nonspecific priming by one or both primers.	Decrease the annealing time and/or increase the annealing temperature.
A generalized smear of amplified DNA that may obscure the desired product.	Amplification of primer dimers. Too much template DNA.	Check that neither primer has homology with highly repetitive sequences in the template DNA. Optimize the concentrations of each primer independently. Use touchdown PCR and/or hot start PCR (please see the information panels). Reduce the amount of template DNA by factors of 2.5 and 10.

TROUBLESHOOTING MAJOR PROBLEMS THAT OCCUR IN PCRs

Table 8-5 describes problems that may be encountered in amplification reactions and provides guidance for how to address major difficulties.

TABLE 8-5 Troubleshooting PCRs

SYMPTOM	POSSIBLE CAUSES	POSSIBLE REMEDIES
Amplification weak or nondetectable.	Defective reagent(s); defective thermal cycler; programming error.	Compare the yields obtained from fresh and old reagents in PCRs incubated in two different thermal cyclers.
	Suboptimal annealing conditions.	Recalculate T_m of primers. Use touchdown PCR, preferably in combination with hot start PCR. Verify the concentration of primers and, if necessary, optimize their concentration. If the primers appear to be the cause of the problem, design and synthesize new primers.
	Suboptimal extension of annealed primers.	Optimize the concentration of $MgCl_2$, template DNA, and dNTPs. Test a range of pH values in the PCR. Consider replacing Tris with tricine, bicine, or EPPs which have a lower temperature coefficient than Tris (Cheng et al. 1994). Use a fresh preparation of thermostable DNA polymerase. Repurify the template DNA to remove inhibitors. Increase the number of cycles at constant annealing temperature (55°C). If problems persist, add an enhancer (e.g., 10% DMSO, 5% PEG 6000, or 10% glycerol). If problems still persist, *either* reamplify a 1:100 dilution of the PCR in fresh PCR buffer and primers for 30 cycles at a constant annealing temperature *or* carry out nested PCR. Use GC-Melt (CLONTECH) in the reaction mixture.
	Ineffective denaturation.	Increase the time or temperature of denaturation.
	Distance between primers too large.	Use preparations of thermostable polymerases capable of amplifying long segments of DNA.
Multiple amplification products.		Use touchdown PCR, preferably in combination with hot start or booster PCR. Optimize the concentration of $MgCl_2$, template DNA, thermostable DNA polymerase, and dNTPs. Test a range of pH values. *Either* reamplify a 1:100 dilution of the PCR in fresh PCR buffer and primers for 30 cycles at a constant annealing temperature (55°C) *or* carry out nested PCR *or* recover the desired band of DNA from a gel and reamplify. Verify the concentration of primers and, if necessary, optimize their concentration. If the problem persists, design and synthesize new primers.
Excessive amounts of primer-dimers.		Use touchdown PCR, preferably in combination with hot start or booster PCR. If the problem persists, design and synthesize new primers, paying particular attention to the sequences of the 3′ ends.

Protocol 2

Purification of PCR Products in Preparation for Cloning

Taq POLYMERASE, AND PRESUMABLY OTHER THERMOSTABLE DNA polymerases, survive extraction with phenol:chloroform, ethanol precipitation, and other regimens commonly used to purify the products of PCRs (Crowe et al. 1991; Barnes 1992). The continuing presence of the DNA polymerase together with residual dNTPs often thwarts methods to tailor the ends of the amplified DNA for cloning. For example, the surviving DNA polymerase will fill recessed 3′ termini created by digestion with restriction enzymes. Undoubtedly, the durability of *Taq* explains in large part the difficulties encountered by many laboratories in cloning PCR products after digestion with restriction enzymes (Bennett and Molenaar 1994).

The following method of purification of amplified DNA is based on procedures described by Crowe et al. (1991) and Wybranietz and Lauer (1998).

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Ammonium acetate (10 M)
Chloroform **<!>**
Ethanol
Phenol:chloroform (1:1, v/v) **<!>**
TE (pH 8.0)

Enzymes and Buffers

Proteinase K (20 mg/ml)
Please see Appendix 4.

Gels

Agarose gel containing 0.5 μg/ml ethidium bromide **<!>**
Please see Step 8. Be sure to include DNA markers of an appropriate size (please see Protocol 1).

Nucleic Acids and Oligonucleotides

Amplified DNA from polymerase chain reactions

Special Equipment

DNA purification resin
Optional, please see note to Step 6.
Water bath preset to 75°C

METHOD

1. Pool up to eight PCRs (400 µl) containing 1 µg of the desired amplification product.

   If nonspecific amplification products are present at significant levels (e.g., are detectable by gel electrophoresis), purify the desired product by electrophoresis through low-melting-temperature agarose before proceeding (please see Chapter 5, Protocol 6).

   If mineral oil was used to prevent evaporation during PCR, centrifuge the pooled samples briefly and transfer the lower (aqueous) phase to a fresh microfuge tube.

2. Add 0.2 volume of 5x proteinase K buffer and proteinase K to a final concentration of 50 µg/ml. Incubate the mixture for 60 minutes at 37°C.

3. Inactivate the proteinase K by heating the reaction mixture to 75°C for 20 minutes.

4. Extract the reaction mixture once with phenol:chloroform and once with chloroform.

5. Add 0.2 volume of 10 M ammonium acetate and 2.5 volumes of ethanol. Mix the solution well and store it for 30 minutes at 4°C.

   dNTPs carried over from the PCR are soluble in ethanolic solutions of ammonium acetate and will not precipitate with the desired product (Okayama and Berg 1983).

6. Recover the precipitated DNA by centrifugation at maximum speed for 5 minutes at 4°C in a microfuge. Discard the supernatant and then wash the pellet with 70% ethanol. Centrifuge the solution again, remove the supernatant, and then allow the pellet of DNA to dry in the air.

   The DNA may be further purified by chromatography on resins such as Wizard PCR Preps Purification System (Promega) or QIAquick (Qiagen) or by gel electrophoresis. This step is recommended when primers have been used to add restriction sites to the ends of the amplified DNA. Unused primers and primer-dimers should be removed before digesting the DNA with the appropriate restriction enzymes (please see Protocol 3).

7. Dissolve the pellet in TE (pH 8.0). Assume that the recovery of amplified DNA is 50–80% and dissolve the DNA in TE (pH 8.0) at an estimated concentration of 25 µg/ml (25 ng/µl).

8. Analyze ~25 ng of the purified DNA by agarose-ethidium bromide gel electrophoresis, using markers of an appropriate size. Check that the amplified band fluoresces with the intensity expected of ~25 ng of DNA. If necessary, adjust the estimate of the concentration of the purified DNA.

Protocol 3

Removal of Oligonucleotides and Excess dNTPs from Amplified DNA by Ultrafiltration

THERE ARE VERY GOOD REASONS TO REMOVE UNUSED OLIGONUCLEOTIDE primers, primer-dimers, and excess dNTPs from preparations of amplified DNA. First, residual dNTPs in the continuing presence of residual thermostable DNA polymerase can compromise many of the methods designed to tailor the ends of the amplified DNA in preparation for cloning (please see Protocols 4, 5, and 6). Second, the overabundance of the oligonucleotide primers used to generate the amplified DNA may lower the efficiency of subsequent PCRs in which the amplified DNA is used as a template. Third, primer-dimers may contribute high concentrations of restriction sites that may successfully compete with the termini of amplified DNA for cleavage. Several methods are available to cleanse amplified DNA of unwanted contaminants, including:

- the traditional extraction with phenol:chloroform (slow, messy, and comparatively inefficient, but good for simultaneous processing of many samples)
- chromatography on anionic silica gel resins (such QIAprep or Qiagen PCR Purification kits), glassmilk (BIO101 Geneclean II), or chaotropic silica-based resins (Promega's Wizard PCR Preps). The strengths and limitations of these chromatographic methods are discussed in detail in Chapter 1, Protocol 9.

Recently, an additional method — spin dialysis through a porous membrane — has become widely popular, which is odd because spin dialysis is slower, less efficient, and less able than chromatography to deal with many samples simultaneously (e.g., please see Mezei and Storts 1994). Despite these problems, spin dialysis, if carried out carefully, can reproducibly deliver amplified DNA in reasonable yield and free of significant amounts of dNTPs and oligonucleotides.

During spin dialysis, the solvent, together with low-molecular-weight solutes, is centrifuged through an anisotropic, hydrophilic, nonabsorbent, porous membrane. Macromolecules larger than the membrane pores are retained in the sample reservoir in a small volume of solvent. Following removal of the solutes, the concentrated sample is reconstituted to the original volume using the desired solvent. This process is repeated until the concentration of the original solutes is reduced to acceptable levels. Commercial concentrators are supplied with membranes of several different porosities that are characterized by a nominal molecular-weight cut-off. For removal of oligonucleotides, and dNTPs, Centricon-100 or Microcon-100 microconcentrators, which retain proteins with a molecular weight of >100,000, are routinely used. These devices allow oligonucleotide primers up to 48 bases in length to pass through the filter, and they retain dou-

ble-stranded PCR products as small as 125 bp (Krowczynska and Henderson 1992). Longer oligonucleotides are best removed by purifying the amplified DNA by gel electrophoresis.

This protocol is a modified version of a method supplied by M.B. Henderson that was originally described by Krowczynska and Henderson (1992).

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Chloroform **<!>**
Ethanol
Sodium acetate (3 M)
TE (pH 8.0)

Nucleic Acids and Oligonucleotides

Amplification reaction products (20–200 µl)

Centrifuges and Rotors

Preparative centrifuge or microfuge

Centricon-100 units will fit in any fixed-angle rotor with adaptors capable of supporting 17 x 150-mm tubes. The centrifuge must be capable of generating a steady force of 1000*g*. Microcon-100 units require a variable-speed microfuge.

Special Equipment

Concentrators (Centricon-100 or Microcon-100, Amicon)

METHOD

1. Place 2 ml of TE (pH 8.0) in the reservoir chamber of a Centricon-100 unit. Carefully separate the amplification reaction products from the upper mineral oil layer by pipetting or by extraction with chloroform. Transfer the amplification reaction products to the reservoir chamber of the Centricon-100 unit.
2. Place the entire unit into an appropriate rotor of a preparative centrifuge (e.g., a fixed-angle rotor). Insert the microconcentrator into the centrifuge with the filtrate cup (translucent portion) toward the bottom of the rotor. Use a concentrator filled with an equivalent amount of fluid or a standard balance tube as a counterbalance.

   ▲ **IMPORTANT** Do not touch the membrane with pipette or pipette tips when loading the microconcentrator.
3. Centrifuge the loaded concentrator at 1000*g* for 30 minutes at a temperature between 4°C and 25°C.
4. Remove the concentrator from the centrifuge, and discard the filtrate cup. Invert the unit, and replace it in the centrifuge (i.e., the retentate tube should now be placed toward the bottom of the rotor). Centrifuge at 300–1000*g* for 2 minutes.

5. Remove the concentrator from the centrifuge; remove the retentate cup and discard the rest of the device. Transfer the fluid in the retentate cup to a fresh microfuge tube.

6. If necessary, precipitate the sample by adding one-tenth volume of 3 M sodium acetate and 2–3 volumes of ethanol. The amplified sample is now ready for subsequent manipulation (DNA sequencing and ligation).

A single centrifugation step through a Centricon-100 membrane removes ~95% of the primers and deoxynucleotides from the PCR. This process also inactivates the thermostable DNA polymerase (presumably by absorption to the membrane). A single purification step is usually sufficient for most subsequent manipulation steps. If necessary, trace oligonucleotide primers can be further removed by performing a second 30-minute centrifugation step. At Step 4 above, empty the translucent filtrate cup, reassemble the device, and add another 2-ml aliquot of TE (pH 8.0) to the reservoir chamber. Repeat Steps 2 through 4.

Smaller-scale and faster purification can be carried out using Microcon-100 units. The overall procedure is the same as that outlined above except that 400 µl of TE is added to the reservoir chamber in Step 1, followed by 20–100 µl of PCR. Centrifugation is carried out in a variable-speed microfuge at 3000*g* for 5–7 minutes. After inversion, the sample is transferred to the retentate cup by a 1-minute spin at 300–1000*g*. This procedure removes ~90% of the oligonucleotide primers and deoxynucleotides and can be repeated as described above to obtain further purification of the amplified DNA.

Cloning PCR Products

CLONING AMPLIFIED SEGMENTS OF DNA GENERATED BY PCRS into plasmid or phagemid vectors turns out to be easier said than done. Many products of PCR are recalcitrant to cloning by the usual methods because:

- Several of the commonly used thermostable DNA polymerases possess a template-independent terminal transferase activity (extendase activity) that results in the addition of a single, unpaired nucleotide at the 3′ ends of amplified DNA fragments (Clark 1988; Mole et al. 1989; Hu 1993). The nucleotide added to the 3′ end depends both on the adjacent base and on the particular DNA polymerase used during PCR (Hu 1993). For example, when the 3′-terminal base of the template DNA is cytidine, *Taq* polymerase will efficiently transfer an adenine residue to the end of the completed chain (Clark 1988; Hu 1993).
- *Taq* polymerase and presumably other thermostable DNA polymerases survive extraction with phenol:chloroform, ethanol precipitation, and other regimens commonly used to purify the products of PCRs (Crowe et al. 1991; Barnes 1992). The continuing presence of the DNA polymerase together with residual dNTPs often thwarts methods to tailor the ends of the amplified DNA for cloning. For example, the surviving DNA polymerase will fill recessed 3′ termini created by digestion with restriction enzymes. Undoubtedly, this carry-over explains in large part the difficulties encountered by many laboratories in cloning PCR products after digestion with restriction enzymes.

Over the years, many methods — some good and some bad — have been devised to circumvent these difficulties (for review, please see Levis 1995). These include:

- ***Using the 3′→5′ exonuclease activity of bacteriophage T4 DNA polymerase*** or *Pfu* DNA polymerase to polish the termini of PCR products that contain extended bases (Hemsley et al. 1989). The polished DNAs can then be phosphorylated by T4 polynucleotide kinase and cloned into a blunt-ended dephosphorylated vector.
- ***Cloning blunt-ended DNA fragments generated by thermostable DNA*** polymerases such as *Pwo* and *Pfu*, which do not exhibit terminal transferase activity and generate blunt-ended products (Hinnisdaels et al. 1996). Blunt-end cloning is notoriously inefficient. Even in the presence of large amounts of bacteriophage T4 DNA ligase, the cloning efficiency of blunt-ended DNA is 10–100-fold lower than the efficiencies attained with DNAs equipped with cohesive termini. In addition, blunt-end ligation provides no opportunity to direct the orien-

tation of the amplified fragment of DNA within the vector. For these reasons, blunt-ended cloning of PCR products has fallen from favor in the last few years and has been largely replaced by methods that rely on ligation of cohesive ends.

- ***Using a linearized plasmid vector fitted with a protruding 3′ thymidylate*** residue at each of its 3′ termini. These T vectors are used to clone DNA fragments that carry a nontemplated, unpaired deoxyadenosyl residue at their 3′ termini (Holton and Graham 1991; Hengen 1995a). A single unpaired 3′ thymidine residue may not seem like much of a cohesive end, but it is enough to provide a strong toehold for the unpaired adenine residue on DNAs amplified in PCRs catalyzed by *Taq* or any other thermostable DNA polymerase that adds 3′ adenosyl overhangs. Cloning into T vectors is reportedly 50 times more efficient than blunt-end cloning of amplified DNA fragments (Holton and Graham 1991; Marchuk et al. 1991). This is almost equal to the efficiency of cloning that can be achieved with DNAs whose 3′ protrusions are a more respectable length.

- ***Adding restriction sites to the 5′ termini of the oligonucleotides*** used to prime PCR. These primer-specific restriction sites are transferred to the termini of the target DNA during amplification (Scharf et al. 1986) and can then be cleaved with appropriate restriction enzymes to generate amplified segments of DNA with cohesive termini. Because the restriction sites may be identical or different in the two primers, this modification allows the investigator to tailor the termini of the amplified DNA fragment to the vectors best suited to the task at hand.

  For years, this method of cloning PCR products was plagued with traps that, if not avoided, would ensnare entire experiments and visit sharp misery upon the investigator. These included the inability of some restriction enzymes to cleave sites efficiently near the termini of DNA molecules and the possible presence of internal restriction sites within amplified DNAs whose internal sequences were unknown (Crouse and Amorese 1986; Jung et al. 1990; Kaufman and Evans 1990). The problems have largely been solved by improving the design of oligonucleotide primers; by understanding the strengths and limitations of restriction enzymes; by converting terminal restriction sites to internal sites by concatemerization of amplified DNAs; and by devising better methods to eliminate primers, dNTPs, and thermostable DNA polymerase from the amplified product before digestion with restriction enzyme(s). For a more detailed discussion, please see the introduction to Protocol 6.

In addition to the basic methods discussed so far, a large variety of more esoteric techniques to clone amplified fragments of DNA have been described in hundreds of papers published over the years. These techniques include ligation-independent cloning (Aslanidis and de Jong 1990; Shuldiner et al. 1991; Haun et al. 1992; Kaluz and Flint 1994; Temesgen and Eschrich 1996; Shuldiner and Tanner 1997), UDG cloning (Nisson et al. 1991; Rashtchian et al. 1992; Smith et al. 1993; for review, please see Levis 1995), directional cloning using exonuclease III (Kaluz et al. 1992), in vivo cloning (Jones and Howard 1991; Oliner et al. 1993), and turbo cloning (Boyd 1993). Many of these methods require special strains of *E. coli*, particular vectors, oligonucleotide primers that contain modified bases, and/or the use of several different enzymes. Although these methods under special circumstances may have some advantage, it is difficult to think of cloning predicaments where the use of occult techniques would be obligatory.

The following four protocols describe how to clone amplified fragments of DNA by blunt-end ligation (Protocol 4), annealing to T vectors (Protocol 5), and addition of terminal restriction sites (Protocol 6) and by use of the principles of genetic engineering (Protocol 7).

Protocol 4

Blunt-end Cloning of PCR Products

THE FOLLOWING ELEGANT AND SIMPLE PROTOCOL FOR POLISHING the termini of amplified DNA, adapted from Weiner (1993) and Chuang et al. (1995), builds on the earlier work of Liu and Schwartz (1992), who showed that incubation of a ligation reaction in the presence of an excess amount of restriction enzyme can dramatically increase the yield of recombinant plasmids. The role of the restriction enzyme is to cleave circular and linear concatemers at restriction sites that are regenerated when plasmid molecules ligate to themselves. The method requires that ligation of the plasmid to a target DNA molecule destroy the restriction site. This prevents the restriction enzyme from destroying recombinants generated during the ligation reaction. The net effect of constant reclamation of unit-length linear vector molecules is to drive the equilibrium of the ligation reaction strongly in favor of recombinants between vector and insert.

The method is efficient because regeneration of vector DNA, ligation, and polishing the termini of PCR-generated fragments of DNA all occur simultaneously in the same reaction mixture.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

ATP (10 mM)

dNTP solution (2 mM) containing all four dNTPs

10x Universal KGB buffer

1 M potassium acetate
250 mM Tris-acetate (pH 7.6)
100 mM magnesium acetate tetrahydrate
5 mM β-mercaptoethanol **<!>**
100 µg/ml bovine serum albumin

Enzymes and Buffers

Bacteriophage T4 DNA ligase

Bacteriophage T4 DNA polymerase

Do not use the Klenow fragment of *E. coli* DNA polymerase as a polishing enzyme because it carries an endogenous terminal transferase activity.

Restriction endonuclease for cloning

The restriction enzyme should generate blunt ends, cleave the vector once, and *not* cleave the amplified DNA (please see Step 1).

Restriction endonucleases

Please see Step 4.

Gels

Agarose gel

Please see Step 5.

Nucleic Acids and Oligonucleotides

Closed circular plasmid DNA (50 µg/ml)

Choose a plasmid vector containing a single site for a restriction enzyme that generates blunt ends (e.g., *Sma*I, *Srf*I, and *Eco*RV). The restriction site should not be present in the amplified DNA, and ligation of the target fragment to the vector should not regenerate the restriction site. Among the plasmid vectors that are commonly used for cloning of blunt-ended PCR products are the Bluescript-type plasmids and plasmids containing abbreviated multiple cloning sites (e.g., pCR-Script Direct, Stratagene). The plasmid vector and its bacterial host should carry a blue/white screening system.

Target DNA (25 µg/ml), amplified by PCR

When the PCR mixture contains more than one or two bands of amplified DNA, purify the target fragment by electrophoresis through low melting/gelling temperature agarose (please see Chapter 5, Protocol 6). If not purified by gel electrophoresis, PCR-amplified DNA should be prepared for ligation by extraction with phenol:chloroform and ultrafiltration through a Centricon-100 filter (please see Protocol 3).

Special Equipment

Water bath preset to 22°C

Additional Reagents

Step 3 of this protocol requires the reagents listed in Chapter 1, Protocol 25 or 26 and Protocol 27.

Step 4 of this protocol may require the reagents listed in Protocol 12 of this chapter.

Step 6 of this protocol requires the reagents listed in Chapter 12, Protocol 6, or Chapter 6, Protocol 10.

METHOD

1. In a microfuge tube, mix the following in the order shown:

50 µg/ml closed circular plasmid vector	1 µl
25 µg/ml amplified target DNA	8 µl
10x universal KGB buffer	2 µl
H_2O (please see note below)	5 µl
10 mM ATP	1 µl
2 mM dNTPs	1 µl
restriction enzyme	2 units
T4 DNA polymerase	1 unit
T4 DNA ligase	3 units

Adjust the amount of H_2O added so that the final reaction volume is 20 µl.

Set up a control reaction that contains all of the reagents listed above except the amplified target DNA.

2. Incubate the ligation mixture for 4 hours at 22°C.

   The restriction enzyme cleaves the plasmid DNA; the 3′-exonuclease activity of T4 DNA polymerase polishes the ends of the amplified DNA in the presence of dNTP.

3. Dilute 5 µl of each of the two ligation mixtures with 10 µl of H_2O and transform a suitable strain of competent *E. coli* to antibiotic resistance as described in Chapter 1, Protocol 25 or 26. Plate the transformed cultures on media containing IPTG and X-gal (please see Chapter 1, Protocol 27) and the appropriate antibiotic.

4. Calculate the number of colonies obtained from each of the ligation mixtures. Pick a number of white colonies obtained by transformation with the ligation reaction containing the target DNA. Confirm the presence of the amplified fragment by (i) isolating the plasmid DNAs and digesting them with restriction enzymes whose sites flank the insert in the multiple cloning site or (ii) colony PCR (Protocol 12).

5. Fractionate the restricted DNA by electrophoresis through an agarose gel using appropriate DNA size markers. Measure the size of the cloned fragments.

6. Confirm the identity of the cloned fragments by DNA sequencing, restriction mapping, or Southern hybridization.

Protocol 5

Cloning PCR Products into T Vectors

THE SINGLE 3′ ADENOSYL EXTENSION GENERATED by *Taq* DNA polymerase provides a highly efficient method to clone PCR products into a vector (T vector) containing a complementary unpaired 3′ thymidyl residue (Holton and Graham 1991; Marchuk et al. 1991). T vectors may be created by the following three methods (Mezei and Storts 1994):

- Digest a vector with restriction enzymes such as *Xcm*I, *Hph*I, and *Mbo*II that generate 3′-terminal unpaired deoxythymidine residues (Kovalic et al. 1991; Mead et al. 1991; Chuang et al. 1995; Borovkov and Rivkin 1997).
- Use terminal transferase and dideoxyTTP to add a single protruding T residue to the 3′ termini of a linearized vector (Holton and Graham 1991).
- Use the template-independent terminal transferase activity of *Taq* DNA polymerase to catalyze the addition of a T residue to the terminal 3′-hydroxyl groups of a linearized vector (Marchuk et al. 1991).

Alternatively, T vectors can be purchased ready-made from many commercial suppliers as components of cloning kits (e.g., pCR-Script [SK+] from Stratagene; pCRII in the TA Cloning kit from Invitrogen; pGEM-T from Promega) (Hengen 1995a).

MATERIALS

Enzymes and Buffers

Bacteriophage T4 DNA ligase

Gels

Agarose gel
Please see Step 5.

Nucleic Acids and Oligonucleotides

Target DNA (25 μg/ml), amplified by PCR
When the PCR mixture contains more than one or two bands of amplified DNA, purify the target fragment by electrophoresis through low melting/gelling temperature agarose (please see Chapter 5,

Protocol 6). If not purified by gel electrophoresis, PCR-amplified DNA should be prepared for ligation by extraction with phenol:chloroform and ultrafiltration through a Centricon-100 filter (please see Protocol 3).

Vectors

T vector

For an outline of the generation of T vectors, please see the introduction to this protocol. T vectors and target DNAs tend to lose their unpaired 3′ residues when frozen and thawed many times.

Special Equipment

Water bath preset to 14°C

Additional Reagents

Step 3 of this protocol requires the reagents listed in Chapter 1, Protocol 25 or 26 and Protocol 27.

Step 6 of this protocol requires the reagents listed in Chapter 12, Protocol 6, or Chapter 6, Protocol 10.

METHOD

1. In a microfuge tube, set up the following ligation mixture:

25 µg/ml amplified target DNA	1 µl
T-tailed plasmid	20 ng
10x ligation buffer	1 µl
bacteriophage T4 DNA ligase	3 units
H_2O	to 10 µl

If necessary, add ATP to a final concentration of 1 mM. A 1:5 molar ratio of vector:amplified DNA fragment is recommended.

Set up a control reaction that contains all the reagents listed above except the amplified target DNA.

2. Incubate the ligation mixture for 4 hours at 14°C.

3. Dilute 5 µl of each of the two ligation mixtures with 10 µl of H_2O and transform a suitable strain of competent *E. coli* to antibiotic resistance as described in Chapter 1, Protocol 25 or 26. Plate the transformed cultures on media containing IPTG and X-gal (please see Chapter 1, Protocol 27) and the appropriate antibiotic.

4. Calculate the number of colonies obtained from each of the ligation mixtures. Pick a number of white colonies obtained by transformation with the ligation reaction containing the target DNA. Confirm the presence of the amplified fragment by (i) isolating the plasmid DNAs and digesting them with restriction enzymes whose sites flank the insert in the multiple cloning site or (ii) colony PCR (Protocol 12).

   The ratio of blue:white colonies varies between 1:5 and 2:1.

5. Fractionate the restricted DNA by electrophoresis through an agarose gel using appropriate DNA size markers. Measure the size of the cloned fragments.

6. Confirm the identity of the cloned fragments by DNA sequencing, restriction mapping, or Southern hybridization.

Protocol 6

Cloning PCR Products by Addition of Restriction Sites to the Termini of Amplified DNA

PAIRS OF OLIGONUCLEOTIDE PRIMERS USED IN PCR are often designed with restriction sites in their 5′ regions. In many cases, the sites are different in the two primers. In this case, amplification generates a target fragment whose termini now carry new restriction sites that can be used for directional cloning into plasmid vectors (Scharf et al. 1986; Kaufman and Evans 1990). The purified fragment and the vector are digested with the appropriate restriction enzymes, ligated together, and transformed into *E. coli* (please see Figure 8-3).

For years, this method of cloning PCR products was beset with technical difficulties. Fortunately, most of these problems have been solved, bringing great improvements in both the efficiency and reproducibility of the technique. However, beware of the following pitfalls.

- Many restriction enzymes fail to cleave recognition sequences located close to the ends of DNA fragments, particularly those generated by PCR (e.g., please see Kaufmann and Evans 1990; Larrick 1992; Jung et al. 1993; Rychlik 1995; Zimmermann et al. 1998).
- The presence of residual polymerase activity and dNTPs after cleavage of the PCR product by restriction enzymes can regenerate a blunt-ended DNA.
- The presence in the reaction mixture of residual single-stranded primers or double-stranded primer-dimers may reduce the efficient cleavage of terminal restriction sites in amplified DNA molecules.

Solutions to these problems lie in the design of the oligonucleotide primers, the choice of restriction enzymes, and, as described above, in the elimination of primers, dNTPs, and thermostable DNA polymerase from the amplified product before digestion with restriction enzyme(s). Listed below are some helpful hints for designing primers.

- Wherever possible, design primers that create a different restriction site on each end of the amplified DNA. Directional cloning can then be used to attach the fragment to an appropriately prepared plasmid.
- Many restriction enzymes fail to cleave recognition sequences located close to the ends of DNA fragments, particularly those generated by PCR (e.g., please see Crouse and Amorese 1986; Ho et al. 1990; Jung et al. 1990, 1993; Kaufman and Evans 1990; Larrick 1992; Rychlik 1995; Zimmermann et al. 1998). Wherever possible, avoid using restriction enzymes such as *Hin*dIII,

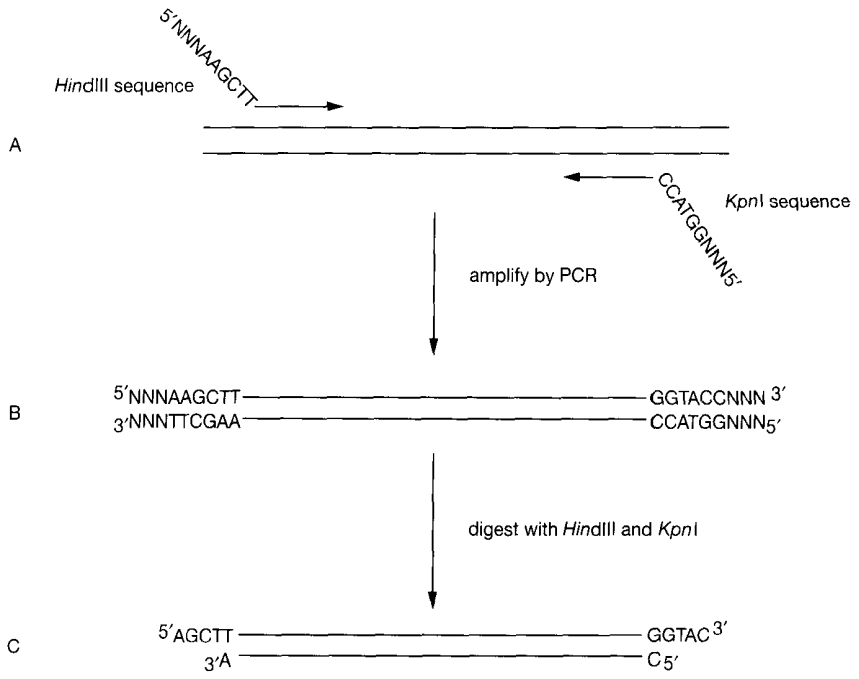

FIGURE 8-3 Cloning PCR Products by Addition of Restriction Sites

Specific PCR primers (represented by arrows) are designed to amplify a region of interest with the desired recognition sequence for the restriction endonuclease included at the 5′ end of the primer. The sense-strand primer contains the sense strand of a restriction site, and the antisense primer contains the complementary sequence of a second restriction site. (*A*) To achieve high efficiency digestion, additional nucleotides must be included on both sides of the restriction endonuclease sequence. In this example, proper recognition and cutting requires at least three additional bases on either side of the *Hin*dIII site, and at least two additional nucleotides on either side of the *Kpn*I site. (*B*) Amplification by PCR produces a specific product with an *Hin*dIII site at the 5′ end and a *Kpn*I site at the 3′ end. (C) Digestion with *Hin*dIII and *Kpn*I produces a PCR product that can be cloned directionally.

*Sal*I, *Xba*I, *Xho*I, and *Not*I, which are known to cleave terminal and subterminal recognition sites inefficiently. The catalogs of many commercial suppliers of enzymes (e.g., New England Biolabs) contain information about the efficiency of cleavage of these sites by restriction enzymes (see Appendix 4). Wherever possible, avoid using restriction enzymes that display "star" activity.

- Wherever possible, avoid using restriction sites that are known to occur naturally within the amplified segment of DNA. If the location and type of restriction sites are unknown, use restriction enzymes that are known to cleave the particular species of DNA very rarely.
- Design a "clamp" sequence at the extreme 5′ ends of the oligonucleotide primers to hold together the ends of the amplified DNA and to provide an adequate toehold for the restriction enzymes. Unfortunately, there is no agreement about the minimal number of additional bases required to stabilize the termini of the amplified DNA. Early estimates ranged from 4 (Jung et al. 1990) to 20 (Ho et al. 1990) additional bases. More recent data (Zimmermann et al. 1998) suggest that in most cases, only 3 additional bases are required for efficient digestion by a variety of restriction enzymes. Perhaps the best advice is to add as many bases as reason and budget will allow to the 5′ ends of the oligonucleotide primers.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Chloroform **<!>**
EDTA (0.5 M, pH 8.0)
Ethanol
Phenol:chloroform (1:1, v/v) **<!>**
Sodium acetate (3 M, pH 5.2)
TE (pH 7.5)

Enzymes and Buffers

Bacteriophage T4 DNA ligase
Restriction endonucleases

Gels

Agarose gel
Please see Step 12.

Nucleic Acids and Oligonucleotides

Forward primer (20 μM) in H_2O and Reverse primer (20 μM) in H_2O
Design forward and reverse primers carrying the appropriate restriction sites. The 3′ end of each primer should be an exact complement of ~15 consecutive bases at a selected site in the target DNA. The 5′ terminus of each primer serves as a clamp to hold together the termini of the amplified DNA and to provide a landing site for the restriction enzyme. The clamp should be 3–10 nucleotides in length. The midportion of the primer contains the recognition site for the restriction enzyme. Each primer should therefore be 24–31 nucleotides in length and contain approximately equal numbers of the four bases, with a balanced distribution of G and C residues and a low propensity to form stable secondary structures. For further details, please see the introduction to this protocol and the introduction to this chapter (Design of Oligonucleotide Primers for Basic PCR).

Oligonucleotide primers synthesized on an automated DNA synthesizer can generally be used in standard PCR without further purification.

Target DNA

Vectors

Plasmid DNA cleaved with the appropriate restriction enzyme(s) and purified by gel electrophoresis
If the linearized plasmid DNA carries compatible termini that can be ligated to each other, use alkaline phosphatase to remove the 5′-phosphate groups and suppress self-ligation (please see Chapter 1, Protocol 20).

Special Equipment

Water bath preset to 16°C
Water bath preset to optimum temperature for the restriction endonuclease digestions
Please see Step 3.

Additional Reagents

Step 1 of this protocol requires the reagents listed in Protocol 1 of this chapter.
Step 10 of this protocol requires the reagents listed in Chapter 1, Protocol 25 or 26 and Protocol 27.
Step 11 of this protocol may require the reagents listed in Protocol 12 of this chapter.
Step 13 of this protocol requires the reagents listed in Chapter 12, Protocol 6, or Chapter 6, Protocol 10.

METHOD

1. Use forward and reverse primers designed as outlined in the Materials section of this protocol to set up and carry out four identical amplification reactions (50-µl volume) to amplify the target fragment (please see Protocol 1). Combine the four PCRs, which, in aggregate, should contain 200–500 ng of the desired amplification product.

2. If the PCR mixture contains more than one or two bands of amplified DNA, purify the target fragment by electrophoresis through low melting/gelling temperature agarose (please see Chapter 5, Protocol 6). If not purified by gel electrophoresis, prepare PCR-amplified DNA for ligation by extraction with phenol:chloroform and ultrafiltration through a Centricon-100 filter (please see Protocol 3). Dissolve the purified product in TE (pH 7.5) at a concentration of 25 µg/ml.

3. In a reaction volume of 20 µl, digest ~100 ng of purified PCR product with 1.0–2.0 units of the relevant restriction enzyme(s). Incubate the reactions for 1 hour at the optimum temperature for digestion.

4. At the end of the digestion, adjust the volume of the reaction mixture to 100 µl with H_2O, and add 0.5 M EDTA to a final concentration of 5 mM. Extract the reaction mixture once with phenol:chloroform and once with chloroform.

5. Transfer the aqueous phase to a fresh tube and add 3 M sodium acetate (pH 5.2) to achieve a final concentration of 0.3 M. Add 2 volumes of ethanol. Store the mixture for 30 minutes at 0°C.

6. Recover the precipitated DNA by centrifugation at maximum speed for 5 minutes at 4°C in a microfuge. Discard the supernatant, and then wash the pellet with 70% ethanol. Centrifuge the solution again, remove the supernatant, and allow the pellet of DNA to dry in the air for a few minutes.

7. Dissolve the DNA in 10 µl of H_2O.

8. In a microfuge tube, set up the following ligation mixture:

25 µg/ml amplified target DNA	1.0 µl
plasmid DNA	20 ng
10x ligation buffer	1.0 µl
T4 DNA ligase	1 unit
H_2O	to 10 µl

If necessary, add ATP to a final concentration of 1 mM.

When directional cloning is used, the ligation mixture should contain an ~1:1 molar ratio of purified target DNA to cleaved plasmid vector.

Set up a control reaction that contains all the reagents listed above except the amplified target DNA.

9. Incubate the ligation mixtures for 4 hours at 16°C.

10. Dilute 5 µl of each of the two ligation mixtures with 10 µl of H_2O and transform a suitable strain of competent *E. coli* to antibiotic resistance as described in Chapter 1, Protocol 25 or 26. Plate the transformed cultures on media containing IPTG and X-gal (please see Chapter 1, Protocol 27) and the appropriate antibiotic.

11. Calculate the number of colonies obtained from each of the ligation mixtures. Pick a number of white colonies obtained by transformation with the ligation reaction containing the target DNA. Confirm the presence of the amplified fragment by (i) isolating the plasmid DNAs and digesting them with restriction enzymes whose sites flank the insert in the multiple cloning site or (ii) colony PCR (Protocol 12).

    In different experiments, the ratio of blue:white colonies can vary between 1:5 and 2:1.

12. Fractionate the restricted DNA by electrophoresis through an agarose gel using appropriate DNA size markers. Measure the size of the cloned fragments.

13. Confirm the identity of the cloned fragments by DNA sequencing, restriction mapping, or Southern hybridization.

TROUBLESHOOTING

The absence of transformed, white colonies containing the PCR product of interest may be due to low efficiencies of transformation or inefficient ligation. For each experiment, include a positive control to monitor the efficiency of transformation of the preparation of competent *E. coli*. Confirm that the concentrations of vector and target DNAs are correct by analyzing samples of the ligation mixtures and controls using gel electrophoresis.

A high background of nonrecombinant colonies is most likely due to incomplete cleavage of the vector by restriction enzymes.

Protocol 7

Genetic Engineering with PCR

THIS PROTOCOL (PROVIDED BY STEFAN ANDERSSON, UNIVERSITY OF TEXAS Southwestern Medical Center, Dallas) describes a method to introduce simultaneously restriction endonuclease sites at the 5′ and 3′ ends of a cloned mammalian cDNA and to change several codons at the 5′ end of the cDNA to those preferentially utilized in *E. coli*. These types of end modifications are frequently used in engineering cDNAs, or genes, before cloning in various eukaryotic and prokaryotic expression vectors (please see Chapters 15 and 16). Additional methods for modifying the ends of DNA molecules are described in the panel below.

MORE STRATEGIES FOR MUTAGENESIS

The variations on end modification of DNA are numerous. Several clever strategies use this type of amplification reaction in site-directed mutagenesis. For example, Hemsley et al. (1989) describe a modified form of inverse PCR in which the starting plasmid vector and the insert to be mutated are amplified at the same time. The oligonucleotide primers contain the mutations or modifications to be incorporated into the cDNA or gene and proceed outward from two adjacent nucleotides in the target DNA. The amplification reaction produces linear products from the circular plasmid DNA. Intramolecular ligation of the products gives rise to circular molecules, which can be used to transform *E. coli*, a proportion of which contain the desired changes. This method works well for repeated mutagenesis of a previously constructed expression vector. The procedure potentially suffers from two drawbacks: the overall size limit of the PCR (~4 kb) and the tendency of some thermostable DNA polymerases to add unpaired nucleotide residues to the 3′ ends of amplified DNA. A long PCR protocol can overcome the size limit problem (please see Protocol 13) (Barnes 1994). Several remedies to the latter problem are discussed in the introduction to Protocol 1.

End modification can be combined with standard bacteriophage M13 site-specific mutagenesis (please see Chapter 13, Protocol 2) to enact domain swaps between different proteins (Clackson and Winter 1989) and to create cDNA or gene chimeras via overlap extension (Horton et al. 1990). Finally, a deletion can also be introduced into a cloned fragment of DNA by use of inverse PCR and two oligonucleotide primers that abut the desired deletion endpoints (Imai et al. 1991).

MATERIALS

▲ **IMPORTANT** To reduce the chance of contamination with exogenous DNAs, prepare and use a special set of reagents and solutions for PCR only. Bake all glassware for 6 hours at 150°C and autoclave all plasticware. For more information, please see the panel on **CONTAMINATION IN PCR** in the chapter introduction.

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

10x Amplification buffer

dNTP solution (20 mM) containing all four dNTPs (pH 8.0)

Enzymes and Buffers

Appropriate restriction endonucleases

Thermostable DNA polymerase

Gels

Agarose or Polyacrylamide gel **<!>**

Please see Step 5.

Nucleic Acids and Oligonucleotides

Oligonucleotide primer 1 (10 μM) in TE (pH 8.0) and Oligonucleotide primer 2 (10 μM) in TE (pH 8.0)

Positive control DNA

Template DNA

The template DNA could be, for example, a cloned gene or cDNA in a vector or genomic DNA.

Vectors

Vector DNA cleaved with the appropriate restriction enzyme(s) and purified by gel electrophoresis

If the restricted vector DNA carries compatible termini that can be ligated to each other, use alkaline phosphatase to remove the 5′-phosphate groups and suppress self-ligation (please see Chapter 1, Protocol 20).

Special Equipment

Barrier tips for automatic micropipetting device

Microfuge tubes (0.5 ml, thin-walled for amplification) or Microtiter plates

Positive-displacement pipette

Thermal cycler programmed with desired amplification protocol

If the thermal cycler is not equipped with a heated lid, use either mineral oil or paraffin wax to prevent evaporation of liquid from the reaction mixture during PCR.

Additional Reagents

Step 5 of this protocol requires the reagents listed in Chapter 5, Protocol 2, Chapter 12, Protocol 6, or Chapter 6, Protocol 10.

Step 6 of this protocol requires the reagents listed in Protocol 3 of this chapter.

Step 7 of this protocol requires the reagents listed in Protocol 6 of this chapter.

METHOD

1. Design and synthesize the appropriate oligonucleotide primers for the end modifications desired.

   In this example, two primers derived from the 5′ sequence (5′ dATCATATGGCTCTGGATGA ACTGTGCCTGCTGGACATGCT 3′) and the 3′ sequence (5′ dATAAGCTTTTATTAAGACAGAC TCAGCTCATGGGAGGCAA 3′) of the starting cDNA template are used to introduce an *Nde*I (CATATG) site at the 5′ end of the cDNA and to change several codons to those preferentially used in *E. coli*. The underlined nucleotides indicate differences between the oligonucleotide primers and the cDNA template. The number of perfectly matched nucleotides required at the 3′ end of the oligonucleotide primers for a successful amplification has not been rigorously determined; however, eight to ten generally work well.

2. In a sterile 0.5-ml microfuge tube, amplification tube, or the well of a sterile microtiter plate, mix in the following order:

100 ng template DNA	10 µl
10x amplification buffer	5 µl
20 mM solution of four dNTPs	5 µl
10 µM primer 1 (50 pmoles)	5 µl
10 µM primer 2 (50 pmoles)	5 µl
1–2 units of thermostable DNA polymerase	1 µl
H_2O	to 50 µl

   Set up two control reactions. In one reaction, include all of the above additions, except the template DNA. In the other reaction, include a DNA template that has previously yielded a positive result in the PCR. Carry the controls through all subsequent steps of the protocol.

3. If the thermal cycler is not fitted with a heated lid, overlay the reaction mixtures with 1 drop (~50 µl) of light mineral oil. This prevents evaporation of the samples during repeated cycles of heating and cooling. Alternatively, place a bead of wax into the tube if using hot start PCR. Place the tubes or the microtiter plate in the thermal cycler.

4. Amplify the nucleic acids using the denaturation, annealing, and polymerization times and temperatures listed in the table.

Cycle Number	Denaturation	Annealing/Polymerization
20 cycles	1 min at 94°C	3 min at 68°C
Last cycle	1 min at 94°C	15 min at 68°C

   These times are suitable for 50-µl reactions assembled in thin-walled 0.5-ml tubes and incubated in thermal cyclers such as the Perkin-Elmer 9600 or 9700, Master Cycler (Eppendorf), and PTC 100 (MJ Research). Times and temperatures may need to be adapted to suit other types of equipment and reaction volumes.

   A small number of cycles are performed to decrease the chance of introducing spurious mutations.

5. Analyze 5–10% of the amplification on an agarose or polyacrylamide gel and estimate the concentration of the amplified target DNA. Be sure to include DNA markers of an appropriate size. Stain the gel with ethidium bromide or SYBR Gold to visualize the DNA.

   A successful amplification reaction should yield a readily visible DNA fragment of the expected size. The identity of the band can be confirmed by DNA sequencing (please see Chapter 12), Southern hybridization (please see Chapter 6), and/or restriction mapping.

6. If mineral oil was used to overlay the reaction (Step 3), remove the oil from the sample by extraction with 150 µl of chloroform.

   The aqueous phase, which contains the amplified DNA, will form a micelle near the meniscus. The micelle can be transferred to a fresh tube with an automatic micropipette.

   For many purposes, for example, purification of the amplified DNA using a Centricon microconcentrator or cloning amplification products, it is desirable to remove the oil from the sample before proceeding.

   ▲ **IMPORTANT** Do not attempt chloroform extractions in microtiter plates. The plastic used in these plates is not resistant to organic solvents.

7. For subsequent cloning, cleave the DNA fragment at the restriction sites placed (or located) at the 5′ ends of the primers (with *Nde*I and *Hin*dIII in the above example). Purify the digested fragment using gel electrophoresis or ultrafiltration (please see Protocol 3).

8. Set up the appropriate ligation reaction with the desired vector DNA. Use a molar ratio of insert to vector of 3:1 in the ligation reactions.

   Because of the error rate of thermostable DNA polymerases, it is very important to verify the sequence of the amplified DNA after cloning into the expression vector.

TROUBLESHOOTING

The most common result in a failed reaction is the appearance of a smear of bands on the ethidium-bromide-stained gel. This is usually due to the use of too much input template DNA. In this situation, carry out several pilot PCRs in which the amount of input DNA is varied over at least a 100-fold range (i.e., 1–100 ng).

Protocol 8

Amplification of cDNA Generated by Reverse Transcription of mRNA

REVERSE TRANSCRIPTASE–PCR (RT-PCR) IS A METHOD used to amplify cDNA copies of RNA. Sensitive and versatile, RT-PCR is used to retrieve and clone the 5′ and 3′ termini of mRNAs and to generate large cDNA libraries from very small amounts of mRNA. In addition, RT-PCR can be easily adapted to identify mutations and polymorphisms in transcribed sequences and to measure the strength of gene expression when the amounts of available mRNA are limited and/or when the RNA of interest is expressed at very low levels.

The literature is abundantly adorned with descriptions of variants of RT-PCR, many of which have their own acronym. The technical details may vary from one paper to the next, but the underlying concepts are constant and relatively simple: In every case, the first step is the enzymatic conversion of RNA to a single-stranded cDNA template. An oligodeoxynucleotide primer is hybridized to the mRNA and is then extended by an RNA-dependent DNA polymerase to create a cDNA copy that can be amplified by PCR. Depending on the purpose of the experiment, the primer for first-strand cDNA synthesis can be specifically designed to hybridize to a particular target gene or it can bind generally to all mRNAs (please see Figure 8-4).

- Oligo(dT), which binds to the endogenous poly(A)$^+$ tails of mammalian mRNAs, can be used as a universal primer for conventional first-strand cDNA synthesis. Subsequent amplification by PCR generally utilizes one or more internal, gene-specific primers and oligo(dT) to generate copies of the 3′-terminal sequences of a particular mRNA (3′-RACE; please see Protocol 10).

- cDNA synthesis can be primed by a synthetic antisense oligonucleotide that hybridizes specifically to a chosen region in a particular target RNA or family of mRNAs. Amplification of the desired portion of cDNA can be achieved in PCRs primed, for example, by sense and antisense oligonucleotide primers corresponding to specific sequences in particular cDNAs. For maximum specificity, the antisense primer should be located upstream of the oligonucleotide used to prime cDNA synthesis.

  Wherever possible, oligonucleotides that bind to sequences located in different exons of the target RNA should be used as sense and antisense primers for amplification of the cDNA product. In this way, amplification products derived from cDNA and contaminating genomic DNA can be easily distinguished. However, transcripts of intronless genes cannot be differentiated unambiguously from contaminating genomic sequences. In these circumstances, treating the RNA preparation with RNase-free DNase may be helpful (Grillo and Margolis 1990; please see Chapter 9, Protocol 8).

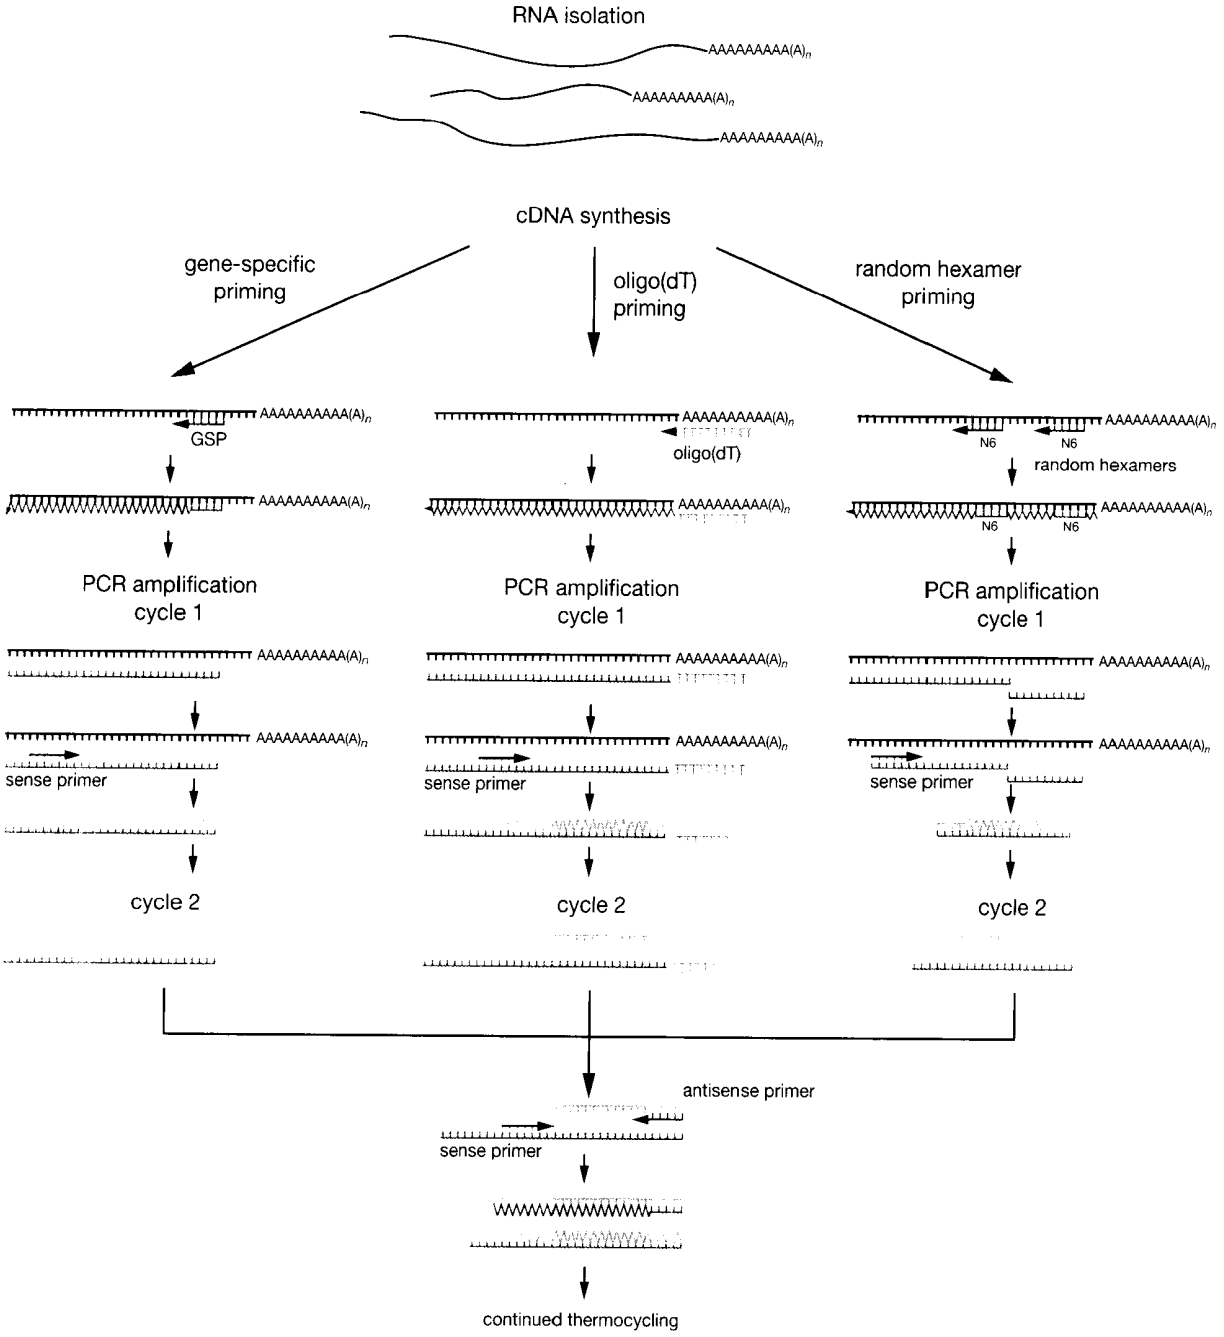

FIGURE 8-4 Schematic Representation of Various Methods for the Amplification of RNA by PCR

The first-strand synthesis of cDNA may be primed using either a gene-specific primer (GSP), oligo(dT), or a random hexamer sequence. Second-strand synthesis (amplification cycle 1) is primed with the sense primer. Amplification of cDNA continues in the presence of both sense and antisense primers. (Modified, with permission, from Dieffenbach and Dveksler 1995.)

- Random hexanucleotides, which are capable of priming cDNA synthesis at many points along RNA templates, generate fragmentary copies of the entire population of RNA molecules. They are useful when the target RNA is extremely long or contains so much secondary structure that cDNA synthesis cannot be efficiently primed by oligo(dT) or synthetic oligonucleotide(s) (Lee and Caskey 1990). Because all mRNAs in the population can serve as templates, gene-specific

amplification is achieved by using sense and antisense primers targeted to sequences in the cDNA.

In most cases, investigators aim to generate a first strand of cDNA that is as long as possible and contains a high proportion of molecules complementary to the target RNA. Synthetic gene-specific oligonucleotides that bind to the 3′-untranslated regions of the target mRNA are therefore the primers of choice. Oligo(dT) is the next best option, and random hexamers, which have no specificity and generate both long and short molecules of cDNA, are used when the other methods of priming fail.

A second primer and a thermostable DNA polymerase are then added for the subsequent PCR-driven amplification step. Positive and negative controls should always be included when setting up RT-PCRs. Negative controls are generated by omitting essential components of the RT stage of the RT-PCR. Positive controls, however, are much trickier because they require standards that can be transcribed into cDNA and amplified in parallel with the authentic target sequence. Ideally, these standards should consist of known amounts of a synthetic RNA transcribed in vitro

REVERSE TRANSCRIPTASES USED IN RT-PCR

The discovery of DNA-dependent RNA polymerases in 1970 solved the long-standing puzzle of how the RNA genomes of certain tumor viruses could be copied into DNA in infected and/or transformed cells (Baltimore 1970; Temin and Mizutani 1970). The name *reverse transcriptase* was coined as a joke by John Tooze, who first used it in an anonymous News and Views article in *Nature*. Much to the annoyance of purists and the delight of Tooze, the name stuck and quickly became iconic.

Three forms of RNA-dependent DNA polymerases are now used in vitro to catalyze the synthesis of DNA complementary to an RNA template:

- ***Mesophilic enzymes encoded by avian myeloblastosis virus (AMV) and the Moloney strain of murine leukemia virus (Mo-MLV).*** Both enzymes require an RNA or DNA template with an RNA or DNA primer bearing a 3′-hydroxyl group. Lacking an editing 3′→5′ exonuclease activity, both enzymes are prone to error. The K_m values for their dNTP substrates are very high, in the millimolar range. To ensure complete transcription of template RNAs, it is essential to include a high concentration of dNTPs in the reaction.

  The enzyme encoded by AMV has a powerful RNase H activity that can digest the RNA moiety of RNA-DNA hybrids and can cleave the template near the 3′ terminus of the growing DNA strand if reverse transcriptase pauses during synthesis (Kotewicz et al. 1988). Thus, the high level of RNase H activity associated with the avian reverse transcriptase tends to suppress the yield of cDNA and restrict its length (for further details, please see the information panel on **RIBONUCLEASE H**).

  The murine enzyme is far better suited for RT-PCR because its RNase H activity is comparatively weak (Gerard et al. 1997). However, the Mo-MLV enzyme reaches maximum activity at a lower temperature (37°C) than the avian enzyme (42°C), which may be a slight disadvantage if the RNA template has a high degree of secondary structure.

- ***Variants of Mo-MLV reverse transcriptase that lack RNase H activity.*** Several such enzymes are sold commercially (e.g., Superscript from Life Technologies and StrataScript from Stratagene). The modified reverse transcriptases transcribe a greater proportion of the template molecules and synthesize longer cDNA molecules than the wild-type enzyme (Gerard et al. 1988, 1997; Kotewicz et al. 1988; Telesnitsky and Goff 1993). In addition, they are capable of cDNA synthesis at high temperatures (up to 50°C in some cases), which is an advantage when the template RNA is rucked into secondary structures.

- ***Thermostable* Tth *DNA polymerase,*** which is encoded by the thermophilic eubacterium *Thermus thermophilus* and exhibits reverse transcriptase activity in the presence of Mn^{2+} (Myers and Gelfand 1991). The chief advantage of using *Tth* polymerase in RT-PCR is that both phases of the reaction (reverse transcription and amplification) are carried out in the same reaction tube (Myers et al. 1994). In our view, this increase in convenience is not sufficient to compensate for the disadvantages of *Tth* polymerase, which are that the average size of the cDNA synthesized by *Tth* is only ~1–2 kb, far less than can be achieved with Mo-MLV reverse transcriptase (~10 kb); in addition, the use of Mn^{2+} is a worry because of the lowered fidelity of DNA synthesis in the presence of this cation. Finally, *Tth* cannot be used with oligo(dT) or random hexamers as primers, since the hybrids will be unstable at temperatures at which the thermostable DNA polymerase is active.

from a cloned, mutated segment of the target DNA. The perfect standard would differ in sequence from the target RNA by only one or two bases required to create one or more novel restriction site(s) in the amplified cDNA products. Both the target RNA and the standard should be able to be amplified with the same pair of primers (Becker-André and Hahlbrock 1989; Wang et al. 1989; Gilliland et al. 1990; Siebert and Larrick 1992). After amplification, the two PCR products are distinguished by digestion with restriction enzyme(s) and agarose gel electrophoresis (for review, please see Becker-André 1993).

Generating a perfect standard requires detailed planning and considerable labor. Most investigators therefore settle for internal standards that fall short of perfection, for example, a cloned segment of cDNA that can be added in varying quantities to the RNA template, or, less desirably, a completely unrelated, endogenous RNA species that can be amplified only with separate primers. Such imperfect controls may be malodorous to purists, but they are certainly preferable to no controls at all. At least they provide a means to measure the overall efficiency of reverse transcription and amplification and provide some indication of the quality of the RNA preparation.

MATERIALS

▲ **IMPORTANT** To reduce the chance of contamination with exogenous DNAs, prepare and use a special set of reagents and solutions for PCR only. Bake all glassware for 6 hours at 150°C and autoclave all plasticware. For more information, please see the panel on **CONTAMINATION IN PCR** in the chapter introduction.

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

10x Amplification buffer

Chloroform **<!>**

dNTP (20 mM) solution containing all four dNTPs (pH 8.0)

Ethanol

$MgCl_2$ (50 mM)

Phenol:chloroform (1:1, v/v) **<!>**

Placental RNase inhibitor (20 units/μl)

Please see the information panel on **INHIBITORS OF RNASES** in Chapter 7.

Enzymes and Buffers

Reverse transcriptase (RNA-dependent DNA polymerase)

Please see the panel on **REVERSE TRANSCRIPTASES USED IN RT-PCR** in the introduction to this protocol.

Thermostable DNA-dependent DNA polymerase

Taq DNA polymerase is the standard and appropriate enzyme for the amplification stage of most forms of RT-PCR. However, where elongation from 3′-mismatched primers is suspected, a thermostable DNA polymerase with 3′→5′ proofreading activity may be preferred (Chiang et al. 1993).

Gels

Agarose or polyacrylamide gel **<!>**

Please see Step 8.

Nucleic Acids and Oligonucleotides

Exogenous reference RNA

Please see Step 2.

Oligonucleotide primers for synthesis of cDNA:

Oligo(dT)$_{12-18}$ (100 µg/ml) in TE (pH 8.0)

Random hexanucleotides (1 mg/ml) in TE (pH 8.0)

Gene-specific oligonucleotide (20 µM) in H_2O (20 pmoles/µl)

The gene-specific oligonucleotide should be complementary to a known sequence in the target mRNA.

Depending on the experiment, oligo(dT)$_{12-18}$, random hexanucleotides, or gene-specific antisense oligonucleotides can be used as primers for synthesis of first-strand cDNA (please see the introduction to this protocol).

Sense and antisense oligonucleotide primers for amplification of cDNA by PCR

The primer used to generate cDNA may also be used as the antisense primer in the amplification stage of standard RT-PCR. However, the specificity of amplification can be improved by using an antisense primer that binds to an upstream sequence in the target transcript. Both sense and antisense primers are gene-specific synthetic oligonucleotides, which should be 20–30 nucleotides in length and contain approximately equal numbers of the four bases, with a balanced distribution of G and C residues, and a low propensity to form stable secondary structures. Wherever possible, use specific oligonucleotides that bind to sequences located in different exons of the target RNA as sense and antisense primers for amplification of the cDNA product. In this way, amplification products derived from cDNA and contaminating genomic DNA can be easily distinguished. For further details, please see Design of Oligonucleotide Primers for Basic PCR in the introduction to this chapter.

Bases encoding restriction sites can be added to the 5′ termini of the sense and antisense primers used in PCR (please see Protocol 6). This addition greatly facilitates cloning of the amplified product.

Oligonucleotide primers synthesized on an automated DNA synthesizer can generally be used in standard RT-PCR without further purification. However, amplification of low-abundance mRNAs is often more efficient if the oligonucleotide primers are purified by chromatography on commercially available resins (e.g., NENSORB, NEN Life Science Products) or by denaturing polyacrylamide gel electrophoresis, as described in Chapter 10, Protocol 1.

Use the following formula to calculate the molecular weight of the oligonucleotides:

$$M_r = (C \times 289) + (A \times 313) + (T \times 304) + (G \times 329)$$

where C = number of C residues in the oligonucleotide
A = number of A residues
T = number of T residues
G = number of G residues

The gram molecular weight of a 20-mer will be ~6000; 100 pmoles of the oligonucleotide will be equivalent to ~0.6 µg.

Total RNA (100 µg/ml) in H_2O or Poly(A)$^+$ RNA (10 µg/ml) in H_2O

Total RNA extracted from cells with chaotropic agents is generally the template of choice for RT-PCR for mRNAs that are expressed at moderate to high abundance (Liedtke et al. 1994). Poly(A)$^+$ is preferred as a template for all forms of RT-PCR when the target mRNA is expressed at low abundance. RNA suitable for use as a template in RT-PCR may be prepared from small numbers of cultured cells as follows:

i. Pellet the cells (10–100 cells) by centrifugation for 5 seconds at 4°C in a microfuge.

ii. Remove the supernatant by aspiration. Add 10–20 µl of an ice-cold lysis solution of 0.5% Nonidet P-40 (NP-40), 10 mM Tris-Cl (pH 8.0), 10 mM NaCl, 3 mM $MgCl_2$. Vortex the tube very gently to disperse the cells throughout the lysis solution.

iii. Store the tube for 5 minutes on ice, and then centrifuge at maximum speed for 2 minutes at 4°C in a microfuge. Use the supernatant directly as the template in a cDNA-driven PCR as described below.

Note that it may be necessary to carry out preliminary experiments to determine the optimum concentration of NP-40 in the lysis buffer. The concentration of 0.5% recommended in the protocol works well for lymphocytes. Higher concentrations may be required for other types of mammalian cells.

Special Equipment

Barrier tips for automatic micropipettes

Microfuge tubes (0.5 ml, thin-walled for amplification) or Microtiter plates

Positive-displacement pipette

Thermal cycler programmed with desired amplification protocol

If the thermal cycler is not equipped with a heated lid, use either mineral oil or paraffin wax to prevent evaporation of liquid from the reaction mixture during PCR.

Water baths preset to 75°C and 95°C

Additional Reagents

Step 8 of this protocol requires the reagents listed in Chapter 5, Protocol 2, Chapter 12, Protocol 6, or Chapter 6, Protocol 10.

Step 10 of this protocol requires the reagents listed in Protocols 3 and 4, 5, or 6 of this chapter.

METHOD

1. Transfer 1 pg to 100 ng of poly(A)$^+$ mRNA or 10 pg to 1 µg of total RNA to a fresh microfuge tube. Adjust the volume to 10 µl with H_2O. Denature the RNA by heating at 75°C for 5 minutes, followed by rapid chilling on ice.

2. To the denatured RNA add:

10x amplification buffer	2 µl
20 mM solution of four dNTPs (pH 8.0)	1 µl
primers (optimized, please see below)	1 µl
~20 units/µl placental RNase inhibitor	1 µl
50 mM $MgCl_2$	1 µl
100–200 units/µl reverse transcriptase	1 µl
H_2O	to 20 µl

Incubate the reaction for 60 minutes at 37°C.

$MgCl_2$ is added to meet the needs of the reverse transcriptase.

The optimum ratio of primer to template should be ascertained empirically for each preparation of RNA. As a starting point for optimization, we recommend adding varying amounts of primers to 20-µl reactions:

synthetic oligonucleotide complementary to the target RNA:	5–20 pmoles
oligo(dT)$_{12-18}$:	0.1–0.5 µg
random hexanucleotides:	1–5 µg

cDNA synthesis can be measured by determining the proportion of radioactivity incorporated in reactions that have been supplemented with 10–20 µCi of [^{32}P]dCTP (sp. act. 3000 Ci/mmole). The size of the first-strand cDNA molecules can be estimated by electrophoresis through alkaline agarose gels (please see Chapter 5, Protocol 8).

Set up three negative control reactions. In one reaction, include all of the components of the first-strand reaction, except the RNA template. In another reaction, include all of the components, except the reverse transcriptase. Omit primers from the third reaction. Carry the controls through all subsequent steps of the protocol. These controls provide reassurance that the cDNA product is not due to contamination or self-priming by RNA.

Whenever possible, set up positive controls containing varying amounts of an exogenous reference RNA equipped with a set of primer annealing sites identical to those used in the authentic target

RNA (Wang et al. 1989). With some foresight, it is often possible to generate an appropriate reference by cloning synthetic copies of the sense and antisense primer-binding sites on either side of an exogenous DNA sequence. The recombinant clone may then be transcribed in vitro into an RNA template that can serve as a positive control in RT-PCR.

3. Inactivate the reverse transcriptase and denature the template-cDNA complexes by heating the reaction to 95°C for 5 minutes.

   The reverse transcriptase must be inactivated to ensure efficient synthesis during the amplification phase of RT-PCR (Sellner et al. 1992; Chumakov 1994). Sometimes, inactivation of reverse transcriptase by heat is not sufficient. It is then necessary to purify the first-strand cDNA by extraction with phenol:chloroform and precipitation with ethanol before setting up the PCRs. Presumably, contaminants in the reverse transcriptase enzyme lead to a decreased efficiency of the amplification reactions.

4. Adjust the reaction mixture so that it contains 20 pmoles of the sense and antisense primers.

   The 20 pmoles of antisense oligonucleotide primer in the amplification reaction includes any gene-specific oligonucleotide used to prime the synthesis of the first-strand cDNA. The presence of excess oligonucleotide primers can lead to amplification of undesirable (nontarget) sequences, whereas a dearth of primers reduces the efficiency of amplification. It may be necessary to remove excess oligonucleotide and random hexamer primers from the cDNA preparation and then to optimize the concentrations of the sense and antisense primers in the amplification reaction (please see Step 3 of Protocol 9).

5. Add to the reaction mixture:

1x amplification buffer (or volume required to bring reaction mixture to 99 µl)	77 µl
1–2 units thermostable DNA polymerase	1 µl

6. If the thermal cycler is not fitted with a heated lid, overlay the reaction mixtures with 1 drop (~50 µl) of light mineral oil. Alternatively, place a bead of paraffin wax into the tube if using a hot start protocol. Place the tubes or the microtiter plate in the thermal cycler.

7. Amplify the nucleic acids using the denaturation, annealing, and polymerization times and temperatures listed in the table.

Cycle Number	Denaturation	Annealing	Polymerization
35 cycles	45 sec at 94°C	45 sec at 55°C	1 min 15 sec at 72°C
Last cycle	1 min at 94°C	45 sec at 55°C	1 min 15 sec at 72°C

   These times are suitable for 100-µl reactions assembled in thin-walled 0.5-ml tubes and incubated in thermal cyclers such as the Perkin-Elmer 9600 or 9700, Master Cycler (Eppendorf), and PTC 100 (MJ Research). Times and temperatures may need to be adapted to suit other types of equipment and reaction volumes.

   Polymerization should be carried out for 1 minute for every 1000 bp of length of the target DNA.

   Most thermal cyclers have an end routine in which the amplified samples are incubated at 4°C until they are removed from the machine. Samples can be left overnight at this temperature, but should be stored thereafter at –20°C.

8. Withdraw a sample (5–10 µl) from the test reaction mixture and the four control reactions and analyze them by electrophoresis through an agarose or polyacrylamide gel. Be sure to include DNA markers of an appropriate size. Stain the gel with ethidium bromide or SYBR Gold to visualize the DNA.

   A successful amplification reaction should yield a readily visible DNA fragment of the expected size. The identity of the band can be confirmed by DNA sequencing (please see Chapter 12, Protocol 6), Southern hybridization (please see Chapter 6, Protocol 10), and/or restriction mapping.

   If no product is visible after 30 cycles of amplification, add fresh *Taq* polymerase and continue the amplification reaction for a further 15–20 cycles.

9. If mineral oil was used to overlay the reaction (in Step 6), remove the oil from the sample before cloning by extraction with 150 µl of chloroform.

   The aqueous phase, which contains the amplified DNA, will form a micelle near the meniscus. The micelle can then be transferred to a fresh tube with an automatic micropipette.

   ▲ **IMPORTANT** Do not attempt chloroform extractions in microtiter plates. The plastic used in these plates is not resistant to organic solvents.

10. Clone the amplified products into an appropriately prepared vector by any of the methods described in Protocol 4, 5, or 6. Before cloning, separate the amplified DNA from the residual thermostable DNA polymerase and dNTPs (please see Protocol 3). The DNA can then be ligated to a blunt-ended vector or a T vector, or it can digested with restriction enzymes and ligated to a vector with compatible termini.

Poor yields of product in RT-PCR may be due to inefficient cDNA synthesis or, more frequently, to ineffective amplification of cDNA. Investigate the latter possibility by setting up a series of reactions in which variable amounts of cDNA template are added to the PCR. Suboptimal amounts of cDNA template may generate a number of discrete amplification products, which may be larger or smaller than the authentic target sequence. A more common problem is a nonspecific smear of amplified products, as visualized on a stained gel. This outcome is caused by spurious priming, which occurs when excess cDNA template is present in the PCR. For this reason, many experimenters use ≤ 10% of the cDNA generated in the reverse transcriptase reaction as template in the subsequent PCR. In this case, additional dNTPs must be added to the PCR.

Once the best concentration of template has been established, the other parameters of PCR can be optimized in a systematic fashion by varying the concentration of Mg^{2+}, altering annealing conditions, and so on. If problems still persist:

- Check the integrity of the RNA preparation by electrophoresis through an agarose gel containing formaldehyde.
- Set up test reactions containing a control mRNA, an oligo(dT) primer, and a radiolabeled tracer to measure the efficiency of cDNA synthesis. The total amounts of first-strand cDNA synthesis can be measured by determining the proportion of radioactivity incorporated in reactions that have been supplemented with 10–20 µCi of [^{32}P]dCTP (sp. act. 3000 Ci/mmole). The size of the first-strand cDNA molecules can be estimated by electrophoresis through alkaline agarose gels (see Chapter 5, Protocol 8).
- Test for the presence of inhibitors in the preparation of RNA by mixing varying amounts of the preparation with a control and comparing the yields of cDNA.
- Purify the cDNA as described in the footnote to Step 3 before proceeding to PCR.

Protocol 9

Rapid Amplification of 5′cDNA Ends

NOTHING IN MOLECULAR CLONING IS MORE FRUSTRATING than to isolate a cDNA clone that lacks sequences representative of the 5′ end of the corresponding mRNA. Partial clones of this type, which occur commonly in cDNA libraries, arise when reverse transcriptase fails to extend first-strand cDNA along the full length of the mRNA template. The longer the starting mRNA and the higher its content of secondary structure, the greater the risk of isolating an incomplete cDNA clone. Before the advent of PCR, the investigator's best hope of rectifying the situation was to re-screen the cDNA library in greater depth in the hope of fastening onto a full-length clone. In many instances, however, the consequence was further frustration and redoubled disappointment. The only course then open was to generate and screen additional cDNA libraries. In the late 1980s, however, a better solution was found when methods were devised to capture missing segments of cDNA and to amplify them by PCR. Frohman et al. (1988) described a general procedure for the rapid amplification of cDNA ends (RACE); Loh et al. (1989) designed anchored PCR to clone the variable 5′ regions of mRNAs encoding T-cell receptors; and Ohara et al. (1989) used essentially the same technique (One-sided PCR) to clone full-length cDNAs corresponding to mRNAs encoding skeletal muscle α-tropomyosins of the European common frog and zebrafish (*Brachydanio rerio*).

These techniques differ from conventional PCR in that they require knowledge of only a small region of sequence within either the target RNA or a partial clone of cDNA (please see Figure 8-5). During PCR, the thermostable DNA polymerase is directed to the appropriate target RNA by a single primer derived from the region of known sequence; the second primer required for PCR is complementary to a general feature of the target — in the case of 5′-RACE, to a homopolymeric tail added (via terminal transferase) to the 3′ termini of cDNAs transcribed from a preparation of mRNA. In effect, this synthetic tail provides a primer-binding site upstream of the unknown 5′ sequence of the target mRNA. The products of the amplification reaction are cloned into a plasmid vector for sequencing and subsequent manipulation.

5′-RACE is not as easy as its sounds. The technique involves three sequential enzymatic steps (reverse transcription, addition of homopolymeric tails, and PCR), none of which is foolproof. The specificity of amplification depends entirely on the anchoring primer and is generally low. The population of amplified DNAs is therefore enriched for 5′ sequences of the target mRNA but is by no means pure. In addition, the amplified DNAs are of such variable length that they usually appear as a smear on an agarose gel. Finally, the fraction of amplified DNAs that extends to the 5′ terminus of the target RNA is small, perhaps because reverse transcriptase has difficulty in transcribing RNA templates that have a high degree of secondary structure in their 5′ regions.

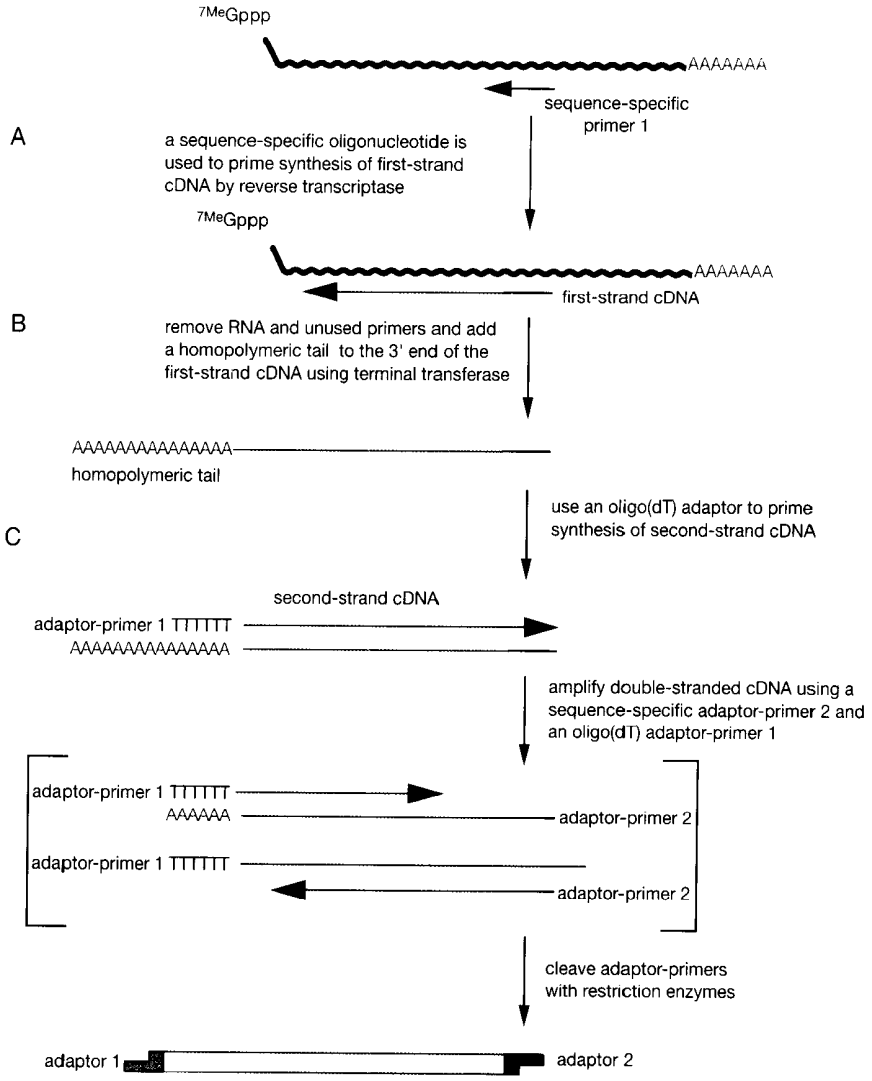

FIGURE 8-5 Determination of the 5′ End of mRNA Using 5′-RACE

(*A*) A sequence-specific primer 1 complementary to a region of known sequence is annealed to the RNA. First-strand synthesis is achieved using reverse transcriptase and dNTP. The DNA extends to the 5′ end of the mRNA. (*B*) The primers are removed from the reaction products by spin dialysis, and a homopolymeric tail is added to the 3′ end of the DNA using terminal transferase. Typically, dATP is used to generate a poly(dA) tail; however, some investigators prefer to use dCTP to make a poly(dC) tail, particularly if terminal As are already present from reverse transcription of the RNA. (*C*) The $(dT)_{17}$ adaptor-primer 1 is used to prime the synthesis of the second strand. Amplification is continued to generate enough product for cloning into a plasmid vector and for subsequent sequencing.

Truncated cDNAs generated during 5′-RACE have the same termini as full-length molecules (i.e., a primer at their 3′ end and a homopolymeric tail at their 5′ end). Both full-length and truncated molecules are therefore amplified in the PCR phase of 5′-RACE. Many refinements of the original techniques have been introduced to alleviate these and other problems (for reviews, please see Frohman 1995; Schaefer 1995; Chen 1996). The following protocol is based on a modification by W.J. Chen (Glaxo-Wellcome) of the original method of Frohman et al. (1988). Further elaborations and modifications drawn from a variety of other sources are described at the end of the protocol.

MATERIALS

▲ **IMPORTANT** To reduce the chance of contamination with exogenous DNAs, prepare and use a special set of reagents and solutions for PCR only. Bake all glassware for 6 hours at 150°C and autoclave all plasticware. For more information, please see the panel on **CONTAMINATION IN PCR** in the chapter introduction.

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

10x Amplification buffer

Chloroform **<!>**

dATP (1 mM) (disodium salt)

dNTP (20 mM) solution containing all four dNTPs (pH 8.0)

Placental RNase inhibitor (20 units/μl)

Please see the information panel on **INHIBITORS OF RNASES** in Chapter 7.

TE (pH 7.6)

Enzymes and Buffers

5x Reverse transcriptase buffer

Reverse transcriptase (RNA-dependent DNA polymerase)

Please see the panel on **REVERSE TRANSCRIPTASES USED IN RT-PCR** in Protocol 8.

Terminal deoxynucleotidyl transferase (terminal transferase)

Please see the information panel on **TERMINAL TRANSFERASE.**

5x Terminal transferase buffer

Thermostable DNA polymerase

Taq DNA polymerase is the standard and appropriate enzyme for the amplification stage of most forms of RT-PCR. However, where elongation from 3′-mismatched primers is suspected, a thermostable DNA polymerase with 3′→5′ proofreading activity may be preferred (Chiang et al. 1993).

Gels

Agarose or polyacrylamide gel **<!>**

Please see Step 9.

Nucleic Acids and Oligonucleotides

Adaptor-primer (10 μM) (5′ GACTCGAGTCGACATCG 3′) in H_2O (10 pmoles/μl)

The adaptor-primer is used in conjunction with a gene-specific sense primer to amplify a particular target cDNA. After amplification, the desired product can comprise as little as 1% and as much as 100% of the total yield of DNA. If necessary, the yield of desired product can be improved by setting up a second round of amplification using the adaptor-primer and a nested gene-specific antisense primer that binds to a sequence within the amplified segment of target DNA. After this second round of nested amplification, almost all of the product detected by ethidium bromide staining contains sequences corresponding to the 5′ region of the desired mRNA.

Oligonucleotide primers synthesized on an automated DNA synthesizer can generally be used in standard RT-PCR without further purification. However, amplification of low-abundance mRNAs is often more efficient if the oligonucleotide primers are purified by chromatography on commercially available resins (e.g., NENSORB, NEN Life Science Products) or by denaturing polyacrylamide gel electrophoresis, as described in Chapter 10, Protocol 1.

$(dT)_{17}$-Adaptor-primer (10 μM) (5′ GACTCGAGTCGACATCGA$(T)_{17}$ 3′) in H_2O (10 pmoles/μl)

The $(dT)_{17}$-adaptor-primer binds to the poly(A)$^+$ tract added to the 5′ terminus of cDNAs by terminal transferase. In the example given in this protocol, one of the termini of the amplified DNAs becomes equipped with recognition sites for *Xho*I, *Sal*I, *Acc*I, *Hin*cII, and *Cla*I restriction enzymes.

Gene-specific antisense oligonucleotide primers (10 μM) in H_2O (10 pmoles/μl)

The gene-specific antisense primers should be complementary to the known sequence of the target mRNA, should be 20–30 nucleotides in length, and should contain approximately equal numbers of the four bases, with a balanced distribution of G and C residues and a low propensity to form stable secondary structures. For further details, please see Design of Oligonucleotide Primers for Basic PCR in the introduction to this chapter. Gene-specific primer 1 is used in the reverse transcriptase reaction (Step 2) to prime synthesis of gene-specific first-strand cDNA. Gene-specific primer 2 is complementary to a sequence in the target mRNA that is 5′ to primer 1 and is used in the amplification stage of the reaction. As discussed below, restriction sites are always designed into adaptor-primers. However, they can also be incorporated into the gene-specific oligonucleotides. The presence of restriction sites simplifies cloning of the amplified cDNAs.

Random hexanucleotides (1 mg/ml) in TE (pH 8.0) (optional)

In an emergency, random hexanucleotides can be used in place of the gene-specific antisense oligonucleotide to prime synthesis of cDNA (Harvey and Darlison 1991). Subsequent use of a gene-specific sense primer in the PCR phase of the 5′-RACE reaction generates the desired product (Harvey and Darlison 1991; Apte and Siebert 1993). Random oligonucleotides are clearly not the first choice for 5′-RACE since they do not have the ability to discriminate between the target and any other sequence in the starting population of mRNAs. They may provide a way to leap the hurdle of cDNA synthesis in the absence of a gene-specific antisense oligonucleotide, but they also delay the introduction into the 5′-RACE protocol of a crucial selective step. Because only a small fraction of the cDNAs generated by random priming will also contain a binding site for the gene-specific sense primer, the yields of amplified product are typically very low when random hexanucleotides are used to prime cDNA synthesis in RACE.

Total RNA (100 μg/ml) in H_2O or Poly(A)$^+$ RNA (10 μg/ml) in H_2O

Total RNA extracted from cells with chaotropic agents is generally the template of choice for RT-PCR for mRNAs that are expressed at moderate to high abundance (Liedtke et al. 1994). Poly(A)$^+$ is preferred as a template for all forms of RT-PCR when the target mRNA is expressed at low abundance. RNA suitable for use as a template in RT-PCR may be prepared from small numbers of cultured cells according to the directions in Protocol 8.

Centrifuges and Rotors

Preparative centrifuge

Centricon-100 devices will fit in any fixed-angle rotor with adaptors capable of supporting 17 x 150-mm tubes. The centrifuge must be capable of generating a steady force of 1000*g*.

Sorvall SS-34 rotor

Special Equipment

Barrier tips for automatic micropipettes

Concentrators (Centricon-100, Amicon)

Microfuge tubes (0.5 ml, thin-walled for amplification) or Microtiter plates

Positive-displacement pipette

Thermal cycler programmed with desired amplification protocol

If the thermal cycler is not equipped with a heated lid, use either mineral oil or paraffin wax to prevent evaporation of liquid from the reaction mixture during PCR.

Rotary vacuum evaporator (Optional)

For example, the Speed-vac from Savant Inc. (Hicksville, New York). Please see Step 3.

Water baths preset to 75°C and 80°C

Additional Reagents

Step 9 of this protocol requires the reagents listed in Chapter 5, Protocol 2, Chapter 12, Protocol 6, or Chapter 6, Protocol 10.

Step 11 of this protocol requires the reagents listed in Protocols 3 and 4, 5, or 6 of this chapter.

METHOD

Reverse Transcription

The success or failure of 5′-RACE is determined here, at the beginning of the experiment. If the reverse transcription step works efficiently, the chance of isolating clones that contain the 5′-termi-

nal sequences of the target mRNA is high. On the other hand, no amount of work on the later steps of the protocol can compensate for ineffective reverse transcription. It is therefore worthwhile to take the time to optimize the reverse transcriptase reaction by determining the optimum ratio of primer to template for each preparation of RNA and by varying the concentration of Mg^{2+} in the reaction.

1. Transfer 1 pg to 100 ng of poly(A)$^+$ mRNA or 10 pg to 1 μg of total RNA to a fresh microfuge tube. Adjust the volume to 9 μl with H_2O. Denature the RNA by heating for 5 minutes at 75°C, followed by rapid chilling on ice.

2. To the denatured RNA add:

5x reverse transcriptase buffer	4 μl
20 mM solution of four dNTPs (pH 8.0)	1 μl
10 μM gene-specific antisense primer 1	4 μl
~20 units/μl placental RNase inhibitor	1 μl
100–200 units/μl reverse transcriptase	1 μl
H_2O	to 20 μl

Incubate the reaction for 60 minutes at 37°C. Set up three negative control reactions. In one reaction, include all of the components of the first-strand reaction, except the RNA template. In another reaction, include all of the components, except the reverse transcriptase. Omit primer from the third reaction. Carry the controls through all subsequent steps of the protocol. These controls provide reassurance that the cDNA product synthesized in the main reaction is not due to contamination with genomic DNA or oligonucleotide fragments, or self-priming by template molecules.

Total cDNA synthesis can be estimated from the proportion of trichloroacetic acid (TCA)-precipitable radioactivity incorporated in reverse transcription reactions supplemented with 10–20 μCi of [^{32}P]dCTP (sp. act. 3000 Ci/mmole; please see Appendix 8). Be sure to set up a control reaction that contains no oligonucleotide primer. Radioactivity incorporated in the absence of primer results from self-priming of RNA molecules. The length of the population of first-strand cDNA molecules can be estimated by electrophoresis of the radiolabeled products through an alkaline agarose gel (Chapter 5, Protocol 8), followed by autoradiography.

To monitor the efficiency of *gene-specific* DNA synthesis, set up a primer-extension reaction containing the gene-specific antisense oligonucleotide radiolabeled at its 5′ end by bacteriophage T4 polynucleotide kinase and [γ-^{32}P]ATP (please see Chapter 7, Protocol 12). The products of the reverse transcriptase reaction, which in general will be heterogeneous in length, should be analyzed by electrophoresis through an alkaline agarose gel (Chapter 5, Protocol 8), followed by autoradiography. Extended exposure times (>24 hours) will most likely be required to detect the primer-extension product(s) complementary to low-abundance mRNAs.

Purification of the Reverse Transcriptase Products

Unused dNTPs and primers must be removed at the completion of the reverse transcriptase reaction. Otherwise, there is a chance that dNTPs will be incorporated into the tail added to the 3′ end of the cDNA by terminal transferase. This would be a total disaster as the presence of unwanted bases would compromise the ability of the tail to serve as a primer-binding site. The presence of unused primers would also be a problem because their 3′ termini would compete with cDNA in the tailing reaction.

3. Remove excess oligonucleotide or random hexanucleotide primer by diluting the reverse transcriptase reaction to a final volume of 2 ml with H_2O and then applying the solution to a Centricon-100 microconcentrator (Frohman 1993; for a description of this procedure, please see Protocol 3). Centrifuge the solution at 500–1100*g* (2000–3000 rpm in a Sorvall SS-34 rotor) for 20 minutes at a temperature between 4°C and 25°C. Repeat the dilution step and centrifuge again. Transfer the retentate to a fresh 0.5-ml microfuge tube and reduce the volume to ~10 μl in a rotary vacuum evaporator.

Alternatively, remove the dNTPs and unused primers by precipitating the cDNA twice in 2.5 M ammonium acetate and 3 volumes of ethanol. Two sequential precipitations of DNA in the presence of 2.5 M ammonium acetate result in the removal of >99% of dNTPs and oligonucleotides from preparations of DNA (Okayama and Berg 1983).

4. To the cDNA in a volume of 10 µl add:

5x terminal transferase buffer	4 µl
1 mM dATP	4 µl
terminal transferase	10–25 units

Incubate the reaction for 15 minutes at 37°C.

The tailing reaction can be optimized by setting up mock reactions containing ~50 ng of a control DNA fragment, 100–200 nucleotides in length. After tailing, the size of the fragment should increase by 20–100 nucleotides as measured by electrophoresis through a 1% neutral agarose gel. More accurate estimates of the average number of bases added to 3′ termini can be obtained by setting up a control reaction containing ~10 ng of a synthetic oligonucleotide ~30 bases in length and labeled at its 5′ terminus with ^{32}P (please see Chapter 10, Protocol 2). The products of the tailing reaction are separated by electrophoresis through a 10% polyacrylamide sequencing gel and analyzed by autoradiography. The tailed products form a ladder of bands differing in length by a single nucleotide. Ideally, the homopolymeric tails should, on average, be ~20 nucleotides in length and should be attached to the vast majority of the cDNA substrates.

5. Inactivate the terminal transferase by heating the reaction for 3 minutes at 80°C. Dilute the dA-tailed cDNA to a final volume of 1 ml with TE (pH 7.6).

Amplification

6. In a sterile 0.5-ml microfuge tube, amplification tube, or the well of a sterile microtiter plate, set up a series of PCRs containing the following:

diluted cDNA	0–20 µl
10x amplification buffer	5 µl
20 mM solution of four dNTPs	5 µl
10 µM $(dT)_{17}$-adaptor-primer (16 pmoles)	1.6 µl
10 µM adaptor-primer (32 pmoles)	3.2 µl
10 µM gene-specific primer 2 (32 pmoles)	3.2 µl
1–2 units of thermostable DNA polymerase	1 µl
H_2O	to 50 µl

It is essential to set up a series of amplification reactions to find the amount of tailed cDNA that generates the largest quantity of amplified 5′ termini. The control reaction containing no cDNA template serves as a control for contamination.

7. If the thermal cycler is not fitted with a heated lid, overlay the reaction mixtures with 1 drop (~50 µl) of light mineral oil. Alternatively, place a bead of paraffin wax into the tube if using a hot start protocol. Place the tubes or the microtiter plate in the thermal cycler.

8. Amplify the nucleic acids using the denaturation, annealing, and polymerization times and temperatures listed in the table.

Cycle Number	Denaturation	Annealing	Polymerization
First cycle	5 min at 94°C	5 min at 50–58°C	40 min at 72°C
Subsequent cycles (30)	40 sec at 94°C	1 min at 50–58°C	3 min at 72°C
Last cycle	40 sec at 94°C	1 min at 50–58°C	15 min at 72°C

These times are suitable for 50-µl reactions assembled in thin-walled 0.5-ml tubes and incubated in thermal cyclers such as the Perkin-Elmer 9600 or 9700, Master Cycler (Eppendorf), and PTC 100 (MJ Research). Times and temperatures may need to be adapted to suit other types of equipment and reaction volumes.

The polymerization reaction in the first cycle is carried out for an extended period of time (40 minutes) to ensure the synthesis of long cDNAs by the thermostable DNA polymerase.

The optimum temperature for annealing of the oligonucleotide primers should be determined empirically. Start at 50°C and gradually work up to the highest temperature that generates the maximum yield of specific product.

9. Withdraw a sample (5–10 µl) from the test reaction mixture and the four control reactions and analyze them by electrophoresis through an agarose or polyacrylamide gel. Be sure to include DNA markers of an appropriate size. Stain the gel with ethidium bromide or SYBR Gold to visualize the DNA.

A successful amplification reaction should yield a readily visible DNA fragment of the expected size. The identity of the band can be confirmed by DNA sequencing (please see Chapter 12, Protocol 6), Southern hybridization (please see Chapter 6, Protocol 10), and/or restriction mapping.

If no product is visible after 30 cycles of amplification, add fresh *Taq* polymerase and continue the amplification reaction for a further 15–20 cycles.

If amplification of the tailed cDNA preparation results in a smear of DNA after gel electrophoresis, recover the longest products of the amplification reaction from a preparative agarose gel. An aliquot of this material can then be reamplified for a limited number (15–20) of additional cycles of PCR.

10. If mineral oil was used to overlay the reaction (in Step 7), remove the oil from the sample before cloning by extraction with 150 µl of chloroform.

The aqueous phase, which contains the amplified DNA, will form a micelle near the meniscus. The micelle can be transferred to a fresh tube with an automatic micropipette.

▲ **IMPORTANT** Do not attempt chloroform extractions in microtiter plates. The plastic used in these plates is not resistant to organic solvents.

11. Separate the amplified DNA from the residual thermostable DNA polymerase and dNTPs (please see Protocol 3).

The DNA can now be ligated to a blunt-ended vector or a T vector, or it can digested with restriction enzymes and ligated to a vector with compatible termini (please see Protocols 4, 5, and 6).

LOW YIELDS OF FULL-LENGTH CLONES

Many of the problems with low yields of full-length clones are due to the inefficiency of the reverse transcription step. If the RNA is degraded or if the 5′ end of the target mRNA is rich in GC, reverse transcriptase may have difficulty in traversing the resulting stable secondary structures. The yield of clones can be enhanced by one of the following methods:

- ***Carrying out the reverse transcriptase reaction at higher temperatures*** (up to 55°C with murine reverse transcriptase), or use a thermostable reverse transcriptase (e.g., *Tth* polymerase, Retrotherm).
- ***Fractionating the cDNA products on agarose or polyacrylamide gels*** before homopolymeric tailing and amplification.
- ***Incorporating modified bases, such as 7-deaza-dGTP,*** that reduce secondary structure (McConlogue et al. 1988). Bear in mind that the incorporation of 7-deaza-dGTP into the first-strand cDNA product may increase the efficiency of the amplification step, but it may also block subsequent cleavage of the amplified DNA by some restriction enzymes, including *Alu*I, *Dde*I, *Hin*fI, *Sau*3AI, *Acc*I, *Bam*HI, *Eco*RI, *Pst*I, *Sal*I, and *Sma*I. However, DNAs modified with 7-deaza-GTP are cleaved efficiently by *Mae*I, *Hin*dIII, and *Xba*I.
- ***Carrying out five cycles of linear amplification*** on the d(A)-tailed cDNA with the gene-specific primer before adding the d(T) adaptor-primer (Rother 1992).
- ***Purifying the tailed and amplified DNA by electrophoresis*** through an agarose or polyacrylamide gel. The longest molecules are then recovered from the gel and subjected to a second round of amplification using the adaptor-primer and the gene-specific primer.

For further suggestions, please see the panel at the end of Protocol 8.

Protocol 10

Rapid Amplification of 3′cDNA Ends

PARTIAL CDNA CLONES THAT LACK SEQUENCES CORRESPONDING to the 3′ regions of the cognate mRNA occur infrequently in oligo(dT)-primed cDNA libraries. How and when these rarities arise during cDNA synthesis and cloning is not known for certain. Possibilities include random breakage of first-strand cDNA, failure of the DNA polymerase to reach the end of the template strand during synthesis of the second strand of cDNA, priming on internal adenylate tracts, or deletion of 3′ sequences adjacent to poly(dA:dT) tracts during cloning. Partial cDNAs that lack 3′ regions are common in random hexamer-primed cDNA libraries because these primers anneal at many positions in the mRNA.

3′-RACE reactions are used to isolate unknown 3′ sequences and to map the 3′ termini of mRNAs, for example, when investigators are faced with multiple mRNA species transcribed from a single gene, arising from differential polyadenylation.

3′-RACE like its more illustrious sibling, 5′-RACE, requires knowledge of a small region of sequence within either the target RNA or a partial clone of cDNA (Figure 8-6). A population of mRNAs is transcribed into cDNA with an adaptor-primer consisting at its 3′ end of a poly(T) tract and at its 5′ end of an arbitrary sequence of 30–40 nucleotides. Reverse transcription is usually followed by two successive PCRs. The first is primed by a gene-specific sense oligonucleotide and the antisense (dT)adaptor-primer. If necessary, the products of the first PCR can be used as templates for a second, nested PCR, which is primed by a gene-specific sense oligonucleotide internal to the first, and a second antisense oligonucleotide whose sequence is identical to the central region of the (dT)adaptor-primer. The products amplified in the second PCR are isolated from an agarose gel, cloned, and characterized.

The following protocol is based on a modification by W.J. Chen (Glaxo-Wellcome) of the methods first described by Frohman et al. (1988) and elaborated in later publications (e.g., please see Frohman 1995; Schaefer 1995; Bespalova et al. 1998)

MATERIALS

▲ **IMPORTANT** To reduce the chance of contamination with exogenous DNAs, prepare and use a special set of reagents and solutions for PCR only. Bake all glassware for 6 hours at 150°C and autoclave all plasticware. For more information, please see the panel on **CONTAMINATION IN PCR** in the chapter introduction.

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

10x Amplification buffer
Chloroform <!>

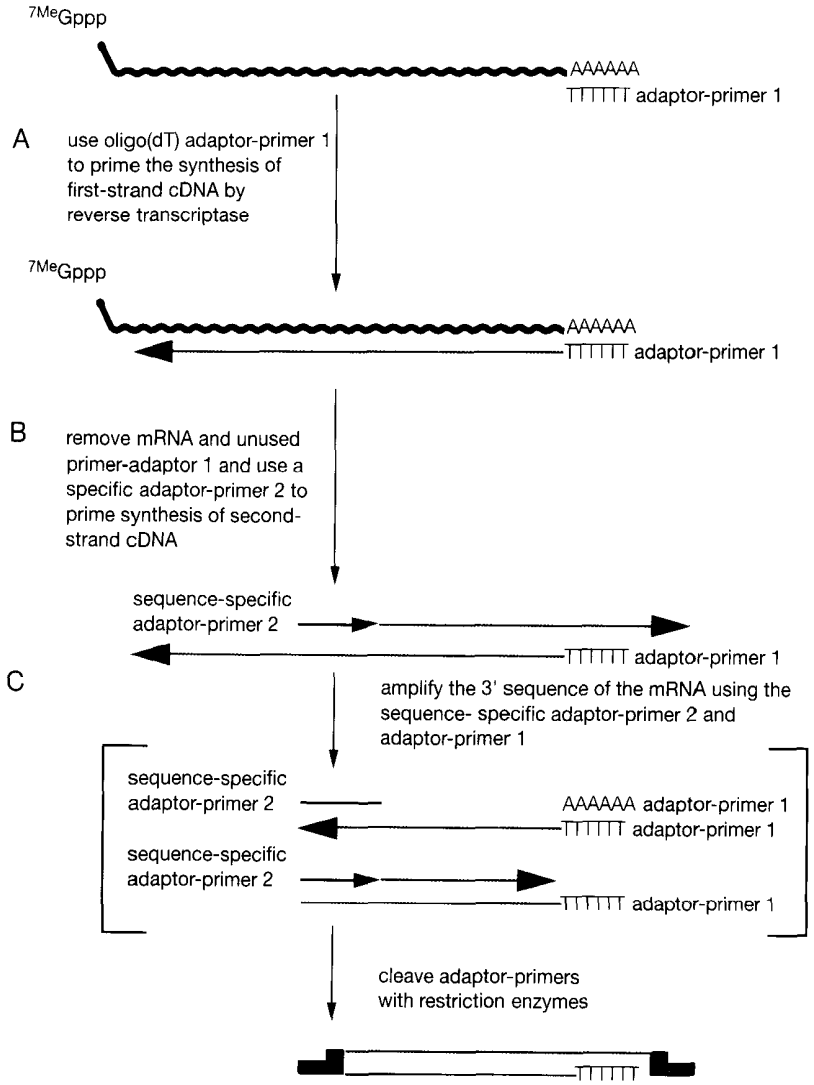

FIGURE 8-6 Determination of the 3′ End of mRNA Using 3′-RACE

The strategy known as 3′-RACE is used to isolate unknown 3′ sequences and to map the 3′ termini of mRNA. (*A*) The $(dT)_{17}$-adaptor-primer (represented by the black arrow) is annealed to the population of mRNA. First-strand synthesis (primed by $(dT)_{17}$) is achieved using reverse transcriptase and dNTPs. (*B*) Second-strand synthesis is primed by a sequence-specific primer. (C) Amplification is continued in the presence of the sequence specific primers and a primer complementary to the arbitrary adaptor sequence, to generate sufficient product for cloning into a plasmid vector and for subsequent sequencing.

dNTP (20 mM) solution containing all four dNTPs (pH 8.0)

Placental RNase inhibitor (20 units/μl)

Please see the information panel on **INHIBITORS OF RNASES** in Chapter 7.

TE (pH 7.6)

Enzymes and Buffers

Reverse transcriptase (RNA-dependent DNA polymerase)

Please see the panel on **REVERSE TRANSCRIPTASES USED IN RT-PCR** in Protocol 8.

5x Reverse transcriptase buffer

Thermostable DNA polymerase

Taq DNA polymerase is the standard and appropriate enzyme for the amplification stage of most forms of RT-PCR. However, where elongation from 3′-mismatched primers is suspected, a thermostable DNA polymerase with 3′→5′ proofreading activity may be preferred (Chiang et al. 1993).

Gels

Agarose or polyacrylamide gel **<!>**

Please see Step 6.

Nucleic Acids and Oligonucleotides

Adaptor-primer (10 μM) (5′ GACTCGAGTCGACATCG 3′) in H_2O (10 pmoles/μl)

The adaptor-primer is used in conjunction with a gene-specific sense primer to amplify a particular target cDNA. After amplification, the desired product can comprise as little as 1% and as much as 100% of the total yield of DNA. If necessary, the yield of desired product can be improved by setting up a second round of amplification using the adaptor-primer and another gene-specific sense primer that binds to a sequence within the amplified segment of target DNA. After this second round of nested amplification, almost all of the product detected by ethidium bromide staining contains sequences corresponding to the 3′ region of the desired mRNA.

Oligonucleotide primers synthesized on an automated DNA synthesizer can generally be used in standard RT-PCR without further purification. However, amplification of low-abundance mRNAs is often more efficient if the oligonucleotide primers are purified by chromatography on commercially available resins (e.g., NENSORB, NEN Life Science Products) or by denaturing polyacrylamide gel electrophoresis, as described in Chapter 10, Protocol 1.

$(dT)_{17}$-Adaptor-primer (10 μM) (5′ GACTCGAGTCGACATCGA$(T)_{17}$ 3′) in H_2O (10 pmoles/μl)

The oligo(dT) region of the $(dT)_{17}$-adaptor antisense primer binds to the poly(A)$^+$ tract at the 3′ end of mRNA, leaving the adaptor sequences unpaired. During amplification, the adaptor sequences are converted to double-stranded cDNA that, in the example given in this protocol, is equipped with recognition sites for *Xho*I, *Sal*I, *Acc*I, *Hinc*II, and *Cla*I restriction enzymes.

Gene-specific sense oligonucleotide primer (10 μM) in H_2O (10 pmoles/μl)

The gene-specific sense primer should encode a known region of sequence of the target mRNA, should be 20–30 nucleotides in length and contain approximately equal numbers of the four bases, with a balanced distribution of G and C residues and a low propensity to form stable secondary structures. For further details, please see Design of Oligonucleotide Primers for Basic PCR in the introduction to this chapter. As discussed below, restriction sites are always designed into adaptor-primers. However, they can also be incorporated into the gene-specific oligonucleotides. This addition generates amplified cDNAs carrying restriction sites at both ends, which can facilitate cloning.

Total RNA (100 μg/ml) in H_2O or Poly(A)$^+$ RNA (10 μg/ml) in H_2O

Total RNA extracted from cells with chaotropic agents is generally the template of choice for RT-PCR (Liedtke et al. 1994) for mRNAs that are expressed at moderate to high abundance. Poly(A)$^+$ is preferred as a template for all forms of RT-PCR when the target mRNA is expressed at low abundance. RNA suitable for use as a template in RT-PCR may be prepared from small numbers of cultured cells according to the directions in Protocol 8.

Special Equipment

Barrier tips for automatic micropipettes

Microfuge tubes (0.5 ml, thin-walled for amplification) or Microtiter plates

Positive-displacement pipette

Thermal cycler programmed with desired amplification protocol

If the thermal cycler is not equipped with a heated lid, use either mineral oil or paraffin wax to prevent evaporation of liquid from the reaction mixture during PCR.

Water baths preset to 75°C

Additional Reagents

Step 6 of this protocol requires the reagents listed in Chapter 5, Protocol 2, Chapter 12, Protocol 6, or Chapter 6, Protocol 10.

Step 8 of this protocol requires the reagents listed in Protocols 3 and 4, 5, or 6 of this chapter.

METHOD

Reverse Transcription

The success or failure of 3′-RACE is determined here, at the beginning of the experiment. If the reverse transcription step works efficiently, the chance of isolating clones that contain the 3′-terminal sequences of the target mRNA is high. On the other hand, no amount of work on the later steps of the protocol can compensate for ineffective reverse transcription. It is therefore worthwhile to take the time to optimize the reverse transcriptase reaction by determining the optimum ratio of primer to template for each preparation of RNA and by varying the concentration of Mg^{2+} in the reaction.

1. Transfer 1 pg to 100 ng of poly(A)$^+$ mRNA or 10 pg to 1 μg of total RNA to a fresh microfuge tube. Adjust the volume to 10 μl with H_2O. Denature the RNA by heating at 75°C for 5 minutes, followed by rapid chilling on ice.

2. To the denatured RNA add:

5x reverse transcriptase buffer	10 μl
20 mM solution of four dNTPs	1.5 μl
10 μM $(dT)_{17}$-adaptor-primer (80 pmoles)	8.0 μl
~20 units/μl placental RNase inhibitor	1 μl
100–200 units/μl reverse transcriptase	1 μl
H_2O	to 50 μl

Incubate the reaction for 60 minutes at 37°C. Set up three negative control reactions. In one reaction, include all of the components of the first-strand reaction, except the RNA template. In another reaction, include all of the components, except the reverse transcriptase. Omit primer from the third reaction. Carry the controls through all subsequent steps of the protocol. These controls provide reassurance that the cDNA product synthesized in the main reaction is not due to contamination with genomic DNA, oligonucleotide fragments, or self-priming by template molecules.

Total cDNA synthesis can be estimated from the proportion of TCA-precipitable radioactivity incorporated in reverse transcriptase reactions supplemented with 10–20 μCi of [^{32}P]dCTP (sp. act. 3000 Ci/mmole; please see Appendix 8). Be sure to set up a control reaction that contains no $(dT)_{17}$ adaptor antisense primer. Radioactivity incorporated in the absence of primer results from self-priming of RNA molecules. The length of the population of first-strand cDNA molecules can be estimated by electrophoresis of the radiolabeled products through an alkaline agarose gel (Chapter 5, Protocol 8), followed by autoradiography.

3. Dilute the reverse transcriptase reaction (cDNA) to a final volume of 1 ml with TE (pH 7.6).

It may be necessary to remove excess oligonucleotide and random hexamer primers from the cDNA preparation and then to optimize the concentrations of the sense and antisense primers in the amplification reaction (please see Step 3 of Protocol 9).

Amplification

4. In a sterile 0.5-ml microfuge tube, amplification tube, or the well of a sterile microtiter plate, set up a series of PCRs containing the following:

diluted cDNA	0–20 μl
10x amplification buffer	5 μl
20 mM solution of four dNTPs	5 μl
10 μM $(dT)_{17}$-adaptor-primer (16 pmoles)	1.6 μl
10 μM adaptor-primer (32 pmoles)	3.2 μl
10 μM gene-specific, sense oligonucleotide primer (32 pmoles)	3.2 μl
1–2 units thermostable DNA polymerase	1 μl
H_2O	to 50 μl

It is essential to set up a series of amplification reactions to find the amount of cDNA that generates the largest quantity of amplified 3′ termini. The control containing no cDNA template serves as a control for contamination.

5. If the thermal cycler is not fitted with a heated lid, overlay the reaction mixtures with 1 drop (~50 µl) of light mineral oil. Alternatively, place a bead of paraffin wax into the tube if using a hot start protocol. Place the tubes or the microtiter plate in the thermal cycler. Amplify the nucleic acids using the denaturation, annealing, and polymerization times and temperatures listed in the table.

Cycle Number	Denaturation	Annealing	Polymerization
First cycle	5 min at 94°C	5 min at 50–58°C	40 min at 72°C
Subsequent cycles (20)	40 sec at 94°C	1 min at 50–58°C	3 min at 72°C
Last cycle	40 sec at 94°C	1 min at 50–58°C	15 min at 72°C

These times are suitable for 50-µl reactions assembled in thin-walled 0.5-ml tubes and incubated in thermal cyclers such as the Perkin-Elmer 9600 or 9700, Master Cycler (Eppendorf), and PTC 100 (MJ Research). Times and temperatures may need to be adapted to suit other types of equipment and reaction volumes.

The polymerization reaction in the first cycle is carried out for an extended period of time (40 minutes) to ensure the synthesis of long 5′-extended cDNAs by the thermostable DNA polymerase.

6. Withdraw a sample (5–10 µl) from the test reaction mixture and the four control reactions and analyze them by electrophoresis through an agarose or polyacrylamide gel. Be sure to include DNA markers of an appropriate size. Stain the gel with ethidium bromide or SYBR Gold to visualize the DNA.

A successful amplification reaction should yield a readily visible DNA fragment of the expected size. The identity of the band can be confirmed by DNA sequencing (please see Chapter 12, Protocol 6), Southern hybridization (please see Chapter 6, Protocol 10), and/or restriction mapping.

If no product is visible after 30 cycles of amplification, add fresh *Taq* polymerase and continue the amplification reaction for a further 15–20 cycles.

If amplification of the tailed cDNA preparation results in a smear of DNA after gel electrophoresis, the longest products of the amplification reaction should be recovered from a preparative agarose gel. An aliquot of this material can then be reamplified for a limited number (15–20) of additional cycles of PCR.

7. If mineral oil was used to overlay the sample, remove the oil from the sample before cloning by extraction with 150 µl of chloroform.

The aqueous phase, which contains the amplified DNA, will form a micelle near the meniscus. The micelle can be transferred to a fresh tube with an automatic micropipette.

▲ **IMPORTANT** Do not attempt chloroform extractions in microtiter plates. The plastic used in these plates is not resistant to organic solvents.

8. Separate the amplified DNA from the residual thermostable DNA polymerase and dNTPs (please see Protocol 3).

The DNA can now be ligated to a blunt-ended vector or a T vector, or it can digested with restriction enzymes and ligated to a vector with compatible termini (please see Protocols 4, 5, and 6).

If problems arise, please see the remedies and variations described for the 5′-RACE reaction (Protocol 9) which apply also to the 3′-RACE procedure.

Protocol 11

Mixed Oligonucleotide-primed Amplification of cDNA

THESE DAYS, THE BEST WAY TO CLONE A GENE WHEN ONLY a fragmentary sequence of the protein is known is to use amino acid sequences to design oligonucleotides that can be used either as probes to screen libraries or to amplify the target sequence by PCR. An obvious problem with both methods is the degeneracy of the genetic code. There are 64 possible codons and only 20 amino acids; most amino acids are represented by more than one codon. Because there are no rules that guarantee selection of the correct codon, a certain sequence of amino acids can be encoded by a large number of different oligonucleotides. Unless the designer is incredibly lucky and chooses the correct codon in every single position, the oligonucleotide will not form a perfect hybrid with the target gene or cDNA.

Oligonucleotide probes used to screen genomic and cDNA libraries by hybridization usually correspond to amino acid sequences that are 5–25 amino acids in length. Because of the degeneracy of the genetic code, there obviously are many thousands of nucleotide sequences that could code for such a sequence of amino acids. Until the advent of PCR-based methods such as mixed oligonucleotide-primed amplification of cDNA (MOPAC), investigators simply made intelligent guesses about the most likely codon used at each position and then synthesized an oligonucleotide probe — a "guessmer" — that incorporated all of these hunches (Lathe 1985). The aim was to generate a probe of sufficient length so that the detrimental effects of the inevitable mismatches were outweighed by the stability of extensive tracts of perfectly matched bases. Guessmers reached their height of popularity in the mid 1980s when fledgling recombinant DNA companies were desperately trying to clone genes of commercial value. For them, serendipity was often handsomely rewarded since the cDNA and genomic DNA clones of many useful and lucrative genes were obtained during this period.

In recent years, however, guessmers have been eclipsed by PCRs primed by degenerate pools of oligonucleotides. These pools are not random samples of all possible sequences that can encode a particular peptide. Rather, they are skewed populations of oligonucleotides that, on statistical grounds, are most likely to correspond to the coding sequence of the authentic gene. In PCRs containing genomic or cDNA templates, there is a good chance that the degenerate pools of oligonucleotides will drive amplification of part of the gene of interest with high specificity. The resulting DNA product is identical in sequence to a segment of the target gene and can be used under conditions of high stringency to probe cDNA and genomic libraries and to detect

homologous sequences in Southern and northern blots. Experience indicates that the MOPAC procedure is more reliable and more sensitive than direct screening of libraries with guessmers. This advantage is chiefly because PCR-based methods such as MOPAC require far shorter tracts of amino acid sequence and because PCR methods are more tolerant of redundancy. Pools of highly degenerate primers (even those consisting of a mixture of 60 or more different oligonucleotides) work well in PCR (Girgis et al. 1988; Knoth et al. 1988; Lee et al. 1988).

In the standard MOPAC procedure, the amino-terminal and carboxy-terminal sequences of a peptide are used to design two redundant families of oligonucleotides encoding the amino- and carboxy-terminal sequences of the peptide (Lee et al. 1988). The primers are used either to amplify a segment of cDNA prepared by RT-PCR from a tissue known to express the protein or to amplify a segment of DNA from an established genomic or cDNA library. Because the length of the peptide is known, the size of the expected PCR product can be predicted exactly. After gel electrophoresis to resolve the amplification products, DNAs of the correct size are isolated, cloned, and sequenced. At least some of the clones should contain a DNA segment of the correct length that specifies the sequence of the starting peptide. Once identified, the entire cloned segment or the unique sequence lying between the two oligonucleotide primers is used as a probe to screen a cDNA library. Variations on this general protocol involve:

- ***Using degenerate oligonucleotide primers derived from two separate peptide sequences,*** each at least 6–7 amino acids in length, to amplify the segment of DNA that codes for the tract of amino acids located between the two peptides. Since in many cases, the relative orientation of the peptides in the protein will be unknown, pools of degenerate oligonucleotides derived from both strands of the DNA must be synthesized and used in different combinations. The length of the amino acid sequence lying between the two peptides may also be unknown, which eliminates the possibility of purifying a PCR product of the correct length prior to cloning.
- ***Using only one degenerate primer in combination with a unique primer*** that binds to flanking sequences in the cloning vector or to a synthetic homopolymeric tail attached to first-strand cDNA. The chief problem with this approach is the high background of clones that results from using a primer that recognizes every clone in a library. If sufficient amino acid sequence is available, a second set of oligonucleotides can be used to prime a nested PCR using DNA templates generated by the original outer primer pair.

The crucial step in MOPAC is the design of degenerate pools of oligonucleotides. Although no rules exist that guarantee selection of the correct codon at a position of ambiguity, the chance of success can be increased by following these simple rules.

- ***Use the region of the available amino acid sequence*** that has the least degeneracy. If possible, choose a region that is rich in Met and Trp, each of which has one codon. Cys, Asp, Glu, Phe, His, Lys, Gln, and Tyr are also desirable amino acids because they each have only two codons. Avoid regions rich in Leu, Arg, and Ser (each specified by six codons).
- ***Design the longest primers possible*** without allowing the number of oligonucleotides in the degenerate pool to exceed 64. The specificity of primers reduces markedly when their length is <17 nucleotides. Both the efficiency and specificity of priming by degenerate pools of oligonucleotides decrease as a function of their complexity.
- ***Consult tables of codon usage*** (Wada et al. 1992; please see Appendix 7). For amino acids specified by three or more codons, use the two codons that are most prevalent in genes of the organism under study.

- ***When necessary, limit the degeneracy of primers*** by using a universal nucleotide such as inosine, whose neutral base, hypoxanthine, forms stable base pairs with cytosine, thymine, and adenine (please see the information panel on the **USE OF INOSINE IN DEGENERATE POOLS OF OLIGONUCLEOTIDES USED FOR PCR**).
- ***Wherever possible, end the oligonucleotides*** at a Met or Trp residue. This strategy guarantees that the three nucleotides at the 3′ ends of all of the oligonucleotides in the degenerate pool will form an exact match with the target sequence precisely. Alternatively, end the oligonucleotides at the second position of a codon specifying Cys, Asp, Glu, Phe, His, Lys, Gln, or Tyr. This strategy guarantees that the two bases at the 3′ ends of all of the oligonucleotides will match the target sequence. Do not use inosine at the 3′ end of the degenerate oligonucleotides (Sommer and Tautz 1989). As with other types of PCR, the 5′ end of the degenerate oligonucleotides may be designed to carry restriction sites and other useful features.

The DNA template for MOPAC reactions can consist of cDNA prepared from a source that expresses the target protein, genomic DNA, or total DNA from a cDNA or genomic library (representing at least 10^5 to 10^6 clones) that is thought to contain the cDNA or gene of interest. If there is uncertainty regarding the tissue specificity of a particular mRNA, start with cDNA prepared from a tissue with a high complexity of transcribed genes, such as the mammalian brain (Sutcliffe 1988) or from a source of germ cells (e.g., mammalian testes; Strathmann et al. 1989). In the case of cDNA libraries cloned in bacteriophage λ vectors, an aliquot of the bacteriophage preparation itself can sometimes be amplified without purification of the DNA. However, in general, the cleaner the input template, the more efficient the MOPAC reaction. It is essential to remove any primers used to generate the cDNA template by centrifugation through Centricon-100 microconcentrators (Protocol 3) before carrying out the MOPAC reaction.

Finally, pools of highly degenerate primers can be used for purposes other than to clone genes from fragmentary protein sequences, including isolation of members of multigene families from a particular species (e.g., please see Buck and Axel 1991) and isolation of the homologous genes from diverse species (please see the section below, Screening of Libraries for Related Genes Using MOPAC; for reviews, please see Preston 1993; Peterson and Tjian 1993). Highly degenerate primers may also be used for rapid amplification of cDNA ends (5′- and 3′-RACE) (please see Protocols 9 and 10) (Frohman et al. 1988).

SCREENING OF LIBRARIES FOR RELATED GENES USING MOPAC

Variations on the MOPAC theme can be used to isolate members of a multigene family (e.g., please see Buck and Axel 1991), homologs from evolutionarily distant species (e.g., please see Lewis and Pelham 1990), or isozymes (e.g., please see Strathmann et al. 1989). For such purposes, oligonucleotides representing amino acid sequences conserved between members of protein families are used as primers to screen cDNA or genomic libraries. The exact size of the desired product cannot be predicted with confidence because insertions and deletions may have occurred during evolution of the target gene. However, amplified products that fall within a chosen size range can be isolated and analyzed. In the design of the oligonucleotide primers and the choice of starting template, reasonable assumptions can be made concerning the positions of introns if a gene structure of a family member or homolog is known.

MATERIALS

▲ **IMPORTANT** To reduce the chance of contamination with exogenous DNAs, prepare and use a special set of reagents and solutions for PCR only. Bake all glassware for 6 hours at 150°C and autoclave all plasticware. For more information, please see the panel on **CONTAMINATION IN PCR** in the chapter introduction.

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

10x Amplification buffer

dNTP solution (20 mM) containing all four dNTPs (pH 8.0)

Enzymes and Buffers

Thermostable DNA polymerase

Taq DNA polymerase is the standard and appropriate enzyme for the amplification stage of most forms of RT-PCR. However, where elongation from 3′-mismatched primers is suspected, a thermostable DNA polymerase with 3′→5′ proofreading activity may be preferred (Chiang et al. 1993).

Gels

Polyacrylamide gel **<!>**

Please see Step 4.

Nucleic Acids and Oligonucleotides

DNA template (100 μg/ml) (cDNA, genomic DNA, or cDNA library) in TE (pH 8.0)

Any DNA that contains the target sequence(s) can be used as a template in MOPAC reactions. Genomic DNA, uncloned preparations of cDNA, or cDNAs extracted from established libraries have all been used successfully. However, the chance of success increases as a function of the concentration of target sequences in the preparation. Thus, cDNAs prepared from mRNAs that contain the target sequence in abundance are more likely to succeed than the corresponding genomic DNAs. As in all forms of PCR, the cleaner the template DNA, the more efficient the amplification. Nevertheless, in the case of cDNA libraries cloned in bacteriophage λ vectors, an aliquot of the bacteriophage preparation itself can sometimes be used as a template without further purification of the DNA. Before carrying out the MOPAC, it is essential to remove any primers (such as oligo[dT]) that were used to prime synthesis of cDNA templates (for details, please see Protocol 3).

Family of antisense oligonucleotide primers (10 μM) in TE (pH 8.0)

Oligonucleotide primers synthesized on an automated DNA synthesizer can generally be used in standard RT-PCR without further purification. However, amplification of low-abundance mRNAs is often more efficient if the oligonucleotide primers are purified by chromatography on commercially available resins (e.g., NENSORB, NEN Life Science Products) or by denaturing polyacrylamide gel electrophoresis, as described in Chapter 10, Protocol 1.

For details on the use of primers containing inosine, please see the information panel on **USE OF INOSINE IN DEGENERATE POOLS OF OLIGONUCLEOTIDES USED FOR PCR**.

Family of sense oligonucleotide primers (10 μM) in TE (pH 8.0)

Special Equipment

Barrier tips for automatic micropipettes

Microfuge tubes (0.5 ml, thin-walled for amplification) or Microtiter plates

Positive-displacement pipette

Thermal cycler programmed with desired amplification protocol

If the thermal cycler is not equipped with a heated lid, use either mineral oil or paraffin wax to prevent evaporation of liquid from the reaction mixture during PCR.

Additional Reagents

Step 4 of this protocol requires the reagents listed in Chapter 5, Protocol 2, and Chapter 12, Protocol 6.

METHOD

1. In a sterile 0.5-ml microfuge tube, amplification tube, or the well of a sterile microtiter plate, mix in the following order:

0.5 µg of template DNA	5 µl
10x amplification buffer	5 µl
20 mM solution of four dNTPs	5 µl
10 µM sense primer family (70 pmoles)	7 µl
10 µM antisense primer family (70 pmoles)	7 µl
1–2 units thermostable DNA polymerase	1 µl
H_2O	to 50 µl

Set up several control reactions. In one reaction, include all of the above components, except the template DNA. In two other reactions, include all the components minus one or the other of the oligonucleotide primers.

These controls show whether amplified DNAs arise from a single primer, information that is remarkably useful if the desired product is not detected and new families of degenerate primers are required (Bernasconi et al. 1989).

2. If the thermal cycler is not fitted with a heated lid, overlay the reaction mixtures with 1 drop (~50 µl) of light mineral oil. Alternatively, place a bead of paraffin wax into the tube if using a hot start protocol. Place the tubes or the microtiter plate in the thermal cycler.

3. Amplify the nucleic acids using the denaturation, annealing, and polymerization times and temperatures listed in the table.

Cycle Number	Denaturation	Annealing	Polymerization
First cycle	5 min at 94°C	2.5 min at 40°C	5 min at 50°C
Subsequent cycles (35)	1.5 min at 94°C	2.5 min at 40°C	5 min at 50°C

These times are suitable for 50-µl reactions assembled in thin-walled 0.5-ml tubes and incubated in thermal cyclers such as the Perkin-Elmer 9600 or 9700, Master Cycler (Eppendorf), and PTC 100 (MJ Research). Times and temperatures may need to be adapted to suit other types of equipment and reaction volumes.

The amplification conditions described above are based on 32-member degenerate families of oligonucleotide primers that are 17–20 bases in length. Higher annealing and polymerization temperatures can be used with longer and/or less complex mixtures of oligonucleotides. However, if too many amplification products are obtained, or if no specific products are synthesized, optimum annealing and polymerization temperatures, as well as cycle number and ionic conditions, should be determined in a series of test reactions.

The specificity of MOPAC can be increased (i) by using a thermal cycler program that includes a temperature ramping protocol (Kolodkin et al. 1993), (ii) by using touchdown PCR (Don et al. 1991; please see the information panel on **TOUCHDOWN PCR**), or (iii) by incorporating cosolvents into the amplification reactions.

4. Withdraw a sample (5–10 µl) from the test reaction mixture and the control reactions and analyze them by electrophoresis through a neutral polyacrylamide gel. Be sure to include DNA markers of an appropriate size. Stain the gel with ethidium bromide or SYBR Gold to visualize the DNA.

A successful amplification reaction should yield a readily visible DNA fragment of the expected size. The identity of the band can be confirmed by DNA sequencing (please see Chapter 12, Protocol 6). If the band of interest is only one of a number of amplified fragments, please see the panel on **BAND-STAB PCR**.

If a single contiguous amino acid sequence was used to design both sense and antisense primers for the MOPAC reaction, the exact size of the desired product will be known. In most cases, thin polyacrylamide gels (≤6%) should allow size fractionation at nucleotide resolution and unambiguous identification of the desired product. Once identified, the product can be end-labeled (Chapter 9, Protocol 14) and subjected to chemical sequencing (Chapter 12, Protocol 7) to determine a unique sequence linking the two families of oligonucleotide probes. This unique sequence can in turn be synthesized and used as a probe to isolate longer cDNAs. Alternatively, the MOPAC product itself can be radiolabeled during a second round of PCR and used as a probe. If restriction sites are incorporated at the 5′ ends of the starting oligonucleotide primers, then the amplified product can easily be cloned after digestion with the appropriate enzyme into appropriate plasmid or bacteriophage vectors. Blunt-ended fragments can be cloned as indicated in Protocol 4.

5. If mineral oil was used to overlay the reaction (Step 2), remove the oil from the sample by extraction with 150 µl of chloroform.

The aqueous phase, which contains the amplified DNA, will form a micelle near the meniscus. The micelle can be transferred to a fresh tube with an automatic micropipette.

For many purposes, e.g., purification of the amplified DNA using a Centricon microconcentrator or cloning amplification products, it is desirable to remove the oil from the sample before proceeding.

▲ **IMPORTANT** Do not attempt chloroform extractions in microtiter plates. The plastic used in these plates is not resistant to organic solvents.

BAND-STAB PCR

Amplification of DNA using MOPAC often generates a number of products of differing molecular weights. Many of these DNAs are irrelevant and unwanted since they are generated by nonspecific priming; others may contain the desired target sequences. In some cases, when a suitable probe is available, the desired fragment(s) can be located by Southern hybridization; in others, all of the amplified bands must be recovered and tested individually. This sampling is best achieved by Band-Stab PCR (Bjourson and Cooper 1992) as described below.

After the agarose gel has been stained with ethidium bromide and analyzed by UV illumination, remove excess fluid by placing a piece of Whatman 3MM paper on the surface for a few seconds. Remove the damp paper and sample each band of interest by stabbing perpendicularly into the gel with the beveled tip of a 21-gauge hypodermic needle. Be careful to avoid parallax errors and use a fresh needle for each band. Withdraw the needle from the gel and then wash the tip in a fresh PCR mixture and reamplify the band of DNA. Whenever possible, reamplification should be carried out using nested PCR.

When recovering bands from polyacrylamide gels by band-stab PCR, *do not use* Whatman 3MM paper to dry the surface of the gel. Instead, carefully remove as much fluid as possible by gentle wiping with a gloved hand. Then use a needle to transfer a small fragment of polyacrylamide containing the band of interest to the fresh PCR. Allow the template DNA to diffuse into the reaction mixture for an hour or two before beginning the amplification.

Protocol 12

Rapid Characterization of DNAs Cloned in Prokaryotic Vectors

THE POLYMERASE CHAIN REACTION CUTS THE TIME REQUIRED to characterize segments of cDNA cloned in bacteriophage λ and plasmid vectors from several days to a few hours, with a commensurate reduction in effort (Güssow and Clackson 1989; Dorfman 1993; Costa and Weiner 1995). Transformed bacterial cells or bacteriophage λ particles can be picked from colonies or plaques and transferred directly into the PCR mixtures lacking thermostable DNA polymerase but containing primers targeted to vector sequences immediately flanking the putative segment of cloned DNA. The reaction mixtures are heated to boiling to liberate template DNA and to inactivate nucleases and proteases. A thermostable DNA polymerase is then added and ~30 cycles of standard PCR are performed. A successful amplification reaction yields a DNA fragment whose size can be estimated by agarose gel electrophoresis and whose identity can be confirmed by DNA sequencing (Chapter 12), Southern hybridization (Chapter 6), and/or restriction mapping.

Many colonies or plaques can be assayed simultaneously and, because the technique is so rapid, there is usually no need to store large numbers of candidate clones for extended periods of time. The method can easily be adapted to screen cDNA libraries in a stepwise fashion (please see Chapter 11), to work out the orientation of foreign segments of DNA within individual recombinant clones, and to generate templates for DNA sequencing (Krishnan et al. 1991). Finally, the technique can be extended to eukaryotic cells and used, for example, to analyze gene disruptions in yeasts (please see the additional protocols at the end of this protocol) and to identify clones of murine ES cells that have undergone modification by homologous recombination (Loukianov et al. 1997). For further details, please see the additional protocols at the end of this protocol.

The following protocol, modified from Saiki et al. (1988), Güssow and Clackson (1989), and Sandhu et al. (1993), was provided by Diane F. Jelinek (Mayo Clinic, Rochester, Minnesota).

MATERIALS

▲ **IMPORTANT** To reduce the chance of contamination with exogenous DNAs, prepare and use a special set of reagents and solutions for PCR only. Bake all glassware for 6 hours at 150°C and autoclave all plasticware. For more information, please see the panel on **CONTAMINATION IN PCR** in the chapter introduction.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

10x Amplification buffer

dNTP solution (20 mM) containing all four dNTPs (pH 8.0)

Tris-Cl (10 mM, pH 7.6)

Enzymes and Buffers

Thermostable DNA polymerase

Gels

Agarose gel

Please see Step 9.

Nucleic Acids and Oligonucleotides

Forward primers (20 μM) in H_2O and Reverse primers (20 μM) in H_2O (20 pmoles/μl)

Oligonucleotide primers used for sequencing DNA segments cloned into most common prokaryotic and eukaryotic vectors may be purchased commercially or synthesized locally. For details, please see the information panel on **UNIVERSAL PRIMERS** and the accompanying tables of primer sequences.

Oligonucleotide primers synthesized on an automated DNA synthesizer can generally be used to screen bacteriophage λ plaques or lysed bacterial colonies in PCR without further purification.

Template DNAs

This method uses unpurified templates obtained by cracking bacteriophage λ particles or transformed bacterial cells. Essentially the same methods can be used to analyze viral DNAs in productively infected mammalian or yeast cells transformed by multicopy vectors. For further details, please see the panels on **ADDITIONAL PROTOCOL: SCREENING YEAST COLONIES BY PCR** and **ADDITIONAL PROTOCOL: SCREENING BACTERIOPHAGE λ LIBRARIES**.

Special Equipment

Barrier tips for automatic micropipettes

Boiling water bath

Microfuge tubes (0.5 ml) or Microtiter plates

Positive-displacement pipette

Thermal cycler programmed with desired amplification protocol

If the thermal cycler is not equipped with a heated lid, use either mineral oil or paraffin wax to prevent evaporation of liquid from the reaction mixture during PCR.

Additional Reagents

Step 9 of this protocol may require the reagents listed in Chapter 5, Protocol 2, and Chapter 6, Protocol 10.

METHOD

Screening Individual Bacterial Colonies or Bacteriophage λ Plaques

1. Calculate the number of bacterial colonies or bacteriophage λ plaques that are to be screened. Prepare the appropriate amount of master mix; analysis of each colony or plaque requires 25 µl of master mix; *1 ml of master mix contains:*

10x amplification buffer	100 µl
20 mM solution of four dNTPs	50 µl
forward primer	1 nmole
reverse primer	1 nmole
H_2O	to 1 ml

2. Dispense 25-µl aliquots of the master mix into the appropriate number of amplification tubes.

3. Use a sterile 200-µl pipette tip (NOT a toothpick) to touch each bacterial colony or bacteriophage λ plaque. Working quickly, wash the pipette tip in 25 µl of master mix.

   Please see the panel on **TROUBLESHOOTING** following Step 9.

4. Close the caps of the tubes. Incubate the closed tubes in a boiling water bath for 10 minutes (bacterial colonies) or 2 minutes (bacteriophage λ plaques).

   When screening bacterial colonies, it is important not to skimp on this step, which is required to liberate and denature the DNA templates and to inactivate proteases and nucleases. Bacteriophage λ plaques, by contrast, do not always require boiling. In some protocols (e.g., please see Dorfman 1993), individual plaques are transferred directly into complete reaction mixtures, which are then used immediately in conventional PCR. In our hands, however, boiling for a short time before the addition of *Taq* DNA polymerase improves the consistency of the method and enhances the yield of amplified product.

5. While the tubes are incubating, dilute the required amount of *Taq* DNA polymerase to a concentration of 1 unit/µl in 10 mM Tris (pH 7.6). Store the diluted enzyme on ice until needed.

6. Allow the samples (from Step 4) to cool to room temperature. Centrifuge the tubes briefly to deposit all of the fluid in the bottom and then add 1 µl of the diluted *Taq* DNA polymerase to each tube.

7. Set up two control reactions. In one reaction, include all of the components, except the template DNA. In the other reaction, include a recombinant bacteriophage λ plaque or transformed bacterial lysate that has previously produced a positive result in this assay. The fragment amplified in the positive control reaction should be larger than the fragment expected in the test reactions. Successful amplification of the larger, control fragment provides some assurance that the thermostable DNA polymerase is capable of amplifying fragments of the appropriate length.

8. If the thermal cycler does not have a heated lid, overlay the reaction mixtures with 1 drop (~50 µl) of light mineral oil. Place the tubes in the thermal cycler. Amplify the nucleic acids using the denaturation, annealing, and polymerization times and temperatures listed in the table.

Cycle Number	Denaturation	Annealing	Polymerization
30 cycles	1 min at 94°C	2 min at 50°C	2 min at 72°C

These times are suitable for reactions assembled in thin-walled 0.5-ml tubes and incubated in thermal cyclers such as the Perkin-Elmer 9600 or 9700, Master Cycler (Eppendorf), and PTC 100 (MJ Research). Times and temperatures may need to be adapted to suit other types of equipment and reaction volumes.

9. Withdraw a sample (5–10 μl) from the test reaction mixture and the control reactions and analyze them by electrophoresis through an agarose gel. Be sure to include DNA markers of an appropriate size. Stain the gel with ethidium bromide or SYBR Gold to visualize the DNA.

   A successful amplification reaction should yield a readily visible DNA fragment. Nonrecombinant PCR products will be equal to the length of DNA between the locations of the 5′ termini of the two primers in the cloning vector. Recombinant PCR products will be the sum of (i) the length of the insert and (ii) the distance between the 5′ termini of two primers in the vector. If necessary, the identity of the band can be confirmed by restriction mapping and Southern hybridization.

   The technique can be easily adapted to screen large numbers of bacterial colonies or bacteriophage M13 clones by setting up PCRs in 96-well microtiter dishes (Trower 1996).

TROUBLESHOOTING

The chief causes of failure with this method are (i) the addition of too much bacterial lysate, which may alter the ionic balance of the reaction and (ii) the accidental inclusion of agar fragments in the reaction mixture, which may inhibit amplification by the thermostable DNA polymerase. Because only a few hundred molecules of template DNA are required, avoid overloading the reaction with template when sampling plaques and colonies.

The absence of a PCR product in the control and test reactions may indicate that the insert is simply too large to amplify efficiently. In this case, a preparation of thermostable DNA polymerase capable of amplifying longer templates can be used instead of conventional *Taq* DNA polymerase. Alternatively, a primer specific to the insert can be used in place of one of the vector-specific primers. The orientation of the cloned segment within the vector can be ascertained by using an insert-specific primer with primers from each of the flanking regions of the vector.

ADDITIONAL PROTOCOL: SCREENING YEAST COLONIES BY PCR

Additional Materials

Boiling water bath
Yeast colonies

Method

1. Use a sterile 200-μl pipette tip to transfer a small amount of a yeast colony that has been growing for 2–4 days to an amplification tube containing 50 μl of PCR master mix (please see Step 1 of the main protocol). Resuspend the cells by pipetting up and down five times.
2. Boil the suspension of yeast cells for 5 minutes.
3. Proceed with Steps 5–9 of the main protocol.

   Some investigators (e.g., please see Huxley et al. 1990; Sathe et al. 1991) omit the boiling step and proceed directly to PCR after suspending the cells in master mix containing a thermostable DNA polymerase. Other investigators (Ling et al. 1995) lyse the cells with zymolyase before setting up the PCR. In our experience, the boiling step increases the efficiency of PCR, whereas converting cells to spheroplasts with zymolyase is unnecessary and, in our hands, gives erratic results.

ADDITIONAL PROTOCOL: SCREENING BACTERIOPHAGE λ LIBRARIES

Screening bacteriophage λ libraries for clones of interest is usually carried out according to the Benton-Davis method of hybridization (Benton and Davis 1977). However, PCR can also be used to find out whether a given library contains a desired clone and to screen cDNA libraries in a stepwise fashion for one or more targets (e.g., please see Griffin et al. 1993; Israel 1993; McAlinden and Krawetz 1994; Watanabe et al. 1997; for review, please see Yu and Bloem 1996). The technique is particularly useful when screening cDNA libraries for clones that contain sequences from the 5′ or 3′ ends of cDNA.

Additional Materials

Bacteriophage λ library
Boiling water bath
Nitrocellulose filters (132 mm)
Petri dishes (150 mm)
SM

Method

1. Plate the bacteriophage λ library in top agarose on 150-mm plates as described in Chapter 2, Protocol 1. Incubate the plates and transfer the colonies onto numbered nitrocellulose filters as described in Steps 4–6 of Protocol 21 (Chapter 2). There is no need to key the filters to the plates.

   Nitrocellulose filters are preferred to nylon filters since they are less expensive. Charged nylon filters should not be used because the bacteriophage λ particles stick so tightly that they cannot easily be washed free.

2. Use blunt-ended forceps to remove the filters carefully one by one. Place each filter in a separate 150-mm dish containing 3–5 ml of SM. Jiggle the filter to encourage the bacteriophage particles to float into the fluid phase. Remove the filter and hold it over the dish until no more bacteriophage suspension drips from the filter. Discard the filter.

   Wrap the numbered agar plates in Saran Wrap. Store the plates at 4°C.

3. Transfer the bacteriophage suspension to a sterile, labeled tube. Use a separate tube for each plate.

   These tubes provide a source of material that can be screened many times without further plating of the library.

4. Transfer 25 μl of each of the bacteriophage suspensions to an amplification tube. Close the tube and heat it in a boiling water bath for 5 minutes.

5. Chill the boiled suspension in ice and then use 5 μl of the supernatant as a template in PCRs primed by oligonucleotides that are specific for the target sequence.

   When screening libraries for clones containing the 5′ or 3′ sequences of cDNAs, one of the primers should anneal to the appropriate flanking vector sequences and the other should anneal to the desired region of the target gene.

   Wherever possible, include both positive and negative controls with each batch of PCRs. For example, each of the bacteriophage suspensions can be spiked with a known amount of a purified clone. Sets of primers specific for the known clone and the target clone can then be used simultaneously in the same PCR.

6. After a desired recombinant has been identified, replate the appropriate bacteriophage suspension(s). Plate enough bacteriophages to obtain fivefold coverage of the subpopulation of the library. Transfer the bacteriophages to a nitrocellulose filter that has been previously marked into 12 or more sectors. Before removing the filter from the plate, orient the filter to the plate and mark the locations of the sectors on the bottom of the plate.

   Wrap the sectored agar plate in Saran Wrap. Store the plate at 4°C.

7. Transfer the nitrocellulose filter (bacteriophage side uppermost) to a sterile Petri dish. Working quickly, cut the filter into sectors and recover the bacteriophage particles from each segment in ~0.5 ml of SM.

8. Using ~25 μl of each of the secondary suspensions (Step 7), repeat Steps 4 and 5 to detect the desired recombinant by PCR.

   Continue this step-wise analysis for one or two more rounds, until the calculated complexity of the last suspension is $<10^4$ recombinant bacteriophages. At this stage, the suspension should be plated onto 10–20 plates at a density of ~2500 pfu/plate. The resulting plaques should be screened by conventional Benton-Davis hybridization to identify and isolate the clone of interest (please see Chapter 2, Protocol 22). If necessary, the sectored agar plates (Step 6) can be used as an additional source of bacteriophages.

   A similar stepwise procedure can be used to screen cDNA libraries constructed in plasmid vectors (Trower 1996; Takumi 1997).

Protocol 13

Long PCR

UNDER STANDARD REACTION CONDITIONS, PCR IS EASILY CAPABLE of amplifying segments of DNA 1–2 kb in length. This capacity is sufficient for many routine manipulations of DNA (e.g., sequencing and mutagenesis), but it is not enough to amplify an entire mammalian gene — even one of modest size — nor a cDNA of average dimensions. Explanations proposed for the inability of standard PCR to amplify long segments of DNA include:

- ***Damage to the template and product DNAs*** during exposure to high temperature in buffers that may not adequately maintain control over pH.
- ***The presence of stray divalent cations*** (Mn^{2+} is always the prime suspect) that may promote cleavage of DNA at high temperature.
- ***Difficulties in denaturing very long DNA molecules*** during the heating step of the PCR cycle.
- ***The inability of DNA polymerases to remain attached*** to the template DNA, particularly in regions of secondary structure.
- ***The high rate of incorporation of incorrect bases*** by thermostable polymerases such as *Taq* that lack an editing function. The incorporation of a mismatched base at the 3′ end of a growing strand may cause the enzyme to seize up and may limit the size of the PCR product.

Four of these problems were fixed (at least in part) by simple adjustments to the reaction conditions (for review, please see Foord and Rose 1994). The fifth, however, required an original thought. Wayne Barnes (1994) realized that the obstacles created by mismatched 3′ termini could be eliminated by using two different thermostable DNA polymerases to catalyze the amplification reaction. One of the polymerases would be an efficient but error-prone workhorse (Klentaq1, in Barnes' case), whereas the second, used in much smaller amounts, would provide a 3′→5′ exonuclease function that would resect mismatched ends (e.g., *Pfu*). These improvements have become embodied in cocktails, sold by a number of manufacturers (e.g., TaqPlus Long PCR System, Stratagen; Expand Long Template PCR System, Boehringer Mannheim), that generate high yields from long targets.

The following protocol, supplied by Rob Rawson (University of Texas Southwestern Medical Center, Dallas) can be used to amplify DNA over the entire length (up to 25 kb) of genomic DNA segments cloned in bacteriophage λ vectors or smaller segments (10–12 kb) of preparations of total mammalian DNA.

MATERIALS

▲ **IMPORTANT** To reduce the chance of contamination with exogenous DNAs, prepare and use a special set of reagents and solutions for PCR only. Bake all glassware for 6 hours at 150°C and autoclave all plasticware. For more information, please see the panel on **CONTAMINATION IN PCR** in the chapter introduction.

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Chloroform <!>

dNTP solution (20 mM) containing all four dNTPs (pH 8.0)

10x Long PCR buffer

500 mM Tris-Cl (pH 9.0 at room temperature)
160 mM ammonium sulfate
25 mM $MgCl_2$
1.5 mg/ml bovine serum albumin

Sterilize the 10x buffer by filtration through an 0.22-μm membrane. Divide the sterile buffer into aliquots and store the aliquots at –20°C.

Higher concentrations of Tris are used to maintain correct pH during the long extension times required for amplification of long templates (Ohler and Rose 1992). The pH of the stock solution is also increased to 9.0 (at room temperature) to compensate for the large downward shift in pK_a that occurs when Tris buffers are heated (Good et al. 1966; Ferguson et al. 1980); for further details, please see Appendix 1. Alternatively, Tris can be replaced by Tricine (pH 8.4 at room temperature; final concentration 30 mM) (Ponce and Micol 1991). The temperature dependence of the pK_a of Tricine buffers is far less than that of Tris (Good and Izawa 1972).

KCl (100 mM) can be used in place of ammonium sulfate in the 10x long PCR buffer, and gelatin can be used at a concentration of 0.01% in the final reaction in place of bovine serum albumin.

Additional components reported by Foord and Rose (1994) to improve the efficiency of long PCR include *glycerol* at a concentration of 5% (v/v) in the final reaction mixture to promote separation of DNA strands at lower temperatures, and *EDTA* at a concentration of 0.75 mM in the final reaction mixture to chelate divalent cations such as Mn^{2+} that might promote scission of DNA strands.

Enzymes and Buffers

Thermostable DNA polymerase mix

Klentaq1 can be obtained from AB Peptides (St. Louis, Missouri), and *Pfu* polymerase can be obtained from Stratagene. A typical mixture contains 0.187 unit of *Pfu* and 33.7 units of Klentaq1 in a total volume of 1.2 μl (Foord and Rose 1994).

Gels

Agarose gel

Please see Step 4.

Nucleic Acids and Oligonucleotides

Template DNA

Long PCR works well on a variety of templates including recombinant PACs, BACs, cosmids, and bacteriophage λ clones, as well as high-molecular-weight genomic DNAs. However, the quality of the DNA is paramount. The average length of the template DNAs (assayed by agarose gel or pulsed-field gel electrophoresis) should be at least three times greater than the length of the desired PCR product. The DNAs should also be extensively purified to reduce the concentration of inhibitors. It may seem to be outmoded, slow, and expensive, but in our hands, the best way to prepare genomic DNAs for long PCR is by equilibrium density centrifugation in CsCl gradients, followed by dialysis against TE (pH 8.0) (please see Chapter 1, Protocol 10).

Forward primers (20 μM) in H_2O and Reverse primers (20 μM) in H_2O (20 pmoles/μl)

The rules for the design of primers (please see Design of Oligonucleotide Primers for Basic PCR in the introduction to this chapter) must be followed closely. However, primers used for long PCR are generally slightly longer (25–30 nucleotides) than those used for standard PCR. It is particularly important to strive for equality between the melting temperatures of the two primers. If the difference in melting temperatures exceeds one centigrade degree, mispriming and preferential amplification of one strand may become a problem.

Oligonucleotide primers synthesized on an automated DNA synthesizer can sometimes be used successfully in long PCR without further purification. However, amplification is usually more efficient if the oligonucleotide primers are purified by chromatography on commercially available resins (e.g., NENSORB, NEN Life Science Products) or by denaturing polyacrylamide gel electrophoresis, as described in Chapter 10, Protocol 1.

Special Equipment

Barrier tips for automatic micropipettes

Microfuge tubes (0.5 ml, thin-walled for amplification)

Positive-displacement pipette

Thermal cycler programmed with desired amplification protocol

If the thermal cycler is not equipped with a heated lid, use either mineral oil or paraffin wax to prevent evaporation of liquid from the reaction mixture during PCR.

Additional Reagents

Step 4 of this protocol requires the reagents listed in Chapter 5, Protocol 2, and Chapter 6, Protocol 10.

METHOD

1. In a thin-walled amplification tube, add and mix in the following order:

10x long PCR buffer	5 μl
20 mM solution of four dNTPs	5 μl
20 mM forward primer	1 μl
20 mM reverse primer	1 μl
thermostable DNA polymerase mix	0.2 μl
template DNA	100 pg to 2 μg
H_2O	to 50 μl

Templates purified from individual recombinant clones constructed in bacteriophage λ, cosmid, bacteriophage P1, PAC, and BAC vectors should be used in amounts ranging from 100 pg to 300 ng. Larger amounts of total genomic DNAs are required, usually between 100 ng and 1 μg per reaction. In long PCR, there is little flexibility in the amount of template used in the reaction. Too little and no product is detectable; too much and the loss of specificity can be dramatic. The optimum amount of template and the optimum ratio of primers:template should be ascertained empirically for each new preparation of DNA.

2. If the thermal cycler is not fitted with a heated lid, overlay the reaction mixtures with 1 drop (~50 μl) of light mineral oil. Alternatively, place a bead of paraffin wax into the tube if using a hot start PCR. Place the tubes or the microtiter plate in the thermal cycler. Amplify the nucleic acids using the denaturation, annealing, and polymerization times and temperatures listed in the table.

Cycle Number	Denaturation	Annealing	Polymerization
24 cycles	1 min at 94°C	1 min at 60–67°C	5–20 min at 68°C

These times are suitable for 50-μl reactions assembled in thin-walled 0.5-ml tubes and incubated in thermal cyclers such as the Perkin-Elmer 9600 or 9700, Master Cycler (Eppendorf), and PTC 100 (MJ Research). Times and temperatures may need to be adapted to suit other types of equipment and reaction volumes.

The temperature used for the annealing step depends on the melting temperature of the oligonucleotide primers. Because the primers used in long PCR are generally 27–30 nucleotides in length, the annealing temperatures used in long PCR can be considerably higher than those used in standard PCR.

Polymerization should be carried out for 1 minute for every 1000 bp of length of the target DNA. Foord and Rose (1994) recommend increasing the polymerization time by 30 seconds in each cycle of PCR. However, in our hands, extension of the polymerization time has not led to any improvements in specificity or yield.

3. If mineral oil was used to overlay the reaction (Step 2), remove the oil from the sample by extraction with 150 µl of chloroform.

   The aqueous phase, which contains the amplified DNA, will form a micelle near the meniscus. The micelle can be transferred to a fresh tube with an automatic micropipette.

   ▲ **IMPORTANT** Do not attempt chloroform extractions in microtiter plates. The plastic used in these plates is not resistant to organic solvents.

4. Analyze an aliquot of the aqueous phase by electrophoresis through an agarose gel using markers of an appropriate size. In many cases, the amount of amplified product may be too small to be detected by conventional staining with ethidium bromide. In this case, stain the DNA in the gel with SYBR Gold or transfer to a nylon or nitrocellulose filter and probe by Southern hybridization (please see Chapter 6, Protocol 10).

   Although long PCR is more demanding than standard PCR, it does not differ in any essential principle. The problems with long PCR and standard PCR are similar and almost always involve specificity and yield. In the vast majority of cases, these can be solved by careful optimization of all phases of the reaction (please see Tables 8-4 and 8-5 in Protocol 1).

Protocol 14

Inverse PCR

STANDARD PCR AMPLIFIES SEGMENTS OF DNA that lie between two inward-pointing primers. By contrast, inverse (also known as inverted or inside-out) PCR is used to amplify and clone unknown DNA that flanks one end of a known DNA sequence and for which no primers are available. The technique, developed independently by several groups (Ochman et al. 1988; Triglia et al. 1988; Silver and Keerikatte 1989), involves digestion by a restriction enzyme of a preparation of DNA containing the known sequence and its flanking region (please see Figure 8-7). The individual restriction fragments (many thousands in the case of total mammalian genomic DNA) are converted into circles by intramolecular ligation, and the circularized DNA is then used as a template in PCR. The unknown sequence is amplified by two primers that bind specifically to the known sequence and point in opposite directions.

The product of the amplification reaction is a linear DNA fragment containing a single site for the restriction enzyme originally used to digest the DNA. This site marks the junction between the previously cloned sequence and the flanking sequences. The size of the amplified fragment depends on the distribution of restriction sites within known and flanking DNA sequences. By setting up reactions with template DNA that has been cleaved by different restriction enzymes, as much as 4 kb of flanking DNA can be recovered by inverse PCR (Jones and Winistorfer 1993). Both upsteam and downstream flanking regions can be obtained in a single inverse PCR by using a restriction enzyme that does not cleave within the known DNA sequence.

Inverse PCR has been used chiefly to generate end-specific probes for chromosome walking (Garza et al. 1989; Silverman et al. 1989; Silverman 1993, 1996), to clone unknown cDNA sequences from total RNA (Huang et al 1990, 1993), and to recover integration sites used by viruses, transgenes, and transposons (Ochman et al. 1988, 1990, 1993; Triglia et al. 1988; Silver and Keerikatte 1989). However, inverse PCR remains one of the more problematic techniques in molecular cloning and success is not guaranteed. Because the method works best with DNA templates whose sequence complexity is $<10^9$ bp, it is unlikely that inverse PCR will work when total mammalian genomic DNA is used as a template. To increase the chance of success, genomic DNA can be fractionated according to size after digestion with a restriction enzyme, or genomic DNA libraries can be subdivided into aliquots whose sequence complexity is $<10^9$ bp. The use of nested sets of primers in sequential reactions can also help (Takagi et al. 1992).

The following protocol, an amalgam of several reported in the literature, was provided by Dennis McKearin (University of Texas Southwestern Medical Center, Dallas).

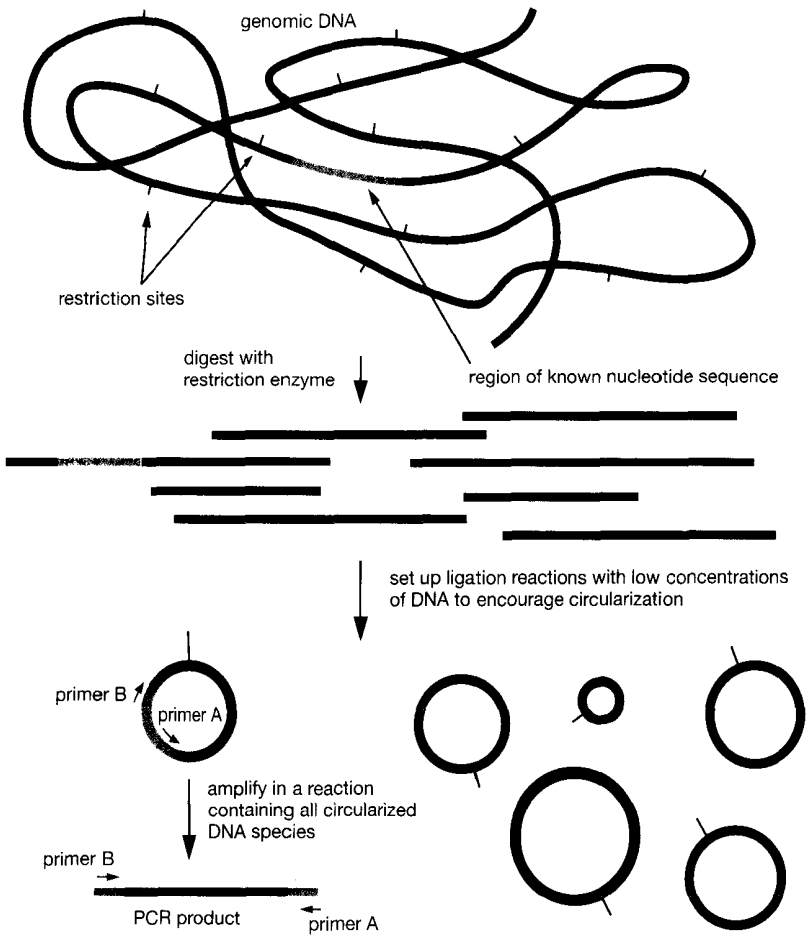

FIGURE 8-7 Schematic Representation of Inverse PCR

Inverse PCR is used to amplify DNA of unknown sequence (*dark shading*) that is adjacent to known DNA sequence (*light shading*). Genomic DNA is digested with an enzyme that produces a fragment (among others) carrying the known DNA, as determined by Southern blotting. The DNA fragments are circularized by ligation, and specific sequence primers, designed to extend outward from the known sequence, are used to amplify unknown sequences adjacent to the region of known sequence.

MATERIALS

▲ **IMPORTANT** To reduce the chance of contamination with exogenous DNAs, prepare and use a special set of reagents and solutions for PCR only. Bake all glassware for 6 hours at 150°C and autoclave all plasticware. For more information, please see the panel on **CONTAMINATION IN PCR** in the chapter introduction.

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

10x Amplification buffer

ATP (10 mM)

Chloroform <!>
dNTP solution (20 mM) containing all four dNTPs (pH 8.0)
Ethanol
Phenol:chloroform (1:1, v/v) <!>
Sodium acetate (3 M)
TE (pH 8.0)
Tris-Cl (10 mM, pH 7.6)

Enzymes and Buffers

Bacteriophage T4 ligase (1 unit/μl)
Restriction endonucleases
Thermostable DNA polymerase

Gels

Agarose or Polyacrylamide gel <!>
Please see Step 7.

Nucleic Acids and Oligonucleotides

Oligonucleotide primer 1 (20 μM) in H_2O and Oligonucleotide primer 2 (20 μM) in H_2O
There is nothing unusual about the primers used in inverse PCR except their placement on the template molecule (please see Figure 8-7). The standard rules for design of primers therefore apply. Each primer should be 20–30 nucleotides in length and should contain approximately equal numbers of the four bases, with a balanced distribution of G and C residues and a low propensity to form stable secondary structures. Restriction sites can be added to the 5′ ends of the primers to facilitate subsequent cloning and manipulation of the amplified products. For further details, please see Design of Oligonucleotide Primers for Basic PCR in the introduction to this chapter.

Oligonucleotide primers synthesized on an automated DNA synthesizer can generally be used in standard PCR without further purification. However, amplification of single-copy sequences from mammalian genomic templates is often more efficient if the oligonucleotide primers are purified by chromatography on commercially available resins (e.g., NENSORB, NEN Life Science Products) or by denaturing polyacrylamide gel electrophoresis, as described in Chapter 10, Protocol 1.

Template DNA in 10 mM Tris-Cl (pH 7.6) containing <0.1 mM EDTA
Inverse PCR requires a circular DNA as template. Steps 1–4 of this protocol describe how such templates can be generated from conventional preparations of linear DNAs, which can be a purified fragment of DNA; a preparation of total genomic DNA, fractionated according to size; a bacteriophage λ cDNA library; an aliquot of a cosmid or bacteriophage P1 genomic library; or any other DNA whose sequence complexity is $< 10^9$ bp. Use at least 1 μg of each linear DNA template to allow circularization and PCR to be carried out at several DNA concentrations.

Special Equipment

Barrier tips for automatic micropipettes
Microfuge tubes (0.5 ml, thin-walled for amplification) or Microtiter plates
Positive-displacement pipette
Thermal cycler programmed with desired amplification protocol
If the thermal cycler is not equipped with a heated lid, use either mineral oil or paraffin wax to prevent evaporation of liquid from the reaction mixture during PCR.
Water bath preset to 16°C

Additional Reagents

Step 7 of this protocol requires the reagents listed in chapter 5, Protocol 2, Chapter 6, Protocol 10, or Chapter 12, Protocol 6.

METHOD

1. Design and synthesize oligonucleotide primers 1 and 2 based on the known sequence of DNA.

2. Digest 2–5 µg of DNA template (sequence complexity $<10^9$ bp) with an appropriate restriction enzyme (please see note below). Extract the digested DNA with phenol:chloroform, and then with chloroform alone. Precipitate the DNA with 0.1 volume of 3 M sodium acetate and 2.5 volumes of ethanol. Recover the precipitated DNA by centrifugation and dissolve it in TE (pH 8.0) at a concentration of 100 µg/ml.

   Alternatively, heat the digested DNA to 65°C for 15–20 minutes to inactivate the restriction enzyme.

   Southern hybridization (Chapter 6, Protocol 10) may be used to identify a restriction enzyme that generates a fragment of the appropriate size (1–4 kb). Wherever possible, choose an enzyme that yields complementary cohesive termini. This choice increases the efficiency of circularization of the template DNA during ligation. Enzymes that generate blunt ends can be used as a last resort. In this case, however, polyethylene glycol should be added to the ligation buffer (please see Chapter 1, Protocol 19 and the information panel on **POLYETHYLENE GLYCOL** in Chapter 1) to promote circularization.

3. In sterile 0.5-ml microfuge tubes, amplification tubes, or the wells of a sterile microtiter plate, set up a series of ligation reactions containing cleaved template DNA at concentrations ranging from 0.1 to 1 µg/ml.

template DNA	10 ng to 100 ng
10x ligation buffer	10 µl
1 unit/µl bacteriophage T4 DNA ligase	4 µl
10 mM ATP	10 µl
H_2O	to 100 µl

   Incubate the reactions for 12–16 hours at 16°C.

   Some commercial ligase buffers contain ATP. When using such buffers, the addition of ATP to the ligation reaction is no longer required.

   Conditions that favor the formation of monomeric circles during ligation are well understood in theory (Collins and Weissman 1984) but are difficult to achieve in practice. The molar concentration of DNA ends must obviously be low in order to favor the formation of intramolecular circles over concatenates. However, it is difficult to calculate an appropriate concentration when the DNA molecules in the population differ in size and when the proportion of damaged termini is unknown. Under these circumstances, it is best to set up a series of ligation reactions with DNA concentrations ranging from 1 to 10 µg/ml and to carry the products of these reactions through the subsequent steps of the protocol.

4. Extract the ligated DNA with phenol:chloroform, and then with chloroform alone. Precipitate the DNA with 0.1 volume of 3 M sodium acetate and 2.5 volumes of ethanol. Recover the precipitated DNA by centrifugation and dissolve it in 10 mM Tris (pH 7.6) or H_2O at a concentration of 100 µg/ml.

5. In a sterile 0.5-ml thin-walled amplification tube, add and mix in the following order:

10x amplification buffer	5 µl
20 mM solution of four dNTPs (pH 8.0)	1 µl
20 µM oligonucleotide primer 1	2.5 µl
20 µM oligonucleotide primer 2	2.5 µl
1–5 units/µl thermostable DNA polymerase	1.0 µl
H_2O	28–33 µl
ligated template DNA	5–10 µl
Total volume	50 µl

The efficiency of inverse PCR is sometimes improved by amplification of linear, rather than circular, DNA templates. Linearization of the template can be achieved by digesting the circularized molecules with a restriction enzyme that cleaves in the region of known DNA, between the 5′ termini of the two primers. Ideally, the enzyme should not cleave the unknown sequences. Alternatively, the circular molecules can be linearized, albeit less efficiently, by heating the samples to 100°C for 15 minutes before setting up the amplification reactions (Triglia et al. 1988; Ochman et al. 1993).

Set up two control reactions. In one reaction, include all of the above reagents, except the template DNA. In the other reaction, replace the template with a plasmid of known size, containing the DNA insert from which the oligonucleotide primers were derived. The first control ensures that any product visualized is not due to the presence of extraneous DNA. The second tests the fidelity of the PCR reagents. Carry each control reaction through all subsequent steps of the protocol.

6. If the thermal cycler is not fitted with a heated lid, overlay the reaction mixtures with 1 drop (~50 µl) of light mineral oil. This prevents evaporation of the samples during repeated cycles of heating and cooling. Alternatively, place a bead of wax into the tube if using hot start PCR. Place the tubes or the microtiter plate in the thermal cycler. Amplify the nucleic acids using the denaturation, annealing, and polymerization times and temperatures listed in the table.

Cycle Number	Denaturation	Annealing	Polymerization
30 cycles	30 sec at 94°C	30 sec at 60°C	2.5 min at 72°C
Last cycle	30 sec at 94°C	30 sec at 60°C	10 min at 72°C

These times are suitable for 50-µl reactions assembled in thin-walled 0.5-ml tubes and incubated in thermal cyclers such as the Perkin-Elmer 9600 or 9700, Master Cycler (Eppendorf), and PTC 100 (MJ Research). Times and temperatures may need to be adapted to suit other types of equipment and reaction volumes.

Most thermal cyclers have an end routine in which the amplified samples are incubated at 4°C until they are removed from the machine. Samples can be left overnight at this temperature, but should be stored thereafter at –20°C.

The exact annealing temperature should be established empirically for the primer pairs ueed in a given amplification reaction. An extended polymerization time (up to 10 minutes per cycle) should be tried if the target DNA is long (>4 kb). Alternatively, the use of mutant thermostable DNA polymerases that lack exonuclease activity (e.g., Klentaq1 enzyme, AB Peptides, St. Louis, Missouri) and/or that contain a low level of 3′-exonuclease activity (e.g., *Pfu*, *Vent*, or *DeepVent* enzymes from Stratagene and New England Biolabs, respectively) may produce longer templates. Also, please see the note on long PCR in Protocol 13, Step 2.

7. Withdraw a sample (5–10 µl) from the test reactions and the control reactions and analyze them by electrophoresis through an agarose or polyacrylamide gel. Be sure to include DNA markers of an appropriate size. Stain the gel with ethidium bromide or SYBR Gold.

A successful amplification reaction should yield a readily visible DNA. The identity of the band can be confirmed by DNA sequencing (please see Chapter 12, Protocol 6), and/or restriction mapping and/or Southern hybridization using probes homologous to the known DNA sequence (please see Chapter 6, Protocol 10).

If low yields are a problem, the desired fragment can be purified by gel electrophoresis, isolated by band-stab (please see the panel on **BAND-STAB PCR** in Protocol 11), and reamplified using oligonucleotide primers 1 and 2.

If nonspecific amplification is a problem, nested primers should be used in the second round of PCR (Takagi et al. 1992).

Protocol 15

Quantitative PCR

PCR CAN BE USED TO ESTIMATE THE CONCENTRATION of a particular target DNA or RNA relative to a standard (for reviews, please see Ferre 1992; Foley et al. 1993; Raeymaekers 1993, 1995; Gause and Adamovicz 1994; Cross 1995; Reischl and Kochanowski 1995; Freeman et al. 1999; Halford 1999) (please see the panel on **REAL TIME PCR** at the end of this protocol). However, quantitative PCR, more than any other form of PCR, is littered with booby traps and is not for the technically challenged. Many of the difficulties stem from the nature of PCR itself. Because PCR is an exponential process, small differences in efficiency at each cycle of the reaction can lead to large differences in the yield of the amplified product. Anything that can affect exponential amplification can compromise quantitation of target sequences. For example, the presence of different amounts of inhibitors in a series of samples containing the same amount of template DNA could lead to differences in the final yield of amplified product, as could small differences in efficiency between primer pairs used to amplify standard and target sequences. So sensitive are PCRs to minor differences in conditions that the coefficient of variability of yield of amplified product is typically 10–20% in replicate samples (e.g., please see Wiesner et al. 1992; Hill et al. 1996; Halford et al. 1999). For this reason, methods that simply quantify the amount of amplified DNA that accumulates over the course of a PCR (so-called end-point methods) are generally regarded as unreliable. In recent years, more sophisticated methods have been developed in which amplified DNA is quantified during the exponential phase of the PCR. These methods, some of which have been automated (please see the panel on **REAL TIME PCR**), have eliminated much of the variation associated with end-point measurement.

An early method of quantitative PCR involved comparing the amount of specific product generated in different samples from a particular target sequence. In this technique, the amounts of amplified product were measured at several time points during the exponential phase of the reaction and were then analyzed by linear regression (Wiesner et al. 1992; Clifford et al. 1994). When working at its best, this method could be used to detect picomolar concentrations of target sequence and was accurate enough to distinguish twofold differences in concentration of target sequence in different samples. However, the method often fell prey to tube-to-tube variability and, for this reason, is no longer in common use.

Two types of controls described below can be used to monitor tube-to-tube variability: endogenous standards and externally added references.

- ***Endogenous standards*** are control sequences (usually housekeeping genes or their mRNAs) that are present in the same preparation of DNA or RNA as the target sequences. Quantification is achieved by comparing the amount of amplified product generated by the

endogenous standard and the target sequence (Chelly et al. 1990). The method works well if the amplified products are measured during the exponential phase of the reaction, if the reference and target sequences are amplified with equal efficiency, and if they are present in the sample at approximately equal concentrations. However, these conditions are rarely fulfilled because the amplified products are almost always different from the endogenous reference in size, sequence, and abundance. These imbalances between reference and target become manifest as systematic differences in amplification efficiency between the two nucleic acids. In addition, there is no guarantee that the housekeeping genes chosen as endogenous standards are invariant in their levels of expression from one sample to the next. The levels of expression of these genes are not constant from one mammalian tissue to another nor from one cell line to another (e.g., please see Mansur et al. 1993; Spanakis 1993; Bhatia et al. 1994). Differences in the amount of amplified product generated by the reference and the target may therefore result from differential amplification or from changes in the level of transcription of the target gene and/or the standard gene, or from both.

- ***Externally added reference*** molecules are DNAs or RNAs that are added in known amounts to a series of amplification reactions (Wang et al. 1989; Gilliland et al. 1990). Because the reference templates and target sequences are present in the same amplification reaction and use the same primers (please see below), the effect of the variables mentioned earlier is nullified. Quantification is achieved by comparing the amount of amplified products generated by the reference and target sequences. The purpose of the experiment — to find out the ratio of reference sequences to target sequences in the reaction mixture at cycle zero — can be achieved in two ways. A series of reactions can be set up containing different ratios of reference and target molecules. A curve is constructed showing the relationship between the amount of amplified product and the amount of reference added to the reaction. The target sequence can then be quantified by interpolation (please see Figure 8-8). Thus, in a reaction that yields equal amounts of the two amplified products, the ratio of target molecules to reference molecules at the beginning of the PCR is said to be unity. However, this conclusion is true only if amplification efficiencies of target and reference molecules are equal throughout the course of the PCR.

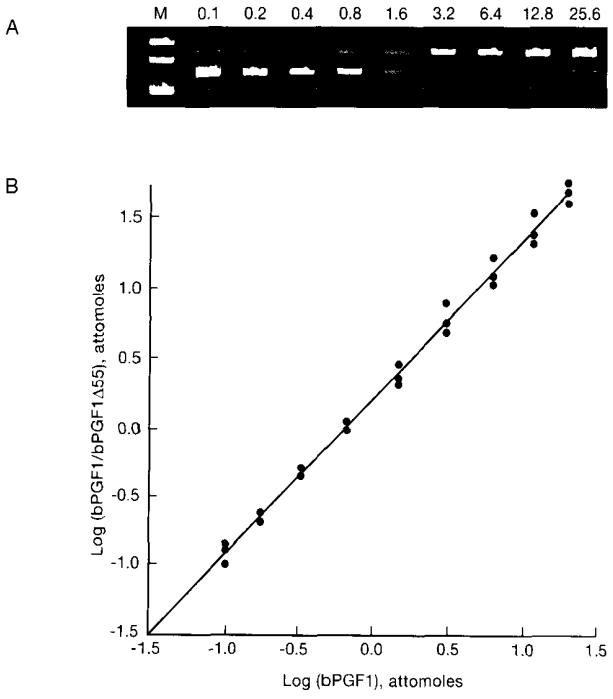

FIGURE 8-8 Quantitation of mRNA by Amplifying Varying Amounts of a Standard (Native) DNA Fragment with a Constant Amount of Competitor DNA

In this example, a fragment of native bovine FP receptor cDNA (bPGF1) is amplified in the presence of a competitor fragment of bovine FP receptor DNA carrying an internal deletion of 55 bp (bPGF1Δ55). (*A*) Resulting amplification products from reactions containing different ratios of bPGF1 to bPGF1Δ55 are shown as ethidium-bromide-stained bands after separation by electrophoresis through 5% polyacrylamide. (*B*) Composite standard curve is derived from four independent experiments. The log ratio of native to competitor product was plotted against the log amount of initial native added to the RT-PCR. (Modified, with permission, from Tsai and Wiltbank 1996.)

To eliminate this source of doubt, a more sophisticated method is available. This approach involves quantifying the amounts of reference and target sequences in consecutive cycles within the exponential phase of PCR. Amplified products accumulate during this phase according to the following equation (please see the panel on **PCR IN THEORY** in the chapter introduction):

$$\log N_f = n \log (1 + Y) + \log N_0$$

where N_f is the copy number of the amplified sequence after n cycles of amplification, N_0 is the initial copy number of the target sequence in the DNA template, and Y is the efficiency of amplification per cycle.

A semilogarithmic graphical plot of log concentration of a particular amplified product against cycle number yields a straight line (please see Figure 8-9) (Tsai and Wiltbank 1996; Harting and Wiesner 1997). The equation describing the accumulation of the product can then be derived using regression analysis. If, as is most desirable, the target sequences and the reference sequences are amplified with equal efficiency, the regression lines will be parallel to each other. The ratio between the target and reference molecules can be calculated from the intersection of the regression lines with a single, midexponential cycle (Harting and Wiesner 1997).

DNAs encoding reference templates are constructed and cloned into vectors equipped with a promoter for bacteriophage-encoded DNA-dependent RNA polymerases. In most cases, the reference templates are constructed by modifying a clone of the target sequence in a way that allows the coamplified products to be distinguished from one another. For example, the reference and the target might differ slightly in size by insertion or deletion of a small fragment of DNA or in sequence by alteration of one or two bases that are required to create a new restriction site or remove a naturally occurring site. In general, references and targets that differ slightly in size are preferred because they can be easily distinguished by gel electrophoresis. In the case of RT-PCR, reference templates are transcribed from the engineered plasmid using a bacteriophage-encoded RNA polymerase, purified, and quantified by absorbance at 260 nm. Measured amounts of reference template are added to test RNAs prepared from a known number of cells expressing the genes of interest, and the mixture is converted into cDNA by reverse transcription. Because the reference and the target RNAs are both present throughout all phases of RT-PCR, they are copied

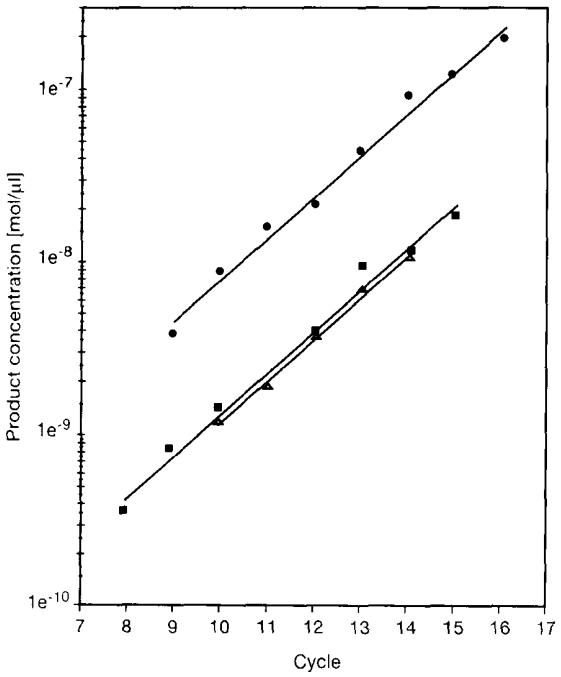

FIGURE 8-9 Quantitation by Accumulation of Products in RT-PCR vs. Cycle Number

In this example, product accumulation is shown for amplification (RT-PCR) of three samples: 12S rRNA (*circles*), cytochrome C oxidase (COX I) mRNA (*squares*), and a reference template sequence from the D-loop region of mitochondrial DNA (*triangles*). The data are shown as product concentration vs. cycle number in a semilogarithmic plot with respective linear regression lines. In this experiment, the ratios for 12S:D-loop and COX I:D-loop are 5.77 and 1.1, respectively. (Adapted, with permission, from Harting and Wiesner 1997.)

simultaneously into DNA by reverse transcription and are then coamplified using the same primers (Becker-André and Hahlbrock 1989; Wang et al. 1989; Gilliland et al. 1990; Siebert and Larrick 1992). For this reason, reference molecules of this type are sometimes called "competitors."

RNA references are not for the faint-hearted: They are the mark of investigators with a strong commitment to esthetic values and a high level of technical skill. A much easier alternative is to use DNA references, which are more durable and much easier to handle (e.g., please see Siebert and Larrick 1992). DNA references are entirely suitable for quantitative PCR of DNA templates, but they are clearly less appropriate for quantification of RNAs.

In summary, before attempting quantitative PCR, it is essential to address the following issues. First, rigorously optimize the reagents and conditions used in the amplification reaction (please see Parameters That Affect Polymerase Chain Reactions in the chapter introduction). Second, suppress the competing reactions that occur in the amplification reaction due to mispriming. This goal is best accomplished using a hot start PCR or touchdown PCR protocol. Third, carry out calibration experiments in which progressively smaller amounts of standard templates are amplified. Fourth, establish the reproducibility of the methods by performing a statistically significant number of multiple assays on the same sets of templates and, finally, on independently processed samples. Finally, perform control experiments showing that the efficiency of amplification of target and reference molecules are equal during the course of the PCR. With this groundwork in place, it becomes possible to draw confident conclusions about the relative or absolute concentration of the target sequence from the yield of amplified product in a standard PCR.

In its most basic form, quantitative RT-PCR involves coamplification of two templates: a constant amount of an RNA preparation containing the desired target sequence and serial dilutions of a reference template that is added in known amounts to a series of amplification reactions. The concentration of the target sequence is determined by simple interpolation into a standard curve (Gilliland et al. 1990; Freeman et al. 1999; please see Figure 8-9 and accompanying text). Once this basic technique is established in the laboratory, the method can easily be extended to include the more accurate regression analysis of the accumulation of the amplification products during successive cycles of PCR (Harting and Wiesner 1997). For a variation of this procedure, please see the panel on **MEASURING MULTIPLE GENE PRODUCTS BY RT-PCR.**

Because of the amount of work involved in setting up competitive quantitative PCR in a fashion that will satisfy sceptics, alternative methods (semiquantitative PCR) have been developed that do not include externally added standards. In some hands, these semiquantitative methods yield results that are identical to those obtained by more stringent experimentation (for review, please see Halford 1999). However, because the value of semiquantitative PCR remains controversial, it seems more prudent at the moment to include the full range of standards and reference templates.

In recent years, commercial systems have been developed to quantify specific sequences in preparations of DNA or RNA by measuring the intensity of signals emitted by DNAs generated in successive cycles of a PCR. Because these systems allow the simultaneous amplification and quantification of specific nucleic acid sequences in real time, they eliminate the need to withdraw aliquots at different stages during the PCR. Real time PCR and the commercial instruments needed to carry out the method are discussed in detail in the panel on **REAL TIME PCR** at the end of this protocol.

MEASURING MULTIPLE GENE PRODUCTS BY RT-PCR

A clever improvement of the method presented in this protocol is described by Wang et al. (1989). A plasmid vector is first engineered that contains a bacteriophage T7 RNA polymerase promoter and pairs of 5′ and 3′ oligonucleotide primer sequences derived from genes whose mRNA concentrations are to be measured. The pairs of oligonucleotide primers are derived from as many as 12 different genes and are spaced variable, but known, distances apart in the vector. The distance separating a gene-specific pair of oligonucleotide primers in the standard template plasmid is similar to, but slightly different from, the distance separating the primer sequences in the natural mRNA. This difference allows the amplification products from the cDNA and plasmid DNA templates to be distinguished.

MATERIALS

▲ **IMPORTANT** To reduce the chance of contamination with exogenous DNAs, prepare and use a special set of reagents and solutions for PCR only. Bake all glassware for 6 hours at 150°C and autoclave all plasticware. For more information, please see the panel on **CONTAMINATION IN PCR** in the chapter introduction.

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

10x Amplification buffer

dNTP solution (20 mM) containing all four dNTPs (pH 8.0)

$MgCl_2$ (50 mM)

Placental RNase inhibitor (20 units/μl)

Please see the information panel on **INHIBITORS OF RNASES** in Chapter 7.

Enzymes and Buffers

Appropriate restriction endonuclease

Please see Step 7.

Reverse transcriptase (100–200 units/μl)

Thermostable DNA polymerase

Taq DNA polymerase is the standard and appropriate enzyme for the amplification stage of most forms of quantitative PCR.

Radioactive Compounds

[α-^{32}P]dCTP (sp. act. 3000 Ci/mmole) at 10 mCi/ml **<!>**

Gels

Agarose or Polyacrylamide gels **<!>**

Please see Steps 1 and 7.

Nucleic Acids and Oligonucleotides

Externally added reference (either DNA or RNA) of known concentration

For a discussion of the design of this template, please see the introduction to this protocol. Use a DNA reference to measure the concentration of DNA sequences by conventional PCR and, whenever possible, an RNA reference to measure the concentration of a target RNA by quantitative RT-PCR. The basic method for the construction of reference RNAs is described in Chapter 15, Protocol 2. For details on plasmid construction for synthesis of reference RNAs, please see Diviacco et al. (1992), Schneeberger et al. (1995), and Schneeberger and Zeillinger (1996).

Sense primer (20 μM) in H_2O and Antisense primer (20 μM) in H_2O

Each primer should be 20–30 nucleotides in length and contain approximately equal numbers of the four bases, with a balanced distribution of G and C residues and a low propensity to form stable secondary structures. For further details, please see Design of Oligonucleotide Primers for Basic PCR in the introduction to this chapter.

Oligonucleotide primers synthesized on an automated DNA synthesizer can generally be used in quantitative PCR without further purification.

Target nucleic acid

The target can be a preparation of DNA or RNA, either total or poly(A)$^+$. Dissolve preparations of total RNA at a concentration of 0.5–1 mg/ml and preparations of poly(A)$^+$ RNA at a concentration of 10–100 μg/ml. Dissolve DNA targets in 10 mM Tris-Cl (pH 7.6) at the following concentrations: mammalian genomic DNA, 100 μg/ml; yeast genomic DNA, 1 μg/ml; bacterial genomic DNA, 0.1 μg/ml; and plasmid DNA, 1–5 ng/ml.

Special Equipment

Barrier tips for automatic micropipettes
Microfuge tubes (0.5 ml, thin-walled for amplification) or Microtiter plates
Positive-displacement pipette
Thermal cycler programmed with desired amplification protocol
If the thermal cycler is not equipped with a heated lid, use either mineral oil or paraffin wax to prevent evaporation of liquid from the reaction mixture during PCR.
Water baths, preset to 94°C and to 75°C and 95°C (for template RNA only)

METHOD

Preparation of the Reference Template

1. Use the guidelines given in the introduction to design and prepare a reference template suitable for the task at hand. Measure the concentration of the reference template as carefully as possible, preferably by fluorometry (please see Appendix 6). Alternatively, estimate the amount of reference template after gel electrophoresis and ethidium bromide staining.
2. Make a series of tenfold dilutions (in H_2O) containing concentrations of the reference template ranging from 10^{-6} to 10^{-12} M. After using the dilutions in Step 3, they should be stored at –70°C for use in Step 8.
   It is important to use H_2O rather than TE as the diluent to avoid altering the concentration of Mg^{2+} in the PCR.

Preparation of cDNA

3. If starting from RNA, denature the target RNA by incubating aliquots for 5 minutes at 75°C, followed by rapid chilling in ice water. Then, without delay, set up a series of reverse transcription reactions containing increasing amounts of reference template in sterile 0.5-ml microfuge tubes. For each reaction in the series, prepare the following:

10x amplification buffer	2 µl
20 mM solution of four dNTPs (pH 8.0)	1 µl
20 µM antisense primer	2.5 µl
~20 units/µl placental RNase inhibitor	1 µl
50 mM $MgCl_2$	1 µl
denatured target RNA	10 pg to 1.0 µg
100–200 units/µl reverse transcriptase	1 µl
tenfold dilution of reference template	1 µl
H_2O	to 20 µl

   $MgCl_2$ is added to meet the needs of the reverse transcriptase.
   For advice on setting up reverse transcriptase reactions, please see the panel on **REVERSE TRANSCRIPTASES USED IN RT-PCR** in Protocol 8.

   Incubate the reaction for 60 minutes at 37°C and then denature the reverse transcriptase by heating to 95°C for 20 minutes.

Amplification of Reference and Target Nucleic Acids

4. In sterile 0.5-ml microfuge tubes, amplification tubes, or the wells of a sterile microtiter plate, set up amplification reactions with each reaction in the series from Step 3:

reverse transcriptase reaction (Step 3) or target DNA	5 µl
20 µM sense primer	1.5 µl
20 µM antisense primer	1.25 µl
10x amplification buffer	5 µl
[α-^{32}P]dCTP (3000 Ci/mmole)	10 µCi
20 mM solution of four dNTPs	1 µl
Taq DNA polymerase	2 units
H_2O	to 50 µl

▲ **IMPORTANT** Do not reduce the concentration of unlabeled dCTP in the reaction mixture to increase the specific activity of the precursor pool. There is a danger that the amount of the nucleotide could become limiting at late stages in the amplification reaction.

5. If the thermal cycler is not fitted with a heated lid, overlay the reaction mixtures with 1 drop (~50 µl) of light mineral oil. This prevents evaporation of the samples during repeated cycles of heating and cooling. Alternatively, place a bead of wax into the tube if using hot start PCR. Place the tubes or the microtiter plate in the thermal cycler.

6. Amplify the nucleic acids using the denaturation, annealing, and polymerization times and temperatures listed in the table.

Cycle Number	Denaturation	Annealing	Polymerization
30 cycles	30 sec at 95°C	30 sec at 55°C	1 min at 72°C
Last cycle	1 min at 94°C	30 sec at 55°C	1 min at 72°C

These times are suitable for 50-µl reactions assembled in thin-walled 0.5-ml tubes and incubated in thermal cyclers such as the Perkin-Elmer 9600 or 9700, Master Cycler (Eppendorf), and PTC 100 (MJ Research). Times and temperatures may need to be adapted to suit other types of equipment and reaction volumes.

Detection and Quantification of PCR Products

A variety of different methods have been used to detect and quantify amplified products. These include solid-phase assays, anion-exchange high-performance liquid chromatography (HPLC), and fluorescence labeling of amplified nucleic acids (please see Reischl and Kochanowski 1995). However, such recondite techniques are neither widely available nor strictly necessary. Excellent results can be obtained by gel electrophoresis followed by more standard methods, such as the use of fluorescently labeled primers quantified with an automated DNA sequencer (Porcher et al. 1992), fluorometry (please see Appendix 9), computer analysis of images of gels stained with ethidium bromide or other intercalating dyes (Schneeberger et al. 1995; Tsai and Wiltbank 1996), or measurement of radioactivity incorporated during amplification (as is done in this protocol).

7. Analyze and quantitate the amplified products.

When using a reference template that differs from the target sequence in size

a. Analyze the sizes of the amplified products in a 20-µl aliquot of each of the reactions by gel electrophoresis and autoradiography.

b. Excise the amplified bands of the control template and target sequences from the gel, and measure the amount of radioactivity in each band in a liquid scintillation counter. Alternatively, scan the gel with the appropriate detector (e.g., Ambis scanner or phosphorimager).

c. Calculate the relative amounts of the two radiolabeled DNAs in each of the PCRs.

Remember to correct the amount of radioactivity to allow for differences in the molecular weights of the two radiolabeled DNAs.

WHEN USING A REFERENCE TEMPLATE THAT CONTAINS A NOVEL RESTRICTION SITE OR LACKS A NATURALLY OCCURRING SITE

a. Heat the samples to 94°C for 5 minutes following the final round of amplification.

b. Allow the samples to cool gradually to room temperature and then digest a 20-µl aliquot of each of the reactions with the appropriate restriction enzyme.

c. Analyze the sizes of the amplified DNA fragments by gel electrophoresis and autoradiography.

d. Excise the amplified bands of the control template and target sequences from the gel, and measure the amount of radioactivity in each band in a liquid scintillation counter. Alternatively, scan the gel with the appropriate detector (e.g, Ambis scanner or phosphorimager).

e. Calculate the relative amounts of the two radiolabeled DNAs in each of the PCRs.

Remember to correct the amount of radioactivity to allow for differences in the molecular weights of the two radiolabeled DNAs.

The aim of this denaturation and reannealing step is to allow efficient formation of heteroduplexes consisting of one strand of reference template and one strand of target sequence. When equal concentrations of the two templates are present in the original reaction mixture, the reannealed products will consist of 50% heteroduplexes and 25% of each type of homoduplex. Only one of the two types of homoduplexes will be susceptible to digestion with the appropriate restriction enzyme. Thus, when the amplified products consist of equal quantities of target and reference templates, one quarter of the reannealed molecules will be susceptible to cleavage by a restriction enzyme. Which of the two types of homoduplexes will be susceptible to cleavage depends on whether the reference template carries an extra restriction site or lacks a site that is present in the target sequence.

Heteroduplex formation is far less efficient when the target and reference templates differ significantly in size. For example, very little heteroduplex formation can be observed between a target sequence of 300 nucleotides and a reference template of 250 nucleotides. Under these circumstances, the ratio of cleaved to uncleaved products can approach unity. If the fragments differ significantly in size, they can be directly separated by gel electrophoresis and quantified.

8. Examine the results to determine the concentration of reference template that yields approximately the same amount of amplified product as the target sequence. Set up a second series of amplification reactions (please see Step 4) containing a narrower range of concentrations of reference template.

It is best to generate this series of dilutions from the appropriate tenfold dilution of the reference template (Step 2).

9. Repeat Steps 5, 6, and 7. For each amplification reaction, measure the ratio of the yield of amplified reference template to the yield of amplified target sequence. Plot this ratio against the amount of reference template added to each amplification reaction. From the resulting straight line, determine the equivalence point (i.e., the amount of reference template that gives exactly the same quantity of amplified product as the target sequence in the reaction). Calculate the concentration of the target sequence in the original sample.

REAL TIME PCR

Real time PCR (sometimes called kinetic PCR) is used in research laboratories to quantify gene expression and to confirm differential expression of genes detected by array technology. In analytical laboratories, real time PCR is used to measure the abundance of particular DNA or RNA sequences in clinical and industrial samples and, in both types of laboratories, to screen for mutations and single nucleotide polymorphisms. Real time PCR uses commercially available fluorescence-detecting thermocyclers to amplify specific nucleic acid sequences and measure their concentration simultaneously. Because the target sequences are amplified and detected in the same instrument, there is no need to withdraw aliquots during the reaction or to process them. Instead, the instrument plots the rate of accumulation of amplified DNA over the course of an entire PCR. The greater the initial concentration of target sequences in the reaction mixture, the fewer the number of cycles required to achieve a particular yield of amplified product (Becker et al. 1996; Gibson et al. 1996; Heid et al. 1996; Freeman et al. 1999). The initial concentration of target sequences can therefore be expressed as the fractional cycle number (C_T) required to achieve a present threshold of amplification. A plot of C_T against the $\log_{10}$ of the initial copy number of a set of standard DNAs yields a straight line (Higuchi et al. 1993). The target sequences in an unknown sample may be easily quantified by interpolation into this standard curve. Unlike other forms of quantitative PCR (please see the introduction to Protocol 15), internal standards are not required in real time PCR.

The ability to quantify the amplified DNA during the exponential phase of the PCR, when none of the components of the reaction are limiting, results in an improved precision in the quantitation of target sequences. By contrast to methods that measure the amount of product at the end of the reaction, real time PCR is not affected to a significant extent by slight variations in the components of the reaction and is less sensitive to differences in the efficiency of amplification.

The earliest of the real time PCR instruments used a fluorometer coupled to a thermal cycler to measure the enhanced fluorescence by dyes that intercalate into, or bind to the grooves of, double-stranded DNA. During the "exponential" phase of a PCR, the amount of amplified product synthesized in each cycle increases in a quasi-geometric fashion (please see the panel on **PCR IN THEORY** in the introduction to this chapter). The yield of amplified DNA may therefore be estimated at any point from the amount of fluorescence emitted by dyes such as ethidium bromide (Higuchi et al. 1992, 1993), SYBR Green I (Wittwer et al. 1997a), or certain oxazole yellow derivatives (Ishiguro et al. 1995).

Because of the high sensitivity of fluorometric detection, real time PCR is capable of measuring the initial concentration of target DNA over a range of five or six orders of magnitude (Heid et al. 1996; Wittwer et al. 1997a). Currently, the limit of detection when fluorescent dyes such as SYBR Green I are used is ~10–100 copies of template DNA in the starting specimen (Higuchi et al. 1993; Wittwer et al. 1997a).

Generic DNA-binding dyes such as ethidium bromide and SYBR Green I are universal probes that detect any double-stranded DNA generated during PCR, independent of the template and primers used in the reaction. Because many molecules of the dyes can bind to each DNA product, the intensity of signal generated is high and is proportional to the total *mass* of DNA generated during the PCR and is independent of the *number of types* of molecules produced. High levels of sensitivity are achieved only in real time PCRs that generate a single amplification product. Nonspecific amplification or the formation of primer-dimers can generate significant errors in quantifying small numbers of target molecules when universal dyes are used as reporters. In the worst cases, the emitted fluorescence may bear little or no relationship to the amount of starting target DNA or to the amount of full-length product produced. Several methods have been developed to confirm the specificity of the amplified products of real time PCRs:

- ***Melting temperatures.*** At the end of the PCR, the thermocycler/fluorometer can be programmed to generate a thermal denaturation curve of the amplified DNA and to measure the melting temperature (T_m) of the PCR product(s). The shape of the melting curve indicates whether the amplified products are homogeneous and the T_m provides reassurance that the correct product has been specifically amplified. Primer-dimers, which generate much of the background noise in real time PCR, because of their short length, generally denature at much lower temperatures and can easily be distinguished from the amplified target DNA (Ririe et al. 1997).

- ***Fluorescently labeled oligonucleotide probes.*** Two methods have been developed in which fluorescently labeled oligonucleotide probes are used to quantify the amount of the target sequences generated by real time PCR. In each case, the fluorescent signal is generated after extension of the oligonucleotide by *Taq* polymerase. The strength of the signal is therefore proportional to the amount of the target DNA and is not influenced by the accumulation of nonspecific products such as primer-dimers, which do not hybridize to the labeled oligonucleotide probe.

- ***The* TaqMan *method of real time PCR*** (Holland et al. 1991; Livak et al. 1995), uses an oligonucleotide that anneals to an internal sequence within the amplified DNA fragment. The oligonucleotide, usually 20–24 bases in length, is labeled at one end with a fluorescent group (Fam<Hex or Tet) at its 5′ end and a quenching group (usually Tamra) at its 3′ end, which is blocked with PO_4, NH_2, or a blocked base. The labeled oligonucleotide is added to the PCR together with primers required to drive the amplification of the target sequence. When both the fluorescent and quenching groups are present in close apposition on the intact hybridization probe, any emission from the reporter dye during the course of real time PCR is absorbed by the quenching dye, and the fluorescent emission is low. As the reaction progresses, and the amount of target DNA increases, progressively greater quantities of oligonucleotide probe hybridize to the denatured target DNA. However, during the extension phase of the PCR cycle, the 5′→3′ exonuclease activity of the thermostable polymerase cleaves the fluorophore from the probe. Because the fluorophore is no longer in close proximity to the quencher, it begins to fluoresce. The intensity of fluorescence is in direct proportion to the amount of target DNA synthesized during the course of the PCR. Both the LightCycler and the Prism system can use fluorogenic hydrolysis to detect multiple PCR products. The number of targets that can be detected simultaneously in a single PCR has increased recently through the use of Dabcyl, a universal quencher that can replace Tamra at the 3′ end of TaqMan probes (Nasarabadi et al. 1999).
- ***Binary hybridization probes*** labeled with different fluorescent dyes can also be used to differentiate the products of real time PCRs (Lee et al. 1993; Wittwer et al. 1997a,b). By themselves, these probes emit only low levels of fluorescence. However, when brought into close proximity by hybridization to adjacent sequences in a target DNA during the course of real time PCR, the fluorescent dyes act in synergy to generate a powerful fluorescent emission. Binary oligonucleotide probes labeled with different fluorescent groups can also be used in conjunction with a multicolor detection system in the LightCycler to scan amplified segments of DNA for mutations of polymorphisms. Oligonucleotides that form a mismatched hybrid with the target DNA melt at a lower temperature than the corresponding perfectly matched hybrid. The resulting differences in melting temperature are sufficient to distinguish between target DNAs carrying wild-type or mutant sequences (Lay and Wittwer 1997; Bernard et al. 1998).

INSTRUMENTS FOR REAL TIME PCR

The three most popular real time PCR instruments are the GeneAmp 5700 Sequence Detection System and the ABI Prism 7700 Sequence Detection system (both marketed by Perkin-Elmer Biosystems) and the LightCycler (marketed by Roche).

The GeneAmp 5700 System consists of two instruments — an optical detector and a GeneAmp PCR System 9600 — whose activities are coordinated by software. Up to 96 PCRs can be run simultaneously, and the accumulation of amplified DNA at each cycle of the reaction is measured from the intensity of fluorescence emitted by SYBR I Green or TaqMan probes. Up to 96 reactions may be irradiated simulateously, and the image is captured on a CCD array. Software provides spacial resolution of the 96 wells. The system is basically a single-color detector but is capable of using an internal reference dye (ROX) to eliminate well-to-well variation in base-line fluorescence.

The ABI Prism 7700 has a built-in thermal cycler and a laser whose beam is directed by fiber-optic cables to each of the 96 reactions. The wells are irradiated in sequence and the signals are captured and resolved on a CCD array. Unlike the GeneAmp 5700, the Prism system can detect signals across the entire fluorescent spectrum and is therefore capable of quantitating the signals from different fluorophores used in the same reaction. Like the 5700, the Prism system uses ROX as an internal reference dye. Fluorescent output from ROX is measured during the denaturing step of each cycle of PCR, thus providing a base line against which non-PCR-related, well-to-well variations can be normalized.

In the LightCycler (Roche), the amplification reactions are set up in small sealed glass capillaries that are heated and cooled in an airstream, which greatly reduces the time required for each cycle of PCR. The capillaries are rotated through a sensing station with a built-in three-channel fluorometer (Wittwer et al. 1997b). The data stream from the fluorometer is converted by software into an amplification plot for each of the reactions. Like the Prism system, the LightCycler is capable of distinguishing between fluorophores, so that probes labeled with different reporter groups can be used in the same PCR.

The chief advantages of real time PCR are its ability to measure the concentrations of nucleic acids over a vast dynamic range, its high sensitivity, and its capacity to process many samples simultaneously. Unlike the traditional "endpoint" measurement of PCR products, real time PCR provides immediate information about the kinetics of the PCR. Compensation for differences in efficiency of amplification between different samples can therefore be calculated as described by Hartling and Wiesner (1997) (please see Protocol 15) or embedded in the software used to calculate the concentration of target sequences in the initial reaction mixture.

The chief disadvantage of real time PCR is cost. The machines are expensive to purchase and the maintenance and running costs are considerable. For this reason, the chief beneficiaries of real time PCR have so far been laboratories with an extremely high throughput of samples of a similar type. However, we can hope that the costs of real time PCR will drop in the next few years to the point where the technology becomes readily accessible to individual research laboratories.

Protocol 16

Differential Display–PCR

In 1992, Liang and Pardee, and independently, Welsh et al., described a method for using PCR to amplify and display many cDNAs derived from the mRNAs of a given cell or tissue type. The method relies on two different types of synthetic oligonucleotides: anchored antisense primers and arbitrary sense primers. A typical anchored primer is complementary to ~12 nucleotides of the poly(A) tail of mRNA and the adjacent two nucleotides of the transcribed sequence (please see the discussion on Primers Used in DD-PCR, p. 8.99). Anchored primers therefore anneal to the junction between the poly(A) tail and the 3′-untranslated region of mRNA templates, from where they can prime synthesis of first-strand cDNA. A second primer, an arbitrary sequence of ~10 nucleotides, is then added to the reaction mixture and double-stranded cDNAs are produced by conventional PCR, carried out at low stringency. The products of the amplification reaction are separated by electrophoresis through a denaturing polyacrylamide gel and visualized by autoradiography. By comparing the banding patterns of cDNA products derived from two different cell types, or from the same cell type grown under different conditions, it is sometimes possible to identify the products of differentially expressed genes. Bands of interest can then be recovered from the gel, amplified further, and cloned, and/or used as probes to screen, for example, northern blots and cDNA libraries (please see Figure 8-10).

Differential display offers several theoretical advantages over older methods, such as differential hybridization and differential cDNA cloning, that have been used to identify tissue- and cell-specific mRNAs. First, minimal amounts (0.1–0.5 μg) of poly(A)$^+$ RNA are required. Second, because differential display–PCR (DD-PCR) involves an amplification step, it can in theory be used to detect differential expression of mRNAs that are expressed in very low abundance. Third, because the amplification products from two or more sources are displayed on the same gel, it should be possible to identify both quantitative and qualitative changes in transcription. Finally, differential display can detect changes in expression of closely related RNAs that might be lost from the target population during construction of subtracted cDNA libraries.

Examples of the successful uses of differential display include comparisons of (1) normal and tumor cells (Liang and Pardee 1992), (2) normal and senescent cells (Linskens et al. 1995), (3) stages in developing *Xenopus* and mouse embryos (Zimmermann and Schultz 1994; Adati et al. 1995), (4) cells treated and untreated with hormones (Nitsche et al. 1996), and (5) genes expressed in response to dietary metal ions (Blanchard and Cousins 1996; Wang et al. 1996). The use of differential display has led to the identification of several genes involved in cancer (Liang et al. 1992; Sager et al. 1993), diabetes (Nishio et al. 1994), and heart disease (Utans et al. 1994). Despite these successes, differential display remains a problematic method. It is susceptible to a

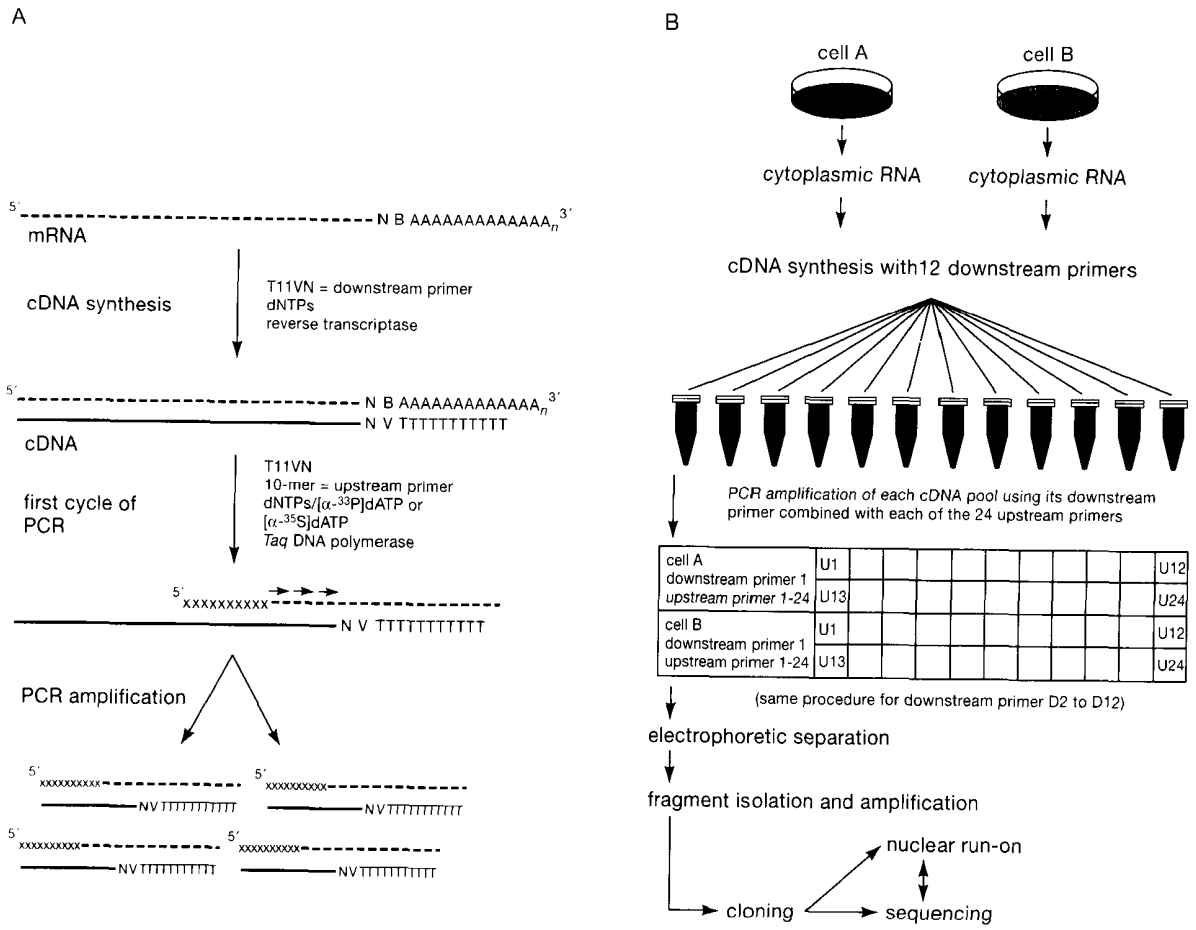

FIGURE 8-10 Schematic Representation of Differential Display

(*A*) Principle of the reactions underlying DDRT-PCR analysis. *N* represents any of the four nucleotides G, A, T, or C. *V* can be any nucleotide except T. *B* can be any nucleotide except A. (*B*) Flow chart of DDRT-PCR analysis with subsequent confirmation of differential regulation and characterization of differentially expressed genes. (Reprinted, with permission, from Warthoe et al. 1995.)

large number of technical difficulties and artifacts, only some of which can be eliminated by control experiments. Although a very large number of projects have been initiated using differential display, the harvest of novel genes has been rather disappointing, and many groups have abandoned the technique in frustration.

Differential display, as presently practiced, is quite incapable of detecting all cDNAs synthesized in cells. First, only a fraction of the mRNA species in a cell fulfills the conditions required for amplification. For an mRNA to be amplified by differential display, it must be able to form a hybrid with a particular anchored 3′ primer and with the arbitrary 5′ primer. Furthermore, this 5′-priming site must lie within 500 bases of the poly(A) tail in order for the amplified product to be displayed on a conventional denaturing polyacrylamide gel. In consequence, only a subset of the mRNAs in a cell will be amplified by a particular pair of primers. With most pairs of primers, between 10 and 100 bands of amplified cDNAs, 100–500 nucleotides in length, are visible on the gel (Bauer et al. 1993; Liang et al. 1993).

Second, the amplification process in DD-PCR is essentially Darwinian in nature. Thus, only those mRNAs that are well-fitted for reverse transcription will be copied efficiently into cDNA. During the subsequent PCR, some of the resulting cDNAs will be more efficiently amplified than others. Over the course of 30 or more cycles of amplification, the population of cDNAs can be

expected to reduce in complexity as Darwinian selection works its will. The strength of selection will depend partly on the conditions used for PCR, partly on the degree of secondary structure in the mRNA, and its degree of complementarity to the arbitrary primer. An abundant mRNA that is poorly amplified may be underrepresented in the final population of cDNAs, whereas a minor RNA that is efficiently amplified may become vastly overrepresented. The population of amplified cDNAs may therefore bear little relationship to the population of mRNAs that engendered it.

Third, DD-PCR is both labor-intensive and expensive to perform. A typical screen using the original Liang and Pardee (1992) method involves setting up individual PCRs with all possible pairwise combinations of 16 5′-oligonucleotide primers and 12 3′-oligonucleotide primers, which works out to 192 separate PCRs (i.e., 12 x 16 = 192) for each mRNA population analyzed. If just two populations of mRNA are compared, then the number of PCRs doubles to 384, and since the reactions should be carried out in duplicate or triplicate to ensure reproducibility (Luce and Burrows 1998), the total number of PCRs increases to 768. Because each PCR is analyzed by electrophoresis on a single lane of a sequencing gel, at least 768 lanes are required to analyze all the reactions. A typical sequencing gel has 40 lanes, meaning that ~20 gels must be poured, run, dried, and subjected to autoradiography to generate the raw data for comparison. Finally, characterization of a cDNA product that exhibits differential expression is no small task. The cDNA band must be eluted from the sequencing gel, reamplified by PCR, subcloned into a plasmid, subjected to DNA sequencing, radiolabeled for use as a probe on an RNA blot to confirm the initial observation of differential expression, and eventually isolated as a full-length cDNA. Thereafter, the really hard work of identifying the physiological function of the encoded product begins. In addition to these concerns, DD-PCR has many other problems, some of which are listed below:

- More than half of the cDNAs that are identified as differentially expressed turn out to be false positives that cannot be confirmed by northern blotting or slot-blotting (e.g., please see Liang et al. 1993; Sager et al. 1993; Aiello et al. 1994; Li et al. 1994; Sun et al. 1994; Utans et al. 1994). It is possible that some of these phantom cDNAs may be derived from mRNAs that are expressed at very low levels in mammalian cells. However, this seems unlikely since differential display shows a strong overall bias toward abundant transcripts (Bertioli et al. 1995).
- The pattern of amplified bands changes when different preparations of RNA or different sources of *Taq* DNA polymerases are used (Haag and Raman 1994; Sompayrac et al. 1995; Sung and Denman 1997).
- Many repetitive sequences are identified as differentially expressed in most screens, and these are of little use in studying the biology of the system at hand.
- At least a portion of the mRNAs in the target cells is not amplified to high levels and is thus missed. These problems arise because of differences in the efficiency with which a given mRNA template is transcribed into cDNA and thereafter amplified. In addition, very short cDNA products and very long cDNA products are not well resolved on the sequencing gels and are thus overlooked.
- Many of the bands are doublets or closely spaced sets of three or four bands of equal intensity. Further analysis suggests that these families of bands correspond to the two complementary strands of the same fragment with or without dA, which is added by *Taq* polymerase at the 3′ ends of completed DNA chains.
- About 25% of the bands can be reamplified solely by the arbitrary primer and not by the anchored primer (Welsh et al. 1992; Mou et al. 1994; McClelland et al. 1995; Jurecic et al. 1996; Graf et al. 1997; Guimaraes et al. 1997). These bands most likely arise as a consequence of amplification of internal sequences of the first-strand cDNA by the arbitrary primer.

- Some of the bands detected in DD-PCR are derived from introns or from sites far removed from the 3′-untranslated region of mRNAs. These problems are thought to arise from annealing of the anchoring primer to regions of the primary transcript that contain tracts of A residues (Luce and Burrows 1998).
- Cloning and sequencing show that many of the bands recovered from the gel contain a mixture of DNA fragments (Callard et al. 1994; Li et al. 1994). This result suggests that amplification by arbitrary primers may be promiscuous (Welsh et al. 1992) and may generate a background of DNA fragments that permeates the gel. Some investigators therefore recommend cloning the DNA eluted from gel and screening individual clones by northern, dot-blot, or slot-blot hybridization (Callard et al. 1994; Li et al. 1994).

PRIMERS USED IN DD-PCR

Anchored Primers

In the original description of this technique (Liang and Pardee 1992), the anchored (antisense) primer $(T)_{11\text{-}12}XY$ was designed to be complementary to the poly(A) tail of mRNA and the last two nucleotides of the transcribed sequence. *X* may therefore be dG, dA, or dC and *Y* may be any one of the four deoxynucleotides. Because dT is not used in the penultimate position, there are 12 possible anchoring primers of this type, each having a different dinucleotide at the 3′ end. Anchored primers with at least one G residue generate the largest number of amplified bands, whereas those ending in A or T are the least efficient (Mou et al. 1994).

A number of protocols have been published in which one (Wang et al. 1998), four (Liang and Pardee 1992), or three (Liang et al. 1994) anchored antisense primers have been used for DD-PCR instead of the original 12 (Liang and Pardee 1992; Bauer et al. 1994). In theory, reducing the number of anchored primers reduces the number of reactions that are required to achieve full coverage of the repertoire of mRNAs of a cell. However, reduction in the number of anchored primers also leads to an increase in the number of DD-PCR products generated in the reaction. Resolution of DNA bands sometimes deteriorates to the point where the bands cannot be adequately resolved.

Liang and Pardee (1992) calculate that 20 arbitrary decanucleotide 5′ primers used in all possible pair-wise combinations with 12 anchoring primers of the sequence $(T_{11\text{-}12}XY)$ would amplify the 3′ termini of 10,000 different mRNA species. These estimates are based on the assumption that mRNAs are only copied into cDNAs when they form perfect hybrids with the anchoring 3′ primer. However, there are strong indications that the penultimate 3′ base of $T_{12}XY$ primers can mispair with an mRNA template without greatly affecting the efficiency of reverse transcription (Liang et al. 1993). These results are depressing because the lack of specificity in the penultimate position effectively reduces the number of available anchoring primers. Since each of these primers generates between 10 and 100 resolvable bands on a gel when paired with any given 5′ primer of arbitrary sequence, a "complete" display of the 3′ termini of 10,000 mRNAs would require, as an absolute minimum, 60 different arbitrary 5′ primers. Using a single "universal" anchoring primer (Wang et al. 1998) makes the problem even worse. In this case, a calculation suggests that a minimum of 200 arbitrary 5′ primers would be required to obtain decent coverage of the mRNA population.

These calculations are only valid if each primer pair samples the same number of mRNAs with equal efficiency, if different cDNAs are amplified with equal efficiency, and if estimates of the number of mRNAs in a eukaryotic cell are accurate. The last of these assumptions is shaky, where-

as the first two are certainly wrong. Theoretical calculations therefore tend to overestimate — perhaps to a great extent — the depth of coverage that can be achieved by DD-PCR. In a given screen, the same differentially expressed mRNA can sometimes be identified with more than one primer pair. This could be interpreted to mean that the coverage of the mRNA population is deep enough to generate multiple hits on the same RNA molecule. However, we and others (Bertioli et al. 1995) find that clones identified by multiple hits tend to be derived from abundant mRNAs, suggesting that abundance can blur the already dubious specificity of primer pairs. The bands generated in DD-PCR may therefore reflect abundance, nucleotide sequence, or some amalgam of the two.

Arbitrary Primers

Arbitrarily defined primers are at least ten nucleotides in length. They should be composed of equal numbers of AT and GC base pairs and should be predicted not to self-anneal or to form stem-loop structures. Arbitrary primers whose 5′ dinucleotide is GC or CG generate the highest number of amplification products, and a G residue at the 3′ terminus is also advantageous (Mou et al. 1994).

Longer Arbitrary Primers

Longer arbitrary sense primers (25–28 mers) greatly increase the reproducibility of DD-PCR (Zhao et al. 1995). However, they also decrease the number of amplified bands detected by gel electrophoresis (Zhao et al. 1998). As the annealing temperature is increased, the stringency of primer annealing is also increased, leading to more specific and reproducible amplification of a smaller subset of cDNAs (Malhotra et al. 1998). The gain in specificity is achieved by reducing the number of cDNAs eligible for amplification.

SUMMARY

The goal of DD-PCR is to display all of the mRNAs of a cell. In addition to the difficulties discussed elsewhere in this protocol, there are doubts about the power and specificity of the primer pairs. Until the problems that presently haunt differential display are solved, the future of the method will remain uncertain. Fortunately, new technologies are coming into use that offer alternative ways to trace the patterns of gene expression in cells. DNA arrays, for example, may be able to bypass many of the difficulties that have held up progress in this area for so long.

Differential display is a technique with high theoretical promise and many practical problems. The nature and dimensions of these problems are still not fully defined. Nevertheless, numerous improvements to the original technique have been reported over the years that have increased the efficiency with which differentially expressed genes can be identified and have decreased the amount of work required to identify these genes (e.g., please see Sompayrac et al. 1995; Zhao et al. 1995; Liang and Pardee 1997). This protocol, which incorporates some of these improvements, was provided by Charles P. Landrum (University of Texas Southwestern Medical Center, Dallas).

MATERIALS

▲ **IMPORTANT** To reduce the chance of contamination with exogenous DNAs, prepare and use a special set of reagents and solutions for PCR only. Bake all glassware for 6 hours at 150°C and autoclave all plasticware. For more information, please see the panel on **CONTAMINATION IN PCR** in the chapter introduction. For an alternative approach to reagents, please see the panel on **DIFFERENTIAL DISPLAY KITS**.

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

10x Amplification buffer

5x DD-PCR reverse transcriptase buffer

250 mM Tris-Cl (pH 8.3)

375 mM KCl

15 mM $MgCl_2$

Autoclave the 5x buffer for 10 minutes at 15 psi (1.05 kg/cm^2) on liquid cycle. Divide the sterile buffer into aliquots. Store the aliquots at –20°C.

Dithiothreitol (DTT) (100 mM)

dNTP solution (20 mM) containing all four dNTPs (pH 8.0)

Placental RNase inhibitor (20 units/ml)

Please see the information panel on **INHIBITORS OF RNASES** in Chapter 7.

5x Sequencing gel-loading buffer

Enzymes and Buffers

Reverse transcriptase (RNA-dependent DNA polymerase)

Please see the panel on **REVERSE TRANSCRIPTASES USED IN RT-PCR** in Protocol 8. For DD-PCR, a reverse transcriptase that is deficient in RNase H is required (e.g., Superscript from Life Technologies or StrataScript from Stratagene).

Thermostable DNA polymerase

Taq DNA polymerase is the standard and appropriate enzyme for the amplification stage of most forms of DD-PCR.

Nucleic Acids and Oligonucleotides

Anchoring 3′ oligonucleotide primers (300 µg/ml) in 10 mM Tris-Cl (pH 7.6), 0.1 mM EDTA

The anchoring 3′ oligonucleotides are a family of 12 primers with the general structure 5′-d$(T)_{12}$*VN*-3′, where *V* is either C, A, or G, and *N* is C, T, A, or G. For example, one primer in the series is 5′-d$(T)_{12}$CC-3′, the next is 5′-d$(T)_{12}$CT-3′, etc.

Purify each oligonucleotide primer by chromatography on commercially available resins (e.g., NENSORB, NEN Life Science Products) or by denaturing polyacrylamide gel electrophoresis, as described in Chapter 10, Protocol 1.

Arbitrary 5′ oligodeoxynucleotide primers (50 µg/ml) in 10 mM Tris-Cl (pH 7.6), 0.1 mM EDTA

Sixteen arbitrary 5′ oligonucleotide primers are required, each ten nucleotides in length. The sequence of each primer is chosen at random, but it should contain approximately equal numbers of the four bases, with a balanced distribution of G and C residues, and a low propensity to form stable secondary structures.

Purify each oligonucleotide primer by chromatography on commercially available resins (e.g., NENSORB, NEN Life Science Products) or by denaturing polyacrylamide gel electrophoresis, as described in Chapter 10, Protocol 1.

Total RNA (100 µg/ml)

Total RNA extracted from cells with chaotropic agents is generally the template of choice for DD-PCR. RNAs to be compared by DD-PCR should be prepared in an identical fashion. Poly(A)$^+$ RNA is not ideal as a template in differential display because the methods used for isolation of Poly(A)$^+$ RNA often contaminate the preparation with significant amounts of oligo(dT) that can prime DNA synthesis at various points along the poly(A) tail, resulting in smearing of bands on the gel (Liang et al. 1995).

Gels

Agarose gel (1%)
Please see Step 20.

Electrolyte gradient sequencing gel
For details on setting up this gel, please see Chapter 12, Protocol 10. Please see Steps 10 and 13.

Radioactive Compounds

Radiolabeled dATP (10 μCi/μl, sp. act. 3000 Ci/mmole) **<!>**
DNA labeled with α-^{35}S or α-^{33}P generates sharper bands on autoradiographs than does DNA labeled with α-^{32}P.

Special Equipment

Barrier tips for automatic micropipettes

Microfuge tubes (0.5 ml, thin-walled for amplification) or *Microtiter plates*
Use 96-well plates designed for use in a thermal cycler.

Positive-displacement pipette

Thermal cycler programmed with desired amplification protocol
If the thermal cycler is not equipped with a heated lid, use either mineral oil or paraffin wax to prevent evaporation of liquid from the reaction mixture during PCR.

Water baths preset to 65°C and 94°C

Additional Reagents

Steps 10 and 13 of this protocol require the reagents listed in Chapter 12, Protocols 10 and 11.

Step 22 of this protocol requires the reagents listed in Protocol 5 of this chapter.

Step 23 of this protocol requires the reagents listed in Protocol 12 of this chapter.

Step 24 of this protocol requires the reagents listed in Chapter 7, Protocol 8 or 11, and Protocol 15 of this chapter.

DIFFERENTIAL DISPLAY KITS

Several companies sell DD-PCR kits that contain control mRNAs, purified oligonucleotide primers, and appropriate instructions for programming a thermal cycler. The kits differ mainly in the sequences of the primers used in the PCRs, with some being similar to those described in the original Liang and Pardee study (1992). Other kits contain oligonucleotides that (1) reduce the complexity of the banding pattern, (2) increase the length of the PCR products obtained, and (3) facilitate subsequent analysis of the differential display products. Given the capricious nature of DD-PCR, this may be one of the few occasions when the purchase of a kit actually makes sense.

METHOD

Optimizing RNA Concentrations: Preparation of First-strand cDNAs

1. In sterile 0.5-ml microfuge tubes, set up a series of trial reactions to establish the optimum concentrations of "control" and "test" RNAs required to produce a pattern of 100–300 amplified cDNA bands after gel electrophoresis and autoradiography. Make fivefold serial dilutions in H_2O of the RNA preparations to produce concentrations of between 1 μg/ml and 100 μg/ml.

2. Choose one or more primers from the collection of anchored 3′ oligonucleotides and set up a series of annealing reactions that contain different amounts of diluted RNA templates:

template RNA	8.0 µl
anchored 3′ oligonucleotide primer	2.0 µl

Incubate the reactions for 10 minutes at 65°C and then place them in a 37°C water bath.

The total amount of RNA in the annealing reactions should vary between 8 ng and 800 ng.

3. Add the following to the annealing reactions:

5x DD-PCR reverse transcriptase buffer	4 µl
100 mM dithiothreitol	2 µl
200 µM solution of four dNTPs	2 µl
~25 units/µl placental RNase inhibitor	0.25 µl
200 units/µl reverse transcriptase	0.25 µl
H_2O	to 20 µl

Incubate the tubes at 37°C for 1 hour.

A reverse transcriptase that is deficient in RNase H is required for DD-PCR (e.g., Superscript from Life Technologies or StrataScript from Stratagene).

To test for contaminating genomic DNA, set up one or more control reactions that contain no reverse transcriptase enzyme and carry these through Step 10 of the protocol. Contamination with genomic DNA is not usually a problem unless the RNA has been prepared from cells that are undergoing apoptosis or from tissue that is necrotic. If necessary, the RNA preparation can be treated with RNase-free DNase I either as a separate step during purification or in the same reaction tube that will later be used to synthesize cDNA (Dilworth and McCarrey 1992; Huang et al. 1996; please see the entry on DNase I in Appendix 4).

4. Inactivate the reverse transcriptase by incubating the reaction mixtures for 10 minutes at 94°C.

Steps 3 and 4 can be carried out in a thermal cycler programmed with a single cycle of 37°C for 1 hour/94°C for 10 minutes, followed by a 4°C hold.

Optimizing RNA Concentrations: Preparation and Amplification of Double-stranded cDNAs

5. Set up two series of eight 0.5-ml amplification tubes. Each tube should contain:

10x amplification buffer	2 µl
anchored 3′ oligonucleotide primer	2 µl
20 mM solution of four dNTPs (pH 8.0)	1 µl
[α-^{33}P]dATP or [α-^{35}S]dATP (3000 Ci/mmole)	1 µl
H_2O	9 µl
5 units/µl thermostable DNA polymerase	1 unit

To each tube, add 2 µl of a different arbitrary 5′ primer. Mix the contents by tapping the sides of the tubes.

Wherever possible, use the 10x amplification buffer supplied by the manufacturer of the *Taq* DNA polymerase.

6. Into one series of eight tubes, dispense ~3-µl aliquots of the reverse transcriptase reaction containing the test RNA. Into the other series of eight tubes dispense ~3-µl aliquots of the reverse transcriptase reaction containing the preparation of control RNA. Close the tubes and mix the contents gently.

7. If the thermal cycler is not fitted with a heated lid, overlay the reaction mixtures with 1 drop (~50 µl) of light mineral oil. Place the tubes in the thermal cycler.

8. Amplify the nucleic acids using the denaturation, annealing, and polymerization times and temperatures listed in the table.

Cycle Number	Denaturation	Annealing	Polymerization
30 cycles	15 sec at 94°C	30 sec at 42°C	15 sec at 72°C
Last cycle	15 sec at 94°C	30 sec at 42°C	2 min at 72°C

These times are suitable for 20-µl reactions assembled in thin-walled 0.5-ml tubes and incubated in thermal cyclers such as the Perkin-Elmer 9600 or 9700, Master Cycler (Eppendorf), and PTC 100 (MJ Research). Times and temperatures may need to be adapted to suit other types of equipment and reaction volumes.

Most thermal cyclers have an end routine in which the amplified samples are incubated at 4°C until they are removed from the machine. Samples can be left overnight at this temperature, but should be stored thereafter at –20°C.

9. At the end of the program, remove the tubes from the thermal cycler and add 5 µl of 5x sequencing gel-loading buffer to each.

10. Separate the radiolabeled products of the reactions by electrophoresis through an electrolyte gradient polyacrylamide gel of the type used for DNA sequencing. Electrophoresis is carried at constant electrical power until the xylene cyanol tracking dye has migrated about two-thirds of the length of the gel (please see Chapter 12, Protocols 10 and 11). Dry the gel and expose it to autoradiographic film.

11. Examine the pattern of DNA bands arising from reactions containing different concentrations of control and test RNAs. A good differential display contains between 100 and 250 well-resolved bands. The optimum amount of template RNA varies from preparation to preparation and from one pair of primers to another. Select the concentration of test and control RNAs that work well with the largest number of primer pairs.

Preparation of Amplified cDNAs for Differential Display

12. Repeat the annealing, reverse transcriptase, and amplification reactions using all combinations of primer pairs and the optimum amount of RNA templates. Set up the reactions in 96-well microtiter plates designed for use in a thermal cycler.

13. Separate the products of the amplification reactions by electrophoresis through polyacrylamide sequencing gels, as in Steps 9 and 10.

Load the reactions generated with each primer pair in adjacent lanes on the gel, i.e., load the reaction obtained with primer pair A + B from one RNA preparation next to the reaction obtained with primer pair A + B from the other RNA preparation. Ordering samples in this way greatly simplifies comparison of the autoradiographic patterns.

14. Compare the patterns of bands obtained with each primer pair from the different RNA populations.

When a differentially expressed band is identified, it is advisable to repeat the experiment to make sure that the initial finding is reproducible. Ideally, different batches of the two RNAs should be used, although this precaution may not always be practicable.

Recovery and Reamplification of the Differentially Displayed cDNAs

15. Recover target bands from the dried polyacrylamide gel. Lay the autoradiogram on top of the gel and use a soft pencil to lightly mark the position of the desired band on the autoradiogram. Cutting through the autoradiogram with a clean razor blade, excise each target band and the attached Whatman 3MM paper. Soak each sliver of dried gel/paper overnight at room temperature in a separate 0.5-ml microfuge tube containing 50 µl of sterile H_2O.

16. Puncture the bottom of each 0.5-ml tube with a small-gauge needle. Place each punctured tube inside a 1.5-ml microfuge tube. Centrifuge the tubes for 20 seconds to transfer the eluate to the larger tube. Discard the amplification tube containing the residue of the Whatman 3MM paper and polyacrylamide.

17. Amplify the eluted fragment in a reaction containing the following:

10x amplification buffer	2 µl
DNA eluted from polyacrylamide gel	3 µl
arbitrary 5′ oligonucleotide primer	2 µl
anchoring 3′ oligonucleotide primer	2 µl
20 mM solution of four dNTPs (pH 7.0)	1 µl
H_2O	9.5 µl
5 units/µl *Taq* thermostable DNA polymerase	2 units

To facilitate cloning of the DNA fragment, use a thermostable DNA polymerase such as *Taq* that places a dA residue at the 3′ end of the amplified DNA. Wherever possible, use the 10x amplification buffer supplied by the manufacturer of the *Taq* DNA polymerase.

18. If the thermal cycler is not fitted with a heated lid, overlay the reaction mixtures with 1 drop (~50 µl) of light mineral oil. Place the tubes in a thermal cycler.

19. Amplify the nucleic acids using the denaturation, annealing, and polymerization times and temperatures listed in the table.

Cycle Number	Denaturation	Annealing	Polymerization
30 cycles	15 sec at 94°C	30 sec at 42°C	15 sec at 72°C
Last cycle	15 sec at 94°C	30 sec at 42°C	2 min at 72°C

Polymerization should be carried out for 1 minute for every 1000 bp of length of the target DNA.

Most thermal cyclers have an end routine in which the amplified samples are incubated at 4°C until they are removed from the machine. Samples can be left overnight at this temperature, but should be stored thereafter at –20°C

20. Estimate the concentration of the reamplified DNA fragment by electrophoresis of 5–10% of the reaction through a 1% (w/v) agarose gel.

21. If mineral oil was used to overlay the reaction (Step 18), remove the oil from the sample by extraction with 150 µl of chloroform.

The aqueous phase, which contains the amplified DNA, will form a micelle near the meniscus. The micelle can be transferred to a fresh tube with an automatic micropipette.

▲ **IMPORTANT** Do not attempt chloroform extractions in microtiter plates. The plastic used in these plates is not resistant to organic solvents.

22. Ligate the DNA into a vector that has been tailed with dT (e.g., pGEM T vector from Promega) (please see Protocol 5) and transform *E. coli* with aliquots of the ligation reaction.

23. Isolate plasmid DNA from six or more recombinants and compare the sizes of the inserts released by restriction enzyme digestion.

The sequence of the insert DNA can be established by using universal primers that bind to the flanking regions of the vector. These oligonucleotides can also be used as primers to check the size of the inserts by PCR (please see Protocol 12).

It is important to isolate and sequence more than one plasmid recombinant from the ligation reaction because there may have been more than one DNA fragment in the slice excised from the gel. Compare the cDNA sizes and sequences to each other and to those in the various databases.

24. Confirm the differential expression of a candidate cDNA/mRNA in as many ways as possible, including northern hybridization (Chapter 7, Protocol 8), RNase protection (Chapter 7, Protocol 11), or quantitative PCR (Protocol 15 of this chapter). In situ mRNA hybridization can be used to localize the transcript to a diseased or developing tissue.

To increase the chances of success with DD-PCR:

- Focus on cDNA products that show all-or-none differences in their expression patterns in the mRNA populations being compared. Apparent quantitative differences in expression are frequently the result of artifacts and vagaries of PCR or idiosyncrasies of sampling. Many all-or-none differences, however, turn out to be real, i.e., they can be confirmed by independent methods such as northern hybridization.
- Wherever possible, isolate the RNA used for DD-PCR from pure cell populations. Consistent patterns of differential gene expression can be obtained by comparing RNAs isolated from cultured mammalian cells derived from a single cell type (e.g., epithelia). Most tissues are dynamic and complex and may respond to physiological changes by altering the ratio of one cell type to another. This response may appear in DD-PCR as a change in the apparent abundance of mRNAs, but in reality, it is not. The same caveat holds when comparing normal and cancerous tissues because most tumorigenesis involves transformation of a single cell type, followed by expansion and rapid evolution of the population.
- Just about any insult to cells leads to differential expression of repetitive sequences in the genome, including transposable elements, SINE and LINE sequences, endogenous retroviruses, and other assorted repetitive DNAs. In most instances, it will prove extremely difficult to relate the expression of such sequences to the biology or pathology being studied. Amplification of repetitive DNA sequences can also be substantially reduced by ensuring that the starting mRNA sample is free from contamination by trace amounts of genomic DNA (please see the entry on DNase I in Appendix 4).
- Ignore/discard all cDNAs identified by DD-PCR that do not produce a signal on a northern blot or in an RNase protection assay. The origin(s) of these DNAs is unknown. Perhaps they come from low abundance mRNAs, from introns, or from fragments of genomic DNA that contaminate the preparations of RNA. Whatever their provenance, the differential expression of these RNAs cannot be confirmed and there is no reason to study them further.

By the glare of false science betray'd,
That leads to bewilder, and dazzles to blind.

James Beattie 1735–1803. *The Hermit*

I can forgive Alfred Nobel for having invented dynamite, but only a fiend in human form could have invented the Nobel Prize.

George Bernard Shaw

MULTIPLEX PCR

Multiplex PCR is the term used when more than one pair of primers is used in a polymerase chain reaction. The goal of multiplex PCR is to amplify several segments of target DNA simultaneously and thereby to conserve template DNA, save time, and minimize expense. The yield of each amplified product is reduced in proportion to the number of primer pairs included in the reaction. However, as a general rule, up to eight primer pairs can be used simultaneously in a standard PCR before the yield of each amplified product is reduced to the point of invisibility on an agarose gel.

Unfortunately, multiplex PCR is very tricky to set up. Great care must be taken to ensure that all of the primers in the reaction have approximately the same melting temperature, that the primers are unlikely to interact with one another, and that the amplified products are of approximately the same size but can be unambiguously distinguished from one another by gel electrophoresis. The multiplex reaction must then be optimized as follows.

- Check that all target loci can be amplified efficiently in separate reactions using the same PCR program.
- Titrate the amount of each primer pair to achieve maximum amplification in separate reactions using the same PCR program and reaction conditions.
- Balance the amount of each primer pair in the multiplex reaction to achieve acceptable amplification of all target regions.

The last requirement usually causes the most problems. Frequently, one or two regions of the target DNA yield little or no amplified product, whereas all other primer pairs behave perfectly. The best option is to increase progressively the concentration of the recalcitrant primer pairs while reducing the concentration of the well-behaved primer pairs. Consider adjusting the reaction conditions only if this strategy fails; for example, alter the concentrations of Mg^{2+} or KCl in the reaction mixture. However, if the yields of the multiplex reaction are systematically biased in favor of longer PCR products, the best option is to reoptimize the amount of each primer pair in a series of multiplex reactions containing increased concentrations of KCl (1.0–2.0-fold) and a constant concentration of Mg^{2+} (1.5 mM). Conversely, if the yields are biased in favor of smaller PCR products, increase the concentration of Mg progressively (up to 4.5 mM) while maintaining a constant concentration of KCl.

If all of the products are poorly amplified, try increasing the concentration of template and thermostable DNA polymerase. If no improvement is noted, increase the concentration of all primer pairs by a factor of 2 and use a touchdown program in which the annealing and extension temperatures are decreased in 2°C intervals (please see the information panel on **TOUCHDOWN PCR**).

If nonspecific amplification is a problem, try to identify the guilty primer pairs by setting up another series of amplification reactions each containing only one primer pair. If a particular primer pair can be identified, redesign both primers. Alternatively, if no particular primer pair can be identified, consider the possibility that nonspecific amplification may be the result from synthesis primed with the forward primer of one pair and the reverse primer of another. The best way to unravel this situation is to set up a series of multiplex PCRs, each lacking one primer pair. By a process of elimination, it is usually possible to find out which combinations of primer pairs are responsible for nonspecific amplification.

TAQ DNA POLYMERASE

- *Taq*, a thermostable DNA-dependent DNA polymerase, was first isolated from the thermophilic eukaryote *Thermus aquaticus* in 1976 (Chien et al. 1976; Kaledin et al. 1980). Some years later, the enzyme became famous for its use in PCR (Saiki et al. 1988) and was designated in 1989 as Molecule of the Year (Koshland 1989), for whatever that may mean.
- The gene for *Taq* (Lawyer et al. 1989) encodes an 832-amino-acid protein (M_r = 93.9 kD) consisting of two domains. The amino-terminal region (residues 1–290) is similar in sequence and structure to the 5′→3′ exonuclease domain of members of the polymerase I family of DNA polymerases (including *E. coli* DNA polymerase I and related bacteriophage-encoded polymerases) (Gutman and Minton 1993). The properties of the 5′→3′ exonuclease are described by Longley et al. (1990). The carboxy-terminal domain contains a catalytically inactive 3′→5′ exonuclease (residues 294–422) and a polymerase subdomain of *Taq* (residues 424–831), whose structure is very similar to that of the Klenow fragment of *E. coli* DNA polymerase I. The residues critical for catalytic activity are conserved in both polymerases (for reviews, please see Joyce and Steitz 1994, 1995; Pelletier 1994; Perler et al. 1996).
- The thermal stability of *Taq* DNA polymerase is thought to result from increased hydrophobicity of the core of the enzyme, improved stabilization of electrostatic forces, and enhanced interaction with solvent molecules, due to the presence of additional proline residues on the surface of the enzyme (Kim et al. 1995; Korolev et al. 1995).
- The enzyme originally isolated by Chien et al. (1976) was smaller than the full-length *Taq* protein, had slightly different catalytic properties, and in all probability was a proteolytic fragment that lacked part of the amino-terminal domain. In *T. aquaticus, Taq* polymerase is expressed at such low levels (0.01–0.02% of the cellular protein) that commercial production is not a viable proposition. These days, the enzyme is produced from versions of the *Taq* gene that have been engineered so as to obtain high levels of expression in *E. coli.* Most of these alterations involve modification of the DNA sequences that precede and immediately follow the initiating ATG codon (e.g., please see Engelke et al. 1990; Lawyer et al. 1993; Ishino et al. 1994; Desai and Pfaffle 1995). Since the clones used by various commercial manufacturers may have been engineered in different ways and since the protocols used for purification of the enzyme may also be different, preparations obtained from different manufacturers do not necessarily deliver identical results. However, homemade *Taq* polymerase, which is simple to prepare (Engelke et al. 1990; Pluthero 1993; Desai and Pfaffle 1995), is consistently of high quality and shows little batch to batch variation. Preparations of *Taq* DNA polymerase typically display the following properties:

Optimal reaction temperature: 75–80°C

Optimal reaction conditions: 1.5 mM $MgCl_2$, 50–55 mM KCl (pH 7.8–9.0)

K_m dNTPs: 10–15 μM

K_m DNA: 1.5 nM

Extension rates (dNTPs/sec/enzyme molecule):

75°C	150
70°C	<60
55°C	24
37°C	1.25
22°C	0.25

Processivity (dNTPs/sec/enzyme molecule): 42

Half-life of enzyme:

97.5°C	5–6 minutes
95°C	40 minutes
92.5°C	130 minutes

Error rates: Error rates ranging from 8.9×10^{-5} to 1.1×10^{-4} have been reported by various groups over the years. For more details, please see posting by Paul Hengen (1995b) on the newsgroup bionet.molbio.methds-reagnts.

- To initiate DNA synthesis, *Taq* polymerase, like other DNA polymerases, requires a primer that is annealed to the template strand and carries a hydroxyl group at its 3′ end (please see Primers in the introduction to Protocol 1). During the extension reaction in vitro, *Taq* polymerase removes oligonucleotides carrying a 5′-hydroxyl group that are annealed to the template strand ahead of the growing strand. However, 5′-phosphorylated oligonucleotides cannot be displaced from the template strand of DNA by *Taq* polymerase. The enzyme is not able to continue synthesis when it encounters a depurinated base in the template. Depurination occurs at a significant rate when DNA is incubated at high temperatures, which may place limits on the length of DNA that can be amplified by *Taq* polymerase (Barnes 1994).
- All essential metal-binding sites in the amino-terminal 3′→5′ exonuclease subdomain of *Taq* have been eliminated by mutation (Kim et al. 1995; Korolev et al. 1995). Because of the lack of a proofreading function, the rate of misincorporation of dNTPs is high in PCRs catalyzed by *Taq* (or by other thermostable DNA polymerases that also lack an editing function) (Tindall and Kunkel 1988). More than 50% of the DNA molecules produced after 25 cycles of *Taq*-driven amplification of a 200-bp fragment can be expected to carry mutations of one sort or another.

- During the past years, the enzymatic and physical properties of *Taq* have been summarized by many reviewers, including Cha and Thilly (1993), Bej and Mahbubani (1994), Perler et al. (1996), and Fanning and Gibbs (1997). These reviews provide comprehensive lists of primary references from which the data in this information panel are derived.
- A number of commercial preparations of *Taq* are available that lack 5′→3′ exonuclease activity. These include the Stoffel fragment (Perkin-Elmer), a number of deletion variants, and a number of site-directed mutants (Merkens et al. 1995). In general, these enzymes are less efficient and less processive than *Taq*.
- The cloned gene for *Taq* DNA polymerase I of *T. aquaticus* strain YT-1 is available from ATCC (40336). The pros and cons of isolating and purifying *Taq* polymerase for in-house use are discussed in intelligent articles by Sederoff (1993) and Hengen (1995b). Hoffman-La Roche Inc. currently has legal rights over PCR and *Taq* (U.S. Patents #05352600 and #4889818). However, this position may change in the future because Hoffman-La Roche's claims are under challenge. Many investigators have in the past been wary of purifying their own *Taq* because of the uncertainty about what they can and cannot do without running afoul of the patent law. However, there are several Internet sites that offer useful information on this topic, e.g., http://www.promega.com. The history of the patent disputes between Hoffman-La-Roche, Cetus Inc., and Promega is recounted in News and Views articles by Dickson (1994, 1996) and Abbott (1996).

HOT START PCR

Hot start is a method to optimize the yield of the desired amplified product in polymerase chain reactions and, simultaneously, to suppress nonspecific amplification. This is done by withholding an essential component of the PCR — the DNA polymerase or Mg^{2+}, for example — until the reaction mixture has been heated to a temperature that inhibits nonspecific priming and primer oligomerization.

In the first description of hot start PCR (D'Aquila et al. 1991; Erlich et al. 1991; Mullis 1991), template DNA and primers were mixed together and held at a temperature above the threshold of nonspecific binding of primer to template. All of the components necessary for the extension phase of the PCR were then added except the thermostable polymerase. Thermal cycling was initiated after the final addition of the DNA polymerase to the preheated reaction mixture. The elimination of the warm-up phase preceding the first cycle of PCR reduced the opportunities for nonspecific annealing of oligonucleotide primers, whereas the absence of DNA polymerase activity prevented extension of mismatched primers.

The original method was difficult because the reaction mixtures were assembled in tubes whose temperature was maintained by a heating block. These days, hot start PCR is more easily accomplished. The most popular method involves creating a physical barrier of wax between components of the reaction. For example, the primers, Mg^{2+}, dNTPs, and buffer can be mixed at room temperature in the bottom of the reaction tube and then covered with melted wax (e.g., Ampliwax PCR Gems from Perkin-Elmer or a commercial wax that melts at low temperature [melting point = 53–55°C]). The wax solidifies on cooling and confines the reagents to the bottom of the tube. The remaining components of the reaction are then mixed on top of the wax barrier. During the denaturation step of the first cycle of PCR, the wax barrier melts, allowing the components of the reaction to merge. The melted wax floats to the top of the reaction mixture where it now acts as a barrier to evaporation.

More esoteric variants of hot start PCR include the use of neutralizing monoclonal antibodies to inhibit polymerase activity during the assembly and warm-up phase of the reactions. When the temperature increases, the antibody dissociates from the enzyme and is inactivated during the denaturation step of the first cycle of PCR (Kellogg et al. 1994). Polymerase-antibody complexes are sold by several companies including CLONTECH (TaqStart and tThStart) and Life Technologies (Platinum *Taq* Polymerase). A similar idea is used by Perkin-Elmer, whose enzyme, AmpliTaq Gold, requires heating to ~93°C for ~10 minutes during a specially programmed first cycle of PCR to become fully active (Birch et al. 1996; Kebelmann-Betzing et al. 1998). In another variation, Mg^{2+} embedded in wax beads (HotWax Beads) is released into the reaction mixture as the wax melts. The manufacturer, Invitrogen, claims that the absence of Mg^{2+} during the initial warm-up phase of the reaction significantly reduces nonspecific priming. HotWax Beads are sold in several formulations that provide predetermined concentrations of Mg^{2+} for PCRs of standard volume.

Hot start PCR is not essential in optimized simple PCRs that contain a single pair of well-designed oligonucleotide primers and generate high yields of a specific amplified product. However, the method comes into its own when nonspecific amplification is a problem — for example, when fewer than 10^4 copies of template DNA are present in the reaction, when the template DNA is highly complex (e.g., mammalian genomic DNA), or when PCRs contain several pairs of oligonucleotides (multiplex PCR). In all of these cases, hot start PCR is best used in conjunction with a "touchdown" protocol (please see the information panel on **TOUCHDOWN PCR**).

RIBONUCLEASE H

Ribonuclease H (RNase H) catalyzes the endonucleolytic degradation of the RNA moiety of DNA-RNA hybrids, generating oligoribonucleotides, of varying chain lengths with 3′-hydroxyl and 5′-phosphate termini. It was first recognized and isolated from calf thymus (Stein and Hausen 1969; Hausen and Stein 1970), but it is now known to be present in a wide variety of mammalian tissues, yeasts, prokaryotes, and virus particles. Many types of cells contain more than one RNase H.

In many retroviruses, RNase H is associated with the multifunctional enzyme reverse transcriptase and carries out important functions at several stages during the transcription of the viral genome into DNA. In eubacteria, it is believed to be required for the removal of RNA primers from Okazaki fragments, for processing of transcripts into primers used by DNA polymerase I to initiate DNA synthesis, and to remove R-loops that provide sites for opportunistic initiation of unregulated DNA synthesis at the chromosomal origin of replication in *E. coli.* RNase H is presumed to carry out similar functions in eukaryotic cells.

RNase H has been reported to increase markedly the inhibition of gene expression by antisense oligodeoxynucleotides. Hybrids between these oligonucleotides and specific sequences in mRNAs are sensitive to degradation by the enzyme. RNase H is required for initiation of replication at the origin (*ori*) of colicin E1 (colE1)-type plasmids in vitro. The enzyme also seems to suppress initiation of DNA synthesis at sites other than *ori.*

X-ray crystallographic analysis shows that *E. coli* RNase H consists of two domains, one of which contains an Mg^{2+}-binding site enmeshed in β-strands — a fold previously recognized in DNase I. For further information and references, please see Crouch (1990), Wintersberger (1990), Hostomsky et al. (1993), Jung and Lee (1995), Kanaya and Ikehara (1995), Rice et al. (1996), and Crooke (1998).

TERMINAL TRANSFERASE

Terminal deoxyribonucleotidyl transferase, Tdt, a monomeric enzyme of ~510 amino acids, catalyzes the addition of dNTPs to the 3′ termini of DNA molecules (for review, please see Bollum et al. 1974). Of the several enzymes that are capable of this type of template-independent DNA synthesis, terminal transferase is by far the most efficient: Whereas DNA polymerases such as the Klenow fragment of *E. coli* DNA polymerase and *Taq* have the ability to add single nucleotides to DNA substrates, terminal transferase can, under the right conditions, catalyze the addition of hundreds of nucleotides.

In molecular cloning, terminal transferase is now used chiefly to catalyze the addition of homopolymeric tails to single-stranded DNAs generated in 5′-RACE and 3′-RACE reactions. The enzyme was in considerably greater demand a few years ago when cDNAs were routinely equipped with dG tails and cloned into dC-tailed plasmid vectors. This tailing was always a messy reaction, difficult to control, since the kinetics of the tailing reaction are wonderfully odd, and often disastrous, and since the early commercial preparations of the enzyme were often contaminated with both endo- and exonucleases.

Homopolymeric tailing follows entirely predictable kinetics when all substrates are present in the reaction at high concentrations and when all termini are identical. However, when faced with a set of heterogeneous 3′ termini, the enzyme will first catalyze the rapid tailing of molecules carrying 3′-unpaired extensions, then blunt-ended molecules, and finally, with great reluctance, molecules with recessed 3′ termini. In the case of blunt-ended molecules, the crucial rate-limiting step is the addition of the first nucleotide: Blunt ends that are clamped shut by G:C base pairs are poor substrates, whereas blunt ends rich in A:T are more permissive and are tailed more rapidly and synchronously. If the enzyme finds a blunt-ended molecule with a frayed 3′ terminus and catalyzes the addition of a single nucleotide, subsequent elongation of the homopolymeric tail will proceed rapidly. The more heterogeneous the population of termini, the more quirky and asynchronous the kinetics of the tailing reaction.

Terminal transferase has strange requirements. It is inhibited by many of the cations routinely included in reaction buffers, including ammonium, chloride, and phosphate ions (for review, please see Bollum 1974). Most reactions are carried out in cacodylate (dimethyl arsenic acid) buffers (Kato et al. 1967), although 100 mM Tris-acetate (pH 7.2) is almost as good. Homopolymeric tailing reactions that use dTTP or dCTP as substrates are carried out in the presence of Co^{2+}; Mn^{2+} is the preferred cofactor for homopolymeric tailing reactions involving polymerization of purine residues.

Terminal transferase is expressed in pre-B and pre-T lymphocytes and is routinely used as a marker for certain types of leukemia arising from these cells. During maturation of the immune system, TdT mediates the expansion and diversification of the T-cell receptor repertoire by adding template-independent nucleotides and disrupting homology-directed recombination (for review, please see Gilfillan et al. 1995). For reviews of the molecular biology and enzymology of terminal transferase, please see Chang and Bollum (1986).

TOUCHDOWN PCR

Touchdown PCR is a simple method to optimize yields of amplified DNA when the melting temperature of hybrids between the oligonucleotide primers and their target sequences is not known with certainty, for example:

- when the primers have been designed from amino acid sequences
- when amplifying members of a multigene family
- when the template DNA is extremely complex and occupies a large sequence space
- when amplifying DNA from a species other than that for which the primers were designed
- when using primers containing "universal" bases such as inosine.

In all of these circumstances, mismatches between the oligonucleotide primers and the template DNA can be anticipated, with the potential to generate undesirable nonspecific amplification products. Because neither the number, the location, nor the type of these mismatches is known, it is not possible to calculate from first principles an annealing temperature that will maximize the yield of the desired amplification product while minimizing nonspecific priming. Instead, the optimum annealing temperature must be determined empirically.

One method of optimization involves setting up a series of PCRs that are annealed at different temperatures but are identical in all other respects. However, this type of experiment is both laborious and inefficient unless a special type of thermal cycler (e.g., Stratagene's Robocycler) is available. For most investigators, a better alternative is touchdown PCR (Don et al. 1991; Peterson and Tjian 1993; Roux 1995; Hecker and Roux 1996; Roux and Hecker 1997), in which a range of annealing temperatures are utilized in a single PCR. In touchdown PCR, the annealing temperature during the first two cycles of amplification is set ~3°C above the calculated melting temperature of a perfect hybrid formed between the most GC-rich oligonucleotide primer in the reaction and its target DNA. The annealing temperature is then reduced by one centrigrade degree for each pair of subsequent cycles. At some point, a temperature permissive for specific priming will be reached and amplification of the target sequence will begin. The onset of nonspecific amplification will be delayed for several additional cycles until the annealing temperature has been lowered to the point where nonspecific priming can occur. However, by this time, the specific amplification product will have hegemony over the reaction and will effectively suppress the accumulation of nonspecific amplification products. In theory, a perfectly matched primer-target hybrid will have a 1024-fold advantage over mismatched hybrids whose melting temperature is 5°C lower. Touchdown PCR therefore gives a selective advantage to amplification products generated from correctly primed reactions. In our laboratory, touchdown PCR is the quickest method to optimize PCRs when using new combinations of oligonucleotides and templates, and it, together with hot start PCR or the addition of GC-Melt, is a remedy of first resort when faced with problems such as inefficient priming, mispriming, and formation of primer-dimers.

Modern thermal cyclers such as MJ Research model PTC 100, Perkin-Elmer model 9600, and Master Cycler (Eppendorf) are easily programmed to accommodate touchdown PCR. However, in some types of basic thermal cyclers, programming of a progressive reduction of annealing temperature becomes a nightmare. Individual files for each pair of cycles must be serially linked into a series using extensive commands, a process that is laborious and utilizes large amounts of programming space. A possible compromise is to use fewer but steeper temperature steps to link the initial and final annealing temperatures (Roux 1995; Hecker and Roux 1996). In either case, touchdown PCR works best in conjunction with techniques such as hot start PCR or booster PCR which limit the opportunities for both nonspecific binding between oligonucleotide primers and the template DNA and for formation of primer dimers (please see the information panel on **HOT START PCR**).

USE OF INOSINE IN DEGENERATE POOLS OF OLIGONUCLEOTIDES USED FOR PCR

Below is a list of recommended codons for designing oligonucleotides that are to be used for screening primate cDNA or mammalian cDNA libraries and that contain inosine at positions of ambiguity. The recommendations take into account the natural usage of codons in human genes and the fact that the sequence CpG is underrepresented in human DNA.

Amino Acid		Codon
A	(Ala)	GCI
C	(Cys)	TGC[a]
D	(Asp)	GAT
E	(Glu)	GAI
F	(Phe)	TTC[a]
G	(Gly)	GGI
H	(His)	CAC[a]
I	(Iso)	ATI
K	(Lys)	AAI
L	(Leu)	CTI[c]
M	(Met)	ATG
N	(Asn)	AAC[a]
P	(Pro)	CCI
Q	(Gln)	CAI
R	(Arg)	CGI[c]
S	(Ser)	TCC[b,c]
T	(Thr)	ACI
V	(Val)	GTI
W	(Trp)	TGG
Y	(Tyr)	TAC[a]

[a]If the first nucleotide of the succeeding codon is G, use T in the third position.

[b]If the first nucleotide of the succeeding codon is G, use I in the third position.

[c]Try to avoid amino acids with six codons if at all possible.

UNIVERSAL PRIMERS

Universal primers are synthetic oligonucleotides that anneal to one side or the other of cloning sites in plasmid, phagemid, bacteriophage λ, and bacteriophage M13 vectors. These primers may be used to amplify by PCR or to sequence by the dideoxy method any segment of foreign DNA that has been cloned into these sites. In addition to conventional single-stranded templates, universal primers can be used in sequencing protocols that have been optimized for double-stranded DNA templates.

Universal primers are commercially available for a great variety of vectors. The lists of primers provided in the following tables, which are by no means comprehensive, cover only the most popular standard vectors. We recommend that investigators who wish to amplify or to sequence inserts cloned into more esoteric vectors, particularly commercial expression vectors, to read the relevant catalogs. Most responsible companies now sell universal primers for use with their own specialized vectors.

Primers for Cloning Sites in pBR322

Table 8-6 provides a list of primers that can be used for amplifying or for sequencing target DNAs cloned into pBR322. The accompanying figure (Figure 8-11) illustrates the locations of the sites corresponding to these primer sequences on the plasmid. These primers, which were originally developed in Bruce Wallace's laboratory (Wallace et al. 1981) are sold by New England Biolabs, from whose catalog the figure is reproduced.

Primers for Cloning Sites in Bacteriophage M13/pUC Vectors

Table 8-7 provides a list of primers that can be used for amplifying or for sequencing target DNAs cloned into M13/pUC vectors. The accompanying figure (Figure 8-12) illustrates the alignments of the these primer sequences along the bacteriophage or plasmid sequence. These primers are sold by New England Biolabs, from whose catalog the figure is reproduced.

A report published in *Nucleic Acids Research* describes a pUC18 variant that is present in many laboratories (Lobet et al. 1989). The mutation consists of a deletion of the cytosine nucleotide from the second codon of the *lacZ* gene, just upstream of the polylinker region. Difficulties arise when sequencing with primers that overlap this mutation. DNA sequencing with this pUC18 mutant with New England Biolabs' reverse sequencing primer 1201, a 16-mer whose 3′ end overlaps the mutation, has been difficult even when using conditions of low stringency. To avoid any problems, NEB recommends using the reverse sequencing primer 1233, a 24-mer located immediately upstream (5′) of the position of primer 1201. Primer 1201 can still be used with all similar *lacZ* vectors, including M13 vectors and other pUC vectors for which this deletion has not been found.

A forward primer (5′GGTTTTCCCAGTCACGACG) that binds to bacteriophage M13/pUC vectors at a region ~40 nucleotides upstream of the polylinker has been reported to prime spuriously from a site in the vector sequences (Steffens et al. 1993). This problem can be avoided by using a primer (5′CACGACGTTGTAAAACGAC) that binds to a region ~29 nucleotides upstream of the polylinker.

TABLE 8-7 Primers for M13/pUC

Vector	Code	Direction of Priming	Sequence of Primer
M13/pUC universal primer	1	forward	5′d(GTAAAACGACGGCCAGT)3′
M13/pUC	2	forward	5′d(GTTTTCCCAGTCACGAC)3′
M13/pUC	3	forward	5′d(CGCCAGGGTTTTCCCAGTCACGAC)3′

Chapter 9

Preparation of Radiolabeled DNA and RNA Probes

INFORMATION PANELS

LABELED NUCLEIC ACIDS ARE USED IN MOLECULAR CLONING either as reagents or as probes:

- Labeled fragments of cloned DNA and oligonucleotides of defined size are used as *reagents* in chemical and enzymatic sequencing, nuclease S1 analysis of RNA, and band-shift experiments. In these cases, the labeled reagent is converted to products of different sizes, which can be detected by a variety of methods, gel electrophoresis being the most common.
- Labeled DNA, RNA, and oligonucleotide *probes* are used in hybridization-based techniques to locate and bind DNAs and RNAs of complementary sequence. These techniques include colony and plaque screening, Southern and northern analyses, in situ hybridization, and sequencing by hybridization.

In both cases, success depends on the facile introduction of labels into DNA or RNA by methods such as end-labeling, random priming, nick translation, in vitro transcription, and variations of the polymerase chain reaction (PCR). Some of these methods place the label in specific locations within the nucleic acid (e.g., at the 5′ or 3′ terminus); others generate molecules that are labeled internally at multiple sites. Some methods yield labeled single-stranded products, whereas others generate double-stranded nucleic acids. Finally, some generate probes of defined length, and others yield a heterogeneous population of labeled molecules. Table 9-1 summarizes the options available for radiolabeling nucleic acids and guides investigators to a method of labeling that suits the task at hand.

Basic research may seem very expensive. I am a well-paid scientist. My hourly wage is equal to that of a plumber, but sometimes my research remains barren of results for weeks, months or years and my conscience begins to bother me for wasting the taxpayer's money. But in reviewing my life's work, I have to think that the expense was not wasted. Basic research, to which we owe everything, is relatively very cheap when compared with other outlays of modern society. The other day I made a rough calculation which led me to the conclusion that if one were to add up all the money ever spent by man on basic research, one would find it to be just about equal to the money spent by the Pentagon this past year.

Albert Szent-Györgyi, *The Crazy Ape*

TABLE 9-1 Methods Used to Radiolabel Nucleic Acids In Vitro

Method	Type of Probe	Position of Radiolabel	Size of Probe	Chief Uses	Specific Activity	Protocol Number
Random priming using DNA templates	double-stranded DNA	internal	~400–600 nucleotides	Southern and northern blotting and for screening libraries	~2 x 10^9 dpm/μg	1,2
Random priming using RNA templates	single-stranded DNA or DNA-RNA hybrids	internal	~400–600 nucleotides	differential screening of cDNA libraries; subtracted probes; differential display	~1 x 10^9 dpm/μg	7,9
Oligo(dT) priming of cDNA synthesis from RNA templates	single-stranded cDNA or cDNA-RNA hybrids	internal	~400–600 nucleotides	subtracted probes; differential display	~1 x 10^9 dpm/μg	8
PCR	single- or double-stranded DNA	internal	generates radiolabeled DNAs of defined length, depending on the spacing of primers	mapping 5′ termini and splice junctions in mRNA by nuclease S1 or mung bean nuclease; Southern and northern blotting and for screening libraries by hybridization; the probe represents a specific portion of the target gene	~1 x 10^9 to 2 x 10^9 dpm/μg	3
Nick translation	double-stranded DNA	internal	~400 nucleotides	Southern and northern blotting and for screening libraries	5 x 10^8 to 1 x 10^9 dpm/μg	2[a]
Primer extension using universal or target-specific primers and single-stranded DNA templates	double-stranded DNA	internal	generates radiolabeled DNAs of defined length from bacteriophage M13 or phagemid DNA templates; the length of the DNAs may be 150 bp to 2 kb, depending on the spacing of the primer on the template DNA	mapping 5′ termini and splice junctions in mRNA by nuclease S1 or mung bean nuclease; Southern and northern blotting and for screening libraries by hybridization; the probe represents a specific portion of the target gene	~1 x 10^9 to 2 x 10^9 dpm/μg	4
Primer extension using two primers and single-stranded DNA templates	double-stranded DNA	internal	generates probes of heterogeneous length (usually 200–300 nucleotides)	Southern and northern blotting and for screening libraries	~1 x 10^9 to 2 x 10^9 dpm/μg	5
In vitro transcription of double-stranded DNA templates	single-stranded RNA	internal	generates radiolabeled RNAs of defined length	mapping the termini and splice junctions in mRNAs by RNase protection; Southern and northern blotting and for screening libraries; in situ hybridization	~1 x 10^9 dpm/μg	6
Addition of nucleotides to recessed or protruding 3′ termini of double-stranded DNA	double-stranded DNA	3′-terminal	generates radiolabeled DNAs of of defined length that are labeled in defined positions	Maxam-Gilbert sequencing; mapping the termini and splice junctions in mRNA by nuclease S1 or mung bean nuclease; radiolabeled DNA size markers; footprinting and ribonuclease protection	1 x 10^8 to 2 x 10^8 dpm/μg	10,11,12
Phosphorylation of 5′ termini of double-stranded DNA	double-stranded DNA	5′-terminal	generates radiolabeled DNAs of defined length that are labeled in defined positions	Maxam-Gilbert sequencing; mapping the termini and splice junctions in mRNA by nuclease S1 or mung bean nuclease; radiolabeled DNA size markers; footprinting and ribonuclease protection	1 x 10^8 to 2 x 10^8 dpm/μg	13,14, 15, 16

Protocol 1

Random Priming: Radiolabeling of Purified DNA Fragments by Extension of Random Oligonucleotides

OLIGONUCLEOTIDES CAN SERVE AS PRIMERS for initiation of DNA synthesis on single-stranded templates by DNA polymerases (Goulian 1969). If the oligonucleotides are heterogeneous in sequence, they will form hybrids at many positions, so that the complement of every nucleotide of the template (except those at the extreme 5′ terminus) will be incorporated at equal frequency into the product. These products of DNA synthesis can be radiolabeled by using one [α-^{32}P]dNTP and three unlabeled dNTPs as precursors, generating probes with specific activities of 5×10^8 to 5×10^9 dpm/μg.

Taylor et al. (1976) reported the first use of random priming to generate radiolabeled probes for hybridization. However, the method did not find wide acceptance until the mid 1980s, when the ready availability of commercial DNA polymerases and oligonucleotide primers allowed Feinberg and Vogelstein (1983, 1984) to develop a set of standardized and hardy reaction conditions. These conditions have since been incorporated into labeling kits, which are marketed by several commercial manufacturers. However, random priming reactions are so robust and simple that kits are an unnecessary luxury. Labeling can be carried out with equal efficiency and greater economy using components purchased individually.

Random priming is inherently simpler than nick translation because the requirements for two nuclease activities (DNase I and 5′→3′ exonuclease) are eliminated. The radiolabeled products of random priming reactions are therefore more homogeneous in size and behave more reproducibly in hybridization reactions. In nick translation, the average size of the radiolabeled products cannot be controlled with great accuracy. In random priming, however, the average size of the probe DNA is under the control of the investigator since probe length is an inverse function of the primer concentration (Hodgson and Fisk 1987). These advantages have proven to be so decisive that random priming has almost completely replaced nick translation as the standard method of labeling of double-stranded DNA probes.

COMPONENTS OF RANDOM PRIMING REACTIONS

DNA Polymerase

Random priming reactions may be catalyzed by any of several DNA polymerases including, for example, *Taq* (Sayavedra-Soto and Gresshoff 1992). However, by virtue of its efficiency and tolerance of a wide range of conditions, the enzyme of choice is the Klenow fragment of *Escherichia coli* DNA polymerase I. As discussed in the information panel on ***E. COLI* DNA POLYMERASE I AND THE KLENOW FRAGMENT**, the Klenow fragment lacks 5′→3′ exonuclease activity, so that the radioactive product is synthesized exclusively by primer extension rather than by nick translation and is not subject to exonuclease degradation. The reaction can be carried out at pH 6.6, where the 3′→5′ exonuclease activity of the standard Klenow enzyme is much reduced (Lehman and Richardson 1964). Alternatively, Sequenase version 2.0 (USB Specialty Biochemicals) or variants of the Klenow fragment that lack 3′→5′ exonuclease activity (Stratagene or New England Biolabs) can be used. Both of these enzymes lack the 3′→5′ exonuclease activity of the Klenow fragment.

Radiolabel

Random priming reactions typically contain one radiolabeled [α-^{32}P]dNTP (sp. act. 3000 Ci/mmole) and three unlabeled dNTPs as precursors. Under the reaction conditions described in this protocol, 40–80% of the [α-^{32}P]dNTP is incorporated into DNA and the specific activity of the radiolabeled product varies from 1×10^9 to 4×10^9 dpm/µg, depending on the amount of template DNA in the reaction. Although higher specific activities can be generated using two [α-^{32}P]dNTPs as precursors, the resulting probes degrade very rapidly due to radiochemical decay (Stent and Fuerst 1960) and must therefore be used without delay. When [α-^{32}P]dNTP of lower specific activity is used as a precursor (e.g., 800 Ci/mmole), the yield of DNA is increased fourfold and its specific activity is reduced to $<10^9$ dpm/µg. Such probes are more than adequate for most purposes and can be stored frozen for several days before radiolytic degradation becomes a problem.

Deoxynucleotide triphosphates that carry reporter groups such as digoxigenin can be substituted for radioactive nucleotides. Approximately one modified base is incorporated per 25–35 nucleotides of DNA synthesized during a standard random priming reaction (Kessler et al. 1990). For further information, please see Appendix 9.

Primers

Oligonucleotide primers can be generated by DNase I digestion of calf thymus DNA, by synthesis on an automated DNA synthesizer, or, far more easily, by purchase from a commercial source. The length of the primers is crucial. Oligonucleotides shorter than six bases in length are very poor primers, whereas those longer than seven bases in length have progressively greater tendency to self-anneal and self-prime (Suganuma and Gupta 1995). Ideally, therefore, populations of oligonucleotides used in random priming should be either six or seven nucleotides in length. All possible sequences should be represented in the population at equal frequencies.

The average size of the probe generated during random priming reactions is an inverse function of the concentration of primer (Hodgson and Fisk 1987): The length of radiolabeled product = $k/\sqrt{\ln Pc}$, where P_c is the concentration of primer.

The standard priming reaction described in this protocol contains between 60 ng and 125 ng of random hexamers or heptamers and generates radiolabeled products that are ~400–600

nucleotides in length, as determined by electrophoresis through either an alkaline agarose gel or a denaturing polyacrylamide gel. Higher concentrations of primer lead to steric hindrance or to exhaustion of the [α-^{32}P]dNTP precursor with a concomitant depression of yield; lower concentrations of primer generate populations of radiolabeled products that are so heterogeneous in length (0.4–4 kb; Hodgson and Fisk 1987) that they would be expected to hybridize with anomalous kinetics.

Template DNA

The reaction conditions given in this protocol, adapted from Feinberg and Vogelstein (1983, 1984), are optimized for labeling of linear double-stranded DNA templates up to 1 kb in length. Shorter DNA templates generate probes of low specific activity that do not hybridize well under stringent conditions. Closed circular, double-stranded DNAs are inefficient templates and should be converted to linear molecules by digestion with a restriction enzyme before use in a random priming reaction. Wherever practicable, a purified segment of target DNA should be used as a template, rather than an entire plasmid. This greatly suppresses the level of background when the radiolabeled DNA is used as a hybridization probe (Feinberg and Vogelstein 1983, 1984).

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Ammonium acetate (10 M)
Optional, please see Step 5.

Ethanol
Optional, please see Step 5.

NA stop/storage buffer
50 mM Tris-Cl (pH 7.5)
50 mM NaCl
5 mM EDTA (pH 8.0)
0.5% (w/v) SDS

5x Random priming buffer
250 mM Tris (pH 8.0)
25 mM $MgCl_2$
100 mM NaCl
10 mM dithiothreitol
1 M HEPES (adjusted to pH 6.6 with 4 M NaOH)
Use a fresh dilution in H_2O of 1 M dithiothreitol stock, stored at –20°C. Discard the diluted dithiothreitol after use.

Enzymes and Buffers

Klenow fragment of E. coli *DNA polymerase I*

Gels

Alkaline agarose gel or denaturing polyacrylamide gel **<!>**
Please see Step 4.

Nucleic Acids and Oligonucleotides

dNTP solution containing three unlabeled dNTPs, each at 5 mM

The composition of this solution depends on the [α-^{32}P]dNTP to be used. If radiolabeled dATP is used, the mix should contain dCTP, dTTP, and dGTP each at a concentration of 5 mM. If two radiolabeled dNTPs are used, this solution should contain the other two dNTPs each at a concentration of 5 mM. For advice on making and storing stock solutions of dNTPs, please see the information panel on **PREPARATION OF STOCK SOLUTIONS OF dNTPs AND ddNPTs FOR DNA SEQUENCING** in Chapter 12.

Random deoxynucleotide primers six or seven bases in length (125 ng/μl in TE, pH 7.6)

Because of their uniform length and lack of sequence bias, synthetic oligonucleotides of random sequence are the primers of choice. Oligonucleotides of optimal length (hexamers and heptamers; Suganuma and Gupta 1995) can be purchased from a commercial source (e.g., Pharmacia or Boehringer Mannheim) or synthesized locally on an automated DNA synthesizer. Store the solution of primers at –20°C in small aliquots.

Template DNA (5–25 ng/μl) in TE (pH 7.6)

Purify the DNA to be radiolabeled by one of the methods described in Chapter 5.

This protocol works best when 25 ng of template DNA is used in a standard 50-μl reaction. Larger amounts of DNA generate probes of lower specific activity; smaller amounts of DNA require longer reaction times. Please see note to Step 4.

Radioactive Compounds

[α-^{32}P]dNTP (10 mCi/ml, sp. act. >3000 Ci/mmole) **<!>**

To minimize problems caused by radiolysis of the precursor, it is best, whenever possible, to prepare radiolabeled probes on the day the [^{32}P]dNTP arrives in the laboratory.

Special Equipment

Boiling water bath or heating block preset to 95°C

Microfuge tubes (0.5 ml)

Sephadex G-50 spun column, equilibrated in TE (pH 7.6)

Optional, please see Step 5.

METHOD

1. In a 0.5-ml microfuge tube, combine template DNA (25 ng) in 30 μl of H_2O with 1 μl of random deoxynucleotide primers (~125 ng). Close the top of the tube tightly and place the tube in a boiling water bath for 2 minutes.
2. Remove the tube and place it on ice for 1 minute. Centrifuge the tube for 10 seconds at 4°C in a microfuge to concentrate the mixture of primer and template at the bottom of the tube. Return the tube to the ice bath.
3. To the mixture of primer and template, add:

5 mM dNTP solution	1 μl
5x random priming buffer	10 μl
10 mCi/ml [α-^{32}P]dNTP (sp. act. 3000 Ci/mmole)	5 μl
H_2O	to 50 μl

4. Add 5 units (~1 μl) of the Klenow fragment. Mix the components by gently tapping the outside of the tube. Centrifuge the tube at maximum speed for 1–2 seconds in a microfuge to transfer all the liquid to the bottom of the tube. Incubate the reaction mixture for 60 minutes at room temperature.

To label larger amounts of DNA, assemble reaction mixtures as described in Steps 3 and 4 and then incubate the reaction for 60 minutes. To label smaller amounts of DNA, incubate the reactions for times that are in inverse proportion to the amount of template added. For example, random priming reactions containing 10 ng of template DNA should be incubated for 2.5 hours.

To monitor the course of the reaction, measure the proportion of radiolabeled dNTPs that either is incorporated into material precipitated by trichloroacetic acid (TCA) or adheres to a DE-81 filter (please see Appendix 8).

Under these reaction conditions, the length of the radiolabeled product is ~400–600 nucleotides, as determined by electrophoresis through an alkaline agarose gel (Chapter 5, Protocol 8) or a denaturing polyacrylamide gel (Chapter 12, Protocol 8).

5. Add 10 µl of NA stop/storage buffer to the reaction, and proceed with one of the following options as appropriate.

   - Store the radiolabeled probe at –20°C until it is needed for hybridization.

     or

   - Separate the radiolabeled probe from unincorporated dNTPs by either spun-column chromatography (please see Appendix 8) or selective precipitation of the radiolabeled DNA with ammonium acetate and ethanol (please see Appendix 8). This step is generally not required if >50% of the radiolabeled dNTP has been incorporated during the reaction.

     Assuming that 50% of the radioactivity has been incorporated into TCA-precipitable material during the random priming reaction and that 90% of this material has been generated by random priming events on the template DNA (rather than self-priming of oligonucleotides), then the probe DNA would contain a total of ~4.5×10^7 dpm (enough for two to five Southern hybridizations of mammalian genomic DNA). The specific activity of the probe would be ~1.8×10^9 dpm/µg and the weight of DNA synthesized during the reaction would be 9.7 ng, which is enough to detect single-copy sequences in mammalian DNA by Southern analysis.

Protocol 2

Random Priming: Radiolabeling of DNA by Extension of Random Oligonucleotides in the Presence of Melted Agarose

A VARIATION OF THE METHOD DESCRIBED IN PROTOCOL 1 can be used to radiolabel DNA in slices cut from gels cast with low-melting-temperature agarose (Feinberg and Vogelstein 1983, 1984). Most of the materials required for this protocol are the same as those used in Protocol 1. However, the labeling buffer has been slightly modified to include unlabeled dNTPs and random oligonucleotide primers. According to the investigator's needs, the labeling reaction can be assembled from its individual components, as described in Protocol 1, or from the composite buffer, as described here. For further details concerning materials required for the method and on the specific activity and length of the generated probe, please see the introduction to Protocol 1.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Ammonium acetate (10 M)
Optional, please see Step 5.
Bovine serum albumin (10 mg/ml)
Ethanol
Optional, please see Step 5.
Ethidium bromide <!> *(10 mg/ml) or SYBR Gold staining solution* <!>
NA stop/storage buffer
50 mM Tris-Cl (pH 7.5)
50 mM NaCl
5 mM EDTA (pH 8.0)
0.5% (w/v) SDS

5x Oligonucleotide labeling buffer

250 mM Tris-Cl (pH 8.0)
25 mM $MgCl_2$
20 mM dithiothreitol
2 mM each of the unlabeled dNTPs
1 M HEPES (adjusted to pH 6.6 with 4 N NaOH)
1 mg/ml random deoxynucleotide primers, six bases in length

Store the buffer in small aliquots at –20°C. The buffer may be frozen and thawed several times without harm.

The composition of the 5x oligonucleotide labeling buffer depends on the [α-^{32}P]dNTP to be used. If radiolabeled dATP is to be used, the buffer should contain dCTP, dTTP, and dGTP. If two radiolabeled dNTPs are used, the buffer should contain two unlabeled dNTPs. For advice on making and storing stock solutions of dNTPs, please see the information panel on **PREPARATION OF STOCK SOLUTIONS OF dNTPs AND ddNTPs FOR DNA SEQUENCING** in Chapter 12.

Enzymes and Buffers

Klenow fragment of E. coli *DNA polymerase*

The Klenow fragment (5 units) is required in each random priming reaction.

Gels

Alkaline agarose gel or Denaturing polyacrylamide gel **<!>**

Please see Step 4.

Nucleic Acids and Oligonucleotides

Random deoxynucleotide primers six or seven bases in length (125 ng/μl in TE, pH 7.6)

Because of their uniform length and lack of sequence bias, synthetic oligonucleotides of random sequence are the primers of choice. Oligonucleotides of optimal length (hexamers or heptamers; Suganuma and Gupta 1995) can be purchased from a commercial source (e.g., Pharmacia or Boehringer Mannheim), or synthesized locally on an automated DNA synthesizer. Store the solution of primers at –20°C in small aliquots. Primers are incorporated into the 5x oligonucleotide labeling buffer.

Template DNA

The DNA to be labeled is recovered after electrophoresis through a low-melting-temperature agarose gel (e.g., FMC SeaPlaque LMT Agarose) (please see Steps 1–3 of this protocol). The gel should be cast and run in 1x Tris-acetate electrophoresis buffer (TAE). For details on casting and running low-melting-temperature gels, please see Chapter 5.

This protocol works best when 25 ng of template DNA is used in a standard 50-μl reaction. Larger amounts of DNA generate probes of lower specific activity; smaller amounts of DNA require longer reaction times. Please see note to Step 4.

Radioactive Compounds

[α-^{32}P]dNTP (10 mCi/ml, sp. act. >3000 Ci/mmole) **<!>**

To minimize problems caused by radiolysis of the precursor, it is best, whenever possible, to prepare radiolabeled probes on the day the [^{32}P]dNTP arrives in the laboratory.

Special Equipment

Boiling water bath

Sephadex G-50 spun column, equilibrated in TE (pH 7.6)

Optional, please see Step 5.

METHOD

1. After electrophoresis, stain the gel with ethidium bromide (final concentration 0.5 µg/ml) or SYBR Gold, and excise the desired band, eliminating as much extraneous agarose as possible.
2. Place the band in a preweighed microfuge tube and measure its weight. Add 3 ml of H_2O for every gram of agarose gel.
3. Place the microfuge tube in a boiling water bath for 7 minutes to melt the gel and denature the DNA.

   If radiolabeling is to be carried out immediately, store the tube at 37°C until the template is required. Otherwise, store the tube at –20°C. After each removal from storage, reheat the DNA/gel slurry to 100°C for 3–5 minutes and then store at 37°C until the radiolabeling reaction is initiated.
4. To a fresh microfuge tube in a 37°C water bath or heating block, add in the following order:

5x oligonucleotide labeling buffer	10 µl
10 mg/ml bovine serum albumin solution	2 µl
DNA in a volume no greater than 32 µl	20–50 ng
10 mCi/ml [α-^{32}P]dNTP (sp. act. >3000 Ci/mmole)	5 µl
Klenow fragment (5 units)	1 µl
H_2O	to 50 µl

   Mix the components completely with a micropipettor. Incubate the reaction for 2–3 hours at room temperature or for 60 minutes at 37°C.

   To label larger amounts of DNA, adjust the volume of the reaction mixture proportionately and incubate the reaction for 60 minutes. To label smaller amounts of DNA, incubate the reactions for times that are in inverse proportion to the amount of template added. For example, random priming reactions containing 10 ng of template DNA should be incubated for 2.5 hours.

   To monitor the course of the reaction, measure the proportion of radiolabeled dNTPs that either are incorporated into material precipitated by TCA or that adhere to a DE-81 filter (please see Appendix 8).

   Under these reaction conditions, the length of the radiolabeled product is ~400–600 nucleotides, as determined by electrophoresis through an alkaline agarose gel (Chapter 5, Protocol 8) or a denaturing polyacrylamide gel (Chapter 5, Protocol 9).
5. Add 50 µl of NA stop/storage buffer to the reaction, and proceed with one of the following options as appropriate:

   - Store the radiolabeled probe at –20°C until it is needed for hybridization.

     or

   - Separate the radiolabeled probe from unincorporated dNTPs by either spun-column chromatography (please see Appendix 8) or selective precipitation of the radiolabeled DNA with ammonium acetate and ethanol (please see Appendix 8). This step is not required if >50% of the radiolabeled dNTP has been incorporated during the reaction.

     Assuming that 50% of the radioactivity has been incorporated into TCA-precipitable material during the random priming reaction and that 90% of this material has been generated by random priming events on the template DNA (rather than self-priming of oligonucleotides), then the probe DNA would contain a total of ~4.5 x 10^7 dpm (enough for two to five Southern hybridizations of mammalian genomic DNA). The specific activity of the probe would be ~1.8 x 10^9 dpm/µg and the weight of DNA synthesized during the reaction would be 9.7 ng, which is enough to detect single-copy sequences.

NICK TRANSLATION: AN HISTORICAL NOTE

Until the early 1970s, radioactivity could be incorporated into nucleic acids only by metabolic labeling, in which radioactive precursors (usually in the form of $H_3{}^{32}PO_4$) were introduced into cells that were synthesizing the DNA of interest. This procedure required amounts of radioactivity that would be unthinkable in today's more conservative climate; it involved laborious purification of the radiolabeled nucleic acids, and it could be applied only to a small number of DNAs (e.g., viral genomes). Salvation came in the mid 1970s when nick translation was developed as a method to radiolabel DNAs to high specific activity in vitro (Maniatis et al. 1975; Rigby et al. 1977).

Nick translation requires the activity of two different enzymes (please see Figure 9-1). DNase I is used to cleave (nick) phosphodiester bonds at random sites in both strands of a double-stranded target DNA. *E. coli* DNA polymerase I is used to add deoxynucleotides to the 3′-hydroxyl termini created by DNase I. In addition

(Continued on facing page.)

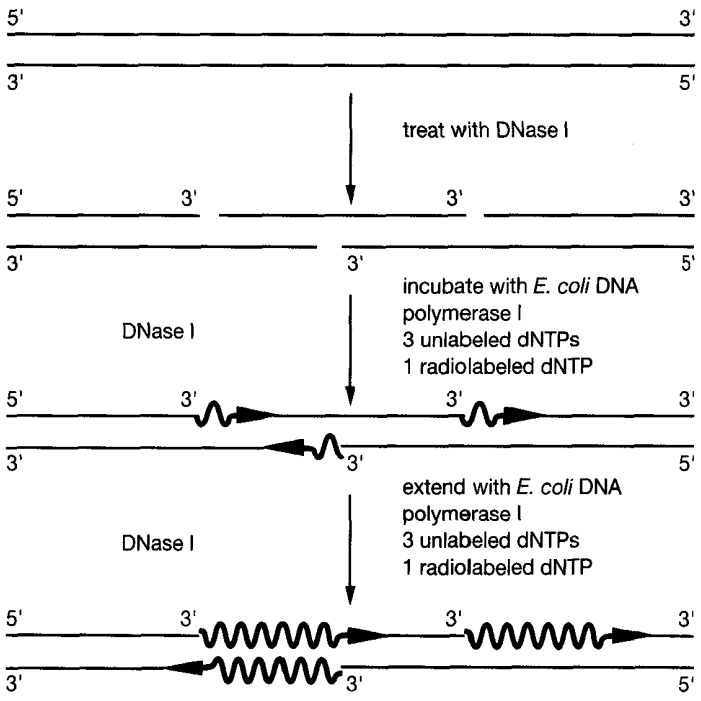

FIGURE 9-1 Nick Translation Using *E. coli* DNA Polymerase

Single-stranded nicks are introduced into the DNA by treatment with DNase I. *E. coli* DNA polymerase (Pol I) binds to the nick or short gap in duplex DNA, and the 5′→3′ exonuclease activity of Pol I then removes nucleotides from one strand of the DNA, creating a template for simultaneous synthesis of the growing strand of DNA. The original nick is therefore translated along the DNA molecule by the combined action of the 5′→3′ exonuclease and the 5′→3′ polymerase. In the reaction represented here, the nick in the upper strand of duplex DNA is translated from left to right by *E. coli* DNA polymerase in the presence of dNTPs. In the lower strand of duplex DNA, nick translation occurs from right to left. The stretches of newly synthesized DNA are represented by the colored wavy arrows.

to its polymerizing activity, DNA polymerase I carries a 5′→3′ exonucleolytic activity that removes nucleotides from the 5′ side of the nick. The simultaneous elimination of nucleotides from the 5′ side and the addition of radiolabeled nucleotides to the 3′ side result in movement of the nick (nick translation) along the DNA, which becomes labeled to high specific activity (Kelly et al. 1970). The reaction requires 100-fold less radioactive precursor than metabolic labeling while producing double-stranded probes whose specific activity is up to 200-fold higher. Such probes can be used for a variety of purposes including screening genomic and cDNA libraries and Southern and northern hybridizations.

After occupying a dominant position for many years, nick translation has been largely displaced by random oligonucleotide priming, which requires only one enzyme, as the method of choice for radiolabeling double-stranded DNA. A major problem with nick translation has always been the difficulty in balancing the activities of DNA polymerase I and DNase I used in the procedure. With the advent of nick translation kits (e.g., NIK-IT, Worthington Biochemical Inc.), this difficulty has been solved, although not in time to blunt the advance of random priming. Nevertheless, in a few laboratories, nick translation is still practiced — chiefly by those who remember its place in the history of cloning.

Optimizing Nick Translation Reactions

The amount of radiolabel incorporated during nick translation depends on the number of 3′-hydroxyl termini created in the template DNA by DNase I. Too much nicking creates an excess of initiation sites, which leads to maximal incorporation of radiolabel but yields DNA fragments that are too short to be useful as hybridization probes. Too little nicking, on the other hand, restricts the number of sites available for initiation of nick translation, resulting in a product of low specific activity. (For additional details on DNase I, please see Appendix 4.) The activity of DNase I varies between preparations, and the amount of DNase contaminating preparations of *E. coli* DNA polymerase I can also differ. It is therefore necessary to titrate each new batch of DNase I to find a concentration that yields probes with the desired specific activity and length. The nicking and polymerization reactions can be carried out simultaneously; in which case, a slight lag is observed before incorporation of nucleotides begins (Rigby et al. 1977), reflecting the time required for DNase I to generate nicks in the template. This lag, which is usually of little practical significance, can be eliminated by carrying out the nicking and polymerization reactions sequentially, rather than simultaneously (Koch et al. 1986).

The aim is to establish empirically a concentration of DNase I that results in incorporation of ~40% of the [α-^{32}P]dNTP. A standard nick translation reaction carried out under these conditions yields a product whose specific activity exceeds 10^8 cpm/μg and whose radiolabeled DNA strands are ~400–750 nucleotides in length. It is thus necessary to determine empirically the optimum amounts of each enzyme required to obtain both high specific activity and appropriate probe length. This optimization is best accomplished by keeping the amount of DNA polymerase added constant (e.g., at 2.5 units) and varying the concentration of input DNase I.

Although *E. coli* DNA polymerase I works adequately with concentrations of dNTPs as low as 2 μM, the enzyme catalyzes DNA synthesis much more efficiently when supplied with higher concentrations of substrates. For reasons of cost, nick translation reactions usually contain minimal concentrations of radiolabeled dNTPs (0.5–5 μM) and much greater concentrations of unlabeled dNTPs (1 mM). The specific activity of the final product depends in large part on the specific activity of the radiolabeled dNTP used in the reaction. By diluting the radiolabeled dNTP with the homologous unlabeled dNTP, it is possible to prepare DNA labeled to different specific activities. If high specific activities (>5 x 10^8 dpm/μg) are required (e.g., for screening recombinant DNA libraries or for detecting single-copy sequences in Southern hybridizations of complex mammalian genomes), the nick translation reaction should contain all four radiolabeled dNTPs (sp. act. >800 Ci/mmole) and no unlabeled dNTPs. For most other purposes, it is adequate to use one dNTP labeled with α-^{32}P (800 Ci/mmole) and three unlabeled dNTPs, or to dilute each [α-^{32}P]dNTP with an appropriate amount of the unlabeled dNTP. The amount of radiolabeled dNTP in a solution of specific activity 800 Ci/mmole (~12 pmoles/μl) is ~3.75-fold higher than that in a solution of specific activity 3000 Ci/mmole (~3.3 pmoles/μl).

Protocol 3

Radiolabeling of DNA Probes by the Polymerase Chain Reaction

THE POLYMERASE CHAIN REACTION (PCR) (PLEASE SEE CHAPTER 8) can be used to produce DNA probes with high specific activity. Listed below are the advantages of the method.

- Defined segments of the target DNA can be amplified and labeled independently of the location or type of restriction sites.
- There is no need to isolate fragments of DNA or to subclone them into vectors containing bacteriophage promoters.
- Only small amounts of template DNA are required (2–10 ng or ~1 fmole).
- The specific activity of the radiolabeled amplified DNA can exceed 10^9 dpm/μg.

Four different methods have been described for simultaneous amplification and radiolabeling of DNA. The first three methods require some information about the sequence of the target DNA, but the fourth method does not.

- ***Double-stranded DNA probes can be produced in conventional PCRs*** containing equal concentrations of two primers, three unlabeled dNTPs at concentrations exceeding the K_m, and one [α-^{32}P]dNTP at a concentration at or slightly above the K_m (2–3 μM) (Jansen and Ledley 1989; Schowalter and Sommer 1989).
- ***Radiolabeled probes biased heavily in favor of one strand of DNA*** can be produced in PCRs in which the concentration of one primer exceeds the other by a factor of 20–200. During the initial cycles of the PCR, double-stranded DNA is synthesized in a conventional exponential fashion. However, when the concentration of one primer becomes limiting, the reaction generates single-stranded DNA that accumulates at an arithmetic rate. By the end of the reaction, the concentration of one strand of DNA is three to five times greater than the concentration of the other (Scully et al. 1990). (For more information, please see the panel on **ADDITIONAL PROTOCOL: ASYMMETRIC PROBES** at the end of this protocol.)
- ***Radiolabeled probes consisting entirely of one strand of DNA*** can be synthesized in thermal cycling reactions that contain a double-stranded DNA template but only one primer. Double-stranded template DNA (20 ng) generates ~200 ng of single-stranded probe over the course of 40 cycles. The length of the probe can be defined by cleaving the template DNA at a restriction site downstream from the binding site of the primer (e.g., please see Stürzl and Roth 1990; Finckh et al. 1991).

- ***The target DNA may be digested with* CviJI**, a restriction enzyme that uses ATP as a cofactor to cleave the recognition sequence GC (except *YGCR*, where *Y* is a pyrimidine and *R* a purine) (Swaminathan et al. 1996). Because the dinucleotide GC occurs frequently in most DNAs, the modal size of the resulting blunt-ended DNA fragments is small — between 20 and 60 nucleotides. These fragments can be used as sequence-specific primers in PCRs in which an aliquot of the target DNA is used as template. The product is a heterogeneous population of double-stranded molecules whose size ranges from a minimum of ~60 bp to a maximum that exceeds the size of the target (Swaminathan et al. 1994). These larger molecules are thought to be complex scrambled versions of the target DNA that are generated from chimeric templates and/or primers. Investigators who feel uneasy about using a probe whose sequence is not co-linear with the original template DNA may wish to avoid this method; others wanting to use a PCR-based technique in the absence of DNA sequence information may embrace it.

The following protocol, provided by Mala Mahendroo and Galvin Swift (University of Texas Southwestern Medical Center, Dallas), remains close to the original procedure of Schowalter and Sommer (1989) for the generation of double-stranded radiolabeled probes. A modification that describes how to generate asymmetric probes by PCR is presented in the panel on **ADDITIONAL PROTOCOL: ASYMMETRIC PROBES** at the end of this protocol.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Ammonium acetate (10 M)

10x Amplification buffer

Carriers used during ethanol precipitation of radiolabeled probe (please see Step 5)

Use *either* glycogen (stock solution = 50 mg/ml in H_2O) *or* yeast tRNA (stock solution 10 mg/ml in H_2O). For more information, please see Appendix 8.

Chloroform **<!>**

Ethanol

TE (pH 7.6)

Enzymes and Buffers

Thermostable DNA polymerase (e.g., Taq DNA polymerase)

Thermostable DNA polymerase (2.5 units) is required for each amplification/labeling reaction.

Nucleic Acids and Oligonucleotides

dCTP (0.1 mM)

Dilute 1 volume of a stock solution of 10 mM dCTP with 99 volumes of 10 mM Tris-Cl (pH 8.0). Store the diluted solution at –20°C in 50-µl aliquots.

dNTP solution containing dATP, dGTP, and dTTP, each at 10 mM

For advice on making and storing stock solutions of dNTPs, please see the information panel on **PREPARATION OF STOCK SOLUTIONS OF dNTP AND ddNTPs FOR DNA SEQUENCING** in Chapter 12.

Forward primer (20 µM) in H_2O and Reverse primer (20 µM) in H_2O

Each primer should be 20–30 nucleotides in length and contain approximately equal numbers of the four bases, with a balanced distribution of G and C residues and a low propensity to form stable secondary structures. Store the stock solutions of primers at –20°C.

Oligonucleotide primers synthesized on an automated DNA synthesizer can generally be used in standard PCR without further purification. However, amplification and radiolabeling of single-copy sequences from mammalian genomic templates is often more efficient if the oligonucleotide primers are purified by chromatography on commercially available resins (e.g., NENSORB, NEN Life Science products) or by denaturing polyacrylamide gel electrophoresis, as described in Chapter 10, Protocol 1.

Template DNA (2–10 ng)

A variety of templates can be used in this protocol, including crude minipreparations of plasmid DNAs (please see Chapter 1, Protocol 1), purified bacteriophage λ DNA or plaque eluates (please see Chapter 2, Protocol 23), bacteriophage M13 single-stranded or double-stranded DNAs (please see Chapter 3, Protocol 5), purified DNA fragments isolated from agarose or polyacrylamide gels (please see Chapter 5, Protocol 1), and genomic DNAs from organisms with low complexity (e.g., bacteria and yeast).

When using the DNAs of recombinant bacteriophage λ or plasmids as templates, a small proportion of the radiolabeled probe may be derived from the vector sequences. This contamination arises if the oligonucleotide primers are complementary to flanking vector sequences or because the PCR will generate long "read-through" strands on the starting template DNA. For most hybridization applications, the presence of low levels of vector sequences will not interfere with the experiment. However, when screening libraries made in bacteriophage λ vectors or high-copy-number plasmid vectors (e.g., pUC, pBluescript, and pGEM vectors), the presence of vector sequences in the probe can lead to a substantial background. To manage this problem (1) use forward and reverse primers that are located within the target region, (2) use a gel-purified DNA fragment as a starting template for the amplification, and (3) cleave the template DNA with restriction enzyme(s) to prevent the synthesis of read-through strands.

Radioactive Compounds

[α-^{32}P]dCTP (10 mCi/ml, sp. act. 3000 Ci/mmole) **<!>**

To minimize problems caused by radiolysis of the precursor, it is best, whenever possible, to prepare radiolabeled probes on the day the [^{32}P]dNTP arrives in the laboratory.

Special Equipment

Barrier tips for automatic micropipettes
Microfuge tubes (0.5 ml, thin-walled tubes designed for PCR)
Positive-displacement pipette
Sephadex G-75 spun column, equilibrated in TE (pH 7.6)
Thermal cycler programmed with desired amplification protocol

If the thermal cycler is not equipped with a heated lid, use either mineral oil or a bead of paraffin wax to prevent evaporation of liquid from the reaction mixture during PCR.

METHOD

1. In a 0.5-ml thin-walled microfuge tube, set up an amplification/radiolabeling reaction containing:

10x amplification buffer	5.0 µl
10 mM dNTP solution	1.0 µl
0.1 mM dCTP	1.0 µl
20 µM forward oligonucleotide primer	2.5 µl
20 µM reverse oligonucleotide primer	2.5 µl
template DNA (2–10 ng or ~1 fmole)	5–10 µl
10 mCi/ml [α-^{32}P]dCTP (sp. act. 3000 Ci/mmole)	5.0 µl
H_2O	to 48 µl

Add 2.5 units of thermostable DNA polymerase to the reaction mixture. Gently tap the side of the tube to mix the ingredients.

If more than one DNA fragment is to be radiolabeled using a single pair of primers, make up and dispense a master mix consisting of all the reaction components except the DNA templates to the PCR tubes. Individual DNA templates can then be added to each tube just before addition of enzyme and initiation of the reaction.

2. If the thermal cycler is not fitted with a heated lid, overlay the reaction mixture with 1 drop (50 µl) of light mineral oil or a bead of paraffin wax to prevent evaporation of the samples during repeated cycles of heating and cooling. Place the tubes in a thermal cycler.

3. Amplify the samples using the denaturation, annealing, and polymerization times listed in the table.

Cycle Number	Denaturation	Annealing	Polymerization
30 cycles	30–45 sec at 94°C	30–45 sec at 55–60°C	1–2 min at 72°C
Last cycle	1 min at 94°C	30 sec at 55°C	1 min at 72°C

   These times are suitable for 50-µl reactions assembled in thin-walled 0.5-ml tubes and incubated in thermal cyclers such as the Perkin-Elmer 9600 or 9700, Master Cycler (Eppendorf), and PTC 100 (MJ Research). Times and temperatures may need to be adapted to suit other types of equipment and reaction volumes.

   Polymerization should be carried out for 1 minute for every 1000 bp of length of the target DNA.

   Most thermal cyclers have an end routine in which the amplified samples are incubated at 4°C until they are removed from the machine. Samples can be left overnight at this temperature, but should be stored thereafter at –20°C.

4. Remove the tubes from the thermal cycler. Use a micropipettor to remove as much mineral oil from the top of the reaction mixture as possible. Extract the reaction mix with 50 µl of chloroform to remove the remaining mineral oil. Separate the aqueous and organic layers by centrifugation for 1 minute at room temperature in a microfuge.

5. Remove the upper, aqueous layer to a fresh microfuge tube, add carrier tRNA (10–100 µg) or glycogen (5 µg), and precipitate the DNA with an equal volume of 4 M ammonium acetate and 2.5 volumes of ethanol. Store the tube for 1–2 hours at –20°C or for 10–20 minutes at –70°C. Collect the precipitated DNA by centrifugation at maximum speed for 5–10 minutes at 4°C.

6. Dissolve the DNA in 20 µl of TE (pH 7.6) and remove remaining unincorporated dNTPs and the oligonucleotide primers by spun-column chromatography through Sephadex G-75 as described in Appendix 8.

   Approximately 60% of the radioactivity should have been incorporated into DNA that elutes in the void volume during spun-column chromatography.

7. Use a liquid scintillation counter to measure the amount of radioactivity in 1.0 µl of the void volume of the spun column. Store the remainder of the radiolabeled DNA at –20°C until required.

   The yield of radiolabeled DNA ranges from 20 ng to 50 ng, and its specific activity is 1×10^9 to 2.5×10^9 dpm/µg.

ADDITIONAL PROTOCOL: ASYMMETRIC PROBES

By limiting the amount of one primer in the amplification reaction, a preponderance of one strand of the double-stranded DNA template will be synthesized during the amplification reaction (Gyllensten and Erlich 1988; Innis et al. 1988; Shyamala and Ames 1989, 1993; McCabe 1990; Scully et al. 1990). The resulting asymmetric probes can be used in northern hybridization to determine which strand of an unknown DNA represents the sense strand of a gene and which represents the antisense strand of a gene.

To synthesize an asymmetric probe in the above reaction, substitute a 0.4 μM solution of *either* the forward oligonucleotide primer *or* the reverse primer for one of the standard 20 μM primer solutions (please see Step 1 of the main protocol). Carry out the remainder of the protocol exactly as described.

Keep in mind that asymmetric amplification initially proceeds at an exponential rate and then slows to an arithmetic rate when the amount of one oligonucleotide primer becomes limiting. The specific activity of the asymmetric probe is the same as that produced in the normal PCR, but the amount of DNA synthesized in the reaction will be much less. Setting up multiple reactions at Step 1 can help compensate for the decrease in total yield of probe.

Also keep in mind that the bias in favor of one radiolabeled strand over the other is usually not more than a factor of 5. If necessary, this ratio can be improved (1) by separating the single- and double-stranded DNA products of the PCR by gel electrophoresis or anion-exchange chromatography (please see Appendix 8) or (2) by using a more complex, two-stage amplification procedure that enables a single-stranded probe to be produced in >20-fold excess (Finckh et al. 1991).

Protocol 4

Synthesis of Single-stranded DNA Probes of Defined Length from Bacteriophage M13 Templates

IN THIS PROTOCOL AND IN PROTOCOL 5, A SYNTHETIC OLIGONUCLEOTIDE annealed to single-stranded DNA derived from a recombinant bacteriophage M13 or phagemid template is used to prime the synthesis of complementary radiolabeled DNA (Ley et al. 1982). Synthesis is catalyzed by the Klenow fragment of *E. coli* DNA polymerase I, which extends the annealed primer for various distances along the single-stranded template DNA. The products of the reaction, which are heterogeneous both in length and in the amount of incorporated radiolabeled dNTPs, are digested with a restriction enzyme to create double-stranded DNA fragments of uniform length, which are subsequently purified by agarose gel electrophoresis. These probes are ideal for nuclease S1 or mung bean nuclease mapping of the 5′ ends of mRNAs, for determining the positions of exons in a gene, for use in solution hybridization to quantitate mRNA, or for producing a probe that lacks vector sequences or represents only a small region of a cDNA or gene.

The oligonucleotide primer is usually complementary to a region of the *lac* gene immediately 3′ to the polycloning site in the mp series of bacteriophage M13 vectors (Yanisch-Perron et al. 1985). This "universal" primer, which is sold by several companies, has the advantage that it can be used to prepare probes complementary to any segment of DNA that has been cloned into any restriction site in the polylinker of the vector (for further details, please see the information panel on **UNIVERSAL PRIMERS** in Chapter 8). However, custom-made oligonucleotides complementary to specific sequences within the cloned DNA can also be used to prepare probes that represent only a portion of the cloned sequence.

The size, specific activity, and yield of the probe synthesized by the Klenow fragment are affected by the relative concentrations of primer, template, and dNTPs. When the concentration of each of the four dNTPs in the reaction is greater than the K_m of the Klenow enzyme, synthesis of DNA occurs at a maximal rate. If the concentration of any one of the four precursors falls below the K_m, the rate of synthesis drops dramatically. Thus, when each of the four dNTPs is present at a concentration less than the K_m, as is often the case when only radiolabeled nucleotides are used as precursors, the yield of product can be extremely low. To avoid this problem, primer-extension reactions are usually carried out with three unlabeled dNTPs, each at a concentration in excess of the K_m, and one radiolabeled dNTP at a lower concentration, which is usually below the K_m. Under these conditions, the proportion of radiolabeled dNTPs incorporated into DNA is very high, even though the rate of the reaction may be far from maximal. The K_m of the enzyme is different for each deoxynucleoside triphosphate: 200 μM for dCTP, 140 μM for TTP, 45 μM for dGTP, and 12 μM for dATP (Travaglini et al. 1975).

When one or more dNTPs are present at limiting concentrations, the size of the product may be unacceptably small unless the amount of template in the reaction is also reduced. For example, in a reaction containing three unlabeled dNTPs each at a concentration in excess of the K_m, 16 pmoles (50 μCi) of a radiolabeled dNTP (sp. act. 3000 Ci/mmole), and 2 pmoles of template (~1 μg), an average of only 28 nucleotides will be added to each primer molecule before the synthesis is brought to a halt by a lack of the radiolabeled dNTP. However, if the template concentration is reduced 100-fold to 0.02 pmole (~10 ng), an average of 3000 nucleotides will be added to each primer before the pool of precursors is exhausted.

To maximize the efficiency with which template molecules are used, the primer must be present in molar excess and the concentrations of primer and template must be high enough to drive the formation of primer-template hybrids to completion. These conditions are met when the primer is present in tenfold molar excess and its concentration is 200 pmoles/ml or greater. For some purposes, however, it is desirable to utilize the primer efficiently (e.g., when the primer is end-labeled). In this case, the primer:template ratio is reversed, so that the reaction contains a five- to tenfold molar excess of template.

Primer-extension reactions are usually carried out in the presence of excess Klenow fragment. If the enzyme is limiting, the number of DNA molecules initiated in the reaction (and hence the overall yield) will be reduced. However, the newly synthesized DNA molecules will be longer, on average, than DNA molecules synthesized when the enzyme is in excess.

Because it is possible to affect the size, specific activity, and yield of the probe by adjusting the conditions of the reaction, it is important to decide what particular combination of properties would be best suited for the task at hand. In RNA blotting and Southern hybridizations, where maximal sensitivity is often the overriding concern, the amount of template in the reaction should be kept to a minimum and the concentration of radiolabeled dNTP(s) should be increased as much as is practicable. When choosing which of the four radiolabeled dNTPs to use in the primer-extension reaction, consider the base composition of the probe to be synthesized and the K_m of the DNA polymerase for the individual dNTPs (please see above). When uniformly labeled probes are prepared for analysis of mRNAs by nuclease S1, the yield of full-length probe may be more important than its specific activity. In this case, the radiolabeled dNTP may be supplemented with unlabeled precursor until their combined concentration approaches the K_m. The yield of the reaction is determined by measuring the incorporation of radioactivity into either TCA-precipitable material or DE-81-bound molecules (please see Appendix 8), whereas the size of the product is assayed by gel electrophoresis.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Ammonium acetate (10 M)
Dithiothreitol (1 M)
EDTA (0.5 M, pH 8.0)
Ethanol
NaCl (5 M)
Phenol:chloroform (1:1, v/v) **<!>**
5x TBE electrophoresis buffer
Optional, please see Step 16.

Tris-Cl (1 M, pH 7.6)
Optional, please see Step 16.

Enzymes and Buffers

10x Klenow basic buffer
500 mM Tris-Cl (pH 7.5)
100 mM $MgSO_4$
Sterilize the buffer by filtration and store it in small aliquots at –20°C.

Klenow fragment of E. coli *DNA polymerase I*

Restriction enzyme(s), as appropriate for generation of the desired probe
The restriction enzyme used to cleave the products of the labeling reaction should cleave between 200 bp and 1 kb downstream from the primer-binding site.

Gels

Denaturing polyacrylamide gel **<!>** *or alkaline agarose gel*
Please see Step 13.

Nucleic Acids and Oligonucleotides

dNTP solution containing unlabeled dCTP, dGTP, and dTTP, each at 20 mM
The composition of this solution depends on the [α-^{32}P]dNTP to be used. If, as in this protocol, radiolabeled dATP is used, the mix should contain dCTP, dTTP, and dGTP each at a concentration of 20 mM. If two radiolabeled dNTPs are used, this solution should contain the other two dNTPs. For advice on making and storing stock solutions of dNTPs, please see the information panel on **PREPARATION OF STOCK SOLUTIONS OF dNTPS AND ddNTPs FOR DNA SEQUENCING** in Chapter 12.

dATP (40 μM and 20 mM)

Oligonucleotide primer (bacteriophage M13 Universal Primer or custom-synthesized oligonucleotide)
The best results are obtained with a purified oligonucleotide (please see the purification strategies using either gel electrophoresis or the oligonucleotide purification cartridge in Chapter 10, Protocol 1). Resuspend the oligonucleotide at a concentration of 5 pmoles/μl in TE (pH 7.6).

Template DNA
Purify the single-stranded bacteriophage M13 or phagemid DNA as described in Chapter 3, Protocol 4 or 8. Measure the concentration of the DNA by absorption spectrophotometry or staining with SYBR Gold as described in Appendix 9. Approximately 1 μg of template DNA in a volume of 15 μl or less is required for each synthetic reaction.

Radioactive Compounds

[α-^{32}P]dATP (10 mCi/ml, sp. act. 800–3000 Ci/mmole) **<!>**
To minimize problems caused by radiolysis of the precursor and the probe, it is best, whenever possible, to prepare radiolabeled probes on the day the [^{32}P]dNTP arrives in the laboratory.

Special Equipment

Adhesive dots marked with radioactive ink **<!>** *or phosphorescent adhesive dots (e.g., Glogos from Stratagene)*

Beaker (250 ml) filled with water at 85°C and a Microfuge tube holder
For an alternative, please see Step 2.

Sephadex G-50 spun column, equilibrated in TE (pH 7.6)
Optional, please see Step 12.

Water baths or heating blocks preset to 68°C and 85°C

Water bath preset to the appropriate temperature for restriction endonuclease digestion

Additional Reagents

Step 17 of this protocol requires the reagents listed in Chapter 5, Protocol 4 or 12.

METHOD

1. In a 0.5-ml microfuge tube, mix:

single-stranded template (bacteriophage M13 or phagemid DNA) (~0.5 pmole)	1 µg
oligonucleotide primer	5 pmoles
10x Klenow basic buffer	3 µl
H_2O	to 20 µl

2. Heat the mixture to 85°C for 5 minutes and then let it cool slowly to 37°C.

   This slow cooling can be achieved by floating the microfuge tube in a piece of Styrofoam in a 250-ml beaker filled with water equilibrated to 85°C. Place the beaker containing the primer-template mix at room temperature until the temperature of the water falls to 37°C (~30 minutes). The same result can be achieved using a thermal cycler programmed to heat at 85°C for 5 minutes before ramping down to 37°C over a 30-minute period.

3. To the tube of annealed primer and template, add:

0.1 M dithiothreitol	2 µl
10 mCi/ml [α-^{32}P]dATP (sp. act. 3000 Ci/mmole)	5 µl
40 µM dATP	1 µl
20 mM solution of dTTP, dCTP, and dGTP	1 µl

   Mix the reagents by gently tapping the side of the tube. Centrifuge the tube at maximum speed for 1–2 seconds in a microfuge to transfer all of the liquid to the bottom.

   As an alternative, substitute [α-^{32}P]dNTPs of sp. act. 800 Ci/mmole in this reaction, in which case, omit the 1 µl of 40 µM dATP.

4. Transfer 0.5 µl of the mixture to a microfuge tube containing 15 µl of 20 mM EDTA (pH 8.0). Store the tube on ice.

5. Add 1 µl (5 units) of the Klenow fragment to the remainder of the mixture. Mix the components of the reaction by gently tapping the side of the tube. Incubate the reaction for 30 minutes at room temperature.

   Approximately 5 units of the Klenow fragment are required for each labeling reaction.

6. Transfer 0.5 µl of the reaction to a fresh microfuge tube containing 20 µl of 0.5 M EDTA (pH 8.0). Store the tube on ice.

7. Add 1 µl of 20 mM unlabeled dATP to the remainder of the reaction. Mix by gently tapping the side of the tube. Centrifuge the tube at maximum speed for 1–2 seconds in a microfuge to transfer all of the liquid to the bottom. Incubate the reaction mixture for a further 20 minutes at room temperature.

   The addition of unlabeled dATP increases the concentration of the precursor ~500-fold and ensures that all newly synthesized products will be extended past the site of restriction enzyme cleavage. If the reaction has gone well, 50–80% of the radioactivity will have been incorporated into DNA. Even though the proportion of the radiolabeled dNTP that has been incorporated is large, the length of the newly synthesized product is small when the sample is withdrawn from the reaction (Step 6). For example, suppose that 50% of the [α-^{32}P]dATP is incorporated into DNA. Since the reaction contained a total of 56 pmoles of dATP (16 pmoles radiolabeled and 40 pmoles unlabeled), a total of 28 pmoles of dATP has been incorporated into DNA. Assuming that each of the four dNTPs is equally represented in the product, a total of 4 x 28 = 112 pmoles of dNTP has been incorporated into DNA. If primer binds to every molecule of template DNA in the reaction and if the Klenow fragment is in excess, then the average length of the product will be 224 nucleotides.

8. During the 20-minute incubation (Step 7), measure the fraction of radioactivity in the samples stored in Steps 4 and 6 that either has become insoluble in 10% TCA or that adheres to a DE-81 filter as described in Appendix 8.

9. Heat the reaction to 68°C for 10 minutes to inactivate the Klenow fragment.

10. Adjust the concentration of NaCl in the reaction to achieve optimal conditions for cleavage of the product by the selected restriction enzyme.

    Remember that the concentration of NaCl in the primer-extension reaction is 50 mM.

    If the restriction enzyme works best in the absence of NaCl, or if the enzyme requires unusual conditions (e.g., high concentrations of Tris or the presence of detergent), transfer the radiolabeled DNA to the appropriate buffer by one of the following two methods. (i) Purify the products of the primer-extension reaction by extraction with phenol:chloroform and precipitate with ethanol. After dissolving the precipitated DNA in 27 µl of TE (pH 7.6), add 3 µl of the appropriate 10x restriction buffer. (ii) Exchange the primer extension buffer by spun-column centrifugation before digestion (please see Appendix 8).

11. Add 20 units of the desired restriction enzyme, and incubate the reaction for 1 hour at the appropriate temperature.

12. Purify the DNA by standard extraction with phenol:chloroform, and remove unincorporated dNTPs by spun-column chromatography or differential precipitation with 2.5 M ammonium acetate and ethanol (for these procedures, please see Appendix 8). Add 0.5 M EDTA (pH 8.0) to a final concentration of 10 mM.

    ▲ **IMPORTANT** It is essential that free magnesium ions not be present when the DNA is exposed to alkali in the next step. Otherwise, the DNA will form an insoluble complex with $Mg(OH)_2$.

13. Isolate the radiolabeled DNA by electrophoresis through a denaturing polyacrylamide gel (please see Chapter 12, Protocol 8) or an alkaline agarose gel (please see Chapter 5, Protocol 8), depending on the size of the fragment.

14. After electrophoresis, prepare the gel for autoradiography. Expose the gel to X-ray film for 5–10 minutes.

15. Align the developed film with the gel, using the images from the phosphorescent dots (Glogos) or radioactive ink spots. Tape the film to the gel and mark the position of the primer-extended radioactive DNA fragment on the back of the gel plate. Remove the film and cut out the segment of the gel containing the desired fragment of DNA.

16. If a polyacrylamide gel was used to separate the DNA fragment from the template, proceed to Step 17. If an alkaline agarose gel was used, neutralize the gel by gentle shaking for 45 minutes in 0.5 M Tris-Cl (pH 7.6), followed by shaking for an additional 45 minutes in 0.5x TBE before the radiolabeled DNA is eluted.

17. Extract the DNA from the gel by electroelution or by crushing and soaking the polyacrylamide gel slice in an appropriate buffer (please see Chapter 5, Protocols 4 and 12, respectively).

    Check the efficiency of the elution process with a hand-held minimonitor.

    The eluted DNA is ready for use as a probe and does not need to be denatured further.

TROUBLESHOOTING: PREMATURE TERMINATION OF NEWLY SYNTHESIZED DNA CHAINS

The most common problem with synthesis of single-stranded probes by primer extension is premature termination of synthesis. This termination occurs for a variety of reasons, most of which originate with the radiolabeled dNTP, which is the rate-limiting component in the reaction mixture. Obviously, if the single-stranded DNA synthesis does not extend to a restriction site either within or downstream from the region of interest, the probe cannot be recovered as a discrete band by gel electrophoresis. To minimize this problem, try the following:

- ***Use fresh radioisotopes.*** Radioactive dNTPs that have been thawed more than twice are incorporated less efficiently into DNA by DNA polymerases.
- ***Use a freshly made reaction mixture.*** Dilute solutions of dNTPs are not stable for long periods when stored at –20°C.
- ***Keep the amount of template in the reaction to a minimum.*** The greater the number of template molecules in the reaction, the shorter the length of the newly synthesized chains.
- ***Engineer the bacteriophage M13 or phagemid recombinant so that the probe will be as short as possible.*** If the average length of the DNA synthesized during the first stage of the reaction (i.e., before addition of the unlabeled dNTP) is less than the final length of the probe, the specific activity of the 5′ terminus of the probe will be considerably higher than that of the 3′ terminus. In general, this asymmetry does not matter when the probes are to be used in northern or Southern hybridization. However, it can vitiate attempts to use the probe in nuclease S1 mapping of RNAs. This problem can be minimized by ensuring that the final length of the probe is less than the length of the DNA synthesized during the first stage of the reaction.

Protocol 5

Synthesis of Single-stranded DNA Probes of Heterogeneous Length from Bacteriophage M13 Templates

THE METHOD DESCRIBED IN PROTOCOL 4 GENERATED PROBES of defined length; however, the technique described in this protocol produces a heterogeneous population of radiolabeled molecules of differing lengths. These probes are synthesized, as before, from a single-stranded DNA template but are then separated from the template by electrophoresis through a denaturing gel from which they are eluted directly into hybridization buffer. During synthesis, the low concentration of radiolabeled dNTP limits the length of the probes to 200–300 nucleotides. However, the length of the newly synthesized DNA can be adjusted from 100 to 1000 nucleotides by varying the concentration of input template and dNTPs as discussed in the introduction to Protocol 4. Probes within this size range work well in most hybridization formats.

The following protocol, based on the method of Church and Gilbert (1984) and provided by M. Lehrman and D. Davis (University of Texas Southwestern Medical Center, Dallas), is useful for synthesizing single-stranded DNA probes of very high specific activity for Southern analysis of single-copy genes in complex genomes or for northern analysis of rare species of mRNAs.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Elution buffer (1x SSPE containing 0.5% SDS)

Formamide dye buffer **<!>**

$MgCl_2$ (1 M)

NaOH (10 N) **<!>**

3x *Probe synthesis buffer*

62 µM each dATP, dTTP, dGTP
0.5 mg/ml bovine serum albumin (Fraction V, Sigma)
625 µM dithiothreitol
32 mM Tris-Cl (pH 7.5)
6.5 mM $MgSO_4$

Store the buffer at –20°C in 100-µl aliquots. Use a fresh aliquot for each batch of radiolabeled probe. Discard the unused portion of each aliquot.

Enzymes and Buffers

Klenow fragment of E. coli *DNA polymerase I*

Gels

Polyacrylamide gel (5%) containing 7 M urea **<!>**

Cast and run the gel in 0.5x TBE as described in Chapter 12, Protocol 8.

Nucleic Acids and Oligonucleotides

Oligonucleotide primer (bacteriophage M13 Universal Primer or custom-synthesized oligonucleotide)

The best results are obtained with a purified oligonucleotide (please see the purification strategies using either gel electrophoresis or an oligonucleotide purification cartridge in Chapter 10, Protocol 1). Resuspend the oligonucleotide at a concentration of 5 pmoles/µl in TE (pH 7.6).

Template DNA

Purify the single-stranded bacteriophage M13 or phagemid DNA as described in Chapter 3, Protocol 4 or 8, respectively. Measure the concentration of the DNA by absorption spectrophotometry as described in Appendix 8. Approximately 0.3 µg of template DNA in a volume of 2–3 µl is required for each synthesis.

Radioactive Compounds

[α-^{32}P]dCTP (10 mCi/ml, sp. act. 800–3000 Ci/mmole) **<!>**

To minimize problems caused by radiolysis of the precursor and the probe, it is best, whenever possible, to prepare radiolabeled probes on the day the [^{32}P]dNTP arrives in the laboratory.

Special Equipment

Air incubator or shaking water bath preset to 50°C
Boiling water bath
Disposable inoculating stick
Fritted column (e.g., Quik-sep columns, Isolab, Inc.)
Heating block preset to 57°C
Plastic snap-cap tubes (12 x 17 mm)

METHOD

1. In a 0.5-ml microfuge tube, mix:

single-stranded template (bacteriophage M13 or phagemid DNA) (~0.15 pmole, ~0.1 µg/µl)	0.3 µg
oligonucleotide primer (5 pmoles/µl)	1 µl
25 mM $MgCl_2$	1 µl

If possible, include in each experiment a reaction tube containing a control DNA template and an oligonucleotide that has worked well previously. This reaction serves as a positive control.

2. Cap the tube and incubate the reaction mixture for 5–10 minutes at 57°C in a heating block.

3. Transfer the tube from the heating block to a bucket of ice, and add to the reaction mixture:

3x probe synthesis buffer	4 µl
10 mCi/ml [α-^{32}P]dCTP (sp. act. 3000 Ci/mmole)	3 µl
Klenow fragment (~2.5 units)	0.5 µl

   Mix the reagents by gently tapping the side of the tube. Centrifuge the tube at maximum speed for 1–2 seconds in a microfuge to transfer all of the liquid to the bottom. Incubate the reaction at 37°C for 40 minutes.

4. While the primer reaction is incubating, pour a 5% polyacrylamide gel containing 7 M urea in 1x TBE buffer (please see Chapter 12, Protocol 8). The gel should be 1.5-mm thick, at least 15-cm long, with 2.5-cm wide slots. Prerun the gel for 15 minutes at 20–25 V/cm of gel length to remove ammonium persulfate from the wells.

5. Stop the primer-extension reaction by adding 25 µl of formamide dye buffer and heating the reaction mixture in a boiling water bath for 3–5 minutes. Transfer the tube to an ice bucket and add 1 µl of 1 N NaOH.

6. Wash urea and loose fragments of polyacrylamide from the wells of the gel using a syringe loaded with 1x TBE, and immediately load the DNA samples. Separate the radiolabeled probe from the template DNA by electrophoresis for 30 minutes at 20–25 V/cm of gel length.

   It is unnecessary to include DNA size standards on the polyacrylamide gel because the xylene cyanol dye migrates to a position comparable to that of a DNA fragment of ~125 bases.

7. After 30 minutes, separate the gel plates, cover the gel with Saran Wrap, and locate the radiolabeled DNA by autoradiography (please see Appendix 9). Expose the gel to X-ray film for ~1 minute.

   The majority of the radiolabeled DNA should have migrated slightly slower than the xylene cyanol (green) tracking dye. Although a continuous smear of radiolabeled material is the expected result, in practice, between three and ten bands of discrete length are usually detected that may be spaced over a distance of 2–3 cm of the gel. The cause of the discrete bands is presumed to be secondary structures in the particular single-stranded DNA template used in the reaction.

8. Cut the radioactive bands out of the gel with a clean razor blade. Place them in the bottom of a 12 x 17-mm plastic snap-cap tube and crush with a disposable inoculating stick. Add 1–2 ml of elution buffer and shake the fragments of gel for >3 hours at 50°C.

   Elution of the radioactive probe is more efficient if individual bands are cut from the gel, rather than excising a wide swath of polyacrylamide that spans all the bands.

9. Place the eluate in a fritted column, place the column in a 12 x 17-mm plastic snap-cap tube, and centrifuge in a desktop clinical centrifuge for 1–2 minutes. Measure the amount of radioactivity in 1 µl of the radioactive probe by liquid scintillation spectroscopy.

   A successful synthesis should yield ~10,000–20,000 dpm/µl.

TROUBLESHOOTING

If the DNA synthesis reaction is inefficient, little or no radiolabeled material will be detected above the position of xylene cyanol in the gel. In the worst case, all of the radioactivity, which corresponds to unincorporated [α-^{32}P]dCTP, will migrate with the bromophenol blue dye. The causes of these problems vary and include:

- ***The quality of the 3× probe synthesis buffer.*** Because this buffer contains dNTPs and dithiothreitol, it is not stable to repeated thawing and freezing. Store the buffer in small aliquots and discard unused buffer after each reaction.
- ***The integrity of the template and the concentration of the oligonucleotide primer.*** Confirm that the template is intact and its concentration is correct by analyzing a small sample by agarose gel electrophoresis. Purify the oligonucleotide primer by polyacrylamide gel electrophoresis or by column chromatography (please see Chapter 10, Protocol 1). If problems persist, purify a new batch of template DNA and resynthesize the primer.
- ***The age and quality of the radioactive dNTP.*** Probes of the highest specific activity and correct length are synthesized on the day of arrival of a radioactive shipment from the manufacturer. As the radiolabeled dNTP decays, the effective concentration of the precursor falls and the size of the DNA products decreases.
- ***The age and quality of the Klenow enzyme.*** Problems with the enzyme can be detected by including an appropriate positive control reaction (please see Step 1).

Protocol 6

Synthesis of Single-stranded RNA Probes by In Vitro Transcription

STRAND-SPECIFIC, SINGLE-STRANDED RNA PROBES not only are easier to make than DNA probes, but also generally yield stronger signals in hybridization reactions than do DNA probes of equal specific activity. This is probably a result of the innately higher stability of hybrids involving RNA (Casey and Davidson 1977). DNA probes continue to be of general utility in, for example, northern and Southern hybridizations, but radiolabeled RNAs are now the probes of choice when analyzing transcripts of mammalian genes. Instead of digesting DNA-RNA hybrids with the idiosyncratic nuclease S1, RNA-RNA hybrids are digested with RNase A, a durable and obedient enzyme that can be used at a wide range of concentrations without compromising the results of the experiment (Zinn et al. 1983; Melton et al. 1984) (please see Chapter 7, Protocol 11).

The templates for transcribing RNA probes are generated by linearizing recombinant plasmids that carry a powerful bacteriophage promoter immediately upstream of the DNA fragment of interest (please see Figure 9-2) or by using PCR to generate templates whose 5′ ends encode a bacteriophage promoter (please see the panel on **ADDITIONAL PROTOCOL: USING PCR TO ADD PROMOTERS FOR BACTERIOPHAGE-ENCODED RNA POLYMERASES TO FRAGMENTS OF DNA** at the end of this protocol).

PLASMID VECTORS USED FOR IN VITRO TRANSCRIPTION

Many plasmid and phagemid vectors are commercially available that contain various combinations of bacteriophage promoters and polycloning sites (e.g., the pGEM series and the pSP series; please see Appendix 3). Some of these vectors also encode the *lacZ* α-complementing fragment, which allows selection by color of recombinants on plates containing X-gal (5-bromo-4-chloro-3-indolyl-β-D-galactopyranoside). The choice among these vectors is largely a matter of personal preference. However, if transcripts of both strands of the template are required, it is better to use a vector carrying two different bacteriophage promoters than to clone the template in two orientations in a vector carrying a single promoter. It is also important to consider the disposition of restriction sites within the template DNA and downstream from it. The 5′ terminus of the transcript is fixed by the bacteriophage promoter, but the 3′ terminus is defined by the downstream site of cleavage by the restriction enzyme. By using different restriction enzymes, RNAs of various lengths can be synthesized from a series of linear templates generated from the same plasmid.

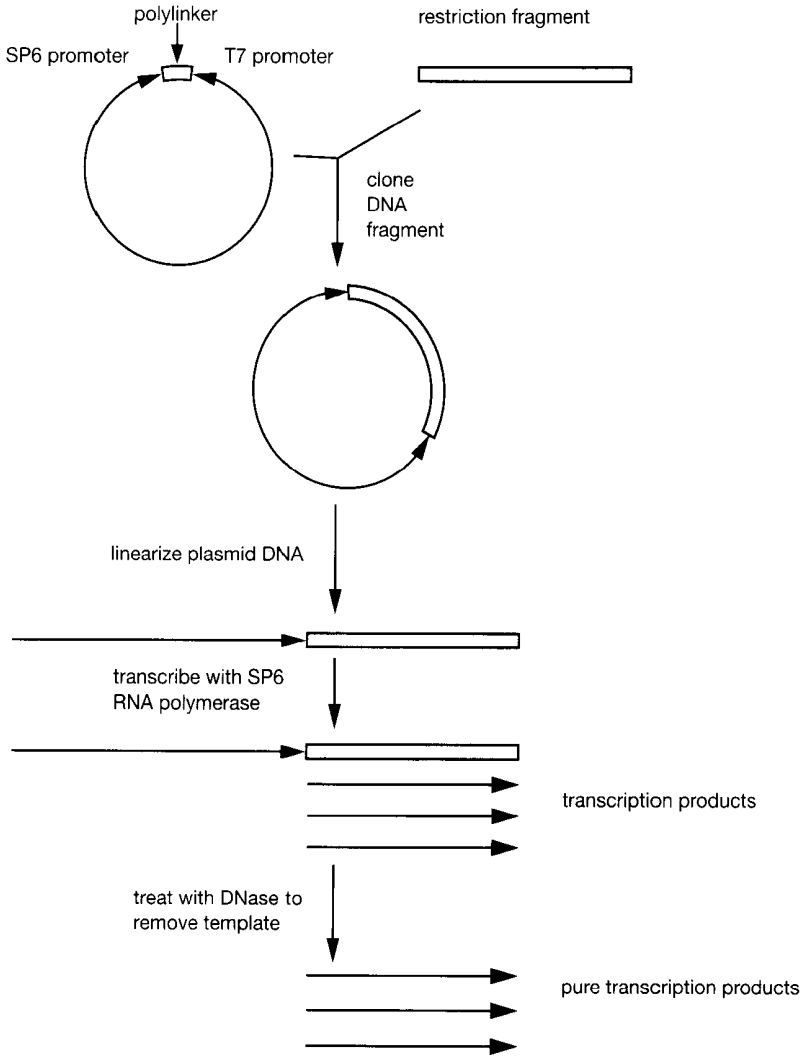

FIGURE 9-2 In Vitro Synthesis of RNA by Bacteriophage-encoded RNA Polymerases

The DNA sequence to be transcribed is cloned into a restriction site in a polycloning region that is flanked by promoters for two bacteriophage polymerases (usually T7 and SP6). The DNA is then linearized with a restriction enzyme that cleaves downstream from the region to be transcribed. This cleavage prevents synthesis of multimeric transcripts from circular template DNA. Transcription begins from the promoter proximal to the insert when the appropriate polymerase and rNTPs are added in a suitable buffer. The RNA products, which are complementary to one strand of the template, are equal in length to the distance between the active promoter and the end of the linear DNA distal to the target sequences. At the end of the reaction, the template is removed by digestion with RNase-free DNase. Unincorporated nucleotides and oligodeoxynucleotides produced by digestion of the template DNA with DNase can be removed by chromatography through Sephadex G-75. (Adapted, with permission, from Krieg and Melton 1987 [©Academic Press].)

However, the presence of plasmid sequences in RNA probes can increase the level of background hybridization to levels that are unacceptable if the probe is to be used to screen a plasmid or cosmid library.

During generation of template DNAs, complete cleavage of superhelical plasmid DNA by a restriction enzyme is essential. Small amounts of circular plasmid DNAs will dramatically reduce yields by producing multimeric transcripts. Restriction enzymes that generate blunt or 5′-pro-

truding termini produce the best linear templates. However, both of these types of termini yield RNA products that show heterogeneity at their 3′ ends (Melton et al. 1984; Milligan and Uhlenbeck 1989). Transcription of templates with 3′-protruding termini results in the synthesis of significant amounts of RNA molecules that are aberrantly initiated at the termini of the templates and thus in the production of double-stranded RNA molecules (Schenborn and Mierendorf 1985). Restriction enzymes that generate protruding 3′ termini should therefore be avoided.

In addition to plasmids, some bacteriophage and cosmid vectors also contain bacteriophage promoters, usually arranged in opposite orientations on either side of the cloning site for foreign DNA. When a recombinant constructed in a vector of this type is digested with a restriction enzyme that cleaves many times within the foreign DNA, a large number of fragments are generated, one of which contains a particular bacteriophage promoter and the foreign sequences that lie immediately adjacent to it. If the fragments do not carry protruding 3′ termini, only the fragment bearing the bacteriophage promoter serves as a template for in vitro transcription. The resulting radiolabeled RNA, which is complementary to sequences located at one end of the original segment of foreign DNA, can then be used as a probe to isolate overlapping clones from genomic DNA or cDNA libraries. These vectors greatly simplify the task of "walking" from one recombinant clone to another along the chromosome. The following are two highly efficient methods available to generate strand-specific RNA probes:

- The relevant DNA fragment may be cloned or subcloned into specialized plasmids that contain promoters for bacteriophage-encoded DNA-dependent RNA polymerases. The recombinant plasmids are a source of double-stranded templates that can be transcribed in vitro into single-stranded RNAs of defined length and strand specificity (Zinn et al. 1983; Melton et al. 1984).
- The DNA fragment to be transcribed may be amplified in PCRs with primers whose 5′ ends encode synthetic promoters for bacteriophage-encoded DNA-dependent RNA polymerases. Following purification, the products of the PCRs are used as double-stranded templates for in vitro transcription reactions (Logel et al. 1992; Bales et al. 1993; Urrutia et al. 1993).

In both cases, the synthesis of RNA is remarkably efficient. When in vitro transcription reactions are saturated with ribonucleoside triphosphates (rNTPs), the templates can be transcribed many times, yielding a mass of RNA that exceeds the weight of the template severalfold. In addition, because bacteriophage-encoded DNA-dependent RNA polymerases function efficiently in vitro in the presence of relatively low concentrations of rNTPs (1–20 μM), full-length probes of high specific activity can be synthesized relatively inexpensively. Finally, RNA probes can be freed from template DNA by treating the reaction products with RNase-free DNase I. Probes usually do not need to be purified by gel electrophoresis. However, when using RNA probes of high specific activity to detect rare mRNA transcripts, background hybridization can be kept to a minimum using probes purified by denaturing gel electrophoresis.

In this protocol, we describe procedures for synthesizing RNA probes of high specific activity from plasmids containing promoters for bacteriophage-encoded RNA polymerases. An additional protocol deals with the generation and transcription of PCR products. Guidance and background information on both methods are provided in the information panels:

- The enzymatic properties of RNA polymerases used in the transcription reactions are described in the information panel on **IN VITRO TRANSCRIPTION SYSTEMS** at the end of this chapter.
- Necessary precautions to reduce problems with contaminating RNases are outlined in the information panel on **HOW TO WIN THE BATTLE WITH RNASE** in Chapter 7.

MATERIALS

▲ **IMPORTANT** Prepare all reagents used in this protocol with DEPC-treated H_2O (please see the information panel on **HOW TO WIN THE BATTLE WITH RNASE** in Chapter 7).

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Ammonium acetate (10 M)
Optional, please see Step 8.

Bovine serum albumin (2 mg/ml, Fraction V, Sigma)

Dithiothreitol (1 M)

Ethanol

Phenol:chloroform (1:1, v/v) **<!>**

Placental RNase inhibitor (20 units/μl)

Sodium acetate (3 M, pH 5.2)

10x Transcription buffer
400 mM Tris-Cl (pH 7.5 at 37°C)
60 mM $MgCl_2$
20 mM spermidine HCl
50 mM NaCl
Sterilize the 10x buffer by filtration and then store it in small aliquots at –20°C. Discard each aliquot after use.

Enzymes and Buffers

Appropriate restriction enzymes
Please see Step 1.

DNA-dependent RNA polymerase of bacteriophage T3, T7, or SP6
These enzymes are available from several companies and are usually supplied at concentrations of 10–20 units/μl. Most manufacturers also supply a 10x transcription buffer that has presumably been optimized for their particular preparation of the DNA-dependent RNA polymerase. The generic 10x transcription buffer (listed under Buffers and Solutions) can be used if the manufacturer's buffer is in short supply.

> Kits for in vitro transcription are sold by many manufacturers (e.g., MAXIscript and MEGAscript from Ambion and Riboprobe Gemini Systems from Promega). These kits are convenient for investigators who are using in vitro transcription methods for the first time, and they are certainly a marvelous help if something goes wrong with the technique. However, the reagents and buffers supplied in the kits can be easily assembled in the laboratory by any competent worker, and the enzymes can be purchased inexpensively as separate items.

RNase-free pancreatic DNase I (1 mg/ml)
This enzyme is available from several manufacturers (e.g., RQ1 RNase-free DNase I from Promega). Alternatively, contaminating RNase can be removed from standard preparations of DNase I by affinity chromatography on agarose 5′-(4-aminophenylphosphoryl)-uridine-2′(3′)-phosphate (Maxwell et al. 1977). Please see Appendix 8 for details.

Gels

Agarose gel (0.8–1.0%)
Please see Step 1.

Nucleic Acids and Oligonucleotides

rNTP solution containing rATP, rCTP, and rUTP, each at 5 mM

rGTP (0.5 mM)
Optional, please see Step 5.

Template DNA
The DNA fragment to be transcribed should be cloned into one of the commercially available plasmids containing bacteriophage RNA polymerase promoters on both sides of the polycloning sequence (e.g., pGEM from Promega or pBluescript from Stratagene). Purify the superhelical recombinant plasmid by one or more of the methods described in Chapter 1.

The DNA used as a template in the in vitro transcription reaction need not be highly purified — crude minipreparations work well. The essential requirement is that the template be free of RNase, a criterion that can usually be fulfilled by extracting the preparation of plasmid DNA twice with phenol:chloroform. However, if RNase was added to the plasmid at a late stage in the purification process, i.e., *after* deproteinization, it should be removed by treatment with proteinase K, as follows:

1. Add to the plasmid DNA preparation: 0.1 volume of 10x proteinase K buffer (100 mM Tris-Cl [pH 8.0]/50 mM EDTA [pH 8.0]/500 mM NaCl), 0.1 volume of 5% (w/v) SDS, and proteinase K (20 mg/ml to a final concentration of 100 µg/ml.
2. Incubate the reaction for 1 hour at 37°C.
3. Extract the DNA with phenol:chloroform and recover the DNA by standard precipitation with ethanol.
4. Resuspend the DNA in RNase-free TE (pH 7.6) at a concentration of ≥100 µg/ml.

Radioactive Compounds

[α-^{32}P]rGTP (10 mCi/ml, sp. act. 400–3000 Ci/mmole) **<!>**
To minimize problems caused by radiolysis of the precursor, it is best, whenever possible, to prepare radiolabeled probes on the day the [^{32}P]dNTP arrives in the laboratory.

Special Equipment

Microfuge tubes (0.5 ml)
Sephadex G-50 spun column, equilibrated with 10 mM Tris-Cl (pH 7.5)
Optional, please see Step 8.
Water bath preset to 40°C (if using bacteriophage SP6 DNA-dependent RNA polymerase in Step 4)

Additional Reagents

Step 2 of this protocol requires the reagents listed in Protocol 11 of this chapter.
Step 8 of this protocol may require the reagents listed in Chapter 5, Protocols 9, 11, and 12.

METHOD

1. Prepare 5 pmoles of linear template DNA by digestion of superhelical plasmid DNA with a suitable restriction enzyme. Analyze an aliquot (100 ng) of the digested DNA by agarose gel electrophoresis. If necessary, add more restriction enzyme and continue incubation until there is no trace of the undigested DNA.

   Approximately 2 µg of a plasmid 3 kb in length is ~1 pmole.

   ▲ **IMPORTANT** It is essential that plasmid DNA templates be cleaved to completion, since trace amounts of closed circular plasmid DNA result in the generation of extremely long transcripts that include plasmid sequences. Because of their length, these transcripts can account for a substantial proportion of the incorporated radiolabeled rNTP.

2. If restriction enzymes, such as *PstI* or *SstI*, that generate protruding 3′ termini must be used, treat the digested DNA with bacteriophage T4 DNA polymerase in the presence of all four dNTPs to remove the 3′ protrusion (please see Protocol 11).

Protruding 3′ termini create an opportunity for the DNA-dependent RNA polymerase to transfer to the complementary strand of the template and to generate long U-turn transcripts with extensive secondary structure.

3. Purify the template DNA by extraction with phenol:chloroform and standard precipitation with ethanol. Dissolve the DNA in H_2O at a concentration of 100 nM (i.e., 200 µg/ml for a 3-kb plasmid).

4. Warm the first six components listed below to room temperature, and in a sterile 0.5-ml microfuge tube, mix *in the following order at room temperature:*

template DNA	0.2 pmole (400 ng for a 3-kb plasmid)
RNase-free H_2O	to 6 µl
5 mM rNTP solution	2 µl
100 mM dithiothreitol	2 µl
10x transcription buffer	2 µl
2 mg/ml bovine serum albumin	1 µl
10 mCi/ml [α-^{32}P]rGTP (sp. act. 400–3000 Ci/mmole)	5 µl

Mix the components of the mixture by gently tapping the outside of the tube. Then add:

placental RNase inhibitor (10 units)	1 µl
bacteriophage DNA-dependent RNA polymerase (~10 units)	1 µl

▲ **IMPORTANT** The components are added in the order shown and at room temperature to avoid the possibility that the template DNA may be precipitated by the high concentration of spermidine in the transcription buffer.

Mix the reagents by gently tapping the outside of the tube. Centrifuge the tube for 1–2 seconds to transfer all of the liquid to the bottom. Incubate the reaction for 1–2 hours at 37°C (bacteriophages T3 and T7 DNA-dependent RNA polymerases) or 40°C (bacteriophage SP6 DNA-dependent RNA polymerase).

The reaction may be scaled from 20 µl to 50 µl to accommodate more dilute reagents.

When the reaction is carried out as described above, 80–90% of the radiolabel will be incorporated into RNA. The yield of RNA will be ~20 ng (sp. act. 4.7×10^9 dpm/µg) when the specific activity of the [α-^{32}P]GTP is 3000 Ci/mmole and ~150 ng (sp. act. 6.2×10^8 dpm/µg) when the specific activity of the precursor is 400 Ci/mmole.

5. (*Optional*) If full-length transcripts are desired, add 2 µl of 0.5 mM rGTP and incubate the reaction mixture for an additional 60 minutes at the temperature appropriate for the polymerase.

6. Terminate the in vitro transcription reaction by adding 1 µl of 1 mg/ml RNase-free pancreatic DNase I to the reaction tube. Mix the reagents by gently tapping the outside of the tube. Incubate the reaction mixture for 15 minutes at 37°C.

7. Add 100 µl of RNase-free H_2O, and purify the RNA by extraction with phenol:chloroform.

If the probe will be used in experiments where length is important (e.g., RNase protection), purify the radiolabeled RNA by polyacrylamide gel electrophoresis (please see Chapter 5, Protocol 9). The aim of this extra step is to eliminate truncated radiolabeled molecules from the preparation.

8. Transfer the aqueous phase to a fresh microfuge tube, and separate the radiolabeled RNA from undesired small RNAs and rNTPs by one of three methods:

TO PURIFY RNA BY ETHANOL PRECIPITATION

a. Add 30 µl of 10 M ammonium acetate to the aqueous phase. Mix, and then add 250 µl of ice-cold ethanol to the tube. After storage for 30 minutes on ice, collect the RNA by centrifugation at maximum speed for 10 minutes at 4°C in a microfuge.

b. Remove as much of the ethanol as possible by gentle aspiration, and leave the open tube on the bench for a few minutes to allow the last visible traces of ethanol to evaporate. Dissolve the RNA in 100 µl of RNase-free H_2O.

c. Add 2 volumes of ice-cold ethanol to the tube and store the RNA at –70°C until needed.

To recover the RNA, transfer an aliquot of the ethanolic solution to a fresh microfuge tube. Add 0.25 volume of 10 M ammonium acetate, mix, and then store the tube for at least 15 minutes at –20°C. Centrifuge the solution at maximum speed for 10 minutes at 4°C in a microfuge. Remove the ethanol by aspiration, and dissolve the RNA in the desired volume of the appropriate RNase-free buffer.

TO PURIFY RNA BY SPUN-COLUMN CHROMATOGRAPHY

a. Prepare a Sephadex G-50 spun column (please see Appendix 8) that has been autoclaved in 10 mM Tris-Cl (pH 7.5).

b. Purify the RNA by spun-column chromatography according to the protocol in Appendix 8.

c. Store the eluate in a microfuge tube at –70°C until the RNA is needed.

TO PURIFY RNA BY GEL ELECTROPHORESIS

a. Prepare a neutral polyacrylamide gel according to Chapter 5, Protocol 9.

b. Add the appropriate gel-loading buffer to the aqueous phase and purify the RNA by gel electrophoresis.

c. Locate the RNA by autoradiography according to Chapter 5, Protocol 11

d. Purify the RNA from the gel slice using the crush and soak method according to Chapter 5, Protocol 12.

e. Store the RNA at –70°C until needed.

Any of these purification schemes should remove >99.0% of unincorporated rNTPs from the RNA.

RNA PROBES FOR IN SITU HYBRIDIZATION

RNA probes for in situ hybridization to mRNA or DNA can be synthesized with radiolabeled (^{3}H, ^{33}P, ^{35}S, ^{125}I) or derivatized (biotinylated, digoxigenin, fluorescein) nucleotides in place of ^{32}P-labeled nucleotides. ^{3}H-, ^{35}S-, and ^{33}P-labeled nucleotides can be used in this protocol, provided the rGTP form of these labeled nucleotides is used. If another nucleotide is substituted for rGTP, then the composition of the 5 mM rNTP solution should be changed accordingly.

To use a biotinylated nucleotide (e.g., biotinylated rUTP), substitute a nucleotide solution containing 5 mM rCTP, rATP, and rGTP, and 2.5 mM rUTP for the nucleotide solution of Step 4 and add 1 µl of a 10 mM solution of biotinylated-rUTP in place of the radiolabeled rNTP. To use a digoxigenin-labeled NTP (e.g., digoxigenin-UTP; Höltke and Kessler 1990), replace the 5 mM rNTP solution and the radiolabeled rNTP with 0.1 volume of an rNTP solution containing 10 mM rATP, rCTP, and rGTP, 6.5 mM rUTP, and 3.5 mM digoxigenin-rUTP, all in 25 mM Tris-Cl (pH 8.0).

In the case of biotin- and digoxygenin-labeled rNTPs, the modified nucleotide is used at a low concentration in the reaction to ensure that only a few labeled nucleotides are incorporated per molecule of probe (~1 labeled nucleotide for every 20–25 nucleotides polymerized). The posthybridization recognition of these labels by antibodies is most efficient when only a few bases are replaced by their labeled counterparts. Greater incorporation of the modified nucleotide can also decrease hybridization of the probe to target mRNAs or DNAs.

Fragments of RNA larger than ~300 nucleotides are unsuitable as in situ hybridization probes. Because small fragments penetrate tissue more efficiently, larger fragments of RNA must be reduced in size by limited alkaline hydrolysis (Cox et al. 1984; Angerer et al. 1987; Bales et al. 1993).

TROUBLESHOOTING: NO RNA IS SYNTHESIZED

The most common cause of an apparent lack of RNA synthesis is contamination of tubes or reagents with RNase. This contamination can be avoided by taking the precautions described in the introduction to Chapter 7.

Less frequently, failure to synthesize RNA is a consequence of precipitation of the DNA template by the spermidine in the 10x transcription buffer. Make sure that the components of the reaction are assembled at room temperature and in the stated order. If necessary, the presence of soluble template can be confirmed by analyzing an aliquot of the reaction by electrophoresis through an agarose gel.

Transcription Is from the Wrong Strand of DNA

Usually, >99.8% of transcripts synthesized in vitro by bacteriophage DNA-dependent RNA polymerases are derived from the correct DNA strand (Melton et al. 1984). However, this high degree of specificity is only achieved provided templates are both linear and lacking protruding 3′ termini. Contamination of the template with superhelical plasmid DNA causes an increase in aberrant initiation of RNA chains on both strands of the DNA. The presence of a protruding 3′ terminus downstream from the bacteriophage promoter leads to the synthesis of transcripts complementary to the full length of the wrong strand of DNA (i.e., U-turn transcripts). Both of these problems can be avoided by careful preparation of the template (please see Steps 1 and 2).

Synthesized Transcripts Are Shorter Than the Desired Length

Synthesis of abbreviated transcripts can be due to the chance occurrence in the template of sequences that terminate transcription by the particular DNA-dependent RNA polymerase being used. Another contributing factor can be limiting concentrations of precursor (usually the radiolabeled rNTP).

The first of these obstacles may be resolved by constructing a new plasmid in which transcription of the desired sequence is driven by a polymerase from a different bacteriophage. Transcription terminator sequences are not always recognized equally by the various bacteriophage DNA-dependent RNA polymerases.

Although the strengths of transcription termination signals vary greatly, all but the strongest of them can be overcome, at least in part, by increasing the concentration of the limiting rNTP. In most cases, it is impractical to increase the concentration of the rNTP that is radiolabeled in the reaction, since the improvement in yield of full-length product is gained at the expense of reducing the specific activity of the probe. In this case, a number of additional steps can be taken:

- Lower the temperature of incubation of the transcription reaction to 30°C (Krieg and Melton 1987).
- Pare the sequences to be transcribed to the minimum. In this way, it may be possible to eliminate the termination sequences from the clone.
- Purify the desired product by electrophoresis through a polyacrylamide or agarose gel as described in Chapter 5, Protocol 1. The transcription reactions are so efficient that it is often possible to purify sufficient quantities of the desired RNA, even if it is only a relatively minor proportion of the total RNA synthesized in the reaction.

ADDITIONAL PROTOCOL: USING PCR TO ADD PROMOTERS FOR BACTERIOPHAGE-ENCODED RNA POLYMERASES TO FRAGMENTS OF DNA

Templates for bacteriophage-encoded RNA polymerases may be generated by cloning target DNA fragments into plasmids carrying bacteriophage promoters (main protocol). Alternatively, templates can be synthesized in PCRs using gene-specific primers whose 5′ ends encode synthetic promoters for bacteriophage-encoded DNA-dependent RNA polymerases. Following purification, the products of the PCRs are used as double-stranded templates for in vitro transcription reactions (Logel et al. 1992; Bales et al. 1993; Urrutia et al. 1993). By using pairs of primers that encode different promoters, DNA fragments are generated that may be transcribed in a strand-specific manner by the appropriate RNA polymerase. The advantages of the PCR method include:

- Probes may be generated directly from DNA templates amplified from a heterogeneous population of DNA fragments.
- The need for cloning and preparation of plasmids is obviated.
- The probes contain no plasmid or polylinker sequences.
- Probes of high specificity and of virtually any size can be created.

RNA polymerases encoded by bacteriophages T3 and T7 transcribe PCR-amplified DNA carrying the appropriate promoters with high specificity. However, the yields of RNA are generally three- to fourfold lower than can be obtained from linearized plasmid templates. When using amplified DNA templates, between 20% and 30% of the labeled rNTP is converted into acid-insoluble material, compared to >75% in reactions containing linearized plasmid DNAs as templates (Logel et al. 1992). Nevertheless, the yield and specific activity of the RNA generated from the amplified products of PCRs are more than sufficient for most purposes. The RNA polymerase encoded by bacteriophage SP6 is reported to transcribe PCR-amplified DNA much less efficiently than linearized plasmid DNAs (Logel et al. 1992). For this reason, we recommend using primers that encode promoters for bacteriophages T3 and T7.

Primer Design

The primers are usually quite long (>50 nucleotides) and consist of three regions:

5′ clamp (~10 nucleotides)	core promoter (~22 nucleotides)	gene-specific sequence 3′ (20 nucleotides)

The sequences of the core promoters recognized by the bacteriophage T3 and T7 RNA polymerases are taken from Jorgensen et al. (1991) (please see the information panel on **IN VITRO TRANSCRIPTION SYSTEMS**):

Bacteriophage T7 core promoter:	5′TAATACGACTCACTATAGGGAGA3′
Bacteriophage T3 core promoter:	5′ATTAACCCTCACTAAAGGGAGA3′

For the T3 promoter, the 3′-most dinucleotide can be GA or AG.

Use a different clamp sequence for each member of a primer pair. Suggested clamp sequences are (Logel et al. 1992) 5′CAGAGATGCA3′ and 5′CCAAGCCTTC3′. The gene-specific segment of the primer should be designed according to the usual rules (please see the discussion on Primer Design in the introduction to Chapter 8).

Amplification Conditions

The amplification reactions contain 10–20 pg of a single species of template DNA or proportionately more of complex populations of DNAs. The remainder of the reagents in the amplification reactions are used at standard concentrations (please see Chapter 8, Protocol 1). The denaturation, annealing, and polymerization times listed below are suitable for 50-µl reactions assembled in thin-walled 0.5-ml tubes and incubated in thermal cyclers such as the Perkin-Elmer 9600 or 9700, Master Cycler (Eppendorf), and PTC 100 (MJ Research). Times and temperatures may need to be adapted to suit other types of equipment and reaction volumes.

Cycle Number	Denaturation	Annealing	Polymerization
1–4	1 min at 94°C	2 min at 54 °C	3 min at 72°C
5–36	1 min at 94°C	1 min at 65 °C	3 min at 72°C

Polymerization should be carried out for 1 minute for every 1000 bp of length of the target DNA.

Most thermocyclers have an end routine in which the amplified samples are incubated at 4°C until removed from the machine. Samples can be left overnight at this temperature, but should be stored thereafter at –20°C.

Purification of Amplified DNA

Although amplified DNA may be used without purification as a template in the in vitro transcription reaction (Bales et al. 1993; Urrutia et al. 1993), the efficiency of RNA synthesis is improved if unused primers and the by-products of the amplification reaction are removed by electrophoresis through a gel cast with low-melting-temperature agarose, by spun-colum chromatography through Sephadex G-75, or by absorbtion/elution on a commercial resin such as Wizard PCR Preps Purification System (Promega) or QIAquick (Qiagen) (please see Chapter 8, Protocol 2).

In Vitro Transcription of Amplified DNA

Approximately 0.5 µg of purified amplified DNA may be used as template in standard transcription reactions catalyzed by the appropriate bacteriophage-encoded DNA-dependent RNA polymerase (please see the main protocol).

Protocol 7

Synthesis of cDNA Probes from mRNA Using Random Oligonucleotide Primers

THIS PROTOCOL DESCRIBES THE GENERATION OF CDNA probes from poly(A)$^+$ RNA in a random priming reaction. Probes of this type are used for differential screening of cDNA libraries. For additional details, please see the information panel on **ISOLATING DIFFERENTIALLY EXPRESSED cDNAs BY DIFFERENTIAL SCREENING AND CLONING.**

MATERIALS

▲ **IMPORTANT** Prepare all reagents used in this protocol with DEPC-treated H_2O (please see the information panel on **HOW TO WIN THE BATTLE WITH RNASE** in Chapter 7).

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Ammonium acetate (10 M)

Dithiothreitol (1 M)

EDTA (0.5 M, pH 8.0)

Ethanol

HCl (2.5 N) <!>

NaOH (3 N) <!>

Phenol:chloroform (1:1, v/v) <!>

Placental RNase inhibitor (20 units/μl)

These inhibitors are sold by several manufacturers under various trade names (e.g., RNAsin, Promega; Prime Inhibitor, 5 Prime→3 Prime; RNaseOUT, Life Technologies). For more details, please see the information panel on **INHIBITORS OF RNASES** in Chapter 7.

SDS (10% w/v)

Tris-Cl (1 M, pH 7.4)

Enzymes and Buffers

Reverse transcriptase

Reverse transcriptase derived from the *pol* gene of the Moloney murine leukemia virus (Mo-MLV) is more efficient in cDNA synthesis than that obtained from the avian myeloblastosis virus (e.g., please see Fargnoli et al. 1990). The cloned version of reverse transcriptase encoded by the Mo-MLV enzyme is the enzyme of choice in this protocol. Mutants of the enzyme that lack RNase H activity (e.g., StrataScript, from Stratagene or Superscript II from Life Technologies) have some advantages over the wild-type enzyme since they (1) produce higher yields of full-length extension product and (2) work equally well at both 47°C and 37°C (Gerard and D'Alessio 1993).

Mo-MLV reverse transcriptase is temperature-sensitive and should be stored at –20°C until needed at Step 2.

10x Reverse transcriptase buffer

Nucleic Acids and Oligonucleotides

dNTP solution containing dATP, dGTP, and dTTP, each at 20 mM

For advice on making and storing solutions of dNTPs, please see the information panel on **PREPARATION OF STOCK SOLUTIONS OF dNTP AND ddNTPs FOR DNA SEQUENCING** in Chapter 12.

dCTP (125 μM)

Add 1 μl of a 20 mM stock solution of dCTP to 160 μl of 25 mM Tris-Cl (pH 7.6). Store the diluted solution in small aliquots at –20°C.

Random deoxynucleotide primers, six or seven bases in length

Because of their uniform length and lack of sequence bias, synthetic oligonucleotides of random sequence are the primers of choice. Oligonucleotides of optimal length (hexamers or heptamers; Suganuma and Gupta 1995) can be purchased from a commercial source (e.g., Pharmacia and Boehringer Mannheim) or synthesized locally on an automated DNA synthesizer. Store the solution of primers at 0.125 μg/μl in TE (pH 7.6) at –20°C in small aliquots.

Template mRNA

Prepare poly(A)$^+$ RNA as described in Chapter 7, Protocol 3 or 4, and dissolve in RNase-free H_2O at a concentration of 250 μg/ml.

Radioactive Compounds

[α-^{32}P]dCTP (10 mCi/ml, sp. act. >3000 Ci/mmole) **<!>**

To minimize problems caused by radiolysis of the precursor and the probe, it is best, whenever possible, to prepare radiolabeled probes on the day the [^{32}P]dNTP arrives in the laboratory.

Special Equipment

Ice water bath

Sephadex G-50 spun column, equilibrated in TE (pH 7.6)

Optional, please see Step 7.

Water baths or heating blocks preset to 45°C, 68°C, and 70°C

METHOD

1. Transfer 1 μg of poly(A)$^+$ RNA to a sterile microfuge tube. Adjust the volume of the solution to 4 μl with RNase-free H_2O. Heat the closed tube for 5 minutes at 70°C, and then quickly transfer the tube to an ice-water bath.
2. To the chilled solution in the microfuge tube, add:

10 mM dithiothreitol	2.5 µl
placental RNase inhibitor	20 units
random deoxyoligonucleotide primers	5 µl
10x reverse transcriptase buffer	2.5 µl
20 mM solution of dGTP, dATP, and dTTP	1 µl
125 µM solution of dCTP	1 µl
10 mCi/ml [α-^{32}P]dCTP (sp. act. >3000 Ci/mmole)	10 µl
RNase-free H_2O	to 24 µl
reverse transcriptase (200 units)	1 µl

▲ **IMPORTANT** Add the reverse transcriptase last.

Reverse transcriptase supplied by different manufacturers varies in its activity per unit. When using a new batch of enzyme, set up a series of extension reactions containing equal amounts of poly(A)$^+$ RNA and oligonucleotide primer and different amounts of enzyme. If possible, the primer should be specific for an mRNA present at moderate abundance in the preparation of poly(A)$^+$ RNA. Assay the products of each reaction by gel electrophoresis as described in this protocol. Use the minimal amount of enzyme required to produce the maximum yield of extension product. The units used in this protocol work well with most batches of StrataScript and Superscript II.

Mix the components by gently tapping the side of the tube. Remove bubbles by brief centrifugation in a microfuge. Incubate the reaction mixture for 1 hour at 45°C.

As an alternative, [α-^{32}P]dCTP of specific activity 800 Ci/mmole can be substituted in this reaction. If this substitution is made, then omit the 125 µM dCTP from the reaction mixture.

3. Stop the reaction by adding:

0.5 M EDTA (pH 8.0)	1 µl
10% (w/v) SDS	1 µl

Mix the reagents in the tube completely.

The single-stranded radiolabeled cDNA is quite sticky and adheres nonspecifically to glass, filters, and some plastics. For this reason, it is important to maintain a minimum of 0.05% (w/v) SDS in all buffers after Step 3 of the protocol, and 0.1–1.0% SDS in hybridization buffers.

4. Add 3 µl of 3 N NaOH to the reaction tube. Incubate the mixture for 30 minutes at 68°C to hydrolyze the RNA.

5. Cool the reaction mixture to room temperature. Neutralize the solution by adding 10 µl of 1 M Tris-Cl (pH 7.4), mixing well, and then adding 3 µl of 2.5 N HCl. Check the pH of the solution by spotting a very small amount on pH paper.

6. Purify the cDNA by extraction with phenol:chloroform.

7. Separate the radiolabeled probe from the unincorporated dNTPs by either spun-column chromatography (please see Appendix 8) or selective precipitation by ethanol in the presence of 2.5 M ammonium acetate (please see Appendix 8).

8. Measure the proportion of radiolabeled dNTPs that either are incorporated into material precipitated by TCA or adhere to a DE-81 filter (please see Appendix 8).

Assuming that 30% of the radioactivity has been incorporated into TCA-precipitable material during the random priming reaction and that 90% of this material has been generated by random priming events on the template mRNA (rather than self-priming of oligonucleotides), then the probe DNA would contain a total of ~6 x 10^7 dpm. The specific activity of the probe would be ~5 x 10^9 dpm/µg, and the weight of DNA synthesized during the reaction would be 11.7 ng.

If a larger amount of radiolabeled cDNA is required, then scale up the reaction by increasing the volumes of all components proportionally. It is important to maintain a ratio of 200 units of reverse transcriptase/µg of input mRNA to ensure maximum yield.

The purified radiolabeled cDNA can be used for hybridization without denaturation. Use 5 x 10^7 dpm of radiolabeled cDNA for each 150-mm filter and 5 x 10^6 to 1 x 10^7 dpm for each 90-mm filter.

Protocol 8

Synthesis of Radiolabeled, Subtracted cDNA Probes Using Oligo(dT) as a Primer

THIS PROTOCOL DESCRIBES THE PREPARATION OF SUBTRACTED cDNA probes by hybridization to an mRNA driver, followed by purification of the single-stranded radiolabeled cDNA by hydroxyapatite chromatography. For additional details, please see the information panel on **ISOLATING DIFFERENTIALLY EXPRESSED cDNAs BY DIFFERENTIAL SCREENING AND CLONING.**

MATERIALS

▲ **IMPORTANT** Prepare all reagents used in this protocol with DEPC-treated H_2O (please see the information panel on **HOW TO WIN THE BATTLE WITH RNASE** in Chapter 7).

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Ammonium acetate (10 M)

Dithiothreitol (1 M)

EDTA (0.5 M, pH 8.0)

Ethanol

HCl (2.5 N) **<!>**

Isobutanol **<!>**

NaOH (3 N) **<!>**

Phenol:chloroform (1:1, v/v) **<!>**

Placental RNase inhibitor (20 units/μl)

These inhibitors are sold by several manufacturers under various trade names (e.g., RNAsin, Promega Inc; Prime Inhibitor, 5 Prime→3 Prime; RNaseOUT, Life Technologies). For more details, please see the information panel on **INHIBITORS OF RNASES** in Chapter 7.

SDS (10% w/v)

SDS/EDTA solution

30 mM EDTA (pH 8.0)
1.2% SDS

Sodium phosphate buffer (2 M, pH 6.8)

SPS buffer

0.12 M sodium phosphate buffer (pH 6.8)
0.1% (w/v) SDS

Tris-Cl (1 M, pH 7.4)

Enzymes and Buffers

Reverse transcriptase

Reverse transcriptase derived from the *pol* gene of Mo-MLV is more efficient in cDNA synthesis than that obtained from the avian myeloblastosis virus (e.g., please see Fargnoli et al. 1990). The cloned version of reverse transcriptase encoded by the Mo-MLV enzyme is the enzyme of choice in this protocol. Mutants of the enzyme that lack RNase H activity (e.g., StrataScript from Stratagene or Supercript II from Life Technologies) have some advantages over the wild-type enzyme since they (1) produce higher yields of full-length extension product and (2) work equally well at both 47°C and 37°C (Gerard and D'Alessio 1993).

10x Reverse transcriptase buffer

Nucleic Acids and Oligonucleotides

dCTP (125 μM)

Add 1 μl of a 20 mM stock solution of dCTP to 160 μl of 25 mM Tris-Cl (pH 7.6). Store the diluted solution in small aliquots at –20°C.

dNTP solution containing dATP, dGTP, and dTTP, each at 20 mM

For advice on making and storing solutions of dNTPs, please see the information panel on **PREPARATION OF STOCK SOLUTIONS OF dNTPs AND ddNTPs FOR DNA SEQUENCING** in Chapter 12.

Driver mRNA

Please see Steps 9 and 19.

Oligo(dT)$_{12-18}$

Purchase and dissolve oligo(dT)$_{12-18}$ at 1 mg/ml in TE (pH 7.6). Store at –20°C.

Random deoxynucleotide primers can also be substituted in the cDNA synthesis reaction (please see Protocol 7). Although cDNA synthesized with oligo(dT) tends to be longer than that synthesized with random primers, this is of little advantage in hybridization reactions. The choice of primer depends on the method used to construct the cDNA library to be screened. Use oligo(dT) as a primer in this protocol if the cDNA library was constructed with oligo(dT). Use random primers if the cDNA library was manufactured in any other way.

In rare instances, mRNAs contain middle repetitive sequences in their 3′-untranslated regions and these can cross-hybridize to repetitive sequences in nonhomologous cDNAs derived from the nonexpressing cell. In such cases, synthesize the radiolabeled probe with random primers.

Template mRNA

Prepare poly(A)$^+$ RNA as described in Chapter 7, Protocol 3 or 4, and dissolve in RNase-free H_2O at a concentration of 250 μg/ml.

Radioactive Compounds

[α-^{32}P]dCTP (10 mCi/ml, sp. act. >3000 Ci/mmole) **<!>**

To minimize problems caused by radiolysis of the precursor and the probe, it is best, whenever possible, to prepare radiolabeled probes on the day the [^{32}P]dNTP arrives in the laboratory.

Special Equipment

Apparatus for separation of single-stranded and double-stranded nucleic acids by hydroxyapatite chromatography at 60°C.

Please see Appendix 8.

Boiling water bath

Ice water bath

Mineral oil and pipette tips drawn out to be attached to an automatic pipette or Siliconized, disposable 20-μl glass capillary tubes and file or diamond pen

Sephadex G-50 column (5 ml), equilibrated in TE (pH 8.0)

Sephadex G-50 spun column, equilibrated in TE (pH 8.0) containing 0.1% (w/v) SDS

Siliconized microfuge tubes (1.5 ml)

Water baths or heating blocks preset to 45°C, 68°C, and 70°C

METHOD

▲ **IMPORTANT** Before preparing the probe, it is a good idea to have filters (which contain the cDNA library to be screened) ready to hybridize.

1. Transfer 5–10 µg of poly(A)$^+$ RNA to a sterile microfuge tube. Adjust the volume of the solution to 40 µl with RNase-free H_2O. Heat the closed tube to 70°C for 5 minutes, and then quickly transfer the tube to an ice water bath.

2. To the chilled microfuge tube, add:

0.1 M dithiothreitol	2.5 µl
placental RNase inhibitor	200 units
oligo(dT)$_{12-18}$	10 µl
10x reverse transcriptase buffer	25 µl
20 mM solution of dGTP, dATP, and dTTP	10 µl
125 µM dCTP	10 µl
10 mCi/ml [α-^{32}P]dCTP (sp. act. >3000 Ci/mmole)	100 µl
RNase-free H_2O	to 240 µl
reverse transcriptase (2000 units)	10 µl

▲ **IMPORTANT** Add the reverse transcriptase last.

Reverse transcriptase supplied by different manufacturers varies in its activity per unit. When using a new batch of enzyme, set up a series of extension reactions containing equal amounts of poly(A)$^+$ RNA and oligonucleotide primer, and different amounts of enzyme. If possible, the primer should be specific for an mRNA present at moderate abundance in the preparation of poly(A)$^+$ RNA. Assay the products of each reaction by gel electrophoresis as described in this protocol. Use the minimal amount of enzyme required to produce the maximum yield of extension product. The units used in this protocol work well with most batches of StrataScript and Superscript II.

Mix the components by gently tapping the side of the tube. Collect the reaction mixture in the bottom of the tube by brief centrifugation in a microfuge. Incubate the reaction for 1 hour at 45°C.

As an alternative, [α-^{32}P]dCTP of specific activity 800 Ci/mmole can be substituted in this reaction. If this substitution is made, then omit the 125 µM dCTP from the reaction mixture.

3. Stop the reaction by adding:

0.5 M EDTA (pH 8.0)	10 µl
10% (w/v) SDS	10 µl

Mix the reagents in the tube well.

The single-stranded, radiolabeled cDNA is quite sticky and adheres nonspecifically to glass, filters, and some plastics. For this reason, it is important to maintain a minimum of 0.05% (w/v) SDS in all buffers after Step 3 of the protocol, and 0.1–1.0% SDS in hybridization buffers.

4. Add 30 µl of 3 N NaOH to the reaction tube. Incubate the mixture for 30 minutes at 68°C to hydrolyze the RNA.

5. Cool the mixture to room temperature. Neutralize the solution by adding 100 µl of 1 M Tris-Cl (pH 7.4), mixing well, and then adding 30 µl of 2.5 N HCl. Check the pH of the solution by spotting <1 µl on pH paper.

6. Purify the cDNA by extraction with phenol:chloroform (please see Appendix 8).

7. Measure the proportion of radiolabeled dNTPs that either are incorporated into material precipitated by TCA or adhere to a DE-81 filter (please see Appendix 8). Calculate the yield of cDNA as follows:

In a reaction containing 1.5 nmoles of the limiting dNTP:

$$\frac{\text{cpm incorporated}}{\text{total cpm}} \times 1.5 \text{ nmoles dCTP} \times 330 \text{ ng/nmole} \times 160 = \text{ng of cDNA synthesized}$$

8. Separate the radiolabeled probe from the unincorporated dNTPs by chromatography through a 5-ml column of Sephadex G-50 (please see Appendix 8).

   ▲ **IMPORTANT** Perform this step and all subsequent steps with siliconized tubes (please see Appendix 8).

9. To the radiolabeled cDNA, add tenfold excess by weight of the driver RNA that will be used to subtract the cDNA probe, 0.2 volume of 10 M ammonium acetate, and 2.5 volumes of ice-cold ethanol. Incubate the mixture for 10–15 minutes at 0°C, and then recover the nucleic acids by centrifugation at maximum speed for 5 minutes at 4°C in a microfuge.

10. Remove all of the ethanol by aspiration, and store the open tube on the bench to allow most of the remaining ethanol to evaporate. Dissolve the nucleic acids in 6 µl of RNase-free H_2O.

11. To the dissolved nucleic acids, add:

2 M sodium phosphate (pH 6.8)	2 µl
SDS/EDTA solution	2 µl

12. *Either* cover the solution with a drop of light mineral oil *or* draw the mixture into a siliconized, disposable 20-µl glass capillary tube and seal the ends of the tube in the flame of a Bunsen burner.

13. Place the microfuge tube or sealed capillary tube in a boiling water bath for 5 minutes. Transfer to a water bath set at 68°C, and allow the nucleic acids to hybridize to $C_{r_0} t$ = 1000 moles seconds/liter.

    To calculate the time required to reach this $C_{r_0} t$, solve the following equation for t:

    $$D/D_0 = e^{-kC_{r_0} t}$$

    where D is the remaining single-stranded cDNA at time t, D_0 is the total amount of input cDNA, e is the natural logarithm, k is a rate constant for the formation of RNA-DNA hybrids that is dependent on the complexity of the mRNA population and may be assumed to be ~6.7×10^{-3} liters/mol-sec, and C_{r_0} is the initial concentration of the RNA driver (which does not change appreciably during the hybridization reaction). (For a lucid description of this equation, please see Sargent [1987] and for additional information, page 538 in Davidson [1986].)

14. Remove the microfuge tube or capillary tube from the water bath. Use a drawn-out pipette tip attached to a micropipettor to remove the hybridization solution from the microfuge tube, or open the ends of the capillary tube with a file or diamond pen. Transfer the hybridization mixture into a tube containing 1 ml of SPS buffer.

15. Separate the single-stranded and double-stranded nucleic acids by chromatography on hydroxyapatite at 60°C as described in Appendix 8.

    Measure the amount of radioactivity in each fraction by liquid scintillation counting. At least 90% of the input [^{32}P]cDNA should have hybridized to the mRNA and be present in the >0.36 M sodium phosphate wash.

16. Pool the fractions containing the single-stranded cDNA and concentrate them by *repeated* extractions with isobutanol extraction: Add an equal volume of isobutanol. Mix the two phases by vortexing, and centrifuge the mixture at maximum speed for 2 minutes at room temperature in a microfuge. Discard the upper (organic) phase. Repeat the extraction with isobutanol until the volume of the aqueous phase is <100 µl.

17. Remove salts from the cDNA by spun-column chromatography through Sephadex G-50 equilibrated in TE (pH 8.0) containing 0.1% SDS (please see Appendix 8).

    ▲ **IMPORTANT** Do not use ethanol precipitation to concentrate the cDNA as the presence of phosphate ions interferes with precipitation. Do not use dialysis to remove phosphate ions, as the cDNA will stick to the dialysis bag.

18. Measure the amount of radioactivity in the sample and calculate the weight of DNA in the subtracted probe.

19. Repeat Steps 9–18.

    Between 10% and 30% of the cDNA will form hybrids with the driver RNA during the second round of hybridization.

    It is not necessary to concentrate or remove salts from the final preparation of cDNA if it is to be used to probe a cDNA library. The radiolabeled cDNA can be used for hybridization without denaturation. Probes radiolabeled to high specific activity are rapidly damaged by radiochemical decay. The subtractive hybridizations should therefore be carried out as rapidly as practicable, and the probe should be used without delay. Use 5×10^7 dpm of radiolabeled cDNA for each 150-mm filter and 5×10^6 to 1×10^7 dpm for each 90-mm filter.

    If a genomic DNA library is screened with the radiolabeled subtracted probe, oligo(dA) can be added to the prehybridization and hybridization reactions at 1 μg/ml to prevent nonspecific hybridization between the oligo(dT) tails of the cDNA and oligo(dA) tracts in the genomic DNA.

Protocol 9

Radiolabeling of Subtracted cDNA Probes by Random Oligonucleotide Extension

IN THIS PROCEDURE, SYNTHESIS OF CDNA IS CARRIED OUT in the presence of saturating concentrations of all four dNTPs and trace amounts of a single radiolabeled dNTP. After subtraction hybridization, the enriched single-stranded cDNA is radiolabeled to high specific activity in a second synthetic reaction by extension of random oligonucleotide primers using the Klenow fragment of *E. coli* DNA polymerase I. Because the concentrations of dNTP in the first reaction are nonlimiting, both the amounts and size of cDNA generated are greater than those achieved in standard labeling protocols (e.g., please see Protocol 8). The subtractive hybridization step can therefore be carried out with higher efficiency. Because the resulting population of cDNA is not vulnerable to radiolytic cleavage, it can be stored indefinitely and radiolabeled to higher specific activity when needed.

The protocol works best when the cDNA synthesized in the initial synthetic reaction is full length or close to it. For this reason, synthesis of cDNAs is primed by oligo(dT) rather than random hexanucleotide primers. By contrast, the subsequent radiolabeling reaction is primed by random oligonucleotides, yielding shorter DNA products whose size is ideal for hybridization.

The cDNA prepared as described in Steps 1–10 of this protocol can be converted into double-stranded DNA (please see Chapter 11, Protocol 1 [Stage 2]) and cloned into a bacteriophage or plasmid vector to produce a subtracted cDNA library (e.g., please see Sargent and Dawid 1983; Davis 1986; Rhyner et al. 1986; Fargnoli et al. 1990). The cDNA library can then be screened with a subtracted probe. Because subtracted libraries are enriched for cDNA clones corresponding to nonabundant mRNAs, the amount of screening required to find a clone corresponding to a rare mRNA may be reduced by a factor of 10. Subtracted probes radiolabeled as described here can detect cDNAs corresponding to mRNAs expressed at a level as low as five molecules/mammalian cell. For additional details, please see the information panel on **ISOLATING DIFFERENTIALLY EXPRESSED cDNAs BY DIFFERENTIAL SCREENING AND CLONING.**

MATERIALS

▲ **IMPORTANT** Prepare all reagents used in this protocol with DEPC-treated H_2O (please see the information panel on **HOW TO WIN THE BATTLE WITH RNASE** in Chapter 7).

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Dithiothreitol (1 M)

EDTA (0.5 M, pH 8.0)

Ethanol

HCl (2.5 N) **<!>**

NaOH (3 N) **<!>**

Phenol:chloroform (1:1, v/v) **<!>**

Placental RNase inhibitor

These inhibitors are sold by several manufacturers under various trade names (e.g., RNAsin, Promega; Prime Inhibitor, 5 Prime→3 Prime; RNaseOUT, Life Technologies). For more details, please see the information panel on **INHIBITORS OF RNASES** in Chapter 7.

5x Random primer buffer

250 mM Tris (pH 8.0)
25 mM $MgCl_2$
100 mM NaCl
10 mM dithiothreitol
1 M HEPES (adjusted to pH 6.6 with 4 M NaOH)

Use a fresh dilution in H_2O of 1 M dithiothreitol stock, stored at –20°C. Discard the diluted dithiothreitol after use.

SDS (20% w/v)

Sodium acetate (3 M, pH 5.2)

Tris-Cl (1 M, pH 7.4)

Enzymes and Buffers

Klenow fragment of E. coli *DNA polymerase I*

Reverse Transcriptase

Reverse transcriptase derived from the *pol* gene of Mo-MLV is more efficient in cDNA synthesis than that obtained from the avian myeloblastosis virus (e.g., please see Fargnoli et al. 1990). The cloned version of reverse transcriptase encoded by the Mo-MLV enzyme is the enzyme of choice in this protocol. Mutants of the enzyme that lack RNase H activity (e.g., StrataScript from Stratagene or Supercript II from Life Technologies) have some advantages over the wild-type enzyme since they (1) produce higher yields of full-length extension product and (2) work equally well at both 47°C and 37°C (Gerard and D'Alessio 1993).

10x Reverse transcriptase buffer

Nucleic Acids and Oligonucleotides

dNTP solution (complete) containing four dNTPs, each at 5 mM

dNTP solution containing dCTP, dGTP, and dTTP, each at 5 mM

▲ **IMPORTANT** Omit the dATP from this solution.

For advice on making and storing solutions of dNTPs, please see the information panel on **PREPARATION OF STOCK SOLUTIONS OF dNTPs AND ddNTPs FOR DNA SEQUENCING** in Chapter 12.

Oligo(dT)$_{12-18}$

Purchase and dissolve oligo(dT)$_{12-18}$ at 1 mg/ml in TE (pH 7.6). Store at –20°C.

Random deoxynucleotide primers six or seven bases in length

Because of their uniform length and lack of sequence bias, synthetic oligonucleotides of random sequence are the primers of choice. Oligonucleotides of optimal length (hexamers and heptamers; Suganuma and Gupta 1995) can be purchased from a commercial source (e.g., Pharmacia and Boehringer Mannheim) or synthesized locally on an automated DNA synthesizer. Store the solution of primers at 0.125 µg/µl in TE (pH 7.6) at –20°C in small aliquots.

Template RNAs:

Two-pass poly(A)$^+$-enriched mRNA prepared from cells or tissue that expresses the mRNA(s) of interest

Two-pass poly(A)$^+$-enriched mRNA prepared from cells or tissue that does not express the mRNA(s) of interest

For mRNA preparation and oligo(dT) chromatography, please see Chapter 7. Both RNAs should be dissolved in H_2O at a concentration of ~1 mg/ml.

Radioactive Compounds

[α-^{32}P]dATP (10 mCi/ml, sp. act. >3000 Ci/mmole) **<!>**

[α-^{32}P]dCTP (10 mCi/ml, sp. act. 800–3000 Ci/mmole) **<!>**

To minimize problems caused by radiolysis of the precursor and the probe, it is best, whenever possible, to prepare radiolabeled probes on the day the [^{32}P]dNTP arrives in the laboratory.

Special Equipment

Sephadex G-50 spun column, equilibrated in TE (pH 7.6)

Siliconized microfuge tubes (1.5 ml)

Water baths preset to 45°C, 60°C, and 68°C

Additional Reagents

Steps 8 and 9 of this protocol require reagents listed in Protocol 8 of this chapter.

METHOD

1. To synthesize first strand cDNA, mix the following ingredients at 4°C in a sterile microfuge tube:

template RNA (1 mg/ml)	10 µl
oligo(dT)$_{12–18}$ (1 mg/ml)	10 µl
5 mM dNTP solution (complete)	10 µl
50 mM dithiothreitol	1 µl
10x reverse transcriptase buffer	5 µl
10 mCi/ml [α-^{32}P]dCTP (sp. act. 800 or 3000 Ci/mmole)	5 µl
placental RNase inhibitor	25 units
RNase-free H_2O	to 46 µl
reverse transcriptase (~800 units)	4 µl

▲ **IMPORTANT** Add the reverse transcriptase last.

Reverse transcriptase supplied by different manufacturers varies in its activity per unit. When using a new batch of enzyme, set up a series of extension reactions containing equal amounts of poly(A)$^+$ RNA and oligonucleotide primer, and different amounts of enzyme. If possible, the primer should be specific for a mRNA present at moderate abundance in the preparation of poly(A)$^+$ RNA. Assay the products of each reaction by gel electrophoresis as described in this protocol. Use the minimal amount of enzyme required to produce the maximum yield of extension product. The units used in this protocol work well with most batches of StrataScript and Superscript II.

Mix the components by gently tapping the side of the tube. Collect the reaction mixture in the bottom of the tube by brief centrifugation in a microfuge. Incubate the reaction for 1 hour at 45°C.

[α-^{32}P]dCTP is used as a tracer to measure the synthesis of the first strand of cDNA.

2. Measure the proportion of radiolabeled dNTPs that either are incorporated into material precipitated by TCA or adhere to a DE-81 filter (please see Appendix 8). Calculate the yield of cDNA using the equation below.

   In a reaction containing 50 nmoles of each dNTP:

   $$\frac{\text{cpm incorporated}}{\text{total cpm}} \times 200 \text{ nmoles dNTP} \times 330 \text{ ng/nmole} = \text{ng of cDNA synthesized}$$

3. Stop the reaction by adding:

0.5 M EDTA (pH 8.0)	2 µl
20% (w/v) SDS	2 µl

   Mix the reagents in the tube completely.

   The single-stranded, radiolabeled cDNA is quite sticky and adheres nonspecifically to glass, filters, and some plastics. For this reason, it is important to maintain a minimum of 0.05% (w/v) SDS in Step 3 of the protocol, and 0.1–1.0% SDS in hybridization buffers.

4. Add 5 µl of 3 N NaOH to the reaction tube. Incubate the mixture for 30 minutes at 68°C to hydrolyze the RNA.

5. Cool the mixture to room temperature. Neutralize the solution by adding 10 µl of 1 M Tris-Cl (pH 7.4), mixing well, and then adding 5 µl of 2.5 N HCl. Check the pH of the solution by spotting <1 µl on pH paper.

6. Purify the cDNA by extraction with phenol:chloroform (please see Appendix 8).

7. Separate the radiolabeled probe from the unincorporated dNTPs by chromatography through a spun column of Sephadex G-50 (Appendix 8).

   ▲ **IMPORTANT** Perform this step and all subsequent steps with siliconized tubes (please see Appendix 8).

8. Carry out two rounds of subtractive hybridization as described in Protocol 8, Steps 9–19.

9. Concentrate the final preparation of cDNA by sequential extractions with isobutanol, and remove salts by chromatography on Sephadex G-50 as described in Protocol 8, Steps 16 and 17.

10. Recover the cDNA by standard precipitation with ethanol (please see Appendix 8). Dissolve the cDNA in H_2O at a concentration of 15 ng/µl.

    ▲ **IMPORTANT** Do not attempt to precipitate the cDNA with ethanol before removing the phosphate ions by spun-column chromatography. The presence of phosphate ions interferes with DNA precipitation.

    The subtracted cDNA prepared through Step 10 of this protocol can be converted into double-stranded DNA (please see Chapter 11, Protocol 1 [Stage 2]) and cloned into a bacteriophage or plasmid vector to produce a subtracted cDNA library (e.g., please see Sargent and Dawid 1983; Davis 1986; Rhyner et al. 1986; Fargnoli et al. 1990).

11. To radiolabel the subtracted cDNA to high specific activity, mix the following in a 0.5-ml microfuge tube:

subtracted cDNA	5 µl
random deoxynucleotide primers (125 µg/ml)	5 µl

12. Heat the mixture to 60°C for 5 minutes, and then cool it to 4°C.

13. To the primer:cDNA template mixture, add:

5x random primer buffer	10 µl
5 mM dNTP solution of dCTP, dGTP, and dTTP	5 µl
10 mCi/ml [α-^{32}P]dATP (sp. act. >3000 Ci/mmole)	25 µl
Klenow fragment (12.5 units)	2.5 µl
H_2O	to 50 µl

Incubate the reaction for 4–6 hours at room temperature.

10–15 units of the Klenow fragment are required in each random priming reaction.

14. Stop the reaction by adding:

0.5 M EDTA (pH 8.0)	1 µl
20% (w/v) SDS	2.5 µl

15. Separate the radiolabeled cDNA from the unincorporated dNTPs by spun-column chromatography through Sephadex G-50 (please see Appendix 8).

The radiolabeled cDNA should be denatured by heating to 100°C for 5 minutes before it is used for hybridization. Use 5 x 10^7 dpm of radiolabeled cDNA for each 138-mm filter and 5 x 10^6 to 1 x 10^7 dpm for each 82-mm filter. Once radiolabeled, use the probe immediately to avoid damage by radiochemical decay.

Protocol 10

Labeling 3′ Termini of Double-stranded DNA Using the Klenow Fragment of *E. coli* DNA Polymerase I

THE SIMPLEST WAY TO LABEL LINEAR DOUBLE-STRANDED DNA is to use the Klenow fragment of *E. coli* DNA polymerase I to catalyze the incorporation of one or more [α-^{32}P]dNTPs into a recessed 3′ terminus (Telford et al. 1979; Cobianchi and Wilson 1987). For a summary of other methods that may be used to label the termini of DNA, please see Table 9-2 at the end of this protocol. Fragments suitable as templates for the end-filling reaction are produced by digestion of DNA with an appropriate restriction enzyme. The Klenow enzyme is then used to catalyze the attachment of dNTPs to the recessed 3′-hydroxyl groups (please see the information panel on ***E. COLI* DNA POLYMERASE I AND THE KLENOW FRAGMENT**). The labeling reaction is versatile and quick and has the advantage that it can be carried out in the restriction digest, without any change of buffer. Because the Klenow enzyme has an indolent 3′→5′ exonuclease activity, its ability to incorporate nucleotides at blunt or 3′-protruding termini is limited. One or both of the 3′ ends of a linear double-stranded DNA molecule can therefore be labeled, depending on the nature of the termini and radiolabeled nucleotide included in the labeling reaction (please see Labeling Recessed and Blunt-ended 3′ Termini below). However, under most circumstances, it is best to include unlabeled dNTPs in the labeling reaction. This allows the labeling of the recessed 3′ terminus at any position. In addition, unlabeled dNTPs incorporated downstream from the labeled dNTP shield the labeled nucleotide from the action of the indolent 3′→5′ exonuclease. Fragments labeled at both 3′ termini are used as:

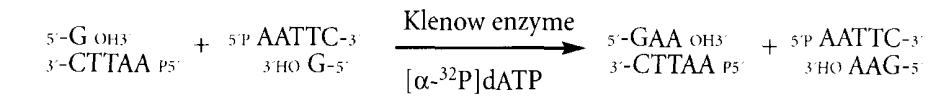
- molecular-weight standards in Southern blotting (please see the panel on **PREPARING RADIOLABELED SIZE MARKERS FOR GEL ELECTROPHORESIS** following Step 4)
- probes in gel-retardation experiments
- tracers for small quantities of DNAs on gels
- low-specific-activity probes for screening bacterial colonies or bacteriophage plaques and for Southern analysis of recombinant cosmids, plasmids, or bacteriophage λ

Fragments labeled at only one terminus are used as:

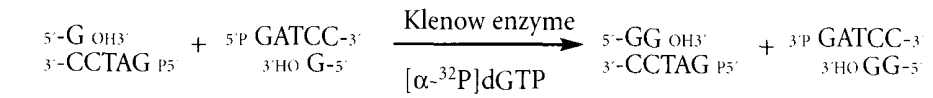
- substrates for sequencing by the Maxam-Gilbert method (Chapter 12, Protocol 7)
- probes for RNA mapping with either nuclease S1 or mung bean nuclease (Chapter 7, Protocol 10)
- primers in primer-extension reactions

LABELING RECESSED AND BLUNT-ENDED 3′ TERMINI

This protocol requires that the DNA to be end-labeled contain a sequence recognized and cleaved by a restriction endonuclease that generates 3′-recessed ends. The choice of which [α-^{32}P]dNTPs to use for the reaction depends on the sequence of the protruding 5′ termini at the ends of the DNA and on the objective of the experiment. For example, ends created by cleavage of DNA with *Eco*RI can be labeled with [α-^{32}P]dATP:



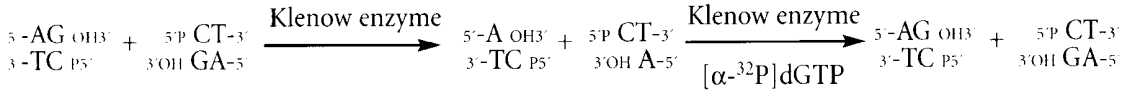
The two proximal 5′-protruding nucleotides are both thymidine residues, and the Klenow enzyme can therefore insert two adenine residues. The resulting fragment with two identical radiolabeled nucleotides incorporated into its 3′ terminus would not be suitable for Maxam-Gilbert sequencing, because a doublet pattern would be obtained on the sequencing autoradiogram. For other purposes, however, such as radiolabeling of DNAs to be used as size standards or generating probes, the incorporation of two identical radiolabeled deoxynucleotides would not compromise the results. Termini created by cleavage of DNA with *Bam*HI can be labeled with [α-^{32}P] dGTP:



Note that only one radiolabeled nucleotide can be incorporated per end in a reaction utilizing [α-^{32}P]dGTP as the radiolabeled substrate. However, if unlabeled dGTP, dATP, and dTTP were included in the polymerization reaction, then the DNA fragment could be radiolabeled with [α-^{32}P]dCTP. The addition of unlabeled dNTPs (1) allows the use of any available radiolabeled dNTP whose complement is included in the protruding 5′ end, (2) eliminates the possibility of exonucleolytic removal of nucleotides from the 3′ terminus of the template by the Klenow enzyme's 3′→5′ exonuclease activity, and (3) ensures that all radiolabeled DNA products will be the same length.

By choosing the appropriate [α-^{32}P]dNTP, it is possible to label only one end of a double-stranded DNA molecule. For example, DNA cleaved by *Eco*RI at one end and by *Bam*HI at the other end can be labeled selectively by including either [α-^{32}P]dATP (to radiolabel the *Eco*RI site) or [α-^{32}P]dGTP (to radiolabel the *Bam*HI site). Furthermore, if the DNA sequence of a fragment to be end-labeled is known, the N nucleotide in the recognition sequence of certain restriction enzymes can be used to label one end of a DNA molecule preferentially. For example, the restriction enzyme *Hin*fI recognizes the sequence 5′-GANTC-3′ and cleaves between the G and A to yield a 3′-recessed end. If the *Hin*fI recognition sequence at the 5′ end of a DNA fragment is 5′-GACTC-3′ and at the 3′ end the sequence is 5′-GAGTC-3′, then the DNA fragment can be selectively labeled at the 5′ end by including unlabeled dATP and [α-^{32}P]dGTP in the reaction or at the 3′ end by including unlabeled dATP and [α-^{32}P]dCTP in the reaction. Numerous variations on this strategy can be used with restriction enzymes such as *Dde*I, *Fnu*4H, *Bsu*36I, and *Eco*O109I.

The terminal nucleotide of a blunt-ended DNA fragment can be replaced by exploiting the weak 3′→5′ exonucleolytic and strong polymerizing activities of the Klenow fragment. For example, incubation of DNA fragments produced by the restriction enzyme *Alu*I, which recognizes the sequence 5′-AGCT-3′ and cleaves between the G and C, with the Klenow enzyme and [α-^{32}P]dGTP results in exonucleolytic removal of the dGMP and replacement with the radiolabeled guanine nucleotide:



Although the specific activity of radiolabeled blunt-ended DNA fragments is not high, it is generally sufficient to allow the fragments to be used as size standards in gel electrophoresis. Blunt-ended molecules can be labeled more efficiently using bacteriophage T4 DNA polymerase, which has a much more powerful 3′→5′ exonuclease than the Klenow fragment.

Finally, the end-filling reaction catalyzed by the Klenow enzyme is not limited to radiolabeled dNTPs. Deoxynucleotides modified with haptens such as biotin, fluorescein, and digoxigenin can also be used. The K_m values for incorporation of these modified nucleotides are usually less than the K_m values of the standard dNTPs and depends on the nature of the hapten. Follow the recommendations of the manufacturer when using modified nucleotides as substrates in labeling reactions catalyzed by the Klenow enzyme.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Ammonium acetate (10 M)
Optional, please see Step 4.

Ethanol

Enzymes and Buffers

Appropriate restriction enzyme(s)
Choose enzymes that produce 3′-recessed termini.

Klenow fragment of E. coli *DNA polymerase I*

Nucleic Acids and Oligonucleotides

dNTP solution containing the appropriate unlabeled dNTPs, each at 1 mM
For advice on making and storing solutions of dNTPs, please see the information panel on **PREPARATION OF STOCK SOLUTIONS OF dNTPs AND ddNTPs FOR DNA SEQUENCING** in Chapter 12.

Template DNA (0.1–5 μg)
Use linear, double-stranded DNA carrying appropriate recessed 3′ termini.

Radioactive Compounds

[α-^{32}P]dNTP (10 mCi/ml, sp. act. 800–3000 Ci/mmole) **<!>**
To minimize problems caused by radiolysis of the precursor and the probe, it is best, whenever possible, to prepare radiolabeled probes on the day the [^{32}P]dNTP arrives in the laboratory.

Special Equipment

Sephadex G-50 spun column, equilibrated in TE (pH 7.6)
Optional, please see Step 4.

Water bath preset to 75°C

METHOD

1. Digest up to 5 µg of template DNA with the desired restriction enzyme in 25–50 µl of the appropriate restriction enzyme buffer.

   The labeling reaction may be carried out immediately after digesting the DNA with a restriction enzyme. There is no need to remove the restriction enzyme or to inactivate it. Because the Klenow fragment works well under a variety of conditions (as long as Mg^{2+} is present in millimolar concentrations), it is unnecessary to change buffers. At the end of the restriction reaction, the Klenow enzyme, unlabeled dNTPs, and the appropriate [α-^{32}P]dNTP are added and the reaction is incubated for a further 15 minutes at room temperature, as described below. The procedure works well even on relatively crude DNA preparations (e.g., minipreparations of plasmids).

2. To the completed restriction digest, add:

10 mCi/ml [α-^{32}P]dNTP (sp. act. 800–3000 Ci/mmole)	2–50 µCi
unlabeled dNTPs	to a final concentration of 100 µM
Klenow fragment	1–5 units

   Incubate the reaction for 15 minutes at room temperature.

   Approximately 0.5 unit of the Klenow enzyme is required for each µg of template DNA (1 µg of a 1000-bp fragment is equivalent to ~3.1 pmoles of termini of double-stranded DNA; Appendix 6). The Klenow enzyme works well in almost all buffers used for digestion by restriction enzymes.

   Reverse transcriptase (1–2 units) can be used in place of the Klenow enzyme in this protocol. However, reverse transcriptase is not as forgiving of buffer conditions as the Klenow enzyme and is therefore used chiefly to label purified DNA fragments in reactions containing conventional reverse transcriptase buffer.

   When the labeled DNA is to be used for sequencing by the Maxam-Gilbert technique (please see Chapter 12, Protocol 7) or for mapping mRNA by the nuclease S1 method (please see Chapter 7, Protocol 10), the concentration of labeled dNTP in the reaction should be increased to the greatest level that is practicable. After the reaction has been allowed to proceed for 15 minutes at room temperature, add all four unlabeled dNTPs to a final concentration of 0.2 mM for each dNTP, and continue the incubation for a further 5 minutes at room temperature. This cold chase ensures that each recessed 3′ terminus will be completely filled and that all labeled DNA molecules will be exactly the same length.

3. Stop the reaction by heating it for 10 minutes at 75°C.

4. Separate the radiolabeled DNA from unincorporated dNTP by spun-column chromatography through Sephadex G-50 (please see Appendix 8) or by two rounds of precipitation with ethanol in the presence of 2.5 M ammonium acetate (please see Appendix 8).

PREPARING RADIOLABELED SIZE MARKERS FOR GEL ELECTROPHORESIS

This protocol generates labeled DNA fragments that can be used as size markers during gel electrophoresis. Because the fragments are labeled in proportion to their molar concentrations and not their sizes, both small and large fragments in a restriction enzyme digest become labeled to an equal extent. Bands of DNA that are too small to be visualized by staining with ethidium bromide can therefore be located by autoradiography.

It is desirable, but not necessary, to remove unincorporated [α-^{32}P]dNTP from the radiolabeled DNA before gel electrophoresis. The [α-^{32}P]dNTP migrates faster than bromophenol blue on both polyacrylamide and agarose gels and does not interfere with the detection of anything but the smallest of DNA fragments. However, removing the unincorporated radiolabel has some advantages: It avoids the possibility of contaminating the anodic buffer chamber of the electrophoresis tank with radioactivity, it allows the amount of radiolabeled DNA applied to the gel to be estimated by a hand-held minimonitor, and it reduces the possibility of radiochemical damage to the DNA.

TABLE 9-2 End-labeling of DNA

Template	Desired Position of Label	Preferred Methods
Single-stranded DNA or RNA	5′ terminus	*Kinase reaction:* A hydroxyl group is first created by removing the unlabeled phosphate residue from the 5′ end of the nucleic acid with an alkaline phosphatase such as CIP or SAP (**Protocol 13**). Bacteriophage T4 polynucleotide kinase is then used to transfer the label from the γ position of ATP to the newly created 5′-hydroxyl group (Wu et al. 1976) (**Protocols 14 and 15**). These reactions can be carried out sequentially in one tube but require inhibition of phosphatase with inorganic phosphate (Chaconas and van de Sande 1980; Cobianchi and Wilson 1987). An alternative procedure has been described in which digestion with a restriction endonuclease and 5′-end labeling with polynucleotide kinase can be carried out in one step without the benefit of alkaline phosphatase (Oommen et al. 1990). The mechanism of this reaction is obscure. *Exchange reaction:* The unlabeled phosphate residue is transferred from the 5′ terminus of the nucleic acid to ADP and is then replaced by labeled phosphate from the γ position of ATP (**Protocol 16**). Both of these reactions are catalyzed by bacteriophage T4 polynucleotide kinase and proceed simultaneously in the same test tube in the presence of excess ADP and limiting amounts of γ-labeled ATP (Berkner and Folk 1977). When labeling single-stranded DNAs that are >300 nucleotides in length, the overall efficiency of the exchange reaction is greatly improved by including a macromolecular crowding agent such as polyethylene glycol (4–10%) in the reaction mixture (Harrison and Zimmerman 1986a,b). Even so, the specific activity of the 5′-labeled DNA is always less than can be achieved with the kinase reaction. *Note:* Bacteriophage T4 polynucleotide kinase carries a 3′-phosphatase activity that degrades ATP. Several commercial suppliers prepare the enzyme from cells infected with a strain of bacteriophage T4 (amN81 *pseT*1) that carries a mutated version of the gene encoding polynucleotide kinase. This mutant form of the enzyme lacks 3′-phosphatase activity.
Single-stranded DNA	3′ terminus	Template-independent polymerization of [α-^{32}P]NTP to the 3′ terminus of single-stranded DNA is catalyzed by calf thymus terminal deoxynucleotidyl transferase. If the DNA is to be used for Maxam-Gilbert sequencing, use a radiolabeled *ribo*nucleotide as the substrate for the transferase reaction, which then requires Co^{2+} as a cofactor (Deng and Wu 1983). The radiolabeled DNA is then be exposed to alkali and treated with alkaline phosphatase to generate a uniformly labeled DNA fragment of defined length (Roychoudhury et al. 1976, 1979; Wu et al. 1976). Alternatively, incorporation at the 3′ terminus can be limited to just one nucleotide by using [α-^{32}P]dideoxyATP (Yousaf et al. 1984) or [α-^{32}P]cordycepin triphosphate (Tu and Cohen 1980) as a substrate for terminal transferase (**Protocol 12**). Because neither of these molecules carries a 3′-hydroxyl group, no additional molecules can be incorporated. Under most circumstances, [α-^{32}P]dideoxyATP is the preferred substrate for labeling 3′ termini because it is incorporated more efficiently than [α-^{32}P]cordycepin triphosphate. However, DNA molecules carrying cordycepin residues at their 3′ termini have one advantage: They are resistant to digestion with contaminating exonucleases that may remove 3′-terminal ribonucleotide labels from single-stranded DNA. Terminal transferase can also be used to add biotinylated or fluoresceinated deoxy- or dideoxynucleotides to the 3′ termini of single-stranded DNA fragments (e.g., please see Vincent et al. 1982; Schneider et al. 1994).
Double-stranded DNA with protruding 5′ terminus	5′termini	Labeling is carried out with polynucleotide kinase as described above for labeling of the 5′ termini of single-stranded DNA (**Protocol 14**).
Double-stranded DNA with blunt-ended or recessed 5′ termini	5′ termini	Labeling is carried out with polynucleotide kinase as described above for labeling of the 5′ termini of single-stranded DNA (**Protocol 15**). However, double-stranded DNA molecules with blunt ends or recessed 5′ termini are labeled less efficiently by polynucleotide kinase than molecules with protruding 5′ termini. Even a partial reaction at recessed 5′ termini requires large amounts of enzyme and [γ-^{32}P]ATP.
Double-stranded DNA with blunt-ended or recessed 3′ termini	3′ termini	The Klenow fragment, which retains the template-dependent deoxynucleotide polymerizing activity and the 3′→5′ exonuclease of the holoenzyme but lacks its powerful 5′→3′ exonuclease activity, is used to fill recessed 3′ termini of double-stranded DNA (**Protocol 10**). Usually, only one of the four dNTPs present in the reaction mixture is radiolabeled. The presence of the three unlabeled dNTPs serves two purposes: It blocks exonucleolytic removal of nucleotides from the 3′ terminus of the template, and it allows the radiolabled dNTP to be the second, third, or fourth nucleotide added to the recessed 3′ terminus. The presence of only one radiolabeled dNTP in the reaction mixture some-

(Continued on following page.)

TABLE 9-2 *(Continued)*

Template	Desired Position of Label	Preferred Methods
		times permits double-stranded DNA that has been cleaved with two different restriction endonucleases to be labeled selectively at only one end. For example, a DNA that has been cleaved with G G *Bam*H1 CCTAG and *Eco*RI CTTAA can be selectively labeled at the *Bam*HI terminus by using [α-^{32}P]dGTP as the sole source of radioactivity in the fill-in reaction. Alternatively, DNA can be cleaved with one restriction enzyme, radiolabeled, and then cleaved with a second enzyme to generate two DNA fragments, each of which carries radiolabel at only one end. Specialized vectors have been constructed that facilitate the asymmetric labeling of DNA fragments. For example, pSP64CS and pSP65CS contain sites that are cleaved by the restriction enzyme *Tth*111I, which recognizes the redundant sequence ↓ 5′ GACNNNGTC 3′ 3′ CTGNNNCAG 5′ ↑ and generates a terminus with a single protruding 5′ nucleotide. The DNA of interest is cloned between two *Tth*111I sites that yield DNAs with different protruding nucleotides at their termini. After cleavage, the DNA can be selectively labeled at one or both ends by the Klenow fragment and the appropriate [α-^{32}P]dNTP(s) (Volkaert et al. 1984; Eckert 1987). Blunt-ended DNA fragments can be labeled by template-independent addition of a single nucleotide (usually [α-^{32}P]dATP) catalyzed by *Taq* polymerase.
Double-stranded DNA with protruding 3′ termini	3′ termini	Bacteriophage T4 DNA polymerase carries a 5′→3′ polymerase and a 3′→5′ exonuclease activity that is more active on single-stranded DNA than double-stranded DNA. The exonuclease of bacteriophage T4 DNA polymerase is ~200 times more potent than the equivalent exonuclease of the Klenow fragment. T4 DNA polymerase is used to end-label DNA molecules with protruding 3′ termini (**Protocol 11**). This reaction works in two stages. First, the powerful 3′→5′ exonuclease removes the protruding tails from the DNA and creates recessed 3′ termini. Then, in the presence of high concentrations of radiolabeled precursor(s), exonucleolytic degradation is balanced by incorporation of dNTPs at the 3′ termini. This reaction, which consists of cycles of removal and replacement of the 3′-terminal nucleotides from recessed or blunt-ended DNA, is sometimes called an exchange or replacement reaction (O'Farrell et al. 1980). Alternatively, protruding 3′ termini can be labeled by template-independent addition of nucleotides catalyzed by calf thymus terminal deoxynucleotidyl transferase, poly(A) polymerase (please see 3′-terminal labeling of single-stranded DNA and **Protocol 12**) or certain thermostable DNA polymerases, for example, *Taq* (please see Table 8-1 in Chapter 8 and Protocol 3 of this chapter).
RNA	3′ termini	Bacteriophage T4 RNA ligase catalyzes the joining of a terminating radioactive bisphosphate nucleotide ([5′-^{32}P]pNp) to a 3′-hydroxyl terminus of RNA (Uhlenbeck and Gumport 1982). The reaction extends the length of the RNA molecule by one nucleotide and generates a phosphorylated 3′ terminus with a [^{32}P]phosphate in the last internucleotide linkage (England et al. 1977; Kikuchi et al. 1978; Tyc and Steitz 1989). The terminal 3′-phosphate group acts as a chain terminator by preventing formation of further phosphodiester bonds. This method of labeling has been used chiefly with small RNAs. However, perhaps because of steric effects caused by secondary structure, the amount of label incorporated seriously misrepresents the relative abundance of the RNAs used as substrates. Poly(A) polymerase catalyzes the template-independent addition of A residues to the 3′ terminus of RNA. When [α^{32}P]ATP is used as a substrate, the phophodiester bonds in the poly(A) tract contain ^{32}P atoms (Lingner and Keller 1993). Substitution of cordycepin triphosphate (3′-dATP) for ATP results in the addition of a single 3′-dA residue to the end of the RNA, which is a useful method for radiolabeling RNA at the 3′ end. Yeast poly(A) polymerase preferentially labels longer RNA molecules, whereas short RNA molecules are labeled more efficiently by RNA ligase. Terminal transferase has been used to add a biotin-labeled dideoxynucleotide to the 3′ terminus of RNA (Schneider et al. 1994). However, the efficiency of this reaction has not been thoroughly investigated.

Protocol 11

Labeling 3′ Termini of Double-stranded DNA with Bacteriophage T4 DNA Polymerase

RESTRICTION ENZYMES SUCH AS *PstI*, *PvuI*, AND *SacI* CLEAVE DNA asymmetrically to produce fragments with protruding 3′ ends. The termini of these fragments are difficult to label in reactions catalyzed by the Klenow fragment, in part because this enzyme has a weak 3′→5′ exonuclease activity. However, the DNA polymerase encoded by gene 43 of bacteriophage T4 carries a 3′→5′ exonucleolytic activity that is more active against single-stranded substrates than double-stranded substrates and ~200-fold more powerful than the Klenow enzyme. The bacteriophage-encoded enzyme rapidly digests 3′-protruding termini and then continues at a slower pace to remove 3′ nucleotides from the double-stranded portion of the DNA substrate. In the absence of dNTPs, the enzyme degrades double-stranded molecules to approximately half-length single strands. However, in the presence of high concentrations of dNTPs, recessed 3′-hydroxyl termini generated by exonucleolytic activity act as primers for template-directed addition of mononucleotides by the 5′→3′ polymerase. Because the synthetic capacity of bacteriophage T4 DNA polymerase exceeds its exonucleolytic abilities, protruding 3′ termini are converted to termini with flush ends (Richardson et al. 1964b). If one of the four dNTPs is radiolabeled, the resulting blunt-ended double-stranded molecules will be labeled at or near their 3′ termini (Goulian et al 1968). For a summary of methods used to label the termini of DNA, please see Table 9-2 in Protocol 10.

Careful studies of the kinetics of the exonuclease and fill-in reactions catalyzed by bacteriophage T4 DNA polymerase indicate that the incorporation of radiolabel into DNA is nonrandom (Bortner and Griffith 1993). Thus, radiolabeled fragments typically have extensive tracts of newly synthesized DNA, rather than all DNA templates being end-labeled. This labeling pattern apparently arises because the initiation of the exonuclease reaction is the rate-limiting step. Once started, the enzyme continues to digest the DNA in the 3′→5′ direction for a considerable length and then subsequently fills in the resected DNA. If the goal is the generation of an end-labeled population of DNA molecules from a blunt-ended or 5′-recessed template, it is best to carry out a two-stage reaction in which the template is first digested with exonuclease III at reduced temperatures and then regenerated by bacteriophage T4 DNA polymerase (Bortner and Griffith 1993).

In the presence of a single α-radiolabeled dNTP (e.g., [α-^{32}P]dCTP), the enzyme progressively removes nucleotides until it exposes a G residue on the complementary DNA strand. An idling-turnover reaction is then established in which the radiolabeled C residue is removed by the exonuclease and replaced with a fresh radiolabeled residue by the polymerase (Young et al. 1992). In the case of DNA fragments generated by *PstI*, the idling-turnover reaction may be outlined as shown in Figure 9-3.

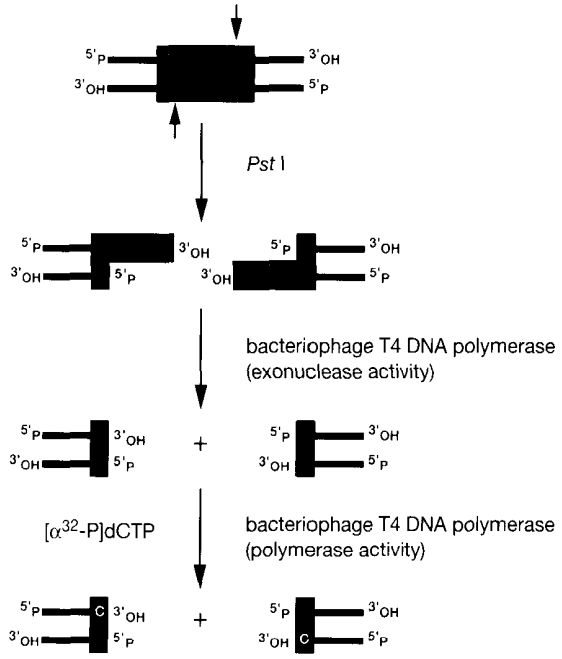


FIGURE 9-3 Labeling Using the Idling/Turnover Feature

Please see text for details.

Fragments radiolabeled by the idling-turnover reaction can be used as probes for mapping RNA with nuclease S1 or mung bean nuclease (Chapter 7, Protocol 10); for Southern analysis of cosmid, plasmid, or bacteriophage DNAs; or for screening bacterial colonies and bacteriophage plaques. In addition, the labeled fragments can be used as size markers during gel electrophoresis and as primers in primer-extension reactions. For further details, please see the introduction to Protocol 10.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Ammonium acetate (10 M)
Ethanol
Phenol:chloroform (1:1, v/v) **<!>**

Enzymes and Buffers

Appropriate restriction enzyme(s)

Choose enzymes that produce blunt or 3′-protruding termini. In many cases, digestion can be carried out in T4 DNA polymerase buffer, allowing the digestion and labeling reactions to be carried out sequentially without an intermediate extraction with phenol:chloroform and precipitation with ethanol. However, not all restriction enzymes work in bacteriophage T4 DNA polymerase buffer, and it is advisable to follow the manufacturer's advice and/or to carry out pilot reactions with the particular restriction enzyme before using this shortcut.

Bacteriophage T4 DNA polymerase
10x Bacteriophage T4 DNA polymerase buffer

Nucleic Acids and Oligonucleotides

dNTP solution containing three unlabeled dNTPs, each at 2 mM

The three dNTPs to be included in this solution depend on the DNA sequence of the restriction endonuclease site to be radiolabeled. None of them should carry the same base as the radiolabeled nucleotide (please see the introduction to Protocol 10). For advice on making and storing solutions of dNTPs, please see the information panel on **PREPARATION OF STOCK SOLUTIONS OF dNTPs AND ddNTPs FOR DNA SEQUENCING** in Chapter 12.

dNTP solution containing one unlabeled dNTP at a concentration of 2 mM

▲ **IMPORTANT** The dNTP used here should carry the same base as the radiolabeled dNTP.

Template DNA (0.1–5 μg)

Use linear, double-stranded DNA carrying appropriate blunt or protruding 3′ termini.

Radioactive Compounds

[α-^{32}P]dNTP (10 mCi/ml, sp. act. 800–3000 Ci/mmole) **<!>**

To minimize problems caused by radiolysis of the precursor and the probe, it is best, whenever possible, to prepare radiolabeled probes on the day the [^{32}P]dNTP arrives in the laboratory.

Special Equipment

Sephadex G-50 spun column, equilibrated in TE (pH 7.6)

Optional, please see Step 6.

Water bath preset to 70°C

METHOD

1. Digest 0.1–5.0 μg of the template DNA with a restriction enzyme(s) that generates a blunt or 3′-protruding end.

   Please see the note under Appropriate restriction enzymes in the Materials section of this protocol.

2. Purify the DNA by extraction with phenol:chloroform and precipitation with ethanol in the presence of 2.5 M ammonium acetate (please see Appendix 8).

3. Dissolve the DNA pellet in:

10x bacteriophage T4 DNA polymerase buffer	2 μl
2 mM solution of three unlabeled dNTPs	1 μl
10 mCi/ml [α-^{32}P]dNTP (800–3000 Ci/mmole)	1 μl
bacteriophage T4 DNA polymerase (2.5 units/μl)	1 μl
H_2O	to 20 μl

   Incubate the reaction for 5 minutes at 37°C.

4. Add 1 μl of a 2 mM solution of the unlabeled fourth dNTP. Continue the incubation for a further 10 minutes.

5. Stop the reaction by heating it to 70°C for 5 minutes.

6. Separate the labeled DNA from unincorporated dNTPs by spun-column chromatography through Sephadex G-50 (please see Appendix 8) or by two rounds of precipitation with ethanol in the presence of 2.5 M ammonium acetate (please see Appendix 8).

Protocol 12

End Labeling Protruding 3′ Termini of Double-stranded DNA with [α-^{32}P]Cordycepin 5′-Triphosphate or [α-^{32}P]dideoxyATP

THE 3′-PROTRUDING ENDS OF DNA, SUCH AS THOSE GENERATED by *PstI* or *SacI* or other restriction enzymes, can be labeled by using the enzyme calf thymus terminal transferase to catalyze the transfer of [α-^{32}P]dideoxyATP (Yousaf et al. 1984) or [α-^{32}P]cordycepin triphosphate (Tu and Cohen 1980). Because neither of these molecules carries a 3′-hydroxyl group, no additional nucleotides can be attached to the protruding 3′ end. Under most circumstances, [α-^{32}P]dideoxyATP is the preferred substrate for labeling 3′ termini because it is incorporated more efficiently than [α-^{32}P]cordycepin triphosphate. However, DNA molecules carrying cordycepin residues at their 3′ termini have one advantage: They are resistant to digestion with contaminating exonucleases that can remove 3′-terminal labels from DNA. For a summary of methods used to label the termini of DNA, please see Table 9-2 in Protocol 10.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Ammonium acetate (10 M)
Optional, please see Step 6.
Ethanol
Phenol:chloroform (1:1, v/v) **<!>**

Enzymes and Buffers

Appropriate restriction enzyme(s)
Choose enzymes that produce 3′-protruding termini.
Calf thymus terminal transferase
5x Terminal transferase buffer

Nucleic Acids and Oligonucleotides

Template DNA (0.1–5 µg)
Use linear, double-stranded DNA carrying appropriate protruding 3′ termini.

Radioactive Compounds

[α-^{32}P]Cordycepin triphosphate (10 mCi/ml, sp. act. 5000 Ci/mmole) **<!>**
Cordycepin (3′-deoxyadenosine), isolated from the culture fluids of *Cordyceps militaris* (a club-shaped mushroom), was the first nucleotide antibiotic to be discovered (Cunningham et al. 1951).

or

[α-^{32}P]DideoxyATP (10 mCi/ml, sp. act. 3000 Ci/mmole) **<!>**
To minimize problems caused by radiolysis of the precursor and the probe, it is best, whenever possible, to prepare radiolabeled probes on the day the ^{32}P-labeled nucleotide arrives in the laboratory.

Special Equipment

Sephadex G-50 spun column, equilibrated in TE (pH 7.6)
Optional, please see Step 6.

METHOD

1. Digest 0.1–5 µg of template DNA with the appropriate restriction enzyme.
2. Purify the DNA by extraction with phenol:chloroform and standard precipitation with ethanol.
3. Dissolve the digested DNA in 10 µl of 5x terminal transferase buffer and 34 µl of H_2O.
4. Add 5 µl of 10 mCi/ml [α-^{32}P]cordycepin 5′-triphosphate (5000 Ci/mmole) or [α-^{32}P]dideoxyATP (3000 Ci/mmole) and 1 µl of calf thymus terminal transferase (~20 units).

   20 units of calf thymus terminal transferase are required to catalyze the radiolabeling of ~10 pmoles of protruding 3′ termini.
5. Incubate the reaction for 1 hour at 37°C.
6. Separate the labeled DNA from unincorporated [α-^{32}P]cordycepin 5′-triphosphate (or [α-^{32}P]dideoxyATP) by spun-column chromatography through Sephadex G-50 or by two rounds of precipitation with ethanol in the presence of 2.5 M ammonium acetate (please see Appendix 8).

   RNA can be end-labeled with [^{32}P]cordycepin and yeast-encoded poly(A) polymerase, an enzyme that catalyzes the addition of adenosine residues onto the terminal 3′-hydroxyl group of any oligo- or polyribonucleotide (Lingner and Keller 1993). Substitution of radiolabeled cordycepin triphosphate (3′-dATP) for ATP results in the addition of a single 3′-dA residue to the 3′ end of the RNA. Yeast poly(A) polymerase preferentially labels longer RNA molecules, whereas short RNA molecules are labeled more efficiently by RNA ligase.

   Alternatively, radiolabeled [^{32}P]pCp can be attached to the 3′ ends of RNA substrates with RNA ligase, an enzyme coded by bacteriophage T4 that catalyzes the ATP-dependent intra- and intermolecular formation of phosphodiester bonds between 5′-phosphate and 3′-hydroxyl termini of single-stranded RNA or DNA. The minimal substrate is a nucleoside 3′,5′-diphosphate such as pCp (Uhlenbeck and Gumport 1982).

Protocol 13

Dephosphorylation of DNA Fragments with Alkaline Phosphatase

THE REMOVAL OF 5′ PHOSPHATES FROM NUCLEIC ACIDS is used to enhance subsequent labeling with [γ-^{32}P]ATP, to reduce the circularization of plasmid vectors in ligation reactions, and to render DNA susceptible or resistant to other enzymes that act on nucleic acids (e.g., λ exonuclease). Essentially any nucleotide phosphatase (e.g., bacterial alkaline phosphatase, calf intestinal alkaline phosphatase [CIP], placental alkaline phosphatase, shrimp alkaline phosphatase [SAP], or several acid phosphatases such as sweet potato and prostate acid phosphatase) will catalyze the removal of 5′ phosphates from nucleic acid templates. In fact, these enzymes prefer small substrates such as *p*-nitrophenyl phosphate and the exposed 5′ phosphates of nucleic acids to bulky globular protein substrates. For additional details on alkaline phosphatases, please see the information panel on **ALKALINE PHOSPHATASE**.

Because CIP and SAP are commercially available and readily inactivated, they are the most widely used phosphatases in molecular cloning. Although CIP is less expensive per unit of activity, SAP enzyme has the advantage of being readily inactivated in the absence of chelators. DNA modification reactions (e.g., phosphorylation and ligation) can therefore be carried out in serial fashion in the same reaction tube, thereby avoiding extraction with phenol:chloroform and precipitation with ethanol.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Chloroform **<!>**
EDTA (0.5 M, pH 8.0) or EGTA (0.5 M, pH 8.0), if using CIP
Ethanol
Phenol:chloroform (1:1, v/v) **<!>**
SDS (10% w/v), if using CIP

Sodium acetate (3 M, pH 7.0 [if using CIP] and pH 5.2)
The 3 M sodium acetate solution at pH 7.0 is used because EDTA precipitates from solution at acid pH.
TE (pH 7.6)
Tris-Cl (1 M, pH 8.5)

Enzymes and Buffers

Calf intestinal alkaline phosphatase (CIP) or Shrimp alkaline phosphatase (SAP) (US Biochemicals, Boehringer Mannheim, or Worthington Biochemicals)
10x CIP dephosphorylation buffer or 10x SAP dephosphorylation buffer
Proteinase K
Restriction enzyme(s)

Nucleic Acids and Oligonucleotides

DNA sample (0.1–10 µg [1–100 pmoles])
Dephosphorylation reactions are usually carried out in a volume of 25–50 µl containing 1–100 pmoles of 5′-phosphorylated termini of DNA.

Special Equipment

Water baths or heating blocks preset to 56°C, 65°C, or 75°C (CIP) or 70°C (SAP)

CALCULATING THE AMOUNT OF 5′ ENDS IN A DNA SAMPLE

Use the following formulas to calculate the number of pmoles of 5′ ends present in a given DNA sample.

For double-stranded DNA

Amount of 5′ ends (in pmoles) = $[X/(Y \times 660 \text{ g/mole/base pair})] \times 10^{12}$ pmoles/mole x 2 ends/molecule

Where *X* is the mass of DNA fragment in grams and *Y* is the length of DNA fragment in base pairs. For example, 1 µg of linearized 3-kb plasmid DNA = 1 pmole 5′ ends, and 1 µg of a 1-kb double-stranded DNA fragment = 3 pmoles 5′ ends.

For single-stranded DNA

pmole 5′ ends = $[X/(Y \times 330 \text{ g/mole/nucleotide})] \times 10^{12}$ pmoles/mole

Where *X* is the mass of DNA fragment in grams and *Y* is the length of DNA fragment in nucleotides. For example, 1 µg (~0.03 OD_{260}) of a 25-mer oligodeoxynucleotide is 120 pmoles 5′ ends.

METHOD

1. Use the restriction enzyme of choice to digest to completion 1–10 µg (10–100 pmoles) of the DNA to be dephosphorylated.

   Follow the restriction enzyme manufacturer's recommendations for incubation time and temperature. The progress of the digest can be analyzed by agarose gel electrophoresis.

   CIP and SAP will dephosphorylate DNA at a slightly reduced efficiency in restriction buffers that have been adjusted to pH 8.5 with 10x CIP or 10x SAP buffer, as is done in the next step. If this is unacceptable, the restricted DNA may be purified by extraction with phenol:chloroform and standard precipitation with ethanol and then dissolved in a minimal volume of 10 mM Tris-Cl (pH 8.5).

2. Dephosphorylate the 5′ ends of the restricted DNA with either CIP or SAP.

To dephosphorylate DNA using CIP

a. Add to the DNA:

10x CIP dephosphorylation buffer	5 µl
H_2O	to 48 µl

b. Add the appropriate amount of CIP.

1 unit of CIP will dephosphorylate ~1 pmole of 5′-phosphorylated termini (5′-recessed or blunt-ended DNA) or ~50 pmoles of 5′-protruding termini. These amounts may vary slightly from one manufacturer to the next.

c. Incubate the reaction for 30 minutes at 37°C, add a second aliquot of CIP, and continue incubation for a further 30 minutes.

d. To inactivate CIP at the end of the incubation period, add SDS and EDTA (pH 8.0) to final concentrations of 0.5% and 5 mM, respectively. Mix the reagents well, and add proteinase K to a final concentration of 100 µg/ml. Incubate for 30 minutes at 56°C.

e. Cool the reaction to room temperature and purify the DNA by extracting it twice with phenol:chloroform and once with chloroform alone.

Proteinase K and SDS used to inactivate and digest CIP must be completely removed by extraction with phenol:chloroform prior to subsequent enzymatic treatments (phosphorylation by polynucleotide kinase, ligation, etc.).

▲ **IMPORTANT** A single extraction with chloroform alone is insufficient to reduce the concentration of SDS to the point where it no longer will inhibit polynucleotide kinase. Kurien et al. (1997) suggest that up to four extractions with chloroform may be required.

Glycogen or linear polyacrylamide (Gaillard and Strauss 1990) can be added as a carrier before phenol:chloroform extraction if small amounts of DNA (<100 ng) were used in the reaction. Do not add carrier nucleic acid (tRNA, salmon sperm DNA, etc.), as it will compete with the dephosphorylated DNA for the radiolabeled ATP during the kinasing reaction.

Alternatively, CIP can be inactivated by heating to 65°C for 30 minutes (or 75°C for 10 minutes) in the presence of 10 mM EGTA (pH 8.0)

▲ **IMPORTANT** Use EGTA not EDTA.

To dephosphorylate DNA using SAP

a. Add to the DNA:

10x SAP dephosphorylation buffer	5 µl
H_2O	to 48 µl

b. Add the appropriate amount of SAP.

1 unit of SAP will dephosphorylate ~1 pmole of 5′-phosphorylated termini (3′-recessed or 5′- recessed) or ~0.2 pmole of blunt-ended DNA. These amounts may vary slightly from one enzyme manufacturer to the next.

c. Incubate the reaction for 1 hour at 37°C.

d. To inactivate SAP, transfer the reaction to 70°C, incubate for 20 minutes, and cool to room temperature.

3. Transfer the aqueous phase to a clean microfuge tube, and recover the DNA by standard ethanol precipitation in the presence of 0.1 volume of 3 M sodium acetate (pH 5.2) if SAP was used or 0.1 volume of 3 M sodium acetate (pH 7.0) if CIP was used.

4. Allow the precipitate to dry at room temperature before dissolving it in TE (pH 7.6) at a DNA concentration of >2 nmoles/ml.

To remove 5′ phosphates from RNA, use 0.01 unit of CIP/pmole of 5′ termini. Incubate for 15 minutes at 37°C, followed by 30 minutes at 55°C. Alternatively, use 0.01–0.1 unit of SAP/pmole of 5′ ends to dephosphorylate RNA in a 1-hour incubation at 37°C.

If the dephosphorylated DNA is to be used as a substrate for polynucleotide kinase, it must be rigorously purified by spun-column chromatography, gel electrophoresis, density gradient centrifugation, or chromatography on columns of Sepharose CL-4B to free it from low-molecular-weight nucleic acids. Although such contaminants may make up only a small fraction of the weight of the nucleic acid in the preparation, they contribute a much larger proportion of the 5′ termini. Unless steps are taken to remove them, contaminating low-molecular-weight DNA and RNA molecules can be the predominant species of nucleic acids that are labeled in reactions catalyzed by bacteriophage T4 polynucleotide kinase.

Because ammonium ions are strong inhibitors of bacteriophage T4 polynucleotide kinase, dephosphorylated DNAs should not be dissolved in, or precipitated from, buffers containing ammonium salts prior to treatment with polynucleotide kinase.

Protocol 14

Phosphorylation of DNA Molecules with Protruding 5′-Hydroxyl Termini

THE REMOVAL OF 5′ PHOSPHATES FROM NUCLEIC ACIDS with phosphatases and their readdition in radiolabeled form by bacteriophage T4 polynucleotide kinase is a widely used technique for generating ^{32}P-labeled probes (please see the panel on **LABELING THE 5′ TERMINI OF DNA WITH BACTERIOPHAGE T4 POLYNUCLEOTIDE KINASE**) When the reaction is carried out efficiently, 40–50% of the protruding 5′ termini in the reaction becomes radiolabeled (Berkner and Folk 1977). However, the specific activity of the resulting probes is not as high as that obtained by other radiolabeling methods since only one radioactive atom is introduced per DNA molecule. Nevertheless, the availability of [γ-^{32}P]ATP with specific activities in the 3000–7000 Ci/mmole range allows the synthesis of probes suitable for many purposes, including:

- as hybridization probes to determine the structure and copy number of mRNAs
- as primers in primer-extension experiments to map the 5′ ends of mRNAs
- as substrates in the analysis of RNA structure by nuclease S1 or mung bean nuclease
- as probes in fingerprinting and footprinting experiments
- as primers in DNA sequencing
- as probes in electrophoretic mobility shift assays

This protocol describes a method to label dephosphorylated protruding 5′ termini. For a summary of methods used to label the termini of DNA, please see Table 9-2 in Protocol 10.

LABELING THE 5′ TERMINI OF DNA WITH BACTERIOPHAGE T4 POLYNUCLEOTIDE KINASE

The enzyme of choice to catalyze the labeling of 5′ termini of nucleic acids is bacteriophage T4 polynucleotide kinase, which facilitates transfer of γ-phosphate residues from [γ-^{32}P]ATP to the 5′-hydroxyl termini of dephosphorylated single- and double-stranded DNAs and RNA. In addition, the enzyme will, with much lower efficiency, restore phosphate residues to 5′-hydroxyl groups located at nicks in double-stranded DNA. T4 polynucleotide kinase is a tetrameric protein of M_r ~142,000 composed of four identical subunits encoded by the structural gene *pseT* of bacteriophage T4 (for reviews, please see Richardson 1971; Maunders 1993). Transfer of ^{32}P to the 5′ terminus of DNA catalyzed by bacteriophage T4 polynucleotide kinase can be carried out in two ways (please see Figure 9-4):

- ***In the forward reaction,*** single- or double-stranded DNA is first treated with a phosphatase (CIP or SAP) to remove phosphate residues from the 5′ termini (Protocol 13). The resulting 5′-hydroxyl termini are then rephosphorylated by transferring the γ-phosphate from [γ-^{32}P]ATP in a reaction catalyzed by polynucleotide kinase (this protocol and Protocol 15). The efficiency of radiolabeling depends on the purity of the DNA (due to kinase inhibitors present in an unpurified DNA solution) and on the sequence at the 5′ terminus of the DNA. For unknown reasons, oligonucleotides with a cytosine residue at their 5′ termini are labeled fourfold less efficiently than oligonucleotides beginning with A or T, and sixfold less efficiently than oligonucleotides beginning with G (van Houten et al. 1998).

  Some DNA templates, such as synthetic oligonucleotides, do not have to be treated with a phosphatase enzyme before kinasing. Oligonucleotides are almost invariably synthesized with a free 5′-hydroxyl group. Because the phosphorylation reaction is reversible, T4 polynucleotide kinase will catalyze dephosphorylation of 5′ termini in the presence of a molar excess of a nucleotide diphosphate acceptor, such as ADP (van de Sande et al. 1973). The second method of labeling (the exchange reaction) uses both the forward and reverse reactions catalyzed by the enzyme.

- ***In the exchange reaction*** (Protocol 16), the unlabeled phosphate residues are transferred from the 5′ termini of DNA to ADP. The newly created 5′-hydroxyl residues are then rephosphorylated as described above in the forward reaction.

Because T4 polynucleotide kinase will work, albeit inefficiently, in restriction buffers, the exchange reaction can be carried out at the same time as restriction of DNA with enzymes that generate protruding 5′ termini. The resulting DNA can be used as radiolabeled size markers for gel electrophoresis (Oommen et al. 1990).

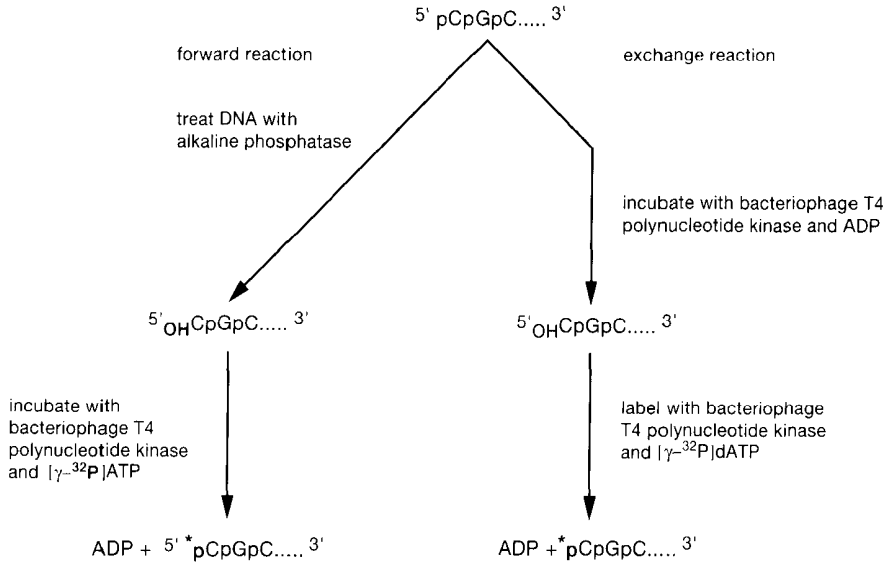

FIGURE 9-4 Forward and Exchange Reactions of Bacteriophage T4 Polynucleotide Kinase

Two different reactions catalyzed by bacteriophage T4 polynucleotide kinase can be used to label the 5′ termini of DNA molecules. The forward reaction is shown in the left arm of the figure, and the exchange reaction is shown in the right arm. For details, please see text.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Ammonium acetate (10 M)

Optional, please see Step 3.

EDTA (0.5 M, pH 8.0)

Ethanol

Enzymes and Buffers

Bacteriophage T4 polynucleotide kinase

Wild-type polynucleotide kinase is a 5′-phosphotransferase and a 3′-phosphatase (Depew and Cozzarelli 1974; Sirotkin et al. 1978). However, mutant forms of the enzyme (Cameron et al. 1978) are commercially available (e.g., Boehringer Mannheim) that lack the phosphatase activity but retain a fully functional phosphotransferase. We recommend that the mutant form of the enzyme be used for 5′ labeling whenever possible; 10–20 units of the enzyme are required to catalyze the phosphorylation of 10–50 pmoles of dephosphorylated 5′-protruding termini.

10x Bacteriophage T4 polynucleotide kinase buffer

Nucleic Acids and Oligonucleotides

DNA (10–50 pmoles)

The DNA should be dephosphorylated as described in Protocol 13 or synthesized with a 5′-hydroxyl moiety. Please see the panel on **CALCULATING THE AMOUNT OF 5′ ENDS IN A DNA SAMPLE** in Protocol 13.

Radioactive Compounds

[γ-^{32}P]ATP (10 mCi/ml, sp. act. 3000–7000 Ci/mmole) **<!>**

To minimize problems caused by radiolysis of the precursor and the probe, it is best, whenever possible, to prepare radiolabeled probes on the day the [^{32}P]dNTP arrives in the laboratory.

Special Equipment

Liquid scintillation spectrometer, capable of quantifying ^{32}P by Cerenkov radiation

Sephadex G-50 spun column, equilibrated in TE (pH 7.6)

or

Sephadex G-50 column (1 ml), equilibrated in TE (pH 7.6)

Both optional, please see Step 3.

METHOD

1. In a microfuge tube, mix the following reagents:

dephosphorylated DNA	10–50 pmoles
10x bacteriophage T4 polynucleotide kinase buffer	5 µl
10 mCi/ml [γ-^{32}P]ATP (sp. act. 3000–7000 Ci/mmole)	50 pmoles
bacteriophage T4 polynucleotide kinase	10 units
H_2O	to 50 µl

Incubate the reaction for 1 hour at 37°C.

Ideally, ATP should be in a fivefold molar excess over DNA 5′ ends, and the concentration of DNA termini should be ≥0.4 μM. The concentration of ATP in the reaction should therefore be >2 μM, but this is rarely achievable in practice. To increase the specific activity of the radiolabeled DNA product, increase the amount of [γ-^{32}P]ATP used in the phosphorylation reaction. Decrease the volume of H_2O to maintain a reaction volume of 50 μl.

2. Terminate the reaction by adding 2 μl of 0.5 M EDTA (pH 8.0). Measure the total radioactivity in the reaction mixture by Cerenkov counting in a liquid scintillation counter.
3. Separate the radiolabeled probe from unincorporated dNTPs by either:
   - spun-column chromatography through Sephadex G-50 (please see Appendix 8)

     or
   - conventional size-exclusion chromatography through 1-ml columns of Sepahadex G-50 (equilibrated in TE)

     or
   - two rounds of selective precipitation of the radiolabeled DNA with ammonium acetate and ethanol (please see Appendix 8)
4. Measure the amount of radioactivity in the probe preparation by Cerenkov counting. Calculate the efficiency of transfer of the radiolabel to the 5′ termini by dividing the amount of radioactivity in the probe by the total amount in the reaction mixture (Step 2).

Protocol 15

Phosphorylation of DNA Molecules with Dephosphorylated Blunt Ends or Recessed 5′ Termini

DNA SUBSTRATES WITH BLUNT ENDS, RECESSED 5′ TERMINI, or internal nicks are labeled less efficiently in the forward reaction of T4 polynucleotide kinase than are molecules with protruding 5′ termini. For example, the incorporation of phosphate residues at internal nicks in DNA is 30-fold less efficient than transfer to 5′ termini (Lillehaug et al. 1976; Berkner and Folk 1977). However, the difficulty of labeling such substrates can be overcome by (1) increasing the concentration of ATP to astronomical levels (>100 μM) (Lillehaug and Kleppe 1975a) or (2) including polyamines or polyethylene glycol 8000 (PEG 8000) in the reaction (Lillehaug and Kleppe 1975b; Harrison and Zimmerman 1986a). In the presence of PEG and magnesium, DNA collapses into a highly condensed state (Lerman 1971). The increased efficiency of the subsequent phosphorylation reaction is thought to be a consequence of the resulting macromolecular crowding (Harrison and Zimmerman 1986b; for review, please see Zimmerman and Minton 1993). The amount of stimulation is crucially dependent on the concentration of PEG. It may therefore be useful to test the efficiency of the reaction in concentrations of PEG ranging between 4% and 10%. The beneficial effects of PEG only become apparent when using DNAs longer than 300 bp. Smaller fragments of DNA are probably too rigid to collapse into a condensed state. For additional information on labeling DNA with T4 polynucleotide kinase, please see the panel on **LABELING THE 5′ TERMINI OF DNA WITH BACTERIOPHAGE T4 POLYNUCLEOTIDE KINASE** in the introduction to Protocol 14. For a summary of methods used to label the termini of DNA, please see Table 9-2 in Protocol 10.

In this protocol, PEG is included, along with high concentrations of ATP and polynucleotide kinase, to enhance the labeling of DNA fragments with blunt-ended or 5′-recessed termini.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Ammonium acetate (10 M)
Optional, please see Step 5.

EDTA (0.5 M, pH 8.0)
Ethanol
10x Imidazole buffer
500 mM imidazole·Cl (pH 6.4)
180 mM $MgCl_2$
50 mM dithiothreitol
1 mM spermidine HCl
1 mM EDTA (pH 8.0)
Polyethylene glycol (24% w/v PEG 8000) in H_2O

Enzymes and Buffers

Bacteriophage T4 polynucleotide kinase
Wild-type polynucleotide kinase is a 5′-phosphotransferase and a 3′-phosphatase (Depew and Cozzarelli 1974; Sirotkin et al. 1978). However, mutant forms of the enzyme (Cameron et al. 1978) are commercially available (e.g., Boehringer Mannheim) that lack the phosphatase activity but retain a fully functional phosphotransferase. We recommend that the mutant form of the enzyme be used for 5′ labeling whenever possible.

Nucleic Acids and Oligonucleotides

DNA (10–50 pmoles in a volume of ≤11 µl)
Dephosphorylate the DNA as described in Protocol 13 or synthesize with a 5′-hydroxyl moiety. Please see the panel on **CALCULATING THE AMOUNT OF 5′ ENDS IN A DNA SAMPLE** in Protocol 13.

Radioactive Compounds

[γ-^{32}P]ATP (10 mCi/ml, sp. act. 3000 Ci/mmole) **<!>**
To minimize problems caused by radiolysis of the precursor and the probe, it is best, whenever possible, to prepare radiolabeled probes on the day the [^{32}P]dNTP arrives in the laboratory.

Special Equipment

Liquid scintillation spectrometer, capable of quantifying ^{32}P by Cerenkov radiation
Sephadex G-50 spun column, equilibrated in TE (pH 7.6)
or
Sephadex G-50 column (1 ml), equilibrated in TE (pH 7.6)
Both optional, please see Step 5.

METHOD

1. In a microfuge tube, mix *in the order given:*

dephosphorylated DNA	10–50 pmoles
10x imidazole buffer	4 µl
H_2O	to 15 µl
24% (w/v) PEG	10 µl

2. Add 40 pmoles of [γ-^{32}P]ATP (10 mCi/ml; sp. act. 3000 Ci/mmole) to the tube and bring the final volume of the reaction to 40 µl with H_2O.
   Ideally, ATP should be in a fivefold molar excess over DNA 5′ ends, and the concentration of DNA termini should be ≥0.4 µM. The concentration of ATP in the reaction should therefore be >2 µM, but this is rarely achievable in practice. To increase the specific activity of the radiolabeled DNA product, increase the amount of [γ-^{32}P]ATP used in the phosphorylation reaction. Decrease the volume of H_2O to maintain a reaction volume of 40 µl.
3. Add 40 units of bacteriophage T4 polynucleotide kinase to the reaction. Mix the reagents gently by tapping the side of tube, and incubate the reaction for 30 minutes at 37°C.

4. Terminate the reaction by adding 2 µl of 0.5 M EDTA (pH 8.0). Measure the total radioactivity in the reaction mixture by Cerenkov counting in a liquid scintillation counter.
5. Separate the radiolabeled probe from unincorporated dNTPs by either:
   - spun-column chromatography through Sephadex G-50 (please see Appendix 8)

     or
   - conventional size-exclusion chromatography through 1-ml columns of Sepahadex G-50 (equilibrated in TE)

     or
   - two rounds of selective precipitation of the radiolabeled DNA with ammonium acetate and ethanol (please see Appendix 8)
6. Measure the amount of radioactivity in the probe preparation by Cerenkov counting. Calculate the efficiency of transfer of the radiolabel to the 5′ termini by dividing the amount of radioactivity in the probe by the total amount in the reaction mixture (Step 4).

Protocol 16

Phosphorylation of DNA Molecules with Protruding 5′ Termini by the Exchange Reaction

THE EXCHANGE REACTION CATALYZED BY BACTERIOPHAGE T4 polynucleotide kinase (van de Sande et al. 1973; Berkner and Folk 1977) is a rapid method to label the 5′ termini of DNA because, unlike the forward reaction, it does not require that the DNA be dephosphorylated. The reaction is carried out at a slightly acidic pH (6.4) in imidazole buffers to stimulate dephosphorylation by the enzyme (Berkner and Folk 1977). Because the optimal K_m values for the exchange reaction (300 μM for ADP and 10 μM for ATP) are higher than can be readily achieved in the test tube, the efficiency of labeling hardly ever exceeds 30%. However, the efficiency of the exchange reaction is greatly improved by including spermidine and polyethylene glycol in the reaction mixture (Lillehaug et al. 1976; Harrison and Zimmerman 1986a). For additional information on labeling DNA with T4 polynucleotide kinase, please see the panel on **LABELING THE 5′ TERMINI OF DNA WITH BACTERIOPHAGE T4 POLYNUCLEOTIDE KINASE** in the introduction to Protocol 14. For a summary of methods used to label the termini of DNA, please see Table 9-2 in Protocol 10.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

ADP (1 mM)

Dissolve solid adenosine diphosphate in sterile 25 mM Tris-Cl (pH 8.0). Store small aliquots (~20 μl) of the solution at –20°C.

Ammonium acetate (10 M)

Optional, please see Step 3.

ATP (10 mM)

Dissolve solid adenosine triphosphate in sterile 25 mM Tris-Cl (pH 8.0). Store small aliqots (~20 μl) of the solution at –20°C.

EDTA (0.5 M, pH 8.0)

Ethanol

10x Imidazole buffer
500 mM imidazole·Cl (pH 6.4)
180 mM $MgCl_2$
50 mM dithiothreitol
1 mM spermidine HCl
1 mM EDTA (pH 8.0)

Polyethylene glycol <!> (24% w/v PEG 8000) in H_2O

Enzymes and Buffers

Bacteriophage T4 polynucleotide kinase
Wild-type polynucleotide kinase is a 5′-phosphotransferase and a 3′-phosphatase (Depew and Cozzarelli 1974; Sirotkin et al. 1978). However, mutant forms of the enzyme (Cameron et al. 1978) are commercially available (e.g., Boehringer Mannheim) that lack the phosphatase activity but retain a fully functional phosphotransferase. We recommend that the mutant form of the enzyme be used for 5′-labeling whenever possible; 20 units of the enzyme are required to catalyze an exchange reaction containing 10–50 pmoles of phosphorylated 5′ termini.

Nucleic Acids and Oligonucleotides

DNA (10–50 pmoles of 5′-phosphorylated termini)
Please see the panel on **CALCULATING THE AMOUNT OF 5′ ENDS IN A DNA SAMPLE** in Protocol 13.

Radioactive Compounds.

[γ-^{32}P]ATP (10 mCi/ml, sp. act. 3000–7000 Ci/mmole) <!>
To minimize problems caused by radiolysis of the precursor and the probe, it is best, whenever possible, to prepare radiolabeled probes on the day the [^{32}P]dNTP arrives in the laboratory.

Special Equipment

Liquid scintillation spectrometer, capable of quantifying ^{32}P by Cerenkov radiation
Sephadex G-50 spun column, equilibrated in TE (pH 7.6)
or
Sephadex G-50 column (1 ml), equilibrated in TE (pH 7.6)
Both optional, please see Step 3.

METHOD

1. Mix the following reagents in a microfuge tube *in the order given:*

DNA with 5′ terminal phosphates	10–50 pmoles
10x imidazole buffer	5 µl
1 mM ADP	5 µl
50 nM ATP	1 µl
10 mCi/ml [γ-^{32}P]ATP (sp. act. 3000–7000 Ci/mmole)	20–100 pmoles
H_2O	to 40 µl
24% (w/v) PEG	10 µl
bacteriophage T4 polynucleotide kinase (20 units)	1 µl

Mix the reagents gently by tapping side of tube, and incubate the reaction for 30 minutes at 37°C.

The concentration of ADP at the beginning of the reaction is 10^5-fold higher than that of ATP.

2. Terminate the reaction by adding 2 µl of 0.5 M EDTA (pH 8.0). Measure the total radioactivity in the reaction mixture by Cerenkov counting in a liquid scintillation counter.
3. Separate the radiolabeled probe from unincorporated dNTPs by either:
   - spun-column chromatography through Sephadex G-50 (please see Appendix 8)

     or
   - conventional size-exclusion chromatography through 1-ml columns of Sepahadex G-50 (equilibrated in TE)

     or
   - two rounds of selective precipitation of the radiolabeled DNA with ammonium acetate and ethanol (please see Appendix 8)
4. Measure the amount of radioactivity in the probe preparation by Cerenkov counting. Calculate the efficiency of transfer of the radiolabel to the 5′ termini by dividing the amount of radioactivity in the probe by the total amount in the reaction mixture (Step 2).

NONRADIOACTIVE LABELING OF NUCLEIC ACIDS

Methods developed in the 1960s to detect and measure reassociation between complementary strands of nucleic acids led an entire generation of molecular biologists to rely exclusively on radioactive isotopes — usually ^{32}P — to detect hybridization between labeled probes and target sequences. The protocol most familiar to investigators today involves the detection of target nucleic acids immobilized on nitrocellulose or nylon membranes. This method descends from the work of Nygaard and Hall (1963, 1964), who were the first to immobilize DNA on nitrocellulose sheets; Denhardt (1966) and Gillespie and Spiegelman (1965), who detected such fixed nucleic acids with radioactive probes; and Southern (1975), who developed methods to detect target sequences in populations of nucleic acid molecules that had been separated according to size by gel electrophoresis. After hybridization, the β particles emitted by radioactive probes were measured and localized by liquid scintillation counting, autoradiography, or more recently, phosphorimaging. Thus, for 30 years, hybridization of nucleic acids and radioactivity were closely intertwined; methods were designed with radioactivity in mind, and laboratory experiments were scheduled around the regular delivery of standing orders of radiolabeled compounds. In this way, both the advantages and impediments of radioactive isotopes became institutionalized and part of the culture of molecular cloning.

Although ^{32}P-labeled probes can detect minute quantities of immobilized target DNA (<1 pg), they suffer from a short half-life (14.3 days) and the inability to be used for high-resolution imaging. Furthermore, when used in large quantity as orthophosphate, ^{32}P must be handled in specially designed isotope laboratories. The exposure of personnel to radiation from the energetic β particles released by decaying ^{32}P may be significant. Not surprisingly, the amount of paperwork and equipment required to order and monitor the use and disposal of radiolabeled materials has increased significantly over the years to the point where it has become a real burden. In addition, the physical and political difficulties in the storage and disposal of low-level radioactive waste have become significant, and they continue to grow. The confluence of these forces has led to a search for alternative methods that are as sensitive, but less hazardous and less costly than radiochemical techniques.

Indirect Nonradioactive Detection Systems

In conventional radiolabeling, fissile atoms are simply woven into the natural fabric of the probe in place of their nonradioactive homologs. In nonradioactive methods, a chemical group or compound not normally found in nucleic acids is conjugated to the probe via enzymatic, photochemical, or synthetic reactions (for reviews, please see Kricka 1992; Mansfield et al. 1995). After hybridization to the target nucleic acid, the modifying groups on the probe are detected by an appropriate indicator system. The first nonradioactive methods of detection developed in the 1980s were based on the labeling of the nucleic acid probe with dinitrophenol (Keller et al. 1988), bromodeoxyuridine (Traincard et al. 1983), or biotin (Langer et al. 1981; Chu and Orgel 1985; Reisfeld et al. 1987). It was this latter compound that provided the most durable and sensitive of these prototypic systems. After hybridization, the biotinylated probe was detected via interaction with streptavidin that had been conjugated to a reporter enzyme — usually alkaline phosphatase. The membrane was then exposed to an enzyme capable of hydrolyzing a colorigenic, fluorogenic, or chemiluminescent substrate. The sensitivity of this system derives from the rapid enzymatic conversion of the substrate to a product that is colored or emits visible or UV light at a specific wavelength. The distribution and intensity of the product correspond to the spatial distribution and concentration of target sequences on the membrane.

Because the reporter enzyme is not conjugated directly to the probe but is linked to it through a bridge (in this case, streptavidin-biotin), this type of nonradioactive detection is known as an *indirect* system. Many of the kits marketed today by commercial companies rely on indirect detection systems that are elaborations of the original biotin:streptavidin:reporter enzyme method. Most of these kits use biotinylated nucleotides (e.g., bio-11-dUTP or bio-7-dUTP) as labeling agents. The biotin moiety is conjugated to the nucleotide via a spacer 4–16 carbon atoms long, which reduces the possibility of steric hindrance during synthesis and detection of biotinylated nucleic acid probes. Under most circumstances, biotinylated probes work very well and are free from problems. However, because biotin (vitamin H) is a ubiquitous constituent of mammalian tissues and because biotinylated probes tend to stick doggedly to certain types of nylon membranes, high levels of background can occur during in situ, northern, and Southern hybridizations. These difficulties can be avoided by labeling probes with a compound that (1) has a low affinity for mem-

Digitalis purpurea.

FIGURE 9-5 ***Digitalis purpurea***

(Redrawn from A *Manual of Materia Medica and Pharmacology*, 7th ed. [D.M.R. Culbreth, 1927; Lea & Febiger, Philadelphia, Pennsylvania].)

branes of all types and (2) does not occur naturally in eukaryotic animals. The cardenolide digoxigenin (Pataki et al. 1953), which is synthesized exclusively by *Digitalis* plants (Hegnauer 1971), fulfills both of these criteria (please see Figure 9-5 and Appendix 9).

Digoxigenin (DIG), like biotin, can be chemically coupled to linkers and nucleotides and, as described below, DIG-substituted nucleotides incorporated into nucleic acid probes by any of the standard enzymatic methods. These probes generally yield significantly lower backgrounds than those labeled with biotin. DIG-labeled hybrids are detected with an anti-DIG Fab fragment conjugated to a reporter enzyme (usually alkaline phosphatase; less frequently, horseradish peroxidase; and even less frequently, β-galactosidase, xanthine oxidase, or glucose oxidase) (Höltke et al. 1990, 1995; Seibl et al. 1990; Kessler 1991).

Kits to synthesize and detect biotinylated probes are marketed by many commercial suppliers (for review, please see Party and Gershey 1995). However, nonradioactive detection systems that use DIG are sold exclusively by Boehringer Mannheim. The availability of two different labels and reporter systems allows two different probes to be used simultaneously to analyze the same blot or histological preparation. A few companies sell systems using fluorescein-labeled probes (fluorescein-12-UTP or -dUTP) that are detected by antifluorescein antibodies conjugated to alkaline phosphatase. Labeling of nucleic acids with fluorescein, biotin, or DIG is equally easy, and the sensitivity of indirect systems based on fluorescein is at least equal to those based on biotin and DIG. All three labeling systems are capable of detecting subpicogram quantities of target nucleic acids on Southern and northern blots. Nevertheless, for reasons that are unclear, indirect systems based on fluorescein have not yet achieved the same degree of acceptance as those based on biotin and DIG.

Methods to Label Probes with Biotin, Digoxigenin, or Fluorescein

Enzymatic Methods

Biotinylated, digoxigeninated, or fluoresceinated nucleotides can be used to label DNA by any of the standard enzymatic techniques: priming with random oligonucleotides, PCR, nick translation, or tailing with

terminal transferase. Labeled RNA can be synthesized in vitro in transcription reactions catalyzed by SP6, T3, or T7 RNA polymerases. The label in all of these reactions is provided as modified uridine ribo- or deoxyribotriphosphates that are used in place of UTP or dTTP in the labeling reaction. For most enzymatic labeling reactions, the substrates of choice are uridine triphosphates carrying adducts at the –11 or –12 position (e.g., biotin-11-UTP, DIG-11-dUTP, or fluorescein-12-dUTP). However, biotin- and DIG-16-dUTP are the preferred substrates for labeling of 3′ termini with terminal transferase. For recent reviews of labeling procedures, please see Viale and Dell'Orto (1992), Kessler (1992, 1994), Düring (1993), and Höltke et al. (1995).

By contrast to labeling with [^{32}P]NTPs or [^{32}P]dNTPs, where the efficiency of incorporation can be monitored and the specific activity of the final probe easily calculated, there is no simple or rapid method to monitor the progress of the nonisotopic labeling reactions or to calculate their efficiency. In the case of biotin- and DIG-labeled probes, the manufacturers recommend that no more than 30–35% of the thymidine residues in the probe be replaced by labeled uridine residues (please see Gebeyehu et al. 1987; Lanzillo 1990). Higher levels of replacement cause a reduction in the sensitivity with which target sequences can be detected, presumably because of the steric hindrance between closely spaced adducts during the hybridization step. However, because of a lack of an effective monitoring system, synthesis of nonradioactive probes remains an ad hoc affair. It is therefore best to carry out a pilot reaction in which samples are withdrawn at intervals during the course of the labeling reaction. The labeled products are tested in dot or slot blots against dilutions of the target DNA. Large-scale labeling reactions can then be designed and carried out with some confidence that the labeled product will have the required sensitivity.

Photolabeling

Biotin and DIG can be attached to nucleic acids in photochemical reactions. In both cases, the label is linked to a nitrophenyl azido group that is converted by irradiation with UV or strong visible light to a highly reactive nitrene that can form stable covalent linkages to DNA and RNA (Forster et al. 1985; Habili et al. 1987). Photochemical labeling is far less efficient than enzymatic labeling: At best, only 1 base in 150 becomes modified, and the resulting probe is not potent enough to detect single-copy sequences in Southern analyses of mammalian DNA. Photoactivatable biotin (Photobiotin) is supplied by Life Technologies.

Detection of Nonradioactively Labeled Probes after Hybridization

Two steps are required to detect probes labeled with biotin, fluorescein, or DIG residues after hybridization to Southern and northern blots. The membrane is first exposed to a synthetic conjugate consisting of the reporter enzyme and a ligand that binds tightly and with high specificity to the labeling moiety. In the case of biotin, most of the detection procedures exploit the high-affinity reaction between biotin and enzyme-conjugated streptavidin. Alternative procedures rely on specific monoclonal or polyclonal antibiotin antibodies. Fluoresceinated or digoxigenated probes are routinely detected by interaction with specific enzyme-conjugated antibodies. The reporter enzyme is then assayed with colorimetric, fluorogenic, or chemiluminescent substrates.

In *colorimetric* assays (e.g., please see Leary et al. 1983; Urdea et al. 1988; Rihn et al. 1995), a combination of two dyes is used to detect alkaline phosphatase that has been captured by labeled hybrids. The enzyme catalyzes the removal of the phosphate group from BCIP (5-bromo-4-chloro-3-indolyl phosphate; Horwitz et al. 1966), generating a product that oxidizes and dimerizes to dibromodichloro indigo. The reducing equivalents produced during the dimerization reaction reduce NBT (nitroblue tetrazolium; McGadey 1970) to an insoluble purple dye, diformazan, that becomes visible at sites where the labeled probe has hybridized to its target (Leary et al. 1983; Chan et al. 1985). The results can be analyzed visually and recorded on conventional photographic film. Colorimetric detection works well with nitrocellulose and PVDF membranes, but less well with nylon and charged nylon. Unfortunately, even when working at their best, colorimetric methods are two or more orders of magnitude less sensitive than other nonradioactive detection methods, for example, chemiluminescence (Bronstein et al. 1989a; Beck and Köster 1990; Kerkhof 1992; Kricka 1992). Detection of single-copy sequences in mammalian genomes is therefore barely within the reach of colorimetric assays (Düring 1993). A final disadvantage is that the colored precipitates are difficult to remove from membranes, making reprobing difficult or impossible. In some cases, the procedures

used to strip the precipitates (100% formamide at 50–60°C) either dissolve the membrane or greatly increase its fragility.

Fluorescent assays for alkaline phosphatase make use of HNPP (2-hydroxy-3-naphthoic acid 2′-phenylanilide phosphate; Kagiyama et al. 1992). After dephosphorylation, HNPP generates a fluorescent precipitate on membranes that can be excited by irradiation at 290 nm from a transilluminator. Light emitted at 509 nm can be captured by CCD cameras or on Polaroid film using the same photographic set-up (filters, etc.) as for conventional ethidium-bromide-stained gels. Fluorescent assays using HNPP are more sensitive than colorimetric methods and are capable of detecting single-copy sequences in Southern blots of mammalian genomic DNA when the membrane is incubated with substrate for 2–10 hours (Diamandis et al. 1993; Höltke et al. 1995). The fluorescent precipitate can be easily removed by washing in ethanol and the filters used for several more rounds of hybridization before the signal-to-noise ratio increases to unacceptable levels.

Chemiluminescence is the fastest and most sensitive assay to detect DNA labeled with biotin, fluorescein, or DIG, via conjugates containing horseradish peroxidase (HRP) or alkaline phosphatase (S. Beck et al. 1989; Bronstein et al. 1989b,c; Schaap et al. 1989). The HRP-luminol detection system (Thorpe and Kricka 1986) is marketed exclusively by Amersham. HRP catalyzes the oxidation of luminol in the presence of hydrogen peroxide, generating a highly reactive endoperoxide that emits light at 425 nm during its decomposition to its ground state. A wide range of compounds, including benzothiazoles, phenols, naphthols, and aromatic amines, can significantly enhance the amount of light generated during the reaction (Thorpe and Kricka 1986; Pollard-Knight et al. 1990; Kricka and Ji 1995). This signal amplification, which can be as much as 1000-fold (Whitehead et al. 1983; Hodgson and Jones 1989), increases the sensitivity of the HRP-luminol system to the point where it can detect single-copy genes in Southern blots of mammalian DNA. Light is produced at a rapid rate for the first few minutes of the reaction, but thereafter declines and is no longer detectable after 1–2 hours. Under ideal conditions, ~1 pg (5×10^{-17} M) of target DNA can be detected on Southern blots after 1 hour of exposure on gray-tinted, blue-light-sensitive X-ray film or a cooled CCD camera (Beck and Köster 1990; Durrant et al. 1990; Kessler 1992). The probes can be stripped from filters by heating to 80°C (Dubitsky et al. 1992).

Many commercial suppliers (please see Party and Gershey 1995) sell detection systems to detect alkaline phosphatase with dioxetane-based chemiluminescent substrates such as AMPPD and Lumigen-PPD and their more recent derivatives CSPD and CDP-*Star*, which is the most sensitive chemiluminescent substrate now available (Edwards et al. 1994; Höltke et al. 1994). CDP-*Star* differs from AMPPD in carrying halogen substituents at the 5 positions in its adamantyl and phenyl rings. This suppresses the tendency of the 1,2-dioxetane to aggregate and reduces background caused by thermal degradation (Bronstein et al. 1991). Cleavage of the phosphate ester of CDP-*Star* by alkaline phosphatase drastically reduces the thermal stability of the dioxetane ring, which consequently decomposes with emission of light at 465 nm. Nylon membranes (either amphoteric or positively charged) strongly enhance the signal (Tizard et al. 1990) by providing hydrophobic domains into which the dephosphorylated intermediate produced in the chemiluminescent reaction becomes sequestered. This stabilizes the intermediate and reduces its nonluminescent decomposition. In consequence, the intensity of the light emitted from the excited dioxetane anion begins as a glow that increases in intensity for several minutes and then persists for several hours (Martin and Bronstein 1994). The hydrophobic interactions between the nylon and the anion also cause a "blue shift" of ~10 nm in the emitted light, i.e., from 477 nm to 466 nm (Beck and Köster 1990; Bronstein 1990).

In most experimental situations, the extended kinetics of chemiluminescence on nylon filters are advantageous because they allow time to capture images at several exposures. However, the slow kinetics may be of practical importance when alkaline-phosphatase-triggered chemiluminescence is used to detect extremely low concentrations of DNA, RNA, or protein, for example, when the target band on a filter is expected to contain only 10^{-18} moles. In such cases, a halogen-substituted derivative of AMPPD, for example, CSPD, may be a better choice. The addition of a chlorine atom to the 5 position of the adamantyl group restricts its interactions with nylon filters. With this compound, the time to reach maximum light emission is markedly reduced so that very small quantities of target molecules can be detected rapidly (e.g., please see Martin et al. 1991).

Under ideal conditions, as little as 1 zeptomole (10^{-21} M) of alkaline phosphatase or 1×10^{-19} moles of DNA can be detected (Schapp et al. 1989; Beck and Köster 1990; Bronstein 1990; Kricka 1992). Such sensitivity means that a single-copy gene in a Southern blot of mammalian genomic DNA can be detected after the nylon membrane has been exposed for ~5 minutes to gray-tinted, blue-light-sensitive X-ray film or a

cooled CCD camera (Höltke et al. 1995). The probes can be stripped by 50% formamide at 65°C (Dubitsky et al. 1992) and the nylon membranes can then be used for several further rounds of hybridization.

Direct Nonradioactive Detection Systems

In this type of detection, nucleic acid probes are labeled directly with fluorescent dyes such as fluorescein, Texas red, or rhodamine (Agrawal et al. 1986); with lanthanide chelates (europium) (Templeton et al. 1991; Dahlén et al. 1994); with acridinium esters (Nelson et al. 1992); or with enzymes, for example, alkaline phosphatase (Jablonski et al. 1986) or horseradish peroxidase (Renz and Kurz 1984). The presence of such covalently attached adducts is assayed by any one of a number of techniques, including colorimetry, chemiluminescence, bioluminescence, time-resolved fluorometry, or energy transfer/fluorescence quenching. Of course, direct detection methods can be converted to indirect methods if an enzyme-antibody conjugate specific for the adduct is available.

Because it forms the basis of automated DNA sequencing methods (Smith et al. 1986; Ansorge et al. 1987; Prober et al. 1987), direct labeling of nucleic acids with fluorescent compounds has revolutionized molecular biology. A single fluorescent adduct per DNA molecule is sufficient for detection by automated DNA sequencers when the DNA is in the gel. Furthermore, the ability of ABI-type automated sequencers to discriminate accurately between different fluors signifies that all four sequencing reactions can be analyzed in a single lane of a gel. The stunning success of direct labeling in automated DNA sequencing has, however, not spread to other areas of molecular cloning, where direct nonradioactive methods of detection are rarely used. This is because:

- The traditional methods used for the direct conjugation of enzymes such as alkaline phosphatase require the extensive use of column chromatography, polyacrylamide gel electrophoresis, and/or HPLC to obtain a pure product (Jablonski et al. 1986; Urdea et al. 1988; Farmar and Castaneda 1991). Commercial kits are available but are expensive and typically yield an impure product. Newer methods of conjugation (e.g., please see Reyes and Cockerell 1993) are simpler but slightly less efficient.

  Whatever method is used, a separate conjugation step is required for each different probe. Once attached, large enzymes such as alkaline phosphatase may reduce the rate of annealing of probes and may be labile under the conditions conventionally used for annealing of nucleic acids. Hybridization and washing must therefore be carried out at low temperature (usually <50°C) in aqueous solvents. Under such nonstringent conditions, high backgrounds are an inevitable problem. Because of the presence of bulky, charged adducts, probes directly labeled with enzymes may bind nonspecifically but tightly to certain types of membranes. For example, the background signal from oligonucleotide probes directly conjugated to alkaline phosphatase is considerably greater on charged nylon than on neutral nylon membranes (Benzinger et al. 1995).
- The detection of single-copy sequences in Southern hybridization of mammalian DNAs lies close to the limit of sensitivity of many direct methods unless specialized equipment is available (Urdea et al. 1988). Detection of fluorescent adducts, for example, requires irradiating with light of one wavelength and acquiring data at another. The signal must then be enhanced electronically and stored digitally.

Because of these problems, it is not surprising that direct detection techniques have fallen from favor and that indirect detection has become the dominant nonradioactive method to locate target nucleic acids in Southern, northern, and in situ hybridizations. However, despite these problems, probes directly labeled with alkaline phosphatase are now produced commercially for forensic and pathological analyses. The sensitivity of these probes can approach that of isotopically labeled probes (Dimo-Simonin et al. 1992; Klevan et al. 1993; Benzinger et al. 1995). The use of such standardized nonisotopically labeled probes is expected to increase greatly in laboratories involved, for example, in constructing large numbers of DNA profiles or in diagnosing infectious diseases.

To Switch or Not to Switch

Great advances in nonradioactive detection methods have been made during the last decade, giving scientists today real choices. The advantages claimed for nonradioactive methods include faster results, more stable probes, and lower cost. However, investigators wishing to switch from radioactive to nonradioactive detection methods will be deluged with advertising from manufacturers of kits and equipment and inun-

dated with claims of superiority for one commercial product or another. The scientific literature is also large and balky, with many inconsistencies. The ranking of techniques and substrates according to the sensitivity of detection is inconsistent; well-controlled comparisons of efficiency are rarely reported, although more of this work is badly needed.

Approximately 50 different nonradioactive detection kits are now available on the commercial market and more are appearing all the time. Claims on the sensitivity and signal-to-noise ratios made on their behalf should be viewed with caution. Many of these claims are based on experiments carried out under idealized conditions, which cannot be immediately or easily reproduced by inexperienced investigators in the hurly-burly of a working laboratory. Frequently, the signal-to-noise ratio is higher than advertised and the neophyte will likely struggle to match the sensitivity of more traditional methods of radiolabeling. Many of the kits are expensive, and nonradioactive detection methods only become cost-effective after they have been optimized for the particular task at hand.

During the past 30 years, almost all of the problems with radiolabeled probes have been uncovered, analyzed, and, to a very large extent, solved. The collective wealth of knowledge about radioactive probes is both vast and easily accessible. This is not yet the case with nonradioactive detection systems, where there simply has not been time to build a body of reliable experimental lore. Nonradioactive detection of target nucleic acids is already well suited to laboratories that use a small number of probes to carry out a limited repertoire of repetitive tests under stringently controlled conditions. Research laboratories that use a wide variety of nucleic acid probes as well as forensic laboratories that must analyze irreplaceable and/or degraded DNA specimens may wish to be more circumspect and to delay embracing nonradioactive detection until the present confusion of claims and methods is resolved.

For recent reviews and papers that deal with various aspects of nonradioactive probes, please see Guesdon (1992), Viale and Dell'Orto (1992), Reischl et al. (1994), and Mansfield et al. (1995).

E. COLI DNA POLYMERASE I AND THE KLENOW FRAGMENT

DNA polymerase I (Pol I) (Kornberg et al. 1956) consists of a single polypeptide chain (M_r ~103,000; Joyce et al. 1982) encoded by the *E. coli polA* gene (De Lucia and Cairns 1969). In addition to a phosphate-exchange activity, Pol I carries out three enzymatic reactions that are performed by three distinct functional domains (please see Table 9-3).

During DNA replication in *E. coli*, the enzymatic activities of Pol I act in a coordinated fashion to remove the RNA primers from the 5′ termini of nascent DNA and to fill gaps between adjacent tracts of DNA. For detailed descriptions of these processes, please see Kornberg and Baker (1992). Pol I can be cleaved by mild treatment with subtilisin into two fragments; the larger fragment (comprising residues 326–928) is known as the Klenow fragment. The DNA polymerase and the 3′→5′ exonuclease activities of Pol I are carried on the Klenow fragment (Brutlag et al. 1969; Klenow and Henningsen 1970; Klenow and Overgaard-Hansen 1970; Klenow et al. 1971), whereas the 5′→3′ exonuclease activity of the holoenzyme is carried on the smaller amino-terminal fragment (residues 1–325), which is nameless (for review, please see Joyce and Steitz 1987; please also see Table 9-3).

The Pol I gene has been sequenced (Joyce et al. 1982) and expressed from prokaryotic expression vectors (Murray and Kelley 1979), making it possible to purify large amounts of the protein for commercial purposes (Murray and Kelley 1979). The segment of the Pol I gene encoding the Klenow fragment has also been cloned into various expression vectors (e.g., please see Joyce and Grindley 1983; Pandey et al. 1993), thereby providing pure protein in amounts large enough for both commercial purposes and biophysical and biochemical studies.

Knowledge of the three-dimensional structure of Klenow fragment, which was obtained in 1985 by X-ray diffraction (Ollis et al. 1985), stimulated a series of elegant structural investigations (Beese and Steitz 1991; Beese et al. 1993a,b), kinetic studies (Kuchta et al. 1987, 1988; Cowart et al. 1989; Catalano et al. 1990; Guest et al. 1991), and mutational analyses (Freemont et al. 1986; Derbyshire et al. 1988, 1991; Polesky et al. 1990, 1992). The results of these various approaches are remarkably consonant, and they confirm that the active sites for polymerization of dNTPs and for 3′→5′ exonucleolytic digestion reside on different structural domains of the Klenow fragment and are separated by 30–35 Å.

The exonuclease activity, which is carried on the smaller (22 kD) domain (Joyce and Steitz 1987), performs a proofreading function by resecting DNA that contains either mismatched bases or frameshift errors (Bebenek et al. 1990). 3′→5′ digestion of double-stranded DNA is thought to follow a three-step pathway: binding of the substrate to a cleft in the polymerase domain, translocation of the 3′ terminus to the active site of the exonuclease domain, and, finally, chemical catalysis (Catalano et al. 1990). During translocation, which is the rate-limiting step of the reaction, melting of the four or five terminal base pairs of duplex DNA (Cowart et al. 1989) generates a frayed 3′ terminus that binds to the active site of the exonuclease domain,

TABLE 9-3 The Domains of *E. coli* DNA Polymerase I

DOMAIN	ACTIVITY	BIOCHEMICAL FUNCTION
Carboxy-terminal domain (residues 543–928, ~46 kD)	5′→3′ DNA polymerase	Addition of mononucleotide residues generated from dNTPs to the 3′-hydroxyl termini of RNA or DNA primers. These termini can be provided by nicks or gaps in a duplex DNA, as well as by short segments of RNA or DNA that are base-paired to a single-stranded DNA molecule.
Central domain (residues 326–542, ~22 kD)	3′→5′ exonuclease	Cleavage of nucleotide residues from 3′-hydroxyl termini creates recessed 3′ termini.
Amino-terminal domain (residues 1–325)	5′→3′ exonuclease	Cleavage of oligonucleotides from base-paired 5′ termini.

The carboxy-terminal and central regions constitute the Klenow fragment of Pol I.

with K_m values in the nanomolar range (Kuchta et al. 1988). Three carboxylic acid residues in the active site interact directly with one or both of the divalent metal ions that are bound to the exonuclease domain and are crucial for enzymatic cleavage. The metals bound to the exonuclease domain interact with the terminal phosphate residue of the substrate (Derbyshire et al. 1991; Han et al. 1991), thereby allowing nucleophilic attack (probably from a hydroxide ion) on the exposed phosphodiester bond (Freemont et al. 1988). This reaction generates a product, dNMP, that at high concentrations can inhibit the 3′→5′ exonuclease reaction (Que et al. 1978) by occupying the same site in the enzyme as the frayed terminus of single-stranded DNA (Ollis et al. 1985). The exonucleolytic degradation of double-stranded substrates is very slow with a k_{cat} of $\sim 10^{-3}$ s^{-1}. Digestion of single-stranded substrates, however, is ~100 times faster, with a k_{cat} of 0.09 s^{-1} (Kuchta et al. 1988; Derbyshire et al. 1991). Using site-directed mutagenesis to change the amino acids within the active site, mutant forms of the Klenow enzyme have been constructed that retain normal polymerase activity but are essentially devoid of exonuclease activity (Derbyshire et al. 1988, 1991). The average error rate for these enyzmes is ~1 base substitution for each 10,000–40,000 bases polymerized. This rate is between 7- and 30-fold times higher than the error rate of the wild-type Klenow enzyme (Bebenek et al. 1990; Eger et al. 1991). Therefore, the high fidelity of the Klenow enzyme results more from highly accurate selection of bases by the polymerase domain than from postreplication editing by the exonuclease domain.

A large cleft in the polymerase domain is the binding site for the primer:template DNA (Beese et al. 1993a). The amino acid residues directly involved in substrate binding and catalysis have been identified by site-directed mutagenesis (Polesky et al. 1990, 1992) and confirmed by X-ray crystallographic analysis of the Klenow fragment bound to duplex DNA (Beese et al. 1993a). The polymerase domains of Pol I and several other type-B DNA polymerases, including those from *Thermus aquaticus* and bacteriophages T5 and T7, share a high degree of homology within the polymerase domain (Delarue et al. 1990; Blanco et al. 1991). This homology includes (1) a cluster of residues directly involved in catalysis and (2) a tyrosine residue involved in binding of dNTPs (Beese et al. 1993b). The current model of the orientation of the primer:template and the two domains of the Klenow fragment is shown in Figure 9-6.

Uses of the Klenow Fragment of *E. coli* Polymerase I in Molecular Cloning

Filling the Recessed 3′ Termini Created by Digestion of DNA with Restriction Enzymes

In many cases, a single buffer can be used both for cleavage of DNA with a restriction enzyme and for the subsequent filling of recessed 3′ termini. The end-filling reaction can be controlled by omitting one, two, or three of the four dNTPs from the reaction and thereby generating partially filled termini that contain novel cohesive ends (please see Figure 9-7 and Protocol 10).

Labeling the 3′ Termini of DNA Fragments by Incorporation of Radiolabeled dNTPs

In general, these labeling reactions contain three unlabeled dNTPs each at a concentration in excess of the K_m and one radiolabeled dNTP at a far lower concentration, which is usually below the K_m. Under these conditions, the proportion of label that is incorporated into DNA can be very high, even though the rate of the reaction may be far from maximal. The presence of high concentrations of three unlabeled dNTPs lessens the possibility of exonucleolytic removal of nucleotides from the 3′ terminus of the template. Which of the four α-labeled dNTPs is added to the reaction depends on the sequence and nature of the termini of the DNA.

- ***Recessed 3′ termini*** can be labeled with any dNTP whose base is complementary to an unpaired base in the protruding 5′ terminus. Radioactivity can therefore be incorporated at any position within the rebuilt terminus depending on the investigator's choice of radiolabeled dNTP. To ensure that all of the radiolabeled molecules are the same length, it may be necessary to complete the end-filling reaction by carrying out a "chase" reaction containing high concentrations of all four unlabeled dNTPs.
- ***Blunt-ended and protruding 3′ termini*** may be labeled in an enzymatic reaction that uses both domains of the Klenow fragment. First, the 3′→5′ exonuclease activity removes any protruding tails from the DNA and creates a recessed 3′ terminus. Then, in the presence of high concentrations of one radiola-

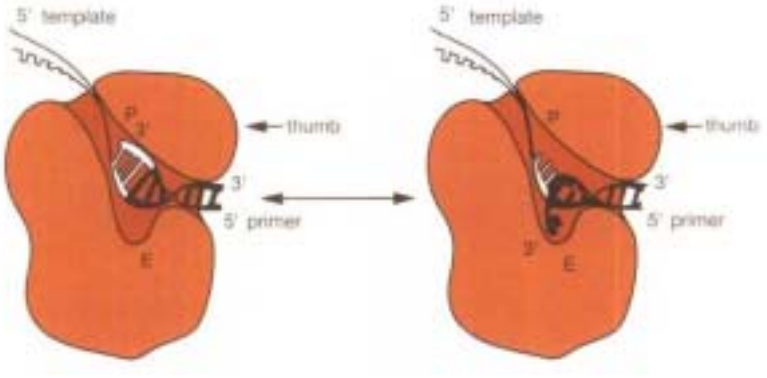

FIGURE 9-6 A Model of DNA Bound to the Klenow DNA Polymerase

The model, which is based on the crystallographic structure of the complex between the Klenow fragment and duplex DNA (Beese et al. 1993a), shows a proposed arrangement of DNA bound at the active sites of the polymerase domain (P) and the exonuclease domain (E). The portion of the DNA observed in the crystal structure is indicated in solid black, and the portion that is modeled is shown in outline; 19–20 bp of DNA interact with the Klenow enzyme (Kolocheva et al. 1989). The template strand, which is bent at an angle of ~80°, binds in the polymerase cleft and is base paired to the primer. The 3′ end of the primer lies near the divalent metal ions that are believed to be important in the polymerase reaction (Polesky et al. 1992). The physical separation of the active sites for the polymerase and exonuclease domains by 30 Å creates problems of switching the primer 3′ terminus from one site to another. The model shown in the figure does not really solve this problem but merely assumes that the growing nascent strand shuttles between the active sites of the exonuclease and polymerase domains. The dynamics of the pathway of the polymerase reaction have been elucidated in great detail: Rate constants have been measured for each of the individual steps in the pathway (Kuchta et al. 1988; Polesky et al. 1990, 1992; Dahlberg and Benkovic 1991). Current models suggest that the catalytic step — a nucleophilic attack on the α-phosphate of the dNTP by the 3′-hydroxyl at the terminus of the primer — is the result of a conformational change in the enzyme caused by binding of DNA and dNTP (Dahlberg and Benkovic 1991). Following formation of the phosphodiester bond, the enzyme undergoes a second conformational change before release of pyrophosphate. The nature of these conformational changes is unknown, as is the mechanism by which translocation of the growing chain occurs at each reiteration of the polymerization step. (Adapted, with permission, from Beese et al. 1993a [Copyright 1993 American Association for the Advancement of Science].)

beled precursor, exonucleolytic degradation is balanced by incorporation of radiolabeled dNTP at the 3′ terminus. This reaction, which consists of cycles of removal and replacement of the 3′ terminus from recessed or blunt-ended DNA, is sometimes called an exchange or replacement reaction. The specific activities that can be achieved with this reaction are modest because the 3′→5′ exonuclease of the Klenow enzyme is rather sluggish, especially on double-stranded substrates. T4 DNA polymerase carries a more potent 3′→5′ exonuclease that is ~200-fold more active than the Klenow fragment and is the enzyme of choice for this type of reaction.

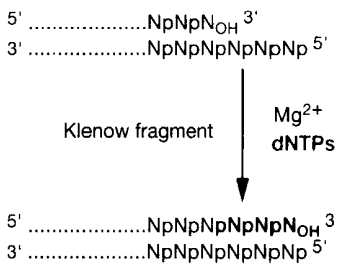

FIGURE 9-7 Filling-in Recessed 3′ Termini of DNA Fragments Using Klenow DNA Polymerase

The 3′ termini generated by digestion with restriction endonucleases may be labeled using the Klenow fragment of DNA polymerase I in the presence of dNTPs and Mg^{2+}.

If a [^{35}S]dNTP is used instead of the conventional [α-^{32}P]dNTP, the reaction is limited to one cycle of removal and replacement since the 3′→5′ exonuclease of *E. coli* DNA Pol I, unlike the exonuclease of T4 DNA polymerase, cannot attack thioester bonds (Kunkel et al. 1981; Gupta et al. 1984).

Labeling Single-stranded DNA by Random Priming

For details, please see Feinberg and Vogelstein (1983, 1984) and Protocols 1 and 2.

Production of Single-stranded Probes by Primer Extension

For details, please see Meinkoth and Wahl (1984), Studencki and Wallace (1984), and Chapter 7, Protocol 12. For many years, the Klenow fragment of Pol I was the highest-quality DNA polymerase that was commercially available and, in consequence, was the enzyme of first and last resort for in vitro synthesis of DNA. However, as polymerases that are better suited to various synthetic tasks have been discovered or engineered, Klenow has been gradually replaced and is no longer the enzyme of first choice for a variety of procedures in molecular cloning. These procedures include:

- ***DNA sequencing by the Sanger method.*** Klenow has been replaced by bacteriophage or thermostable polymerases that give longer read-lengths.
- ***Synthesis of double-stranded DNA from single-stranded templates during in vitro mutagenesis.*** Although the Klenow fragment is still widely used for in vitro synthesis of circular DNAs using mutagenic primers, it is not always the best enzyme for this purpose. Unless large quantities of ligase are present in the polymerization/extension reaction mixture, the Klenow enzyme can displace the mutagenic oligonucleotide primer from the template strand, thereby reducing the number of mutants obtained. This problem can be solved by using DNA polymerases that are unable to carry out strand displacement, including bacteriophage T4 DNA polymerase (Nossal 1974; Lechner et al. 1983; Geisselsoder et al. 1987), bacteriophage T7 DNA polymerase (Bebenek and Kunkel 1989), and Sequenase (Schena 1989).

  Bacteriophage T4 gene *32* protein (a single-stranded DNA-binding protein) can be used in primer-extension reactions catalyzed by DNA polymerases (including the Klenow enzyme) to alleviate stalling problems caused by templates rich in secondary structure (Craik et al. 1985; Kunkel et al. 1987).
- ***Polymerase chain reactions.*** The Klenow fragment was the enzyme used in the first polymerase chain reactions (Saiki et al. 1985). However, it has now been completely replaced by thermostable DNA polymerases that need not be replenished after each round of synthesis and denaturation.

Facts and Figures About the Klenow Fragment

The standard assay used to measure the polymerase activity of the Klenow fragment is that of Setlow (1974) with poly(d[A-T]) as template. One unit of polymerizing activity is the amount of enzyme that catalyzes the incorporation of 3.3 nmoles of dNTP into acid-insoluble material in 10 minutes at 37°C. A sample of pure Klenow fragment has a specific activity of ~10,000 units/mg protein (Derbyshire et al. 1993). The reaction is usually carried out in the presence of Mg^{2+}. Substitution of Mn^{2+} for Mg^{2+} increases the rate of misincorporation and decreases the accuracy of proofreading (Carroll and Benkovic 1990). The K_m of the enzyme for the four dNTPs varies between 4 and 20 μM. For methods to assay the exonuclease activity of the Klenow fragment, please see Freemont et al. (1986) and Derbyshire et al. (1988).

Uses of Pol I in Molecular Cloning

- ***Labeling of DNA by nick translation*** (Maniatis et al. 1975; Rigby et al. 1977). In this reaction, the enzyme binds to a nick or short gap in duplex DNA. The 5′→3′ exonuclease activity of Pol I then removes nucleotides from one strand of the DNA, creating a template for simultaneous synthesis of the growing strand of DNA. The original nick is therefore translated along the DNA molecule by the combined action of the 5′→3′ exonuclease and the 5′→3′ polymerase. In Figure 9-8, the nick in the upper strand of duplex DNA is translated from left to right and the patch of newly synthesized DNA is represented by the shaded arrow. Nick-translation reactions are usually carried out at 16°C to reduce the synthesis of "snap-

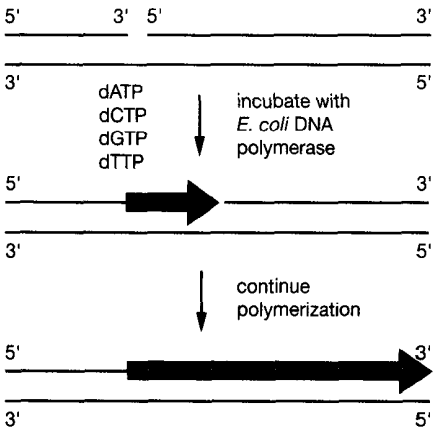

FIGURE 9-8 Nick Translation Schematic

E. coli DNA polymerase binds to the nick in duplex DNA, the exonuclease activity of Pol I then removes nucleotides from one strand of the DNA in a 5′ → 3′ direction from the nick, thereby creating a template for simultaneous synthesis of DNA by the polymerase function of Pol I. Please see the text of the information panel for additional details.

back" DNA, which is produced when the 3′-hydroxyl terminus of a growing strand of DNA loops back on itself and primes synthesis of hairpin-shaped molecules of DNA (Richardson et al. 1964a).

- ***Replacement synthesis of second-strand cDNA*** (e.g., please see Gubler and Hoffman 1983). In this method, the product of first-strand synthesis — a cDNA-mRNA hybrid — is used as a template for a nick-translation reaction. RNase H is used to generate nicks and gaps in the mRNA strand of the hybrid, creating a series of RNA primers that are used by Pol I to initiate the synthesis of second-strand cDNA.
- ***End-labeling of DNA molecules with protruding 3′ tails.*** This reaction works in two stages: First, the 3′→5′ exonuclease activity of the holoenzyme removes protruding 3′ tails from the cDNA and creates a recessed 3′ terminus. Then, in the presence of high concentrations of one radiolabeled precursor, continuing exonucleolytic degradation is balanced by incorporation of dNTPs at the 3′ terminus. Although Pol I catalyzes this exchange or replacement reaction fairly efficiently, bacteriophage T4 DNA polymerase remains the enzyme of choice because of its more potent 3′→5′ exonuclease activity.

Facts and Figures About DNA Polymerase I

- ***Most of the Pol I distributed by commercial manufacturers*** is isolated (Kelley and Stump 1979) from a strain of *E. coli* that is lysogenic for a transducing bacteriophage λ carrying a copy of the *polA* gene (e.g., NM964; Murray and Kelley 1979).
- ***One unit of DNA polymerase is the amount of enzyme*** required to catalyze the conversion of 10 nmoles of total dNTPs to an acid-insoluble form in 30 minutes at 37°C using poly(d[A-T]) as the template primer (Richardson et al. 1964b). The specific activity of the commercial enzyme is usually ~5000 units/mg of protein.
- ***Like all other DNA polymerases, Pol I requires divalent cations*** for activity. Mg^{2+} is preferred for accurate replication, whereas Mn^{2+} may be used to increase the frequency of errors deliberately.

IN VITRO TRANSCRIPTION SYSTEMS

Virtually all in vitro transcription of DNA into RNA is carried out with bacteriophage-encoded DNA-dependent RNA polymerases. The value of using bacteriophage-encoded DNA-dependent RNA polymerases arises because these enzymes (1) initiate efficient and selective transcription from well-defined cognate promoters (Melton et al. 1984) and (2) being composed of a single polypeptide chain (~900 amino acids), need no auxiliary transcription factors, perhaps because they have evolved to transcribe a small number of genes in a specialized genome with high efficiency.

The best-characterized bacteriophage RNA polymerases are those encoded by the *Salmonella typhimurium* bacteriophage, SP6 (Butler and Chamberlin 1982; Green et al. 1983), and the *E. coli* phages, T3 and T7 (Studier and Rosenberg 1981; Davanloo et al. 1984; Tabor and Richardson 1985). The genes encoding these three RNA polymerases have been isolated (Davanloo et al. 1984; Morris et al. 1986), sequenced (Moffatt et al. 1984; McGraw et al. 1985: Kotani et al. 1987), and expressed (Davanloo et al. 1984; Morris et al. 1986). In the case of the T7 polymerase, the crystal structure of the enzyme has been elucidated (Doublie et al. 1998). The SP6, T3, and T7 DNA-dependent RNA polymerases behave in a similar fashion, and there are no distinct biochemical advantages to using one RNA polymerase over the other. The SP6 enzyme is typically four to five times more expensive than the T7- and T3-encoded enzymes, even though it is the easiest of the three to prepare from bacteriophage-infected cells.

Although all three RNA polymerases have the ability to transcribe single-stranded DNA (Salvo et al. 1973; Milligan et al. 1987), virtually all in vitro transcription is carried out with double-stranded linear DNA templates that contain an appropriate promoter (please see Table 9-4).

Since the minimal promoter for bacteriophage RNA polymerases is just 21 bp in length (Jorgensen et al. 1991), portable bacteriophage promoters can easily be manufactured from synthetic oligonucleotides. Double-stranded DNA linkers containing a bacteriophage RNA polymerase promoter can also be ligated directly to purified DNA fragments (Loewy et al. 1989) or PCR products. By synthesizing the appropriate linker/adaptor, one fragment out of a mixture can be modified and subsequently transcribed in vitro.

Synthetic promoters can also be added to the 5′ ends of primers used to amplify DNA by PCR (please see the panel on **ADDITIONAL PROTOCOL: USING PCR TO ADD PROMOTERS FOR BACTERIOPHAGE-ENCODED RNA POLYMERASES TO FRAGMENTS OF DNA** in Protocol 6). Essentially any DNA molecule can therefore be amplified with a bacteriophage promoter at one or both ends of the molecule. The amplified DNA is an efficient template for in vitro transcription reactions. PCR can also be used to introduce convenient restriction sites at the end of the DNA to facilitate linearization of templates and to introduce translation signals at the 5′ end of a DNA fragment to allow the RNA product to be translated efficiently in cell-free protein-synthesizing systems (Browning 1989; Kain et al. 1991; please see Chapter 17).

The affinities of the bacteriophage polymerases for their promoters are rather low (~10^{-7} M^{-1}), and nucleoside triphosphates are required to stabilize transient promoter:enzyme complexes. After a short lag period, RNA synthesis rapidly reaches a rate (for T7 and T3 polymerases) of 200–300 nucleotides/second at 37°C, almost ten times faster than that of *E. coli* RNA polymerase, measured under the same conditions. The K_m values of the T3 and T7 RNA polymerases for ATP, UTP, and CTP are between 40 and 100 μM (Oakley et

TABLE 9-4 Promoter Sequences Recognized by Bacteriophage-encoded RNA Polymerases

BACTERIOPHAGE	PROMOTER				
	−15	−10	−5	+1	+5
	|	|	|	|	|
T7	TAATACGACTCACTATAGGGAGA				
T3	AATTAACCCTCACTAAAGGGAGA				
SP6	ATTTAGG T/G GACACTATAGAAG				

The consensus sequences of promoters are recognized by three bacteriophage-encoded RNA polymerases: T7 (Dunn and Studier 1983), T3 (P.J. Beck et al. 1989), and SP6 (Brown et al. 1986). All of the bacteriophage promoters share a core sequence that extends from −7 to +1, suggesting that this region has a common role in promoter function. The promoters diverge in the region from −8 to −12, suggesting that promoter-specific contacts are made in this region. By convention, the sequence of the nontemplate strand is shown. (Adapted, with permission, from Jorgensen et al. 1991.)

al. 1979). GTP is anomalous, probably because it is used as a chain-initiating nucleotide: RNA chains initiated by T3 RNA polymerase, for example, start with pppGGGA and pppGGGG (for review, please see Chamberlin and Ryan 1982). When the concentration of template DNA is 20 nM and the concentration of each of the rNTPs is >50 μM, the rate of RNA synthesis is linear for at least 1 hour and is proportional to the amount of enzyme added to the reaction. During the course of the reaction, RNA chains are initiated many times on each molecule of template, and, under optimal conditions, between 10 and 20 moles of full-length transcript are generated per mole of template. However, when a radiolabeled or modified base is used as a precursor, the yield is much lower because reaction conditions are modified to optimize incorporation of the rare component. This is generally done by eliminating the homologous nucleotide from the reaction or by lowering its concentration drastically. However, if the concentration of nucleotide in the reaction drops below the K_m not only the total yield, but also the proportion of full-length RNA chains will drop markedly.

Although all three bacteriophage polymerases share many biochemical properties, each displays considerable preference for its own promoter and does not initiate transcription at other promoters at a substantial rate. The bacteriophage enzymes do not recognize bacterial or plasmid promoters or eukaryotic promoters in cloned DNA sequences. Because efficient signals for termination of RNA chains are also rare, bacteriophage-encoded polymerases are able to synthesize full-length transcripts of almost any DNA that is placed under the control of an appropriate promoter. Because these transcripts are complementary to only one strand of the template, they are excellent for use as probes in virtually any technique involving hybridization, including Southern and northern hybridization, in situ hybridization, and RNase protection assays. In addition, the ability to generate large quantities of long RNAs that are identical in sequence to unstable primary transcripts of mammalian genes has led to the development of in vitro assays for splicing and processing of 3′ termini of eukaryotic mRNAs (e.g., please see Green 1991). Synthetic RNAs are also ligands for binding by regulatory proteins such as the *tat* gene product of the human immunodeficiency virus (Roy et al. 1990).

Full-length transcripts prepared in vitro are often used as mRNAs in eukaryotic cell-free protein synthesizing systems. These and other reactions (e.g., in vitro splicing reactions) work efficiently only if the template RNAs are capped at their 5′ termini. The addition of a 5′-cap structure also greatly improves the stability of RNAs injected into oocytes (for references, please see Yisraeli and Melton 1989). Capped RNAs can be synthesized in vitro by lowering the concentration of GTP to 50 μM and including a cap analog (such as G[5′]ppp[5′]G) at a tenfold molar excess in the reaction mixture (Contreras et al. 1982; Konarska et al. 1984). The great majority of transcripts synthesized under these conditions are initiated with a 5′-capped structure. However, once RNA synthesis has begun, the peculiar chemical structure of the cap analog (with two exposed 3′-hydroxyl residues) ensures that no further incorporation of the capping nucleotide can occur.

Finally, the high specificity of bacteriophage RNA polymerases has been exploited in the development of prokaryotic and eukaryotic expression systems. Here, a target cDNA or gene is cloned downstream from a bacteriophage promoter sequence and upstream of an appropriate transcription termination sequence. The resulting recombinant plasmid is then introduced into cells harboring a second plasmid that expresses the bacteriophage RNA polymerase in a regulated fashion. Induction of the polymerase gene results in the transcription of the target DNA on the first plasmid and subsequent abundant expression of its encoded product(s). In *E. coli*, the most widely used binary expression system employs the bacteriophage T7 RNA polymerase and promoter (Tabor and Richardson 1985; Studier and Moffatt 1986; Studier et al. 1990). In eukaryotic cells, the T7 RNA polymerase can be produced by infection with a recombinant vaccinia virus containing the T7 polymerase gene (Fuerst et al. 1986) or by transfection of an expression plasmid.

FACTS AND HINTS

To obtain milligram amounts of RNA from large-scale reactions, the concentration of $MgCl_2$ in the reaction should be adjusted to 6 nM above the total concentration of nucleotides in the reaction (Milligan and Uhlenbeck 1989), and yeast inorganic pyrophosphatase should be included at a concentration of 5 units/ml (Cunningham and Ofengand 1990). The pyrophosphatase prevents sequestration of Mg^{2+} in the form of magnesium pyrophosphate.

Bacteriophage RNA polymerases will accept biotinylated nucleotides as precursors. However, compared to radiolabeled NTPs, incorporation is less efficient and the products of the reaction contain a higher proportion of truncated RNAs (Grabowski and Sharp 1986; Yisraeli and Melton 1989).

T7 RNA polymerase is strongly inhibited by T7 lysozyme (Moffatt and Studier 1987; Ikeda and Bailey 1992). Coexpression of the T7 lysozyme gene has been used as a method to reduce the activity of T7 polymerase in transformed bacteria (for review, please see Studier et al. 1990).

ISOLATING DIFFERENTIALLY EXPRESSED cDNAs BY DIFFERENTIAL SCREENING AND CLONING

Estimates suggest that the human genome may encode 70,000–80,000 genes (Antequera and Bird 1993, 1994; Fields et al. 1994). Within a single type of cell, some genes are expressed at high levels and others at low levels. Measurements of the kinetics of reassociation of mRNA in the presence of a vast excess of genomic DNA (Melli et al. 1971; Hastie and Bishop 1976) show that ~20% of the mammalian mRNA population consists of abundant transcripts (1000–12,000 copies/cell). mRNAs of medium abundance (100–1000 copies/cell) account for a further 25% of the mRNA molecules, and the remaining 50% consist of a small number of copies (≤13 copies/cell) of a large number (~30,000) of genes (Lewin 1975).

Particular types of mammalian cells express specific sets of genes, the majority of which belong to the medium- and low-abundance classes. For example, cultured human cells express 20,000–30,000 genes, over half of which are transcribed into low-abundance mRNAs (Bishop 1974; Bishop et al. 1974; Ryffel and McCarthy 1975). Mammalian brain cells may be exceptional in this regard in that they collectively appear to express almost the entire set of genes encoded by the genome (Bantle and Hahn 1976). In general, however, cells of the same lineage express similar sets of genes, whereas those from different lineages exhibit greater diversity in their expression patterns. For example, the organs of higher eukaryotes differ by expression of ~2000–4000 genes (Axel et al. 1976), whereas closely related cell types, such as B and T lymphocytes, differ by expression of only ~400 genes (Davis et al. 1982).

Differentially expressed genes include not only those that are transcribed in particular types of cells at specific stages of differentiation and development, but also those whose level of expression changes during the cell cycle or during tumorigenesis or as a consequence of pharmacological stimulation. Several methods, none of them easy, are available to isolate such genes, including random sampling and sequencing of cDNA clones, differential screening of cDNA libraries, construction and screening of subtracted cDNA libraries, and differential display (for reviews, please see Soares et al. 1994; Sagerström et al. 1997; Soares 1997; Hess et al. 1998).

Random Sampling

Since the advent of high-throughput automated DNA sequencing, it has become possible to search for differentially expressed genes by sequencing large numbers of cDNA clones picked at random from each of two libraries (e.g., please see Frigerio et al. 1995). This type of large-scale, single-pass sequencing is also used to generate expressed sequence tags (ESTs), which contain enough information to identify a transcript (Adams et al. 1995; Hillier et al. 1996). Because most of the mRNAs in the highest-abundance class are the least likely to be differentially expressed, the chance of isolating differentially expressed gene by sequencing cDNAs at random is low. To avoid sequencing abundant transcripts time and time again, one or more rounds of differential screening can be used to remove clones that have been screened previously or that correspond to highly abundant mRNAs (e.g., please see Hoög 1991; Orr et al. 1994; Ji et al. 1997). Other methods to increase the probability of identifying cDNA clones corresponding to differentially expressed genes include the use of normalized or subtracted libraries (Spangrude et al. 1988; Patanjali et al. 1991; Soares et al. 1994; Bonaldo et al. 1996; Diatchenko et al. 1996), in which the imbalance in abundance between cDNAs is corrected to within one order of magnitude. However, the resulting increase in efficiency in screening comes at a price: mRNAs that display quantitative differences in expression are lost during the subtractive hybridization step required for construction of normalized or subtracted libraries. Consequently, cDNA clones corresponding only to mRNAs that are differentially expressed in an all-or-none fashion can be isolated.

Differential Screening (also Referred to as Plus/Minus Screening)

In the simplest form of this technique (St. John and Davis 1979), a cDNA library is constructed from cells expressing the gene of interest. Duplicate copies of the library are screened separately with labeled cDNA probes synthesized from two preparations of mRNAs: One from a cell type or tissue that expresses the gene(s) of interest in high abundance and the other from a cell type or tissue with a lower abundance of the target mRNA(s). Recombinant clones that hybridize equally to both probes correspond to genes equivalently expressed in both cell types. These clones are not studied further. Recombinant clones that hybridize differentially to the two probes are isolated and analyzed by northern hybridization to determine whether they contain cDNAs derived from differentially expressed mRNAs.

In principle, this method of comparative screening can be used to identify any differentially regulated gene. However, because they are copied from the entire population of mRNAs, cDNA probes used in differential screening are of very high complexity, with each mRNA represented in proportion to its abundance. For the most part, mammalian mRNAs encoding proteins that regulate cellular behavior are expressed at low abundance and are therefore present at low concentration in the labeled probes. It is unlikely that such mRNAs will be detected by simple differential screening. As a rule of thumb, simple differential screening is successful only when the concentration of the target mRNAs in the two preparations differs by a factor of 5 or more, and when the abundance of the mRNA in one of the preparations exceeds 0.05% (for review, please see Sargent 1987).

The success of differential screening depends on the depth and quality of the cDNA library, the use of probes of high sequence complexity that are capable of detecting cDNAs corresponding to low-abundance mRNAs, and the ability to capture and quantify hybridization data efficiently. The efficiency of the technique is greatly improved if the cDNA libraries are organized into a format (e.g., wells of microtiter dishes) that is amenable to automation (e.g, please see Takahashi et al. 1995; Zhao et al. 1995; Schena et al. 1996; Perret et al. 1998). Although 100 or more differentially expressed genes have been identified using some form of plus-minus screening, the amount of labor involved in screening even a few thousand cDNA clones remains formidable. Until recently, efficient mining of differentially expressed genes from entire cDNA libraries was simply beyond reach.

Recently, however, differential screening has begun to bear spectacular and wonderful fruit. With the introduction of automated methods, more complex and more efficient forms of differential screening have been developed using densely arrayed libraries of cDNAs or synthetic oligonucleotides (for reviews, please see Ermolaeva et al. 1998; Khan et al. 1998; Bowtell 1999; Brown and Botstein 1999; Duggan et al. 1999; Rajeevan et al. 1999, and references therein). The arrays are probed with cDNAs that are prepared from two different sources and labeled with different chromophores. An image of the pattern of hybridization of the labeled cDNAs is then captured electronically and normalized by computer to compare the efficiency with which each of the probes hybridizes to each of the immobilized targets. Once differentially expressed genes have been identified, full-length cDNAs can be obtained from a repository.

Array technology is still some years away from routine use in conventional laboratories. To run efficiently, it requires high-speed robotic systems to print validated cDNAs in high-density arrays on to glass microscope slides, sophisticated readers to capture and manipulate images of the hybridization patterns, and access to state-of-the-art bioinformatics. However, the results already obtained give confidence that in the next few years, it will become possible to screen the entire complement of ~100,000 human genes and to map both physiological and pathological changes in the transcriptional landscape of cells and tissues (Schena et al. 1998). In the meantime, however, differential screening and subtractive screening and cloning (see below) remain viable, albeit laborious, options to detect temporal and topographic changes in gene expression.

Subtractive Screening

Subtracted screening uses probes in which the concentration of cDNAs corresponding to highly redundant RNAs is reduced without significantly affecting the concentration of low-abundance sequences. In the simplest method, labeled cDNA generated from one population of mRNA (tester), which contains the sequences of interest, is hybridized to a driver that does not contain these sequences. The driver, which is used in molar excess in the hybridization reaction, is usually a preparation of mRNA from another, closely related source. The cDNA sequences complementary to mRNAs expressed in the driver population form DNA-RNA hybrids, whereas those that are unique to the tester population remain single-stranded. The hybrids are then removed by hydroxyapatite chromatography. Many more complex variations of this basic method have been described. For example:

- RNA labeled by photobiotinylation can be used as a driver, in which case the DNA-RNA hybrids can be removed by extraction with streptavidin-phenol (please see Table 9-5).
- Two cDNA libraries (from driver and tester mRNAs) are constructed by directional cloning in phagemid vectors. The libraries, which are arranged in opposite orientations, are used to generate complementary single-stranded cDNAs that can be used as driver and tester (Duguid et al. 1988; Rubenstein et al. 1990; Rothstein et al. 1993).

- Multiple rounds of subtraction can be carried out using PCR amplification of both the driver and the subtracted cDNAs (e.g., please see Hara et al. 1991, 1993; Wang and Brown 1991; Cecchini et al. 1993; López-Fernández and del Mazo 1993; Sharma et al. 1993; Lönneborg et al. 1995; Diatchenko et al. 1996; Jin et al. 1997; Konietzko and Kuhl 1998).

The decision between these methods turns on the amount of starting materials available and their complexity. The simplest method, where mRNA is used as the driver, may require as much as 20 μg of poly(A)$^+$ mRNA. It is frequently impossible to obtain sufficient mRNA to drive subtractive hybridization to completion. In other circumstances, because the amount of radioactivity in an absorbed probe complementary to any given cDNA is small, hybridization to a subtracted library may be inefficient, and satisfactory signals may be obtained only after prolonged exposure of autoradiographs. In either case, the probability of isolating a cDNA corresponding to a very rare mRNA is remote. If this amount is unavailable, a PCR-based scheme or a method involving hybridization of complementary cDNA libraries must be used.

The ultimate goal is to obtain a subtracted cDNA probe that can be used to screen a cDNA library constructed from mRNA extracted from the tester cell. A subtracted probe offers two potential benefits. First, because abundant sequences common to both cell types are removed, the proportion of radioactivity in the probe corresponding to rare mRNAs is increased, usually by a factor of ~10. Second, the removal of abundant sequences greatly reduces the chance that a rare clone of interest might be lost in the morass of cDNA clones that hybridize strongly to abundant sequences in the radiolabeled probe. This enhancement means that the cDNA library can be plated for screening at a higher density, with a commensurate reduction in the volume of hybridization solution and an increase in the concentration of the absorbed probe. The sensitivity of the probe is therefore increased, so that cDNA clones corresponding to rare mRNAs (0.005–0.01%) now fall within the range of detection (Wu et al. 1994). The increased level of sensitivity is sufficient to allow unambiguous discrimination between populations of mRNAs extracted, for example, from *Dictyostelium* at different stages of development (Timberlake 1980), from the gastrula and ovary of *Xenopus* (Sargent and Dawid 1983), from untransformed murine cells and murine cells transformed by SV40 (Scott et al. 1983), from myoblasts (Davis et al. 1987), from specialized populations of lymphocytes (Hedrick et al. 1984; Davis 1986 and references therein), from the neural plate of frog embryos (Klar et al. 1992), and from a cultured line of human neural tumor cells (el-Deiry et al. 1993).

TABLE 9-5 Methods Commonly Used to Recover Single-stranded Nucleic Acids After Subtractive Hybridization with Driver

METHOD	PROS AND CONS	REFERENCES
Chromatography on hydroxyapatite	efficient but messy	Please see Appendix 8 and the panel on **QUANTITATING RNA** in Chapter 7.
Biotinylation of driver	tricky to prepare drivers with the correct density of biotin residues[1–4]; easy and efficient to separate biotinylated and nonbiotinylated molecules after hybridization by binding to immobilized streptavidin[2,5,6] or by extraction with streptavidin-phenol[7–9]	[1]Syvänen et al. (1986, 1988) [2]Wieland et al. (1990) [3]Swaroop et al. (1991) [4]Lebeau et al. (1991) [5]Syvänen et al. ALKALINE PHOSPHATASE

Several types of alkaline phosphatases (or alkaline phosphomonoesterase) are commonly used in molecular cloning: bacterial alkaline phosphatase (BAP) and calf intestinal alkaline phosphatase (CIP, CIAP, or CAP). Similar enzymes isolated from more esoteric cold-blooded organisms (e.g., SAP from shrimp) have become available in recent years and have the advantage of being easier to inactivate than BAP or CIP at the end of dephosphorylation reactions. Alkaline phosphatases, which are all Zn(II) metalloenzymes, catalyze phosphate monoester hydrolysis through the formation of a phosphorylated serine intermediate. They are used for three purposes in molecular cloning:

- ***To remove phosphate residues*** from the 5′ termini of nucleic acids before radiolabeling of the resulting 5′-hydroxyl group by transfer of ^{32}P from γ-labeled ATP. This second reaction is catalyzed by bacteriophage T4 polynucleotide kinase (Chaconas and van de Sande 1980).
- ***To remove 5′-phosphate residues*** from fragments of DNA to prevent self-ligation. This dephosphorylation reaction is used chiefly to suppress self-ligation of vector molecules and therefore to decrease the number of "empty" clones that are obtained during cloning (Ullrich et al. 1977).
- ***As reporter enzymes*** in nonradioactive systems to detect and localize nucleic acids and proteins. In this case, the alkaline phosphatase is conjugated to a ligand such as streptavidin that specifically interacts with a biotinylated target molecule (Leary et al. 1983).

Dephosphorylation Reactions

Alkaline phosphatases can remove 3′-phosphate groups from a variety of substrate molecules, including 3′-phosphorylated polynucleotides and deoxynucleoside 3′-monophosphates (Reid and Wilson 1971). However, the main use of BAP, CIP, and SAP in molecular cloning is to catalyze the removal of terminal 5′-phosphate residues from single- or double-stranded DNA and RNA. The resulting 5′-hydroxyl termini can no longer take part in ligation reactions but are substrates in radiolabeling reactions catalyzed by polynucleotide kinase (Chaconas and van de Sande 1980).

Although the usefulness of alkaline phosphatases in 5′ labeling of nucleic acids is undisputed, their value in preventing self-ligation is more debatable. There is no doubt that dephosphorylation reduces recircularization of linear plasmid DNA and therefore diminishes the background of transformed bacterial colonies that carry "empty" plasmids (Ullrich et al. 1977; Ish-Horowicz and Burke 1981; Evans et al. 1992). All too frequently, however, there is a parallel decline in the number of colonies that carry the desired recombinant. In addition, some investigators believe that the presence of 5′-hydroxyl groups may lead to an increase in the frequency of rearranged or deleted clones. For these reasons, directional cloning is the preferred method whenever the appropriate restriction sites are available.

Properties of Alkaline Phosphatases

Alkaline phosphatases used in molecular cloning display maximal activity in alkaline Tris buffers (pH 8.0 to pH 9.0) in the presence of low concentrations of Zn^{2+} (<1 mM).

- BAP is secreted in monomeric form (M_r = 47,000) into the periplasmic space of *E. coli*, where it dimerizes and becomes catalytically active (Bradshaw et al. 1981). At neutral or alkaline pH, dimeric BAP contains up to six Zn^{2+} ions, two of which are essential for enzymatic activity (for review, please see Coleman and Gettins 1983). Only one of the two catalytic sites per dimer is active at low concentrations of artificial substrates, whereas both become active at higher concentrations (Heppel et al. 1962; Fife 1967). BAP

Activity: Phosphatase

Substrate: Single- or double-stranded DNA and RNA; rNTPs and dNTPs

Reaction: 5'pDNA or 5'pRNA —(alkaline phosphatase)→ $5'_{OH}$DNA or $5'_{OH}$RNA

FIGURE 9-9 Dephosphorylation Activity of Alkaline Phosphatases

is a remarkably stable enzyme and is resistant to inactivation by heat and detergents. For this reason, BAP is difficult to remove at the end of dephosphorylation reactions.

- CIP is a dimeric glycoprotein, composed of two 514-residue monomers, that is bound to the plasma membrane by a phosphatidylinositol anchor (Hoffmann-Blume et al. 1991; Weissig et al. 1993) and whose optimal enzymatic activity depends on the concentrations of Mg^{2+} and Zn^{2+}. Some Zn^{2+}, bound at a catalytic site, is required for catalytic activity. Mg^{2+}, which binds at a different site, is an allosteric activator. However, Zn^{2+}, if present in high concentrations, will compete for the Mg^{2+} binding site and prevent the allosteric activation (Fernley 1971). CIP can be readily digested with proteinase K and/or inactivated by heating (to 65°C for 30 minutes or 75°C for 10–15 minutes) in the presence of 10 mM EGTA. The dephosphorylated DNA can then be purified by extraction with phenol:chloroform.
- SAP is isolated from arctic shrimp and its enzymatic properties are similar to those of CIP. Unlike BAP, SAP is unstable at elevated temperatures and, according to the manufacturers, can be completely inactivated by heating to 65°C for 15 minutes. However, molecular biology chat sites on the web frequently contain comments from customers who suggest that the enzyme may not be completely inactivated by brief heating. To be fair, about an equal number report that they have no problems in inactivating SAP. However, to be on the safe side, we recommend heating to 70°C for 20 minutes to ensure complete inactivation of SAP.

Alkaline phosphatases as a group are inhibited by inorganic orthophosphate (Zittle and Della Monica 1950), by chelators of metal ions such as EDTA and EGTA, but not to a significant extent by diisopropylfluorophosphate, a powerful inhibitor of other serine hydrolases (Dabich and Neuhaus 1966). L-phenylalanine is a noncompetitive inhibitor of CIP (Weissig et al. 1993).

Chapter 10

Working with Synthetic Oligonucleotide Probes

METHODS TO SYNTHESIZE SHORT TRACTS OF SINGLE-STRANDED DNA, first developed more than 30 years ago, are now refined to a point where almost all chemical syntheses of oligonucleotides are carried out by automated machines (for further details on the chemistry of automated oligonucleotide synthesis, please see the information panel on **OLIGONUCLEOTIDE SYNTHESIS**). In the 1980s, the cost of these machines decreased to a point that many individual laboratories and core facilities could synthesize oligonucleotides at reasonable rates. The current trend in oligonucleotide synthesis is to order individual oligonucleotides from commercial suppliers, who by virtue of bulk purchases and centralized facilities can take advantage of economies of scale.

The ready availability of oligonucleotides of defined sequence, coupled with the development of appropriate hybridization techniques, revolutionized molecular cloning. It led to the primary isolation of cloned copies of genes that were previously inaccessible. Knowledge of the sequence of a few amino acids in a protein was sufficient to allow the rapid isolation of cloned copies of the corresponding gene. Facile and cheap synthesized oligonucleotides also brought site-directed mutagenesis within the range of large numbers of laboratories.

USES OF OLIGONUCLEOTIDE PROBES

Although the use of oligonucleotides as hybridization probes for the initial isolation of a cDNA or a gene has been partly displaced by the polymerase chain reaction (PCR) and cloning strategies such as MOPAC (please see Chapter 8, Protocol 11), oligonucleotides are used widely in a variety of molecular cloning procedures:

- ***Screening cDNA or genomic DNA libraries,*** or subclones derived from them, for additional clones containing segments of DNA that have been isolated previously and whose sequences are known.
- ***Identifying or detecting specific genes*** or their transcripts in Southern, northern, or dot-blot hybridizations.
- ***Examining genomic DNA and PCR-amplified DNA,*** using Southern or dot-blot hybridization, to detect specific mutations in genes of known sequence.
- ***Screening expression libraries for clones*** that encode transcription factors and other proteins that bind to specific sequences of DNA.
- ***Identifying clones that carry specific base changes*** introduced into specific segments of DNA by site-directed mutagenesis.

Success with these techniques begins with the design of an oligonucleotide (1) that hybridizes specifically to its target and (2) whose physical properties (e.g., length and GC content) do not impose unnecessary constraints on the experimental protocol. In a few cases, the investigator has little latitude in the design of the oligonucleotide. For example, when oligonucleotides are used as allele-specific probes for the presence or absence of defined mutations, the salient properties of the oligonucleotides are defined to a very large extent by the particular sequences in which the mutation is embedded. In most other circumstances, however, the chance of success can be increased by careful adjustment of parameters defined by the investigator, such as the length, sequence, and base composition of the oligonucleotide. The rules outlined below were developed to optimize the design of oligonucleotide hybridization probes. However, most of them also apply to the design of primers for PCR or oligonucleotide-primed DNA sequencing.

MELTING TEMPERATURE AND HYBRIDIZATION TEMPERATURE

An ideally designed oligonucleotide probe should form a perfect duplex only with its target sequence. These duplexes should be sufficiently stable to withstand the posthybridization washing steps used to remove probes nonspecifically bound to nontarget sequences. For oligonucleotides of 200 nucleotides or less, the reciprocal of the melting temperature of a perfect hybrid (T_m^{-1}, measured in degrees Kelvin) is approximately proportional to n^{-1}, where n is the number of bases in the oligonucleotide (please see Gait 1984).

Several equations are available to calculate the melting temperature of hybrids formed between an oligonucleotide primer and its complementary target sequence. Since none of these are perfect, the choice among them is largely a matter of personal preference (for additional information on calculating melting temperatures, please see the information panel on **MELTING TEMPERATURES**). The melting temperatures of each member of a primer:target duplex should obviously be calculated using the same equation.

- An empirical and convenient equation known as "The Wallace Rule" (Suggs et al. 1981b; Thein and Wallace 1986) can be used to calculate the T_m to perfect duplexes, 15–20 nucleotides in length, in solvents of high ionic strength (e.g., 1 M NaCl or 6x SSC)

  $$T_m \text{ (in } ^\circ\text{C)} = 2(A+T) + 4(G+C)$$

  where $(A+T)$ is the sum of the A and T residues in the oligonucleotide and $(G+C)$ is the sum of G and C residues in the oligonucleotide.

- The equation derived originally by Bolton and McCarthy (1962) and later modified by Baldino et al. (1989) predicts reasonably well the T_m of oligonucleotides, <100 nucleotides long, in cation concentrations of 0.5 M or less, and with a $(G+C)$ content between 30% and 70%. It also compensates for the presence of base-pair mismatches between the oligonucleotide and the target sequence

  $$T_m \text{ (in } ^\circ\text{C)} = 81.5^\circ\text{C} + 16.6\ (\log_{10}[\text{Na}^+]) + 0.41(\%[\text{G+C}]) - 675/n - 1.0\ m$$

  where n is the number of bases in the oligonucleotide and m is the percentage of base-pair mismatches. This equation can also be used to calculate the melting temperature of an amplified product whose sequence and size are both known. When PCR amplification is carried out under standard conditions, the calculated T_m of the amplified product should not exceed ~85°C, thus ensuring complete separation of its strands during the denaturation step. Note that the denaturation temperature in PCR is more accurately defined as the temperature of irreversible strand separation of a homogeneous population of molecules. The temperature of irreversible strand separation is several degrees higher than the T_m (typically, 92°C for DNA whose content of G+C is 50%) (Wetmur 1991).

- Neither of the above equations takes into account the effect of base sequence (as opposed to base composition) on the T_m of oligonucleotides. A more accurate estimate of the T_m can be obtained by incorporating nearest-neighbor thermodynamic data into the equations (Breslauer et al. 1986; Freier et al. 1986; Kierzek et al. 1986; Rychlik et al. 1990; Wetmur 1991; Rychlik 1994). A relatively straightforward equation, described by Wetmur (1991), is

  $$T_m \text{ (in } ^\circ\text{C)} = (T^\circ\ \Delta H^\circ)/(\Delta H^\circ - \Delta G^\circ + RT^\circ \ln[c]) + 16.6 \log_{10}([\text{Na}^+]/\{1.0 + 0.7[\text{Na}^+]\}) - 269.3$$

  where $\Delta H^\circ = \Sigma_{nn}(N_{nn}\Delta H^\circ_{nn}) + \Delta H^\circ_p + \Delta H^\circ_e$
  $\Delta G^\circ = \Sigma_{nn}(N_{nn}\Delta G^\circ_{nn}) + \Delta G^\circ_i + \Delta G^\circ_e$
  N_{nn} = the number of nearest neighbors (e.g., 13 for a 14-mer)
  R = 1.99 cal/mole-°K
  T° = 298.2°K
  c = the total molar strand concentration
  $[\text{Na}^+] \leq$ 1 M

  A number of the thermodynamic terms can be approximated:

  average nearest-neighbor enthalpies, $\Delta H^\circ_{nn} = -8.0$ kcal/mole
  average nearest-neighbor free energies, $\Delta G^\circ_{nn} = -1.6$ kcal/mole

initiation term, ΔG°_{i} = +2.2 kcal/mole
average dangling end enthalpy, ΔH°_{e} = –8.0 kcal/mole/end
average dangling end free energy, ΔG°_{e} = –1 kcal/mole/end
average mismatch/loop enthalpy, ΔH°_{p} = –8.0 kcal/mole/mismatch

Note that for each mismatch or loop, N_{nn} is reduced by 2.

When the oligonucleotide is used as a probe, hybridization is usually carried out at ~5–12°C below the calculated T_m, and stringent posthybridization washing is carried out at ~5°C below the T_m. Working so close to the calculated T_m has two consequences: (1) It reduces the number of mismatched hybrids and (2) less desirably, it reduces the rate at which perfect hybrids form.

For all practical purposes, hybrid formation between complementary DNA molecules >200 nucleotides in length is an irreversible reaction when annealing is carried out at ~10°C below the calculated T_m. The chance that such a long stretch of perfect double helix will unwind under the conditions conventionally used for hybridization (68°C and ~1 M [Na^+]) is small. However, hybrids (even perfect hybrids) formed between short oligonucleotides and their target sequences at 5–10°C below the T_m are far easier to unwind; thus, hybridization reactions of this type can be considered reversible. This behavior has important practical consequences. The concentration of oligonucleotide in the hybridization reaction should be high (0.1–1.0 pmole/ml) so that the annealing reaction rapidly reaches equilibrium within 3–8 hours. Posthybridization washing, however, should be brief (1–2 minutes) and should be carried out initially under conditions of low stringency, and then under conditions of stringency that at least equal those used for hybridization (Miyada and Wallace 1987).

LENGTH OF OLIGONUCLEOTIDE PROBES

The longer an oligonucleotide, the higher its specificity for the target sequence. The following equations can be used to calculate the probability that a specific sequence string of nucleotides will occur within a sequence space (Nei and Li 1979).

$$K = \frac{[g/2]^{G+C} \times [(1-g)/2]^{A+T}}{N}$$

where K is the expected frequency of occurrence within the sequence space, g is the relative G+C content of the sequence space, and G, C, A, and T are the number of specific nucleotides in the oligonucleotide. For a double-stranded genome of size N (in nucleotides), the expected number (n) of sites complementary to the oligonucleotide is $n = 2NK$.

These equations predict that an oligonucleotide of 14–15 nucleotides would be represented only once in a mammalian genome where N is ~3.0×10^9. In the case of a 16-mer, there is only one chance in ten that a typical mammalian cDNA library (complexity ~10^7 nucleotides) will fortuitously contain a sequence that exactly matches that of the oligonucleotide. However, these estimates are based on the assumption that the distribution of nucleotides in mammalian genomes is random. Unfortunately, this is not the case, due to bias in codon usage (Lathe 1985) and because a significant fraction of the genome is composed of repetitive DNA sequences and gene families. Because of the presence of these elements, no more than 85% of the mammalian genome can be targeted precisely, even by probes and primers that are 20 nucleotides in length (Bains 1994).

To minimize problems of nonspecific hybridization, it advisable to use oligonucleotides longer than the statistically indicated minimum. Any clones that then hybridize to the probe are likely to be derived from the gene of interest. Bear in mind that when a cDNA library is screened

with an oligonucleotide probe, no relationship exists between the observed number of positive clones and their frequency predicted by statistics. For example, if by chance the oligonucleotide should match an expressed sequence that is abundantly represented in mRNA, the number of clones that hybridize to the probe will be much larger than theory predicts. Before synthesizing an oligonucleotide probe or primer, it is advisable to scan DNA databases to ensure that the proposed sequence occurs only in the desired gene and not in vectors, undesired genes, or repetitive elements (e.g., please see Mitsuhashi et al. 1994).

The effect of hybridization between imperfectly matched sequences cannot be easily quantified, since different types of mismatching (mispairing between single bases, loopouts on either strand, multiple mismatches, whether closely or distantly spaced) have different effects on the stability of double-stranded DNA. For example, a single mismatch in the center of a short oligonucleotide (of ~16 nucleotides in length) will destabilize the hybrid by ~7°C (Wetmur 1991) and, consequently, may attenuate the hybridization signal to a very considerable degree. On the other hand, a mismatch at the 3′ end of a probe will have little effect on hybridization signal (Ikuta et al. 1987) but will greatly diminish the ability of an oligonucleotide to prime DNA synthesis.

DEGENERATE POOLS OF OLIGONUCLEOTIDES

In molecular cloning, the situation frequently arises where a short sequence of amino acids has been obtained by sequencing a purified protein. Because of the degeneracy of the genetic code, many different oligonucleotides can potentially code for a given tract of amino acids. For example, 64 possible 18-mers can code for the sequence Asn Phe Tyr Ala Trp Lys. However, only one of these oligonucleotides will exactly match the coding sequence used in the gene of interest. Because there is no way to know a priori which of these oligonucleotides has its true counterpart in the gene, pools of oligonucleotides containing all potential coding combinations are synthesized and used as probes. Depending on the length of the amino acid sequence and the amount of degeneracy at each position, pools can contain up to several hundred oligonucleotides. If hybridization conditions can be found under which only perfectly matched sequences form stable duplexes, cloned copies of the gene of interest can be readily isolated from genomic or cDNA libraries (e.g, please see Goeddel et al. 1980; Agarwal et al. 1981; Sood et al. 1981; Suggs et al. 1981b; Wallace et al. 1981; Toole et al. 1984; Jacobs et al. 1985; Lin et al. 1985).

Pools of degenerate oligonucleotides are generally used to select a series of candidate clones that can then be analyzed further to identify the true target. To ensure that the target clone is represented in the initial group of candidates, screening conditions are usually chosen that allow detection of perfect hybrids formed between the most A/T-rich oligonucleotide in the pool and its potential target. Other hybrids, both perfect and imperfect, that are stable under such conditions will identify additional candidate clones.

It is easy to calculate accurately the T_m of a perfectly matched hybrid formed between a single oligonucleotide and its target sequence. However, when using pools of oligonucleotides whose members have greatly different contents of G+C, it is not feasible to estimate a consensus T_m. Because it is impossible to know which member of the pool will match the target sequence perfectly, conditions must be used that allow the oligonucleotide with the lowest content of G+C to hybridize efficiently. Usually, conditions are chosen to be 2°C below the calculated T_m of the most A/T-rich member of the pool (Suggs et al. 1981a). However, the use of such "lowest common denominator" conditions can generate false positives: Mismatched hybrids formed by oligonucleotides of higher G+C may be more stable than a perfectly matched hybrid formed by the correct oligonucleotide. In most cases, this problem is not serious, since the number of positive clones obtained by screening cDNA libraries with pools of nucleotides is quite manageable. It is

therefore easy to distinguish false positives from true positives by another test (e.g., DNA sequencing or hybridization with a second pool of oligonucleotides corresponding to another segment of amino acid sequence).

QUARTERNARY ALKYLAMMONIUM SALTS

When the number of apparent positives is unacceptably high, it is worthwhile using hybridization solvents that contain quaternary alkylammonium salts such as tetraethylammonium chloride (TEACl) or tetramethylammonium chloride (TMACl) (Melchior and von Hippel 1973; Jacobs et al. 1985, 1988; Wood et al. 1985; Gitschier et al. 1986; DiLella and Woo 1987). By binding to A/T-rich polymers (Shapiro et al. 1969), quaternary alkylammonium salts reduce the preferential melting of A:T versus G:C base pairs (Melchior and von Hippel 1973; Riccelli and Benight 1993). In TEACl or TMACl, the T_m of an oligonucleotide-DNA hybrid becomes less dependent on its base composition and more dependent on its length. By choosing a hybridization temperature appropriate for the lengths of the oligonucleotides in a pool, the effects of potential mismatches can be minimized.

It is important to obtain an accurate estimate of the T_m in TMACl or TEACl before using pools of oligonucleotides to screen cDNA or genomic libraries. Jacobs et al. (1988) measured the T_i (the irreversible melting temperature) of the hybrid formed between the probe and its target as a function of chain length for a number of oligonucleotides of different (G+C) content in solvents containing either sodium ions or tetraalkylammonium ions. Hybrids involving oligonucleotides 16 and 19 nucleotides in length melt over a smaller range of temperatures in solvents containing TMACl than in solvents containing sodium salts. For example, 16-mers melt over a 3°C temperature range in solvents containing TMACl, compared with 17°C in SSC.

The optimal temperature for hybridization is usually chosen to be 5°C below the T_i for the given chain length. The recommended temperature for 17-mers in 3 M TMACl is 48–50°C; for 19-mers, it is 55–57°C; and for 20-mers, it is 58–66°C. Two points are worth emphasizing. First, the T_i of hybrids is uniformly 15–20°C higher in solvents containing TMACl than in solvents containing TEACl. The higher T_i in solvents containing TMACl allows hybridization to be performed at temperatures that suppress nonspecific adsorption of the probe to solid supports (such as nylon membranes). Second, hybridization solvents containing TMACl do not have significant advantages over those containing sodium ions until the length of the oligonucleotide exceeds 16 nucleotides.

GUESSMERS

A guessmer is a long synthetic oligonucleotide (usually 30–75 nucleotides in length), whose sequence corresponds to an amino acid sequence of 15–25 residues. Because of the degeneracy of the genetic code, many thousands of possible nucleotide sequences could code for such a sizeable tract of amino acids. Unless the designer is incredibly lucky and chooses the correct codon in every single position, the guessmer will not form a perfect hybrid with the target gene. However, because most amino acids are specified by codons that differ only in the third position, at least two of the three nucleotides of each codon are likely to be perfectly matched. In addition, the number of mismatches in the third position can be minimized by selecting codons that are used preferentially by a particular organism, organelle, or cell type. In this way, it is possible to make guessmers of sufficient length so that the detrimental effects of mismatches are outweighed by the stability of extensive tracts of perfectly matched bases.

There are no rules that guarantee selection of the correct codon at a position of ambiguity; neither is it possible to predict how many correct choices must be made to achieve success. On the basis of mathematical calculations (Lathe 1985), a probe would be expected to have at least 76% identity with the authentic gene even if all codon choices were made on a random basis. If substitutions are chosen on the statistical basis of known codon usage in the species of interest, the expected homology increases to 82%; it rises still further (to 86%) if regions lacking leucine, arginine, and serine are chosen (each of these three amino acids is specified by six codons). Clearly, as the degree of homology increases, the guessmer becomes a more specific probe for the gene of interest and forms hybrids that are stable under a wider range of hybridization conditions. If the sequences of selected genes, successfully isolated by probing with guessmers, are compared with their corresponding guessmer sequences, the (respective) homologies range from a low of 71% to a high of 97%. Unless the choice of codons is extremely unfortunate, guessmers can be designed whose homology with their target genes lies near the upper end of this range. However, in addition to overall homology, the presence of a perfectly matching sequence of contiguous nucleotides within the guessmer may also be important for success. Almost all guessmers that have been used successfully contain regions that exactly match sequences in their target genes. Although it is not possible to guarantee that a guessmer will contain an exactly matching sequence, the chances increase dramatically as the degree of overall homology rises.

DESIGNING A GUESSMER

- Eliminate codon choices that generate the sequence CpG between codons. This dinucleotide is significantly underrepresented in mammalian DNA (Bird 1980), and CpG occurs at the junction between codons at about one half of the expected frequency (Lathe 1985).
- Choose the codon that most commonly codes for a particular amino acid in the species under study. Comprehensive lists of relative codon frequencies in genes have been published by Wada et al. (1992) or may be found at www.kasuza.or.jp/codon (please see Appendix 7).
- Remember that specific gene families occasionally display a marked bias for or against certain codons. For example, histone genes show a marked preference for codons enriched in A and T residues, whereas proteins expressed abundantly in yeast are biased toward a set of highly preferred codons (Bennetzen and Hall 1982) and, for example, hardly ever use the codons UCG and UAU for serine and isoleucine (Ogden et al. 1984).
- Different mammalian tissues display different patterns of codon usage (e.g., please see Newgard et al. 1986). It would therefore be worthwhile to determine the codon usage in any genes that have already been cloned and are known to be expressed in the same tissue as the gene of interest.
- At positions where the choice is between C and T and there is no strong codon preference, choose T. This rule is still somewhat controversial. There is good evidence indicating that rG:rU base pairs are more stable than rA:rC base pairs (Uhlenbeck et al. 1971). However, the extension to dG:dT base pairs (Wu 1972) has been both challenged (Smith 1983) and upheld (Martin et al. 1985).
- Examine the sequence of the proposed nucleotide for regions of internal complementarity that might reduce hybridization efficiency. Wherever possible, avoid sequences that could form stable duplexes under the conditions used for hybridization.
- Ensure that the 5′-terminal position of the oligonucleotide is not occupied by a cytosine residue. For reasons that are unknown, the efficiency of radiolabeling of oligonucleotides depends on the sequence of the oligonucleotide (van Houten et al. 1998). Oligonucleotides with a cytosine residue at their 5′ termini are labeled fourfold less efficiently than oligonucleotides beginning with A or T, and sixfold less efficiently than oligonucleotides beginning with G.

It is sometimes possible to synthesize a small pool containing two to eight guessmers that includes all possible codon choices at certain amino acid positions. This kind of limited substitution is most useful when an amino acid, whose codon is highly degenerate, separates two tracts

containing only a few potential mismatches. In this way, it may be possible to generate a continuous sequence within the guessmer that is a perfect match for the target gene. However, when using a mixture of guessmers as probes, the strength of the hybridization signal generated by the "correct" probe is usually reduced. For guessmers labeled by phosphorylation or by filling of recessed ends, an eightfold reduction in signal strength typically does not compromise the identification of clones of interest.

Perhaps the most critical step in the use of guessmers is the choice of conditions for hybridization. The temperature should be high enough to suppress hybridization of the probe to incorrect sequences but must not be so high as to prevent hybridization to the correct sequence, even though it may be mismatched. Before using an oligonucleotide to screen a library, perform a series of trial experiments in which a series of northern or genomic Southern hybridizations are carried out under different degrees of stringency (Anderson and Kingston 1983; Wood et al. 1985). Lathe (1985) presents a set of theoretical curves relating the temperature of the washing solution to the length and homology of the probe. Using these curves as a guide, determine the optimal conditions for detection of sequences complementary to the probe by hybridizing the oligonucleotide to a series of nitrocellulose or nylon membranes at different temperatures. The membranes are washed extensively in 6x SSC at room temperature and then briefly (5–10 minutes in 6x SSC) at the temperature used for hybridization. This method, in which both hybridization and washing are carried out under the same conditions of temperature and ionic strength, appears to be more discriminating than the more commonly used procedure of hybridizing under conditions of lower stringency and washing under conditions of higher stringency. If trial experiments are not possible, estimate the melting temperature (T_m) as follows:

1. Calculate the minimum G+C content of the oligonucleotide, assuming that A or T is present at all positions of ambiguity.

2. Use the following formula to calculate the T_m of a double-stranded DNA with the calculated G+C content:

   $$T_m = 81.5°C + 16.6\ (\log_{10}[Na^+]) + 0.41(\%[G+C]) - (500/n)$$

   where n is the number of nucleotides. The term $500/n$ is derived from a compilation (Hall et al. 1980) of measurements, from several laboratories, of the effect of duplex length on melting temperature. This formula only works for Na^+ concentrations of 1.0 M or less.

3. Calculate the maximum amount of possible mismatches assuming that all choices of degenerate codons are incorrect. Subtract 1°C from the calculated T_m for each 1% of mismatch. The resulting number should be the T_m of a maximally mismatched hybrid formed between the probe and its target DNA sequence.

Almost certainly, the actual T_m will be higher than that predicted by this worst-case calculation. If the bases used at positions of ambiguity were chosen at random, one out of four should be correct, and approximately half of these would be expected to be G or C. The observed T_m should therefore be significantly higher than that estimated. However, to minimize the risk of missing the clone of interest, it is best to hybridize and wash at 5–10°C below the T_m estimated as described above. If, under these conditions, the probe hybridizes indiscriminately, repeat the hybridization at a higher temperature or wash under conditions of higher stringency.

Guessmers reached their height of popularity in the mid 1980s, a time when the fledgling recombinant DNA companies were desperately trying to clone genes of commercial value. cDNA and genomic clones of many useful genes were obtained during this period. In recent years, how-

ever, guessmers have been eclipsed by probes generated in PCRs using sets of redundant primers. This is chiefly because PCR-based methods require far shorter tracts of unambiguous amino acid sequence. Nevertheless, when an amino acid sequence of sufficient length is available, guessmers remain the probes of choice. They have a strong track record of success and are free of the artifacts that PCR can visit upon even the best of investigators.

UNIVERSAL BASES

Universal bases have reduced hydrogen-bonding specificity and can therefore "pair" with natural bases at positions of ambiguity without disrupting the DNA duplex. For several years, the "universal" base of choice has been the purine nucleoside inosine, whose neutral base, hypoxanthine, forms stable base pairs with cytosine, thymine, and adenine. Because of the absence of a 2-amino group, base pairing between inosine and cytosine involves two hydrogen bonds (as in A:T base pairs) instead of the three that occur in C:G base pairs (Corfield et al. 1987; Xuan and Weber 1992). In most other respects, however, inosine behaves like guanosine:

- Inosine occurs naturally in the first (wobble) position of some tRNAs, where it pairs with adenosine in addition to cytidine and uridine, the nucleosides that normally pair with guanosine in that position (Crick 1966).
- Inosine is able to occupy the middle position of the anticodon where it again pairs with adenosine (Davis et al. 1973). However, in inosine:adenosine pairs in B-DNA duplexes, inosine adopts a *trans* (anti) orientation with respect to the furanose moiety, whereas adenosine is in the *syn* configuration (Corfield et al. 1987). This is similar to the arrangement that is formed when guanosine mispairs with adenosine (Brown et al. 1986).
- Poly(rI) and poly(dI) form helices with poly(rC) and poly(dC) that are stable enough to serve as templates utilized by various RNA and DNA polymerases. The enzymes can incorporate cytosine into the polymerization products (for review, please see Felsenfeld and Miles 1967; Hall et al. 1985).

Pools of synthetic oligonucleotides and guessmers containing inosine have been used extensively as hybridization probes to screen cDNA or genomic libraries for genes encoding proteins whose amino acid sequence is only partly known. However, although inosine is able to form hydrogen bonds with the three other nucleotides, the resulting base pairs are less stable than the equivalent guanosine-containing base pairs (Martin et al. 1985). The melting temperatures of duplexes containing inosine vary widely depending on the base to which the analog is paired and on the surrounding sequence. In the worst case, the melting temperature of synthetic oligonucleotide duplexes containing inosine opposite any base may be depressed by 15°C, which corresponds to a difference in base pair stability of 2–3 kcal $mole^{-1}$ (Martin et al. 1985; Kawase et al. 1986). Although this situation is less than ideal, it has surprisingly few practical consequences: Inosine-containing oligonucleotides have been used successfully to clone many genes from genomic and cDNA libraries of high complexity (e.g., please see Jaye et al. 1983; Ohtsuka et al. 1985; Takahashi et al. 1985; Bray et al. 1986; Nagata et al. 1986).

Table 10-1 contains a list of codons that are recommended when designing oligonucleotides that are to be used to screen primate or mammalian cDNA libraries and that contain inosine at positions of ambiguity. The recommendations take into account the natural usage of codons in human genes and the fact that the sequence CpG is underrepresented in human DNA.

TABLE 10-1 Inosine-containing Codons Recommended for Use in Oligonucleotide Probes

Amino Acid	Codon	Amino Acid	Codon
A (Ala)	GCI	M (Met)	ATG
C (Cys)	TGC[a]	N (Asn)	AAC[a]
D (Asp)	GAT	P (Pro)	CCI
E (Glu)	GAI	Q (Gln)	CAI
F (Phe)	TTC[a]	R (Arg)	CGI[c]
G (Gly)	GGI	S (Ser)	TCC[b,c]
H (His)	CAC[a]	T (Thr)	ACI
I (Ile)	ATI	V (Val)	GTI
K (Lys)	AAI	W (Trp)	TGG
L (Leu)	CTI[c]	Y (Tyr)	TAC[a]

[a]If the first nucleotide of the succeeding codon is G, use T in the third position.
[b]If the first nucleotide of the succeeding codon is G, use I in the third position.
[c]Try to avoid amino acids with six codons if at all possible.

HYBRIDIZATION OF OLIGONUCLEOTIDES THAT CONTAIN A NEUTRAL BASE AT POSITIONS OF DEGENERACY

Although the conditions for hybridization of probes that contain the neutral base inosine have not been extensively explored, it is possible to make a conservative estimate of the T_m as follows:

- Subtract the number of inosine residues from the total number of nucleotides in the probe to give a value *S*.
- Calculate the G+C content of *S*.
- Estimate the T_m of a perfect hybrid involving *S* using either the Wallace rule, the Baldino algorithm, or the Wetmur equation.
- Use conditions for hybridization that are 15–20°C below the estimated T_m.

The T_m of hybrids involving oligonucleotides that contain neutral bases can also be estimated empirically as described in Protocol 9. Oligonucleotides containing inosine can be used with washing buffers containing TMACl or TEACl (e.g., please see Andersson et al. 1989).

WORKING WITH OLIGONUCLEOTIDES

In the following protocols, we describe several methods to purify synthetic oligonucleotides, to radiolabel oligonucleotides, their use as hybridization probes, and how to determine empirically the melting temperature of an oligonucleotide-target duplex. The chapter concludes with information panels on oligonucleotide synthesis, melting temperatures, and methods of oligonucleotide purification.

Science and technology multiply around us. To an increasing extent they dictate the languages in which we speak and think. Either we use those languages, or we remain mute.

J.G. Ballard

Protocol 1

Purification of Synthetic Oligonucleotides by Polyacrylamide Gel Electrophoresis

SO EFFICIENT ARE PRESENT-DAY AUTOMATED DNA SYNTHESIZERS that oligonucleotides up to ~25 nucleotides in length generally do not contain significant quantities of truncated DNA fragments and hence do not require purification by gel electrophoresis. Purification is also unnecessary when oligonucleotides >25 nucleotides in length are used as hybridization probes or in other circumstances where an oligonucleotide of exact length is not required (please see Chapters 3, 6, and 14).

The longer the oligonucleotide, the greater the chance that it will be contaminated to a significant degree with the by-products of incomplete synthesis. As a rule of thumb, oligonucleotides >25 nucleotides long should be purified by polyacrylamide gel electrophoresis, as should oligonucleotides of any length that yield anomalous results in experiments where the exact length of the oligonucleotide is important, for example, in primer extension experiments to map the 5′ termini of mRNAs (please see Chapter 7, Protocol 12), as a sequencing primer (Chapter 12, Protocols 3–6), to amplify microsatellite markers in mammalian genomes (please see Chapter 8), and as a probe in gel retardation assays (Chapter 17, Protocol 2).

After electrophoresis, the oligonucleotide is eluted from the gel and concentrated by:

- ***Ethanol precipitation.*** This procedure works efficiently provided the volume of the filtered eluate (please see Step 17 of this protocol) is reduced by repeated extractions with *n*-butanol and the oligonucleotide is longer than 18 nucleotides (please see Appendix 8).
- ***Reversed-phase chromatography*** on Sep-Pak C_{18} columns (detailed in this protocol). These columns are available in prepacked form and are easy to use when fitted to the end of a syringe barrel. Isolation on Sep-Pak C_{18} columns takes longer than ethanol precipitation, but it works efficiently with oligonucleotides of all lengths and yields preparations of higher purity.

The method detailed in this protocol is used to purify crude synthetic oligonucleotides by electrophoresis through denaturing polyacrylamide gels; it is a modification of a procedure developed in Michael Smith's laboratory (University of British Columbia, Vancouver, British Columbia) that has been in use for more than 20 years. The method for recovery of oligonucleotides from polyacrylamide gels was provided by Jeffrey Cormier (University of Texas Southwestern Medical Center, Dallas). For additional ways of purifying oligonucleotides, please see the information panel on **METHODS USED TO PURIFY SYNTHETIC OLIGONUCLEOTIDES.**

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents.
Dilute stock solutions to the appropriate concentrations.
The use of sterile, filtered H_2O (Milli-Q or equivalent) is recommended.

Acetonitrile **<!>**

Use 10 ml of high-performance liquid chromatography (HPLC)-grade acetonitrile for each Sep-Pak column.

Ammonium acetate (10 M)

Use 2 ml of 10 mM ammonium acetate solution for each Sep-Pak column.

n-*Butanol* **<!>**

Formamide gel-loading buffer without tracking dyes **<!>**

Gel-loading buffer consists of undiluted formamide without the usual tracking dyes (bromophenol blue and/or xylene cyanol FF). Do not add tracking dyes to the gel-loading buffer; the dyes or contaminants in them may migrate at the same rate as the oligonucleotide and interfere with its detection by absorption of UV light (please see Step 14 of protocol). If desired, 0.2% orange G can be included in the gel-loading buffer. This dye migrates with the buffer front and does not interfere with detection of the oligonucleotide.

Formamide-tracking dye mixture

This solution is a 50:50 mixture of formamide and an aqueous solution of tracking dyes (0.05% xylene cyanol FF and 0.05% bromophenol blue). It is used as a size standard in wells adjacent to those containing the oligonucleotide preparation.

Methanol:H_2O solution **<!>**

Combine 6 ml of methanol with 4 ml of filter-sterilized Milli-Q H_2O. Use 3 ml of methanol:H_2O solution for each Sep-Pak column.

Oligonucleotide elution buffer

0.5 M ammonium acetate

10 mM magnesium acetate

Some investigators include 0.1% (w/v) SDS in the oligonucleotide elution buffer. This is not advisable if the eluted oligonucleotide is to be purified by Sep-Pak C_{18} chromatography (please see the note at Step 16).

TE (pH 8.0)

Nucleic Acids and Oligonucleotides

Crude preparation of synthetic oligonucleotide

Synthetic oligonucleotides are usually supplied by the manufacturer as a lyophilized powder after removal of protecting groups used in the synthetic reactions (please see the information panel on **OLIGONUCLEOTIDE SYNTHESIS**). Deprotection usually involves heating the preparation at 55°C for ~5 hours in concentrated solutions of NH_4OH **<!>**. (Some more recent DNA synthesis protocols use a different protecting group on one or more nucleosides [e.g., acetyl-protected dC] that can be removed in <10 minutes.)

Before purifying an oligonucleotide, confirm that the deprotection reaction has been carried out. If the oligonucleotide is supplied in NH_4OH, transfer 0.5–1.0-ml aliquots to 1.5-ml microfuge tubes and evaporate the NH_4OH to dryness on a centrifugal evaporator (Savant SpeedVac or its equivalent) at room temperature.

When opening a tube of crude oligonucleotide for the first time, vent the tube by opening it *slowly* to allow ammonia gas to escape (preferably into a chemical fume hood). This reduces the chance of spraying the oligonucleotide around the room.

Special Equipment

Millex HV filter (Millipore, 0.45-μm pore size)

Parafilm or Fluorescent thin-layer chromatographic plate

Plates may be purchased from Brinkmann in the United States or from E. Merck in Europe as Merck Silica gel F_{254}, 20 x 20-cm plates.

Sep-Pak classic columns, short body

Sep-Pak classic columns (available from the Waters Division of Millipore) contain 360 mg/column of a hydrophobic (C_{18}) reversed-phase chromatography resin. The separation principle makes use of the fact that the oligonucleotide adsorbs to the column when the polarity of the solvent is high (e.g., aqueous buffers) and elutes from the resin when the polarity of the solvent is reduced (e.g., a mixture of methanol and H_2O). One column is required per 10 OD_{260} units of oligonucleotide loaded onto the polyacrylamide gel.

Syringes (5-cc and 10-cc polypropylene)

One 5-cc and one 10-cc syringe are required for each oligonucleotide to be purified.

Ultraviolet lamp (260 nm, hand-held) **<!>**

Water bath or heating block preset to 55°C

Additional Reagents

Steps 7–9 of this protocol require the reagents listed in Chapter 12, Protocols 8 and 11.

METHOD

Preparation of Crude Synthetic Oligonucleotides for Gel Electrophoresis

1. In a sterile microfuge tube, prepare a 10 μM solution of the crude oligonucleotide in sterile, filtered H_2O (Milli-Q or equivalent). Vortex the solution thoroughly.

   The solution is often slightly cloudy because of the presence of insoluble benzamides generated during the synthesis of the oligonucleotide.

2. Centrifuge the tube at maximum speed for 5 minutes at room temperature in a microfuge. Transfer the supernatant to a fresh, sterile microfuge tube.

3. Extract the solution three times in succession with 400 μl of *n*-butanol (please see Appendix 8). Discard the upper (organic) phase after each extraction.

   If time is short, the extraction with *n*-butanol can be omitted without necessarily causing problems. In this case, centrifuge the solution at maximum speed for 5 minutes at room temperature in a microfuge, and transfer the supernatant to a fresh, sterile microfuge tube. Load 10–30 μl of this solution onto each of six slots (1-cm) of a denaturing polyacrylamide gel as described later in this protocol.

4. Evaporate the solution to dryness in a centrifugal evaporator (Savant SpeedVac or its equivalent). The tube should contain a yellowish pellet and a creamy-white powder.

5. Dissolve the pellet and powder in 200 μl of sterile filtered H_2O (Milli-Q or equivalent).

6. Estimate the amount of oligonucleotide in the preparation as follows: Add 1 μl of the solution to 1 ml of H_2O. Mix the solution well and read the OD_{260}. Calculate the oligonucleotide concentration.

   Amounts of oligonucleotides are often described in OD units. One OD corresponds to the amount of oligonucleotide in a 1-ml volume that results in an optical density of 1 in a 1-cm path-length cuvette.

   Calculate the millimolar extinction coefficient of the oligonucleotide (ε) from the following equation:

   $$\varepsilon = A(15.2) + G(12.01) + C(7.05) + T(8.4)$$

   where *A*, *G*, *C*, and *T* are the number of times each nucleotide is represented in the sequence of the oligonucleotide. The numbers in parentheses are the molar extinction coefficients for each deoxynucleotide at pH 8.0.

For example, a 19-mer containing 5 dA residues, 4 dG residues, 4 dC residues, and 6 dT residues would have a millimolar extinction coefficient of

$$(5 \times 15.2) + (4 \times 12.01) + (4 \times 7.05) + (6 \times 8.4) = 202.64\ mM^{-1}\ cm^{-1}$$

Calculate the concentration (c) of the undiluted solution of oligonucleotide from the following equation:

$$c = (OD_{260})(1000)/\varepsilon$$

Purification of Synthetic Oligonucleotides Using Gel Electrophoresis

7. Pour a denaturing polyacrylamide gel (as described in Chapter 12, Protocol 8) of the appropriate concentration (Table 10-2). The loading slots in the gel should be ~1 cm in length.
8. Run the gel at constant wattage (50–70 W) for ~45 minutes or until the temperature of the gel reaches 45–50°C. Turn off the power supply and disconnect the electrodes.

   Prerunning the gel in this way causes ammonium persulfate to migrate from the wells and, more importantly, warms the gel to a temperature optimal for electrophoresis of DNA.
9. Without delay, load ~2 OD_{260} units of oligonucleotide (in a volume of 10 µl or less for maximum resolution) onto one or more slots of the gel as follows:
   a. Add an equal volume of formamide gel-loading buffer lacking dyes to the oligonucleotide solution. Mix the reagents well by vortexing, and then heat the mixture to 55°C for 5 minutes to disrupt secondary structure.
   b. Flush out the urea from the wells with 1x TBE.
   c. Load the heated oligomer into the slots. Load 5 µl of formamide-tracking dye mixture into an unused slot.

      For further details on loading polyacrylamide gels, please see Chapter 12, Protocol 11.
10. Run the gel at 1500 V until the oligonucleotide has migrated approximately two thirds of the length of the gel.

    The position of the oligonucleotide may be estimated from the positions of the tracking dyes as detailed in Table 10-3. Note that a synthetic oligonucleotide carrying a hydroxyl residue at its 5′ terminus migrates more slowly through a denaturing polyacrylamide gel than does a phosphorylated oligonucleotide of equivalent length. Furthermore, for reasons that are not fully understood, the electrophoretic mobility of an oligonucleotide is dependent on its base composition and sequence. Thus, there may not be an exact correspondence between the predicted and observed positions of the oligonucleotide in the polyacrylamide gel.
11. Lay the gel mold flat on plastic-backed protective bench paper with the smaller (notched) plate uppermost. Allow the gel to cool to <37°C before proceeding.
12. Remove any remaining pieces of electrical tape. Use a spacer or a plate-separating tool to slowly and gently pry apart the plates of the mold. The gel should remain attached to the longer (nonsiliconized) glass plate.

    ▲ **WARNING** Wear safety glasses. Glass plates may chip during this procedure.

TABLE 10-2 Range of Resolution of Gels Containing Different Concentrations of Acrylamide

Acrylamide (%)	Size of Oligonucleotides (in Bases)
20–30	2–8
15–20	8–25
13–15	15–35
10–13	35–45
8–10	45–70
6–8	70–300

TABLE 10-3 Approximate Lengths of Oligonucleotides Comigrating with Tracking Dyes

POLYACRYLAMIDE (%)	XYLENE CYANOL FF	BROMOPHENOL BLUE
20	22	6
15	30	9–10
12	40	~15

If the gel adheres to both plates, replace the partially dislodged, smaller or notched plate back on the gel, invert the plates, and try again.

13. Place a piece of Saran Wrap on the gel, turn the glass plate over, and transfer the gel to the Saran Wrap. Place a piece of Parafilm or a fluorescent thin-layer chromatographic plate under the gel where the oligonucleotide is predicted to be.

14. Use a hand-held UV lamp to examine the gel by illumination from above at 260 nm.

    The DNA in the gel absorbs the UV radiation and appears as dark blue bands against a uniform fluorescent background contributed by the Parafilm or chromatographic plate. If the DNA is difficult to visualize, take the gel into a darkened room and illuminate it with the hand-held UV lamp.

15. Recover the desired oligonucleotide, which should be the slowest-migrating band (i.e., closest to the top of the gel), by excising each DNA band with a sharp, clean scalpel or razor blade. Avoid taking UV-absorbing material smaller in length than the desired oligonucleotide.

    For additional information on excising the desired band of DNA, please see the panel on **VISUALIZING OLIGONUCLEOTIDES IN POLYACRYLAMIDE GELS** at the end of this protocol.

16. Transfer the gel slices to three or four microfuge tubes. Add 1 ml of oligonucleotide elution buffer to each tube. Crush the slices with a disposable pipette tip, using a circular motion and pressing the fragments of gel against the sides of the tubes. Seal the tubes well. Incubate the tubes for 12 hours at 37°C in a shaker incubator.

    Inclusion of SDS in the elution buffer can sometimes lead to the appearance of a whitish precipitate after drying down fractions 2 and 3 from the Sep-Pak column used in the final stage of this protocol. This precipitate is most likely SDS, which binds to the column and elutes slightly after the oligonucleotide during washing with methanol:H_2O. As long as no SDS is present with the oligonucleotide (fraction 1), the detergent will not cause problems and may improve yields. However, if even a small amount of SDS ends up in the oligonucleotide fraction, then it can inhibit subsequent enzymatic reactions (e.g., phosphorylation and primer extension). It is for this reason that SDS *should not be included* in the elution buffer.

17. Centrifuge the tubes at maximum speed for 5 minutes at room temperature in a microfuge. Pool the supernatants, transfer them to a 5-cc disposable syringe and pass them through a Millex HV filter. Collect the effluent in a 15-ml polypropylene tube.

Isolation of Synthetic Oligonucleotides by Sep-Pak C_{18} Chromatography

18. Prepare a Sep-Pak C_{18} reversed-phase column as follows:

    a. Attach the barrel of a disposable 10-cc polypropylene syringe to the longer end of a Sep-Pak C_{18} classic column.

    b. Add 10 ml of acetonitrile to the barrel and slowly push it through the column with the plunger of the syringe.

    c. *Remove the syringe from the Sep-Pak column* and *then* take the plunger out of the barrel. This prevents air being pulled back into the column. Reattach the barrel to the column.

    d. Add 10 ml of sterile filtered H_2O (Milli-Q or equivalent) to the barrel and slowly push it through the column with the plunger. Repeat Step c.

e. Add 2 ml of 10 mM ammonium acetate to the barrel and push it slowly through the column. Again remove the syringe, remove the barrel, and reattach the barrel to the column. The column is now ready for use.

19. Add the solution containing the gel-purified oligonucleotide (from Step 17) to the barrel and slowly push it through the column with the plunger. Collect the effluent in a sterile 50-ml polypropylene tube. Repeat Step 18c.

20. Add 10 ml of H_2O to the barrel and push it slowly through the column with the plunger. Repeat this wash step twice more.

21. Elute the bound oligonucleotide from the Sep-Pak column with three aliquots of 1 ml of methanol:H_2O solution. Repeat Step 18c after each elution. Collect each effluent in a separate microfuge tube. Read the OD_{260} of the solution in each of the three microfuge tubes, using the methanol:H_2O solution as a blank. More than 90% of the oligonucleotide applied to the column should elute in the first fraction.

22. Evaporate the solution containing the oligonucleotide to dryness in a centrifugal evaporator.

23. Dissolve the oligonucleotide in a total volume of 200 µl of H_2O or TE (pH 8.0).

24. Transfer 5 µl of the solution to a cuvette containing 995 µl of H_2O. Mix the contents of the cuvette, and read the OD_{260} of the diluted sample. Calculate the amount of oligonucleotide present in the total solution (Step 23) as described in Step 6 of this protocol.

VISUALIZING OLIGONUCLEOTIDES IN POLYACRYLAMIDE GELS

Preparations of oligonucleotides that are <25 bases in length generally contain only one band that is strong enough to be detected by illuminating the gel with UV light. This is because the efficiency of each coupling step in the synthesis is remarkably high (usually ≥ 95%) in present-day automated DNA synthesizers. Truncated oligonucleotides may be visible if the efficiency of coupling decreases below 80% at one or more steps during the synthesis, because of reagent contamination, a block in one of the delivery lines, exhaustion of a particular nucleotide phosphoramidite, or an unusual secondary structure in the oligonucleotide. Products of incomplete synthesis are detected as faster-migrating species, whose lengths correspond to the synthetic step at which difficulty was encountered. Occasionally, a small number of faster-migrating products are detected whose absorbance is equal to or greater than the full-length synthetic product. Provided enough full-length product is detected, the shorter products can be ignored. If not, then larger amounts of the DNA preparation must be used to purify the oligonucleotide of interest.

Preparations of very long oligonucleotides may contain a ladder of prematurely truncated species extending upward from ~30 nucleotides in size. The slowest-migrating species is usually the desired product. Very occasionally, however, an oligonucleotide may migrate anomalously, traveling further through the gel than its shorter siblings. Keep in mind that sequence differences between the members of pools of redundant oligonucleotides can cause individual DNAs to migrate at slightly different rates, giving rise to a single broad band or to a cluster of closely spaced bands. In these situations, when the spacing of bands is anomalous, or the bands are smeared, it is best to take a conservative approach by extracting all closely spaced bands from the relevant region of the gel.

If a broad smear of bands of approximately equal intensity is produced when purifying an oligonucleotide of unique sequence, it is best to resynthesize the oligonucleotide. In this case, the efficiency of coupling can sometimes be checked by reading the concentration of trityl groups at different stages of the synthetic reaction. However, because of the large numbers of oligonucleotides produced, most core facilities do not keep records of the trityl concentrations even though the synthesizer may be equipped with an in-line measuring device.

Finally, keep in mind that the detection limit for UV light shadowing is ~0.5 OD_{260} unit. If amounts of oligonucleotide less than this quantity are to be purified (e.g., when purifying oligonucleotides >70 bases), consider radiolabeling the preparation by phosphorylation as described in Protocol 2.

Protocol 2

Phosphorylating the 5′ Termini of Oligonucleotides

SYNTHETIC OLIGONUCLEOTIDES LACK PHOSPHATE GROUPS at their 5′ termini and therefore are easily radiolabeled by transferring the γ-^{32}P from [γ-^{32}P]ATP in a reaction catalyzed by bacteriophage T4 polynucleotide kinase. Oligonucleotides radiolabeled in this way are used as hybridization probes, primers for DNA sequencing and 5′-end mapping of mRNAs, and primers for analysis of polymorphic microsatellite markers in mammalian DNA.

When the reaction is carried out under standard conditions, >50% of the oligonucleotide molecules become radiolabeled. However, for reasons that are unknown, the efficiency of radiolabeling of oligonucleotides depends on the sequence of the oligonucleotide (van Houten et al. 1998). Oligonucleotides with a cytosine residue at their 5′ termini are labeled fourfold less efficiently than oligonucleotides beginning with A or T, and sixfold less efficiently than oligonucleotides beginning with G. When designing oligonucleotide probes, it clearly pays to ensure that the 5′-terminal position is not occupied by a cytosine residue.

The reaction described here is designed to label 10 pmoles of an oligonucleotide to high specific activity. Labeling of different amounts of oligonucleotide can easily be achieved by increasing or decreasing the size of the reaction, while keeping the concentrations of all components constant. Similar reaction conditions can be used to add a nonradiolabeled phosphate to the 5′ end of a synthetic oligonucleotide before its use in site-directed mutagenesis (please see Chapter 13, Protocols 2–6).

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

10x Bacteriophage T4 polynucleotide kinase buffer
Tris-Cl (1 M, pH 8.0)

Enzymes and Buffers

Bacteriophage T4 polynucleotide kinase
Wild-type polynucleotide kinase is a 5′-phosphotransferase and a 3′-phosphatase (Depew and Cozzarelli 1974; Sirotkin et al. 1978). However, mutant forms of the enzyme (e.g., please see Cameron et al. 1978)

are commercially available (e.g., Boehringer Mannheim) that lack the phosphatase activity but retain a fully functional phosphotransferase. We recommend that the mutant form of the enzyme be used for 5′ labeling whenever possible; 10–20 units of the enzyme are required to catalyze the phosphorylation of 10–50 pmoles of dephosphorylated 5′-protruding termini.

▲ **IMPORTANT** Be aware that preparations of polynucleotide kinase sold by different manufacturers have been reported to vary widely in their ability to catalyze the phosphorylation of the 5′ termini of single-stranded synthetic oligonucleotides (van Houten et al. 1998).

Nucleic Acids and Oligonucleotides

Oligonucleotide

To achieve maximum efficiency of labeling, purify the oligonucleotide by reversed-phase chromatography as described in Protocol 1. Crude preparations of oligonucleotides are labeled with lower efficiency in reactions catalyzed by polynucleotide kinase (van Houten et al. 1998). When using unpurified preparations of oligonucleotide, make sure that the last cycle of synthesis was programmed to be "trityl-off," i.e., that the dimethoxytrityl blocking group at the 5′ end of the oligonucleotide primer was removed before release of the DNA from the solid synthesis support. The dimethoxytrityl group efficiently protects the 5′-hydroxyl group of the oligonucleotide from 5′ modification.

Radioactive Compounds

[γ-^{32}P]ATP (10 mCi/ml, sp. act. >5000 Ci/mmole) in aqueous solution **<!>**

10 pmoles of [γ-^{32}P]ATP is required to label 10 pmoles of dephosphorylated 5′ termini to high specific activity. To minimize problems caused by radiolysis of the precursor and the probe, it is best, whenever possible, to prepare radiolabeled probes on the day the [^{32}P]ATP arrives in the laboratory.

Special Equipment

Microfuge tubes (0.5 ml)
Water bath preset to 68°C

Additional Reagents

Step 4 of this protocol requires the reagents listed in Chapter 13, Protocol 7 or the reagents listed in Protocol 5 of this chapter.

METHOD

1. Set up a reaction mixture in a 0.5-ml microfuge tube containing:

synthetic oligonucleotide (10 pmoles/μl)	1 μl
10x bacteriophage T4 polynucleotide kinase buffer	2 μl
[γ-^{32}P]ATP (10 pmoles, sp. act. >5000 Ci/mmole)	5 μl
H_2O	11.4 μl

Mix the reagents well by gentle but persistent tapping on the outside of the tube. Place 0.5 μl of the reaction mixture in a tube containing 10 μl of 10 mM Tris-Cl (pH 8.0). Set aside the tube for use in Step 4.

The reaction contains equal concentrations of [γ-^{32}P]ATP and oligonucleotide. Generally, only 50% of the radiolabel is transferred to the oligonucleotide. The *efficiency of transfer* can be improved by increasing the concentration of oligonucleotide in the reaction by a factor of 10. This increase results in transfer of ~90% of the radiolabel to the oligonucleotide. However, the *specific activity* of the radiolabeled DNA is reduced by a factor of ~5. To label an oligonucleotide to the highest specific activity:

- Increase the concentration of [γ-^{32}P]ATP in the reaction by a factor of 3 (i.e., use 15 μl of radiolabel and decrease the volume of H_2O to 1.4 μl).
- Decrease the amount of oligonucleotide to 3 pmoles.

Under these circumstances, only ~10% of the radiolabel is transferred, but a high proportion of the oligonucleotide becomes radiolabeled.

Ideally, ATP should be in a fivefold molar excess over DNA 5′ ends, and the concentration of DNA termini should be ≥0.4 μM. The concentration of ATP in the reaction should therefore be >2 μM, but this is rarely achievable in practice.

2. Add 10 units (~1 μl) of bacteriophage T4 polynucleotide kinase to the remaining reaction mixture. Mix the reagents well, and incubate the reaction mixture for 1 hour at 37°C.

3. At the end of the incubation period, place 0.5 μl of the reaction in a second tube containing 10 μl of 10 mM Tris-Cl (pH 8.0). Heat the remainder of the reaction for 10 minutes at 68°C to inactivate the polynucleotide kinase. Store the tube containing the heated reaction mixture on ice.

4. Before proceeding, determine whether the labeling reaction has worked well by measuring the fraction of the radiolabel that has been transferred to the oligonucleotide substrate in a small sample of the reaction mixture. Transfer a sample of the reaction (exactly 0.5 μl) to a fresh tube containing 10 μl of 10 mM Tris-Cl (pH 8.0). Use this sample (along with the two aliquots set aside in Steps 1 and 3) to measure the efficiency of transfer of the γ-^{32}P from ATP by one of the following methods:

   - Measure the proportion of the radiolabel that binds to DE-81 filters. Oligonucleotides bind tightly to the positively charged filters, whereas [γ-^{32}P]ATP does not. For details of this method, please see Chapter 13, Protocol 7.

     or

   - Measure the efficiency of the labeling reaction by estimating the fraction of label that migrates with the oligonucleotide during size-exclusion chromatography through Sephadex G-15 or Bio-Rad P-60 columns. For details of this method, please see Protocol 5 of this chapter. In some ways, this is the easier of the two methods because the relative amounts of incorporated and unincorporated radioactivity can be estimated during chromatography on a hand-held minimonitor.

5. If the specific activity of the oligonucleotide is acceptable, purify the radiolabeled oligonucleotide as described in Protocol 3, 4, 5, or 6.

   If the specific activity is too low, add an additional 8 units of polynucleotide kinase, continue incubation for a further 30 minutes at 37°C (i.e., a total of 90 minutes), heat the reaction for 10 minutes at 68°C to inactivate the enzyme, and analyze the products of the reaction again, as described in Step 4.

   If an additional round of phosphorylation fails to yield an oligonucleotide of sufficiently high specific activity for the tasks at hand, check whether the oligonucleotide contains a cytosine residue at its 5′ terminus. If so, consider redesigning the oligonucleotide so that it contains a G, A, or T residue at its 5′ end (please see the introduction to this protocol). Alternatively, try purifying the original preparation of oligonucleotide by Sep-Pak chromatography (Protocol 1), and then repeat this protocol.

Protocol 3

Purification of Radiolabeled Oligonucleotides by Precipitation with Ethanol

IF RADIOLABELED OLIGONUCLEOTIDES ARE TO BE USED ONLY AS PROBES in hybridization experiments, then complete removal of unincorporated radiolabel is generally not necessary. However, to reduce background to a minimum, the bulk of the unincorporated radioactivity should be separated from the radiolabeled oligonucleotide. Most of the residual radioactive precursors can be removed from the preparation by differential precipitation with ethanol if the oligonucleotide is more than 18 nucleotides in length (this protocol) or with cetylpyridinium bromide, regardless of the length of the oligonucleotide (Protocol 4). If complete removal of the unincorporated radiolabel is required (e.g., when the radiolabeled oligonucleotide will be used in primer extension reactions), then chromatographic methods (Protocols 5 and 6) or gel electrophoresis (essentially as described in Protocol 1) should be used.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Ammonium acetate (10 M)
Ethanol
TE (pH 7.6)

Nucleic Acids and Oligonucleotides

Radiolabeled oligonucleotide <!>
The starting material for purification is the reaction mixture from Protocol 2 (either Step 3 or Step 5), after it has been heated to 68°C to inactivate bacteriophage T4 polynucleotide kinase.

METHOD

1. Add 40 µl of H_2O to the tube containing the radiolabeled oligonucleotide. After mixing, add 240 µl of a 5 M solution of ammonium acetate. Mix the reagents again and then add 750 µl of ice-cold ethanol. Mix the reagents once more and store the ethanolic solution for 30 minutes at 0°C.

   Ammonium acetate is used in place of sodium acetate to ensure more effective removal of unincorporated ribonucleotides. The solubility constant of ribonucleotides (and deoxyribonucleotides) is higher in ethanolic ammonium acetate solutions than in ethanolic sodium acetate solutions. Unincorporated ribonucleotides remain in the ethanolic phase of the precipitation reaction.

2. Recover the radiolabeled oligonucleotide by centrifugation at maximum speed for 20 minutes at 4°C in a microfuge.

3. Use a micropipettor equipped with a disposable tip to remove all of the supernatant carefully from the tube.

   ▲ **WARNING** The supernatant contains most of the unincorporated [γ-^{32}P]ATP. Phosphorylation reactions are often carried out with >100 µCi of radiolabeled ATP, so the amount of radioactivity in the supernatant may be considerable. Exercise care and be diligent about disposal of unincorporated radioactivity, pipette tips, and microfuge tubes.

4. Add 500 µl of 80% ethanol to the tube, tap the side of the tube to rinse the nucleic acid pellet, and centrifuge the tube again at maximum speed for 5 minutes at 4°C in a microfuge.

5. Use a micropipettor equipped with a disposable tip to remove the supernatant (which will contain appreciable amounts of radioactivity) carefully from the tube. Stand the open tube behind a Plexiglas screen until the residual ethanol has evaporated.

6. Dissolve the radiolabeled oligonucleotide in 100 µl of TE (pH 7.6).

   The radiolabeled oligonucleotide may be stored for a few days at –20°C. However, during prolonged storage, decay of ^{32}P causes radiochemical damage that can impair the ability of the oligonucleotide to hybridize to its target sequence.

Protocol 4

Purification of Radiolabeled Oligonucleotides by Precipitation with Cetylpyridinium Bromide

THIS PROTOCOL DESCRIBES THE SEPARATION OF RADIOLABELED OLIGONUCLEOTIDES from unincorporated radiolabel by quantitative differential precipitation of the oligonucleotides with the cationic detergent cetylpyridinium bromide (CPB). The method, which was originally devised to recover DNA eluted from hydroxyapatite columns in phosphate buffers (Geck and Nász 1983), can also be used to precipitate radiolabeled nucleic acids, including oligonucleotides, from labeling reactions. The nucleic acids are first precipitated from aqueous solution with CPB. The detergent is then removed from the precipitate with ethanol (in which the nucleic acids are insoluble), and the nucleic acids are finally dissolved in the buffer of choice. The method is extremely rapid, efficient, and works well in a variety of circumstances, for example, RNA generated by in vitro transcription reactions with bacteriophage polymerases and oligonucleotides from phosphorylation reactions. However, the technique suffers from one possible disadvantage — the need to use carrier DNA to increase the efficiency with which the labeled oligonucleotides are precipitated by CPB. For most purposes, the presence of the unlabeled carrier DNA in the final preparation of radiolabeled oligonucleotide is either irrelevant or an advantage (e.g., if the radiolabeled oligonucleotide is to be used as a probe). However, in certain specialized cases (e.g., when a radiolabeled oligonucleotide is to be used in primer-extension reactions or DNA sequencing reactions), the presence of carrier DNA may cause complications. In these cases, we recommend that the oligonucleotide be purified by electrophoresis through a 20% polyacrylamide gel (essentially as described in Protocol 1), by chromatography through Bio-Gel P-60 (Protocol 5), or by Sep-Pak column chromatography (Protocol 6). The following protocol, provided by Ray MacDonald and Galvin Swift (University of Texas Southwestern Medical Center, Dallas), is a modification of the original method of Geck and Nász (1983).

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Cetylpyridinium bromide (CPB) (1%, w/v)

Dissolve 1 g of CPB (Sigma) in 100 ml of H_2O. To speed dissolution, heat the solution on a hot plate while agitating it with a magnetic stirrer. After all of the detergent has dissolved, cool the solution to room temperature and filter it through a nitrocellulose filter (0.45-µm pore size).

EDTA-Tris (0.5 M, pH 6.0)

Add 0.1 mole of EDTA to 60 ml of H_2O. While stirring the solution, slowly add Tris base (powder) until the pH of the solution reaches 6.0. By this stage, the concentration of Tris will be ~1.2 M. Adjust the volume of the solution to 200 ml with H_2O. This unconventional method of preparing this solution may be essential for efficient precipitation of nucleic acids with cationic detergents (Sibatani 1970).

EDTA-Tris-DNA solution

Dissolve carrier DNA (e.g., salmon sperm DNA) at a concentration of 50 µg/ml in 50 mM EDTA-Tris (pH 6.0) (i.e., a 1:10 dilution of the 0.5 M EDTA-Tris solution). The DNA used as carrier should be of fairly uniform size and not interfere with the hybridization of the radiolabeled nucleic acid to its target DNA. For most purposes, sonicated or fractionated salmon sperm DNA works well (sonicated salmon sperm DNA 600–5000 bp in length is available from Pharmacia or may be prepared as described in Chapter 6, Protocol 10).

Ethanol–sodium acetate solution

80% (v/v) ethanol

20% (v/v) sodium acetate (0.1 M, pH 5.2)

TE (pH 7.6) or an appropriate prehybridization solution

Please see Step 8.

Nucleic Acids and Oligonucleotides

Radiolabeled oligonucleotide **<!>**

The starting material for purification is the reaction mixture from Protocol 2 (either Step 3 or Step 5), after it has been heated to 68°C to inactivate bacteriophage T4 polynucleotide kinase.

Special Equipment

Dry-ice/ethanol bath **<!>**

METHOD

1. Add 5–10 volumes of the EDTA-Tris-DNA solution to a microfuge tube containing the solution of radiolabeled oligonucleotide. Mix the reagents well.

   For precipitation to be efficient, it is important that the ionic composition of the final mixture be predominantly that of the EDTA-Tris-DNA solution. The final volume of the mixture and the concentration of the radiolabeled oligonucleotide do not appreciably affect the efficiency of the procedure.

2. Add sufficient 1% CPB to the tube to bring the concentration of the detergent in the mixture to 0.1%. Mix well.

3. Place the tube in a dry-ice/ethanol bath until the mixture is frozen. Remove the tube from the bath, and allow the mixture to thaw at room temperature.

4. Centrifuge the solution at maximum speed for 5 minutes at 4°C in a microfuge. Use a Pasteur pipette or a micropipettor equipped with a blue disposable tip to remove all of the supernatant carefully from the tube.

   ▲ **WARNING** The supernatant contains most of the unincorporated [γ-^{32}P]ATP. Phosphorylation reactions are often carried out with >100 μCi of radiolabeled ATP, so the concentration of radioactivity in the supernatant may be considerable. Exercise care and be diligent about disposal of unincorporated radioactivity, pipette tips, and microfuge tubes.

5. Add 500 μl of distilled H_2O to the tube, vortex the mixture for 20 seconds, and again centrifuge the solution as in Step 4.

6. Remove the supernatant from the tube and add 500 μl of the ethanol–sodium acetate solution to the pellet. Vortex the mixture for 15 seconds and then centrifuge the solution at maximum speed for 2 minutes at room temperature in a microfuge.

7. Repeat Step 6.

8. Carefully remove the supernatant and stand the open tube on the bench behind a Plexiglas screen until the last visible traces of ethanol have evaporated. Dissolve the precipitated oligonucleotide in 20–50 μl of TE (pH 7.6) or in a small volume of prehybridization solution if the radiolabeled oligonucleotide is to be used as a probe.

Protocol 5

Purification of Radiolabeled Oligonucleotides by Size-exclusion Chromatography

WHEN RADIOLABELED OLIGONUCLEOTIDES ARE TO BE USED in enzymatic reactions such as primer extension, virtually all of the unincorporated radiolabel must be removed from the oligonucleotide. For this purpose, chromatographic methods (this protocol and Protocol 6) or gel electrophoresis (essentially as described in Protocol 1) are superior to differential precipitation of the oligonucleotide with ethanol or CPB. This protocol describes a method to separate radiolabeled oligonucleotides from unincorporated radiolabel that takes advantage of differences in mobility between oligonucleotides and mononucleotides during size-exclusion chromatography.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Chloroform **<!>**
Optional, please see Step 7.
EDTA (0.5 M, pH 8.0)
Ethanol
Phenol:chloroform **<!>**
Optional, please see Step 7.
Sodium acetate (3 M, pH 5.2)
Optional, please see Step 7.
TE (pH 7.6)
Tris-Cl (1 M, pH 8.0)
Optional, please see Step 7.
Tris-SDS chromatography buffer
10 mM Tris-Cl (pH 8.0)
0.1% (w/v) SDS

Nucleic Acids and Oligonucleotides

Radiolabeled oligonucleotide **<!>**
The starting material for purification is the reaction mixture from Protocol 2 (either Step 3 or Step 5), after it has been heated to 68°C to inactivate bacteriophage T4 polynucleotide kinase.

Special Equipment

Gel filtration resin (e.g., Bio-Gel P-60 fine-grade or Sephadex G-15)

Bio-Gel P-60 (fine grade) may be purchased from Bio-Rad. Sephadex G-15 is available from most suppliers of laboratory chemicals (e.g., Sigma). Bio-Gel P-60 is supplied as a pre-swollen gel; Sephadex G-15 must be swollen and equilibrated before use.

Glass wool

Wrap a small amount of glass wool in aluminum foil and autoclave the package at 15 psi (1.05 kg/cm^2) for 15 minutes on wrapped item cycle.

Microfuge tubes (1.5 ml) in a rack or fraction collector

Used for the collection of radiolabeled oligonucleotides eluting from the column.

Pasteur pipette

Additional Reagents

Step 6 of this protocol may require the reagents listed in Chapter 13, Protocol 7.

METHOD

1. Add 30 µl of 20 mM EDTA (pH 8.0) to the tube containing the radiolabeled oligonucleotide. Store the solution at 0°C while preparing a column of size-exclusion chromatography resin.

   For convenience, Bio-Gel P-60 is used throughout this protocol as an example of a suitable resin. However, the method works equally well with Sephadex G-15.

2. Prepare a Bio-Gel P-60 column in a sterile Pasteur pipette.

   a. Equilibrate the slurry of Bio-Gel P-60 supplied by the manufacturer in 10 volumes of Tris-SDS chromatography buffer.

      If a centrifugal evaporator (Savant SpeedVac or its equivalent) is available, the Bio-Gel P-60 column may be poured and run in a solution of 0.1% ammonium bicarbonate. The pooled fractions containing the radiolabeled oligonucleotide (please see Step 6) can then be evaporated to dryness in a centrifugal evaporator, thereby eliminating the need for extraction of the oligonucleotide preparation with organic solvents and precipitation with ethanol.

   b. Tamp a sterile glass wool plug into the bottom of a sterile Pasteur pipette.

      A glass capillary tube works well as a tamping device.

   c. With the plug in place, pour a small amount of Tris-SDS chromatography buffer into the column and check that the buffer flows at a reasonable rate (one drop every few seconds).

   d. Fill the pipette with the Bio-Gel P-60 slurry. The column forms rapidly as the gel matrix settles under gravity and the buffer drips from the pipette. Add additional slurry until the packed column fills the pipette from the plug of glass wool to the constriction near the top of the pipette.

   e. Wash the column with 3 ml of Tris-SDS chromatography buffer.

      ▲ **IMPORTANT** Do not allow the column to run dry. If necessary, seal the column by wrapping a piece of Parafilm around the bottom of the pipette.

3. Use a pipette to remove excess buffer from the top of the column, and then rapidly load the radiolabeled oligonucleotide (in a volume of 100 µl or less) onto the column.

4. Immediately after the sample has entered the column, add 100 µl of buffer to the top of the column. As soon as the buffer has entered the column, fill the pipette with buffer. Replenish

the buffer as necessary so that it continuously drips from the column. Do not allow the column to run dry.

5. Use a hand-held minimonitor to follow the progress of the radiolabeled oligonucleotide. When the radioactivity first starts to elute from the column, begin collecting two-drop fractions into microfuge tubes.

   ▲ **WARNING** Because phosphorylation reactions are often carried out with >100 μCi of radiolabeled ATP, the amount of radioactivity in these column fractions may be considerable. Exercise care and be diligent about disposal of unincorporated radioactivity, pipette tips, and microfuge tubes.

6. When nearly all of the radioactivity has eluted from the column, use a liquid scintillation counter to measure the radioactivity in each fraction by Cerenkov counting (please see Appendix 8). If there is a clean separation of the faster-migrating peak (the radiolabeled oligonucleotide) from the slower peak of unincorporated [γ-^{32}P]ATP, pool the samples containing the radiolabeled oligonucleotide. If the peaks are not well separated, analyze ~0.5 μl of every other fraction either by adsorption to DE-81 filters (please see Chapter 13, Protocol 7, Step 3) or by thin-layer chromatography. Pool those fractions containing radiolabeled oligonucleotide that do not contain appreciable amounts of unincorporated [γ-^{32}P]ATP.

7. If the radiolabeled oligonucleotide is to be used in enzymatic reactions, then proceed as follows. Otherwise, proceed to Step 8.

   a. Extract the pooled fractions with an equal volume of phenol:chloroform.

   b. Back-extract the organic phase with 50 μl of 10 mM Tris-Cl (pH 8.0), and combine the two aqueous phases.

   c. Extract the combined aqueous phases with an equal volume of chloroform.

   d. Add 0.1 volume of 3 M sodium acetate (pH 5.2), mix well, and add 3 volumes of ethanol. Incubate the sample for 30 minutes at 0°C, and then centrifuge it at maximum speed for 20 minutes at 4°C in a microfuge. Use a micropipettor equipped with a disposable tip to remove the ethanol (which should contain very little radioactivity) from the tube.

8. Add 500 μl of 80% ethanol to the tube, vortex it briefly, and centrifuge the tube again at maximum speed for 5 minutes in a microfuge.

9. Use a micropipettor equipped with a disposable tip to remove the ethanol from the tube. Stand the open tube behind a Plexiglas screen until the residual ethanol has evaporated.

10. Dissolve the precipitated oligonucleotide in 20 μl of TE (pH 7.6) and store it at –20°C.

Protocol 6

Purification of Radiolabeled Oligonucleotides by Chromatography on a Sep-Pak C_{18} Column

THIS PROTOCOL, WHICH IS A MODIFICATION OF PROCEDURES described by Lo et al. (1984), Sanchez-Pescador and Urdea (1984), and Zoller and Smith (1984), describes a method for the separation of radiolabeled oligonucleotides from unincorporated radiolabel that takes advantage of the reversible affinity of oligonucleotides for silica gel.

This protocol can be used only to purify oligonucleotides carrying a 5′-phosphate group, radiolabeled or unlabeled. The method described in Protocol 1 should be used to purify oligonucleotides with free 5′-hydroxyl groups.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Acetonitrile (5%, 30%, and 100%) **<!>**

Use 10 ml HPLC-grade acetonitrile (100%) for each Sep-Pak column. Prepare the diluted solutions of acetonitrile in H_2O just before use.

Ammonium bicarbonate (25 mM, pH 8.0)

Ammonium bicarbonate (25 mM, pH 8.0) containing 5% (v/v) acetonitrile

Mix 5 ml of acetonitrile with 95 ml of 25 mM ammonium bicarbonate.

TE (pH 7.6)

Nucleic Acids and Oligonucleotides

Radiolabeled oligonucleotide **<!>**

The starting material for purification is the reaction mixture from Protocol 2 (either Step 3 or Step 5), after it has been heated to 68°C to inactivate bacteriophage T4 polynucleotide kinase.

Special Equipment

Centrifugal evaporator (Savant SpeedVac or equivalent)

Microfuge tubes (1.5 ml) in a rack or fraction collector

Used for the collection of radiolabeled oligonucleotides eluting from the column.

Sep-Pak classic columns, short body

Sep-Pak classic columns (available from the Waters Division of Millipore) contain 360 mg/column of a hydrophobic (C_{18}) reversed-phase chromatography resin. The separation principle makes use of the fact that the oligonucleotide adsorbs to the column when the polarity of the solvent is high (e.g., aqueous buffers) and elutes from the column when the polarity of the solvent is reduced (e.g., a mixture of methanol and H_2O). A separate column is required for each phosphorylation reaction.

Syringe (10-cc polypropylene)

METHOD

1. Prepare a Sep-Pak C_{18} reversed-phase column as follows:
   - **a.** Attach a polypropylene syringe containing 10 ml of acetonitrile to a Sep-Pak C_{18} column.
   - **b.** Slowly push the acetonitrile through the Sep-Pak column.
   - **c.** *Remove the syringe from the Sep-Pak column* and *then* take the plunger out of the barrel. This prevents air being pulled back into the column. Reattach the barrel to the column.
   - **d.** Flush out the organic solvent with two 10-ml aliquots of sterile H_2O. Repeat Step c after each wash.
2. Dilute the radiolabeled oligonucleotide preparation to 1.5 ml with sterile H_2O, and apply the entire sample to the column through the syringe.
3. Wash the Sep-Pak column with the following four solutions. Repeat Step 1c after each wash.

   10 ml of 25 mM ammonium bicarbonate (pH 8.0)
   10 ml of 25 mM ammonium bicarbonate/5% acetonitrile
   10 ml of 5% acetonitrile
   10 ml of 5% acetonitrile
4. Elute the radiolabeled oligonucleotide with three 1-ml aliquots of 30% acetonitrile. Collect each fraction in a separate 1.5-ml microfuge tube. Repeat Step 1c after each elution.

   ▲ **WARNING** Because phosphorylation reactions are often carried out with >100 µCi of radiolabeled ATP, the amount of radioactivity in these column fractions may be considerable. Exercise care and be diligent about disposal of unincorporated radioactivity, pipette tips, and microfuge tubes.
5. Recover the oligonucleotide by evaporating the eluate to dryness in a centrifugal evaporator (Savant SpeedVac or its equivalent).
6. Dissolve the radiolabeled oligonucleotide in a small volume (10 µl) of TE (pH 7.6).

Protocol 7

Labeling of Synthetic Oligonucleotides Using the Klenow Fragment of *E. coli* DNA Polymerase I

OLIGONUCLEOTIDES ARE USUALLY LABELED IN PHOSPHORYLATION REACTIONS catalyzed by bacteriophage T4 polynucleotide kinase (please see Protocol 2). For some purposes, however (e.g., when using oligonucleotides as probes in Southern hybridizations), it is important to radiolabel to a higher specific activity. At best, phosphorylation results in the incorporation of one atom of ^{32}P per molecule of oligonucleotide. Probes of higher specific activities can be obtained using the Klenow fragment of *E. coli* DNA polymerase I to synthesize a strand of DNA complementary to the synthetic oligonucleotide (Studencki and Wallace 1984; Ullrich et al. 1984b; for review, please see Wetmur 1991). A short primer is hybridized to an oligonucleotide template whose sequence is the complement of the desired radiolabeled probe. The primer is then extended using the Klenow fragment to incorporate [α-^{32}P]dNTPs in a template-directed manner. After the reaction, the template and product are separated by denaturation followed by electrophoresis through a polyacrylamide gel under denaturing conditions (please see Figure 10-1). With this method, it is possible to generate oligonucleotide probes that contain several radioactive atoms per molecule of oligonucleotide and to achieve specific activities as high as 2×10^{10} cpm/μg of probe.

In a modification of this radiolabeling procedure, longer probes can be synthesized from two oligonucleotides that contain complementary sequences at their 3′ termini (Ullrich et al. 1984a). Here, the two oligonucleotides are annealed via their complementary 3′ sequences and then extended with the Klenow fragment. Both strands are extended (and radiolabeled), resulting in a duplex that may be considerably longer than either of the two original oligonucleotides. Although this method requires two oligonucleotides, it has the advantage that both strands of the product are radiolabeled. Strand separation and purification by polyacrylamide gel electrophoresis are therefore no longer mandatory. Instead, the radiolabeled probes can be purified by chromatography through Sephadex G-15 or Bio-Gel P-60, essentially as described in Protocol 5 of this chapter. When planning an experiment of this type, please consider the following points:

- ***The specific activity of the [α-^{32}P]dNTPs in the reaction.*** The specific activity of a dNTP whose α-phosphate has been completely substituted by ^{32}P is ~9000 Ci/mmole. Preparations with lower specific activities contain a mixture of both ^{32}P-labeled and unlabeled molecules. Thus, if a single radiolabeled dNTP with a specific activity of 3000 Ci/mmole is included in the synthetic reaction and there are only three positions at which that nucleotide can be incorporated into the final product, an average of only one atom of ^{32}P will be present in each molecule of probe (i.e., the specific activity will be approximately equal to that of a probe labeled

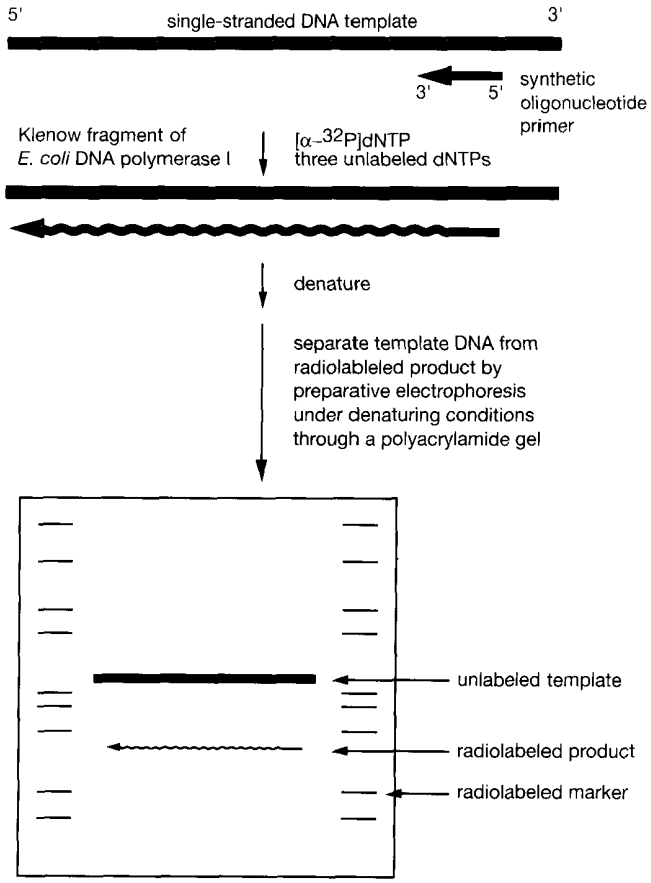

FIGURE 10-1 Labeling of Synthetic Oligonucleotide Using the Klenow Fragment of *E. coli* DNA Polymerase I

Please see text for details.

by bacteriophage T4 polynucleotide kinase). If the sequence of the desired probe and the specific activity of the available precursors are known, it is possible to predict the probe's specific activity when one, two, three, or all four [α-^{32}P]dNTPs are included in the reaction.

- ***The concentration of dNTPs in the reaction.*** Polymerization of nucleotides will not proceed efficiently unless the concentration of each dNTP in the reaction remains at 1 μM or greater (1 μM = ~0.66 ng/μl) throughout the course of the reaction. Calculate the total quantity of each dNTP that would be incorporated into the probe, assuming that all of the single-stranded sequences in the reaction are used as templates. The total amount of each dNTP in the reaction should be the sum of the amount that could be incorporated into the probe plus 0.66 ng/μl.

- ***The primer must be of sufficient length and specificity to bind to the template and promote synthesis at the appropriate position.*** Primers used for this purpose are usually 7–9 nucleotides long and are complementary to sequences at or close to the 3′ terminus of the template oligonucleotide. Because the stability of such short hybrids is difficult to predict, the ratio of primer to template that gives the maximum yield of full-length probe should be determined empirically before embarking on large-scale labeling reactions.

- ***The final product is a double-stranded fragment of DNA whose length is equal to or slightly less than that of the template (depending on the location of the sequences complementary to the primer).*** To be maximally effective as a probe, the unlabeled template strand must be efficiently separated from the complementary radiolabeled product; otherwise, the two complementary strands anneal to each other and the efficiency of hybridization to the desired target sequence is reduced. For oligonucleotides <30 nucleotides in length, electrophoresis through a 20% polyacrylamide gel is the most effective method to separate the complementary strands. The efficiency of the separation is improved if the lengths of the two strands are not exactly the same. Whenever possible, the primer should therefore be designed so that it is complementary to the *subterminal* nucleotides of the template. If the primer cannot hybridize to the two to three nucleotides at the 3′ terminus of the template, the radiolabeled product will be shorter than the unlabeled template and separate from it more effectively during electrophoresis. However, even when their lengths are identical, there is a good chance that the template and product strands will separate to some extent during electrophoresis since the rate of migration of single-stranded nucleic acids through gels is dependent not only on their length, but also on their base composition and sequence.

  The extent of separation can often be increased either by phosphorylating one of the two strands (template or primer) with nonradioactive ATP before synthesis of the probe (please see Protocol 2) or by leaving the dimethoxytrityl group attached to the 5′ terminus of the primer (Studencki and Wallace 1984). Because it is impossible to predict which method will be most effective for a given oligonucleotide, it is usually necessary to carry out a series of trial experiments to determine in each case the efficiency with which an extended product can be separated from the template.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Formamide loading buffer **<!>**
10x Klenow buffer

Enzymes and Buffers

Klenow fragment of E. coli *DNA polymerase I*

Gels

Denaturing polyacrylamide gel **<!>**

The percentage of polyacrylamide in the solution used to form the gel and the conditions under which electrophoresis is carried out vary according to the size of the oligonucleotides in the reaction mixture. Table 10-4 provides useful guidelines.

Polyacrylamide gels are usually cast in 1x TBE (89 mM Tris-borate, 2 mM EDTA), and electrophoresis is carried out in the same buffer. For further details of the methods used to cast and handle polyacrylamide gels, please see Protocol 1 and Chapter 12, Protocol 8.

TABLE 10-4 Percent Polyacrylamide Required to Resolve Oligonucleotides

LENGTH OF OLIGONUCLEOTIDE	POLYACRYLAMIDE (%)
12–15 nucleotides	20
25–35 nucleotides	15
35–45 nucleotides	12
45–70 nucleotides	10

Nucleic Acids and Oligonucleotides

Oligonucleotide primer

Purify the primer as described in Protocol 1. To ensure efficient radiolabeling, the primer should be in three- to tenfold molar excess over the template DNA in the reaction mixture.

Template oligonucleotide

Purify the template as described in Protocol 1. The sequence of the oligonucleotide template *should be the complement* of the desired radiolabeled probe.

Radioactive Compounds

[α-^{32}P]dNTPs <!>

To keep the substrate concentration high, perform the extension reaction in as small a volume as possible. Thus, it is best to use radiolabeled dNTPs supplied in ethanol/H_2O rather than those supplied in buffered aqueous solvents. Appropriate volumes of the ethanolic [α-^{32}P]dNTPs can be mixed and evaporated to dryness in the microfuge tube that will be used to carry out the reaction. To minimize problems caused by radiolysis of the precursor and the probe, it is best, whenever possible, to prepare radiolabeled probes on the day the [^{32}P]dNTP arrives in the laboratory.

Special Equipment

Phosphorescent adhesive labels (available from commercial sources) or adhesive labels marked with very hot radioactive ink <!>

Radioactive ink is made by mixing a small amount of ^{32}P with waterproof black drawing ink. For this protocol, the ink should be "very hot" (>2000 cps on a hand-held minimonitor). Use a fiber-tip pen to apply the ink to adhesive labels. Attach radioactive-warning tape to the pen, and store it in an appropriate place. Reusable alternatives to radioactive ink are chemiluminescent markers available from Stratagene (Glogos). The markers can be re-used many times but must be exposed to fluorescent light just before a new round of autoradiography.

Water bath or heating block preset to 80°C

Additional Reagents

Step 9 of this protocol requires reagents listed in Chapter 5, Protocol 12.

METHOD

1. Transfer to a microfuge tube the calculated amounts of [α-^{32}P]dNTPs necessary to achieve the desired specific activity and sufficient to allow complete synthesis of all template strands (please see the introduction to this protocol).

   The concentration of dNTPs should not drop below 1 μM at any stage during the reaction. To keep the substrate concentration high, the extension reaction should be carried out in as small a volume as possible.

2. Add to the tube the appropriate amounts of oligonucleotide primer and template oligonucleotide.

   To ensure efficient radiolabeling, the primer should be in three- to tenfold molar excess over the template DNA in the reaction mixture.

3. Add 0.1 volume of 10x Klenow buffer to the tube. Mix the reagents well.
4. Add 2–4 units of the Klenow fragment per 5 µl of reaction volume. Mix well. Incubate the reaction for 2–3 hours at 14°C.

   If desired, the progress of the reaction may be monitored by removing small (0.1 µl) aliquots and measuring the proportion of radioactivity that has become precipitable with 10% trichloroacetic acid (TCA) (please see Appendix 8).
5. Dilute the reaction mixture with an equal volume of formamide-loading buffer, heat the mixture to 80°C for 3 minutes, and load the entire sample on a denaturing polyacrylamide gel.
6. Following electrophoresis, disassemble the electrophoresis apparatus, leaving the polyacrylamide gel attached to one of the glass plates (for details, please see Chapter 12, Protocol 11).

   ▲ **WARNING** Unincorporated [α-^{32}P]dNTPs may have migrated into the lower buffer reservoir, making it radioactive. Treat the gel, glass plates, buffers, and electrophoresis apparatus as potential sites of radioactivity. Handle them appropriately, behind a Plexiglas shield.
7. Wrap the gel and its backing plate in Saran Wrap. Note the position of the tracking dyes and use a hand-held minimonitor to check the amount of radioactivity in the region of the gel that should contain the oligonucleotide. Attach a set of adhesive dot labels, marked with either very hot radioactive ink or phosphorescent spots, around the edge of the sample on the Saran Wrap. Cover the radioactive dots with Scotch Tape to prevent contaminating the film holder or intensifying screen with the radioactive ink.
8. Expose the gel to autoradiographic film (please see Appendix 9).

   Usually, the amount of radioactivity incorporated into the probe is so great that the time needed to obtain an image on film is no more than a few seconds.
9. After developing the film, align the images of the radioactive ink with the radioactive marks on the labels, and locate the position of the probe in the gel. Excise the band and recover the radioactive oligonucleotide as described in Chapter 5, Protocol 12.

Protocol 8

Hybridization of Oligonucleotide Probes in Aqueous Solutions: Washing in Buffers Containing Quaternary Ammonium Salts

JACOBS ET AL. (1988) DESCRIBE METHODS AND THEORETICAL REASONS to use hybridization buffers containing quaternary alkylammonium salts. The following protocol is a simple variation of these methods. Hybridization is first carried out in conventional aqueous solvents at a temperature well below the melting temperature, and the hybrids are then washed at higher stringency in buffers containing quaternary alkylammonium salts. TMACl is used with probes that are 14–50 nucleotides in length, whereas TEACl is used with oligonucleotides that are 50–200 nucleotides in length.

The graph in Figure 10-2 can be used to estimate a washing temperature when using oligonucleotide probes of a given length in TMACl buffers. To estimate a washing temperature when using TEACl buffers, calculate the value from the TMACl curve in the figure and then subtract 33°C.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Oligonucleotide hybridization solution

6x SSC (or 6x SSPE)
0.05 M sodium phosphate (pH 6.8)
1 mM EDTA (pH 8.0)
5x Denhardt's solution (Appendix 1)
100 µg/ml denatured, fragmented salmon sperm DNA (Pharmacia or prepare as described in Chapter 6, Protocol 10)
100 mg/ml dextran sulfate (please see the information panel on **DEAE-DEXTRAN** in Chapter 16)

Oligonucleotide prehybridization solution

6x SSC (or 6x SSPE)
0.05 M sodium phosphate (pH 6.8)
1 mM EDTA (pH 8.0)
5x Denhardt's solution (Appendix 1)
100 µg/ml denatured, fragmented salmon sperm DNA (Pharmacia or prepare as described in Chapter 6, Protocol 10)

6x SSC or SSPE

Place these solutions on ice before using in Steps 4 and 5 of the protocol.

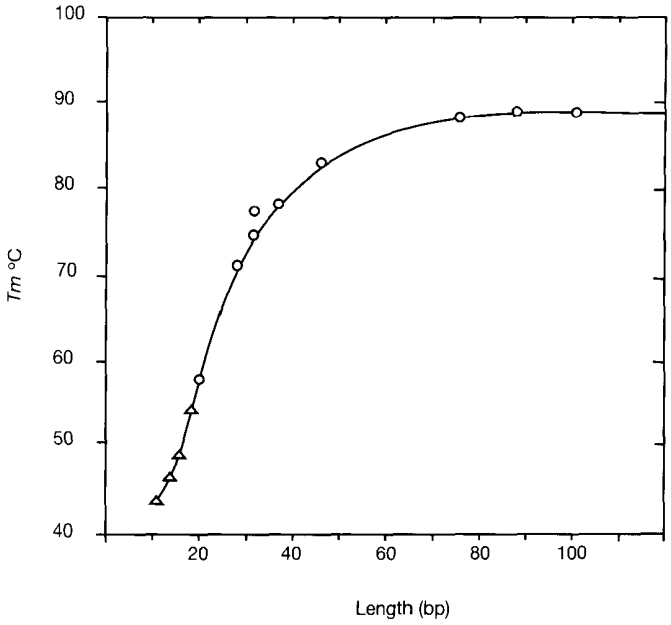

FIGURE 10-2 Estimating T_m in Buffers Containing 3.0 M TMACl

The graph depicts the increase in the T_m as a function of probe length. A series of aliquots of pBR322 DNA was delivered (spotted) onto nitrocellulose membranes, hybridized against pBR322-derived probes of various lengths, and washed in 3 M TMACl. Washes of the duplicate spots were carried out at 3°C intervals. The probes were made by digesting pBR322 DNA with *Sau*3A, treating with alkaline phosphatase, and labeling in a reaction containing T4 polynucleotide kinase and [γ-^{32}P]ATP. The labeled fragments were purified by electrophoresis through a polyacrylamide gel, recovered from the gel, and boiled before hybridization. Data obtained from an autoradiogram of the hybridized membranes were used to determine the T_m for each fragment (*open circles*). The melting data are shown for hybridization of oligonucleotides in Me_4NCl (*open triangles*). (Adapted, with permission, from Wood et al. 1985.)

TEACl wash solution

2.4 M TEACl
50 mM Tris-Cl (pH 8.0)
0.2 mM EDTA (pH 7.6)
1 mg/ml SDS

Use this wash solution for probes 50–200 nucleotides in length. It is essential to warm an aliquot of the solution to the desired temperature before use (please see Steps 6 and 7).

TMACl (5 M) or TEACl (3 M)

Prepare a 5 M solution of TMACl or a 3 M solution of TEACl in H_2O. TMACl is used with probes that are 14–50 nucleotides in length, whereas TEACl is used with oligonucleotides that are 50–200 nucleotides in length. Both chemicals are available from Aldrich. To the solution of TMACl or TEACl, add activated charcoal to a final concentration of ~10% and stir for 20–30 minutes. Allow the charcoal to settle, and then filter the solution of quaternary alkylammonium salts through a Whatman No. 1 paper. Sterilize the solution by passage through a nitrocellulose filter (0.45-µm pore size). Measure the refractive index of the solution, and calculate the precise concentration of the quaternary alkylammonium salts from the equation: $C = (n - 1.331)/0.018$, where C is the molar concentration of quaternary alkylammonium salts and n is the refractive index.

Store the filtered solution in dark bottles at room temperature.

TMACl wash solution

3.0 M TMACl
50 mM Tris-Cl (pH 8.0)
0.2 mM EDTA (pH 7.6)
1 mg/ml SDS

Use this wash solution for probes 14–50 nucleotides in length. It is essential to warm an aliquot of the solution to the desired temperature before use (please see Steps 6 and 7).

Nucleic Acids and Oligonucleotides

Nitrocellulose or nylon filters or membranes containing the immobilized target nucleic acids of interest (e.g., Southern or northern blots, lysed bacterial colonies filters, or bacteriophage plaques)

Probes

Radiolabeled oligonucleotide probe **<!>**

Prepared as described in Protocol 2 or 7. We recommend that phosphorylated probes be purified by precipitation with CPB as described in Protocol 4 before use in hybridization. This method of purification removes unincorporated [^{32}P]ATP and cuts down on the number of intense radioactive spots (pepper spots) on the autoradiographs that can be mistaken for positive hybridization signals.

Special Equipment

Hybridization device

Please see Step 1.

Shaking incubator, water bath, or hybridization apparatus preset to 37°C (Steps 1 and 3) and later to a temperature appropriate for washing (Step 7)

METHOD

1. Prehybridize the filters or membranes for 4–16 hours in oligonucleotide prehybridization solution at 37°C.

   Prehybridization, hybridization, and washing of circular filters are best carried out in Sears Seal-A-Meal bags or plastic boxes with tight-fitting lids. For Southern and northern blots, a hybridization device equipped with sealable glass tubes could be used.

2. Discard the prehybridization solution and replace it with oligonucleotide hybridization solution containing a radiolabeled oligonucleotide probe at a concentration of 180 pM.

   When hybridizing with several oligonucleotides simultaneously, each probe should be present at a concentration of 180 pM and the specific activity of the radiolabeled probe should be 5×10^5 to 1.5×10^6 cpm/pmole.

3. Incubate the filters for 12–16 hours at 37°C.

4. Discard the radiolabeled hybridization solution into an appropriate disposable container. Rinse the filters three times at 4°C with ice-cold 6x SSC or 6x SSPE to remove most of the dextran sulfate.

5. Wash the filters twice for 30 minutes at 4°C in ice-cold 6x SSC or 6x SSPE.

6. Rinse the filters at 37°C in two changes of the TMACl or TEACl wash solution.

   The aim of this step is to replace the SSPE and SSC with the solution of quaternary alkylammonium salts. Unless this step is carried out diligently, the full benefits of using TEACl or TMACl will not be realized.

7. Wash the filters twice for 20 minutes each in TMACl or TEACl wash solution at a temperature that is 2–4°C below the T_m indicated in Figure 10-2.

   Note that the T_m of a hybrid is 33°C lower in a buffer containing TEACl than in a buffer containing TMACl. Make sure that the buffers are prewarmed to the desired temperature and that fluctuations in temperature are less then ±1°C.

8. Remove the filters from the washing solution. Blot them dry at room temperature and autoradiograph them as described in Appendix 9.

Protocol 9

Empirical Measurement of Melting Temperature

THE T_M OF AN OLIGONUCLEOTIDE HYBRIDIZED TO A TARGET SEQUENCE can be calculated as described in the introduction to this chapter (please see Melting Temperature and Hybridization Temperature in the introduction of this chapter), or the T_m may be determined empirically by measuring the temperature (T_i) at which dissociation of the double-stranded DNA becomes irreversible. The experiment is carried out under nonequilibrium conditions that do not favor rehybridization of the released probe to the target. The optimal temperature for hybridization of the oligonucleotide is then derived from T_i.

The procedure requires a cloned target sequence that is complementary (perfectly or imperfectly, depending on the experiment) to the oligonucleotide probe. If a target sequence is not available from "natural" sources, it can be synthesized chemically or, in some cases, derived by PCR.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Denaturation solution (for double-stranded target DNA only)
- 1.5 M NaCl
- 0.5 N NaOH **<!>**

Neutralization buffer (for double-stranded target DNA only)
- 0.5 M Tris-Cl (pH 7.4)
- 1.5 M NaCl

Oligonucleotide prehybridization solution
- 6x SSC (or 6x SSPE)
- 0.01 M sodium phosphate (pH 6.8)
- 1 mM EDTA (pH 8.0)
- 5x Denhardt's solution (please see Appendix 1)
- 0.5% (w/v) SDS
- 100 µg/ml denatured, fragmented salmon sperm DNA (please see Chapter 6, Protocol 10)

Phenol:chloroform (1:1, v/v) (for double-stranded target DNA only) **<!>**

Sodium acetate (3 M, pH 5.2) (for double-stranded target DNA only)

2x SSC

Enzymes and Buffers

Appropriate restriction enzyme for double-stranded target DNA
Please see Step 3.

Nucleic Acids and Oligonucleotides

Control DNA
Single-stranded or double-stranded DNA vector or sequence unrelated to the target DNA. Please see Step 3.

Target DNA
Ideally, this sequence should be cloned into a bacteriophage M13 vector and isolated as a single-stranded DNA (please see Chapter 3). Double-stranded plasmids or PCR products can also be used after denaturation as described in Step 3 of the protocol.

Probes

Oligonucleotide probe
Crude oligonucleotides are acceptable for this procedure provided the preparation can be labeled by phosphorylation to a specific activity $>10^6$ cpm/μg.

Before synthesizing the probe, check for potential homology and/or complementarity between its sequence and that of the vector used to propagate the target. Most of the commercially available programs to analyze DNA can be used to search common vector sequences for matches that might cause problems during hybridization.

Special Equipment

Boiling water bath
Cross-linking device (e.g., Stratalinker, Stratagene; GS Gene Linker, Bio-Rad), or Microwave oven, or Vacuum oven
Forceps, blunt-ended
Glass test tubes (17 x 100 mm)
Nitrocellulose or nylon membrane
Paper-hole punch
Scintillation vials each containing 10 ml of aqueous-based scintillant
Thermometer
Thick blotting paper (e.g., Whatman 3MM, Schleicher & Schuell GB004, or Sigma QuickDraw)
Water bath, circulating, with precise temperature control
Please see Steps 7, 10, and 12.

Additional Reagents

Step 1 of this protocol requires the reagents listed in Protocols 2 and 4 of this chapter.

METHOD

1. Radiolabel 1–10 pmoles of the oligonucleotide to be used as a probe by phosphorylation (Protocol 2), and remove excess unincorporated [γ-^{32}P]ATP by precipitation with CPB (Protocol 4).
2. Use a paper-hole punch to cut four small circles (diameter 3–4 mm) out of a nitrocellulose or nylon membrane for hybridization. Arrange the circles on a piece of Parafilm. Mark two of the membranes with a soft-lead pencil.
3. Apply target and control DNAs to the membrane circles as follows.

Single-stranded target DNA

a. Apply ~100 ng of target DNA in a volume of 1–3 µl of 2x SSC to each of the marked membranes.

b. Apply an equal amount of vector DNA (e.g., single-stranded bacteriophage M13 DNA without insert) to the unmarked membranes.

c. After the fluid has dried, use blunt-ended forceps (e.g., Millipore forceps) to remove the two sets of membranes from the Parafilm, and place them between sheets of thick blotting paper.

d. Fix the DNAs to the membranes by baking for 1–2 hours at 80°C in a vacuum oven.

Alternatively, place the membranes on a sheet of blotting paper and fix the DNA by cross-linking using UV light.

Double-stranded target DNA

a. If the target DNA has been cloned into a plasmid, linearize both the recombinant plasmid and the vector by digestion with a restriction enzyme that does not cleave within the target sequence.

b. Purify the resulting double-stranded DNA or the PCR product by extraction with phenol:chloroform and standard precipitation with ethanol. Dissolve the DNA in 2x SSC at a concentration of 50–100 ng/µl.

c. Apply the solution of target DNA, as well as a control DNA, to the membranes prepared as described above. Use blunt-ended forceps to transfer the membranes to a sheet of thick blotting paper saturated with denaturation solution. Incubate the membranes for 5–10 minutes at room temperature.

d. Transfer the membranes to a fresh sheet of thick blotting paper saturated with neutralization buffer. Incubate the membranes for 10 minutes at room temperature.

e. Transfer the membranes to a dry sheet of thick blotting paper, and leave them at room temperature until all of the fluid has evaporated. Immobilize the DNA to the membranes either by baking for 1–2 hours at 80°C in a vacuum oven or by cross-linking using UV light.

4. Use blunt-ended forceps to transfer all of the membranes to a polyethylene tube containing 2 ml of oligonucleotide prehybridization solution. Seal the tube and incubate, with occasional shaking, at a temperature estimated to be 25°C below the T_m for the solvent being used.

Although the above protocol uses sodium salts in the hybridization solution, other solutes such as TMACl or TEACl can be substituted if desired to determine the T_t in these solvents.

5. After 2 hours, add the radiolabeled oligonucleotide to the prehybridization solution. The final concentration of oligonucleotide should be ~1 pmole/ml. Continue incubating at 25°C below the T_m for a further 2–4 hours, with occasional shaking.

6. Remove the membranes from the hybridization solution, and immediately immerse them in 2x SSC at room temperature. Agitate the fluid continuously. Replace the fluid every 5 minutes until the amount of radioactivity on the membranes remains constant (as measured with a hand-held minimonitor).

7. Adjust the temperature of a circulating water bath to 25°C below the T_m. Dispense 5 ml of 2x SSC into each of 20 glass test tubes (17 x 100 mm). Monitor the temperature of the fluid in

one of the tubes with a thermometer. Incubate the tubes in the water bath until the temperature of the 2x SSC is 25°C below the T_m.

8. Transfer the membranes individually to four empty glass tubes, and add 1 ml of 2x SSC (from one of the tubes prepared in Step 7 and prewarmed to 25°C below the T_m) to each membrane. Place the tubes in the water bath for 5 minutes.

9. Remove the tubes containing membranes from the bath, transfer the liquid to scintillation vials, and wash the tubes and membranes with 1 ml of 2x SSC at room temperature. Add the wash solutions to the appropriate scintillation vials.

10. Increase the temperature of the water bath by 3°C, and wait for the temperature of the 2x SSC in the tubes prepared in Step 7 to equilibrate.

11. Add 1 ml of 2x SSC at the higher temperature to each of the four tubes containing the membranes. Place the tubes in the water bath for 5 minutes.

12. Repeat Steps 9, 10, and 11 at successively higher temperatures until a temperature of 30°C above the T_m is achieved.

13. Place the membranes in separate glass tubes (17 x 100 mm) containing 1 ml of 2x SSC, and heat them to boiling for 5 minutes to remove any remaining radioactivity. Cool the solutions in ice, and transfer them to scintillation vials. Wash the membranes and tubes used for boiling with 1 ml of 2x SSC, and add the washing solutions to the appropriate scintillation vials.

14. Use a liquid scintillation counter to measure the radioactivity (by Cerenkov counting, please see Appendix 8) in all of the vials. Calculate the proportion of the total radioactivity that has eluted at each temperature, using the following equation:

$$x_j = \sum_{i=T_m-25°C}^{T_j} n_i \div \sum_{i=T_m-25°C}^{100°C} n_i$$

where x_j is the fraction of total radioactivity eluted at T_j, n_i is the amount of radioactivity eluted at $i = T_j$, and T_j is the temperature under consideration from 25°C below the T_m to 30°C above the T_m.

If the experiment has worked well, very little radioactivity should be associated with the membranes containing vector DNA alone. Furthermore, this radioactivity should be completely released from the membranes at temperatures much lower than the estimated T_m. On the other hand, considerable radioactivity should be associated with the membranes containing the target DNA; the elution of this radioactivity should show a sharp temperature dependence. Very little radioactivity should be released from the membranes until a critical temperature is reached, and then ~90% of the radioactivity should be released during the succeeding 6–9°C rise in temperature.

The temperature at which 50% of the radioactivity has eluted from the membranes containing the target sequences is defined as the T_i of the hybrid between the probe and its target sequence.

OLIGONUCLEOTIDE SYNTHESIS

Until the early 1980s, the chemical synthesis of defined sequences of DNA was undertaken in smelly laboratories by large teams of investigators. And it was a frustratingly slow and wearisome business. The work for which H. Ghobind Khorana was awarded the Nobel prize in 1968 — synthesis of a functional tRNA gene — took several years and was published in serial form in more than 50 papers. As late as 1977, the state of the art was summarized by Amarnath and Broom: "Chemical methods for the synthesis of oligonucleotides have undergone dramatic improvement in the last two decades, but such goals as the synthesis of a tRNA molecule or the facile preparative synthesis of DNA genes still shimmer in the distance... . We have a long way to go." Elegant prose, but shortsighted, since just 1 year later, a synthetic cDNA encoding the insulin A and B chains was assembled from small synthetic oligonucleotides, cloned, and expressed in *E. coli* (Goeddel et al. 1979).

The key step in the chemical synthesis of DNA is the forging of phosphodiester bonds between specific nucleotides. Because the sugar moiety of deoxynucleotides contains two hydroxyl groups (at the 3′ and 5′ positions of the deoxyribose ring), one must be protected while the other is linked to the next deoxyribonucleoside unit. The transient protecting group must then be removed from the sugar to allow further extension of the oligonucleotide chain. The bases of deoxynucleosides also contain reactive groups (e.g., the exocyclic amino groups of adenine, cytosine, and guanine) that require protection throughout the entire synthetic process (please see Figure 10-3). These "persistent" protective groups must also be removed at the end of chain assembly. Khorana's work was carried out without the full benefit of phosphate-protecting groups, and extension of the growing chain was possible only because phosphodiesters became temporarily converted to substituted pyrophosphates during the coupling reaction, thereby allowing the sugar hydroxyl to participate in the reaction. However, this phosphodiester method was strangulated by the inefficiency of each polymerization reaction and the progressive loss of selectivity during extension of the chain. Since the mid 1980s, virtually all oligonucleotide synthesis has used a combination of protective groups and solid-phase synthesis based on phosphoramidite chemistry (Beaucage and Caruthers 1981; McBride and Caruthers 1983; Sinha et al. 1984; for reviews, please see Atkinson and Smith 1984; Gait 1984; Beattie et al. 1988; Caruthers 1991; Caruthers et al. 1992; Sonveaux 1994; Pon et al. 1996).

A conventional synthetic cycle involves use of a solid-phase support (usually controlled-pore glass, less frequently polystyrene). The oligonucleotide is created one base at a time by esterifying the 3′-phosphate group of an appropriately protected phosphoramidite nucleoside to the 5′-hydroxyl of the terminal residue, which is attached to the solid phase support by a linker. The oligonucleotide therefore grows in a 3′→5′ direction, the opposite of enzymatically catalyzed reactions. A round of coupling involves four types of reactions: mild alkaline hydrolysis, mild acid hydrolysis, nucleophilic displacements, and redox alterations. Unreacted chemicals are simply washed away after each stage of the coupling reaction. The trityl groups, which are released during each round of synthesis, are chromophores that absorb at 498 nm, and they can be used to monitor the efficiency of synthesis after every round of coupling.

The terminal dimethoxytrityl group, being acid-labile, is then removed in trichloroacetic acid (TCA) to generate a compound with a free hydroxyl group, which is the only reactive nucleophile in the growing oligonucleotide (please see Figure 10-4). After the deblocking solution has been completely removed from the column and replaced with acetonitrile, the column is purged with an inert gas (argon or helium) to remove the acetonitrile and any traces of water. A molar excess of the appropriate phosphoramidite monomer is then reacted with the detritylated compound in the presence of an excess of activator (H-tetrazole) to give the phosphite triester intermediate (Figure 10-5). In this reaction, the nitrogen of the phosphoramidite becomes protonated, generating a good leaving group that is susceptible to attack by the free 5′-hydroxyl group of the growing oligonucleotide chain. The new bond between nucleotides is unstable in both acidic and basic solutions but can be reinforced by oxidation of the trivalent phosphorus to pentavalent phosphorus by a partially aqueous solution of iodine (Figure 10-6).

At each cycle in the synthesis, a small fraction (~1–2%) of the column-bound nucleosides do not condense with the incoming activated phosphoramidite. These nonproductive 5′ ends must be capped to prevent them reacting with the next phosphoramidite and hence generating an oligonucleotide that lacks a base. Capping is achieved by acetylating the 5′-hydroxyl group with acetic anhydride in the presence of the catalyst *N*-methylimidazole (NMI) (Figure 10-7). When synthesis is completed, the oligonucleotide remains attached to the solid-phase support via a succinate ester, and the exocyclic groups of the bases still carry

TABLE 10-5 Expected Yield of Oligonucleotide Synthesis

SCALE OF SYNTHESIS	OD_{260} UNITS X NUMBER OF BASES
40 nmoles	0.25–0.5
0.2 μmole	1–1.5
1 μmole	5
10 μmoles	40

their protective groups. Ammonium hydroxide is used both to release the oligonucleotide from the column and to cleave off the cyanoethyl groups protecting the phosphates (Figure 10-8).

Finally, hot ammonia is used to hydrolyze the amides protecting the exocyclic amino groups of deoxyadenosine, deoxycytosine, and deoxyguanosine. An additional (optional) detritylation step is required to remove the protective group from the 5′-hydroxyl group of the final nucleotide added to the oligonucleotide. The solution containing the released oligonucleotide is then evaporated to dryness in a lyophilizer. The completed oligonucleotide is generally supplied to the user in the form of a powder.

Almost all synthetic oligonucleotides are now prepared either individually or in pools by automated instruments sold by a variety of manufacturers. These instruments are capable of synthesizing nanomole, or even micromole, amounts of oligonucleotides as long as 70–100 nucleotides. In addition, many companies will custom-synthesize oligonucleotides of defined sequence at very reasonable prices. The minimum amount of an oligonucleotide synthesized by automatic machines (5–50 nmoles) is far in excess of the quantities usually required for labeling, DNA sequencing, PCR, or site-directed mutagenesis. Table 10-5 (obtained from PE Applied Biosystems) can be used to estimate the amount of oligonucleotide present in a given synthesis.

MELTING TEMPERATURES

Heating a solution of double-stranded DNA unravels the duplexes by disrupting the hydrogen bonds that pin together complementary base pairs. Individual hydrogen bonds are relatively weak (~5 kcal/mole/bond) and thus are easily disrupted by heat. However, the greater the number of hydrogen bonds holding any two complementary strands of DNA together, the higher the temperature necessary to cause all of those bonds to break, separating the nucleic acid into two strands. This transition from double-stranded (helix) to single-stranded (coil) conformations as a function of temperature can be monitored as an increase in absorbance and is marked by a sharp increase in the extinction coefficient at the temperature where the conformational transition takes place. The temperature corresponding to the midpoint of the absorbance rise is called the melting temperature (T_m). In structural terms, the T_m is the temperature at which 50% of the base pairs in a duplex have been denatured. This relationship between nucleic acid structure and thermal stability has been experimentally exploited for four decades.

Marmur and Doty (1959, 1962) used this relationship to establish that for a wide range of DNA samples, the T_m is a linear function of the sample's base composition. The slope of the line is 0.41°C per 1% increase in the (G+C) content. For thermal denaturation profiles of DNA samples (with a G+C content between 30% and 75%) run in 0.15 M NaCl and 15 mM Na citrate, the melting temperature is:

$$T_m = 69.3°C + 0.41(\%[G+C]) \quad (1)$$

This equation makes it possible to estimate accurately the base composition of a DNA sample simply by measuring the T_m of the sample. To determine the T_m of DNA samples run under other salt conditions, use the more general equation:

$$T_m = 81.5°C + 16.6 \log_{10} [M^+] + 0.41(\%[G+C]) \quad (2)$$

where $[M^+]$ is the monovalent cation concentration for $M^+ \leq 0.5$ M.

Molecular Hybridization

The molecular hybridization techniques developed in the 1960s continue to be some of the most useful tools of the molecular biologist. Their simplicity and sensitivity have helped to drive a revolution in our understanding of gene structure, gene expression, and genome organization. These techniques have also been adapted as diagnostic tools in clinical laboratories and pharmaceutical companies.

Establishing optimal conditions for hybridization of a nucleic acid probe and its target sequence requires knowledge of the T_m of the target:probe duplex. Although under some circumstances, the T_m can be experimentally determined (please see Protocol 9 of this chapter), it is more common to calculate the T_m. A variety of equations have been derived that can be used to estimate the T_m of a target:probe duplex under a range of conditions.

At the T_m, when the probe and target are both polynucleotides, the molecules contain stretches of native duplex separated by denatured regions. The transition then from helix to coil is intramolecular and thus is independent of polynucleotide concentration (Wetmur 1991). The T_m is a function of base composition, solvent composition, duplex length, and extent of base pair mismatches (Hall et al. 1980; Wahl et al. 1987; Baldino et al. 1989). For DNA duplexes, Equation 2 has been modified by Wetmur (1991) to permit hybridization in salt up to 1 M NaCl:

$$T_m = 81.5 + 16.6 \log_{10} ([Na^+]/\{1.0 + 0.7[Na^+]\}) + 0.41(\%[G+C]) - 500/n - P - F \quad (3)$$

where n is the length of the duplex, P is the temperature correction for the percent mismatch of base pairs, which is typically 1°C per 1% mismatch, and F is 0.63°C per 1% formamide. For RNA duplexes:

$$T_m = 78 + 16.6 \log_{10} ([Na^+]/\{1.0 + 0.7[Na^+]\}) + 0.7(\%[G+C]) - 500/n - P - F \quad (4)$$

where F is 0.35°C per 1% formamide. For hybrids of RNA and DNA:

$$T_m = 67 + 16.6 \log_{10} ([Na+]/\{1.0 + 0.7[Na^+]\}) + 0.8(\%[G+C]) - 500/n - P - F \quad (5)$$

where F is 0.5°C per 1% formamide. Variations on Equations 4 and 5 have been derived by Bodkin and Knudson (1985) and Casey and Davidson (1977), respectively.

When the probe is an oligonucleotide, at the T_m, half of the duplexes have separated. The transition from helix to coil is intermolecular, and thus the T_m is dependent on the oligonucleotide concentration (Wetmur 1991), as well as the oligonucleotide sequence and the composition of the solvent. Although various permutations of Equations 3 through 5 are frequently used, the use of %(G+C) is not sufficient to predict the T_m. A more accurate estimate of T_m can be obtained from a nearest-neighbor model that permits the incorporation of sequence-related thermodynamic data (Breslauer et al. 1986; Freier et al. 1986; Kierzek et al. 1986; Rychlik et al. 1990; Wetmur 1991; Rychlik 1994). One equation derived from such a model is:

$$T_m \text{ (in °C)} = (T^o \Delta H^o)/(\Delta H^o - \Delta G^o + RT^o \ln[c]) + 16.6 \log_{10}([Na^+]/\{1.0 + 0.7[Na^+]\}) - 269.3 \quad (6)$$

where $\Delta H^o = \Sigma_{nn}(N_{nn}\Delta H_{nn}) + \Delta H^o_p + \Delta H^o_e$
$\Delta G^o = \Sigma_{nn}(N_{nn}\Delta G^o_{nn}) + \Delta G^o_i + \Delta G^o_e$
N_{nn} = the number of nearest neighbors (e.g., 13 for a 14-mer)
R = 1.99 cal/mole-°K
T^o = 298.2°K
c = the total molar strand concentration
[Na+] ≤ 1 M

A number of the thermodynamic terms can be approximated:

average nearest-neighbor enthalpies, $\Delta H^o_{nn} = -8.0$ kcal/mole
average nearest-neighbor free energies, $\Delta G^o_{nn} = -1.6$ kcal/mole
initiation term, $\Delta G^o_i = +2.2$ kcal/mole
average dangling end enthalpy, $\Delta H^o_e = -8.0$ kcal/mole/end
average dangling end free energy, $\Delta G^o_e = -1$ kcal/mole/end
average mismatch/loop enthalpy, $\Delta H^o_p = -8.0$ kcal/mole/mismatch

Note that for each mismatch or loop, N_{nn} is reduced by 2. At the opposite end of the complexity spectrum is the equation:

$$T_m = 2(A+T) + 4(G+C) \quad (7)$$

where $(A+T)$ is the number of adenines and thymines in the oligonucleotide and $(G+C)$ is the number of guanines and cytosines in the oligonucleotide, which works for short oligonucleotides that perfectly match their target sequence (Suggs et al. 1981b). More precisely, this equation predicts the dissociation temperature (T_d) of an oligonucleotide hybridized to a target sequence that is bound to a solid support. For a detailed discussion of T_d, please see Wetmur (1991).

The differences in calculated T_m can be significant. For example, the predicted T_m for hybridization, in 0.5 M NaCl, of a 14-bp oligonucleotide probe that perfectly matches a sequence (with a %[G+C] = 50) in the target DNA will be 59°C using Equation 3, 55°C using Equation 6, and 42°C using equation 7.

METHODS USED TO PURIFY SYNTHETIC OLIGONUCLEOTIDES

Purification of synthetic oligonucleotides may be required following synthesis or after enzymatic modification of the oligonucleotide, such as radiolabeling. Although purification is not always necessary (please see Protocol 1), it can, if required, be achieved by one of several methods.

Oligonucleotides Lacking Trityl Groups

- ***Denaturing polyacrylamide gel electrophoresis:*** Denaturing polyacrylamide gel electrophoresis (PAGE) has a major advantage over other methods of purification: It resolves oligonucleotides according to their size and thereby allows full-length products to be separated from shorter incomplete molecules (Atkinson and Smith 1984). Table 10-6 presents the concentrations of acrylamide required for optimum resolution of synthetic oligonucleotides of different sizes. After electrophoresis, which is usually carried out with at least 1 mg/lane of synthetic oligonucleotide, the bands are located by UV-shadowing, and the oligonu-

TABLE 10-6 Range of Resolution of Gels Containing Different Concentrations of Acrylamide

Acrylamide (%)	Size of Oligonucleotides (in Bases)
20–30	2–8
15–20	8–25
13–15	15–35
10–13	35–45
8–10	45–70
6–8	70–300

cleotide of the correct size is cut from the gel. The oligonucleotide is then recovered from the gel as described in Protocol 1 of this chapter (Atkinson and Smith 1984). Poor recovery of oligonucleotide is the sole disadvantage of denaturing PAGE as a method of purification. Typically, yields are less than 50%.

- ***Reversed-phase cartridges:*** Reversed-phase chromatography may be used to purify detritylated oligonucleotides after extraction from preparative polyacrylamide gels (please see Protocol 1).
- ***Resins:*** Oligonucleotides lacking trityl groups can be purified by chromatography on commercially available resins (e.g., NENSORB [NEN Life Science Products] and MERMAID [Q•BIOgene]). The properties of these solid-phase matrices differ significantly from one another, and it is therefore important to follow the instructions supplied with the resin. These resins do not remove shorter, incomplete oligonucleotides from the preparation but are nevertheless useful for removing low-molecular-weight compounds, for example, residual ammonium ions that may interfere with 5′ phosphorylation of the oligonucleotide by bacteriophage T4 polynucleotide kinase.
- ***High-performance liquid chromatography:*** Oligonucleotides lacking a trityl group are fractionated according to charge. HPLC is not commonly used because it has a lower capacity (50–200 μg) and lower resolving power than PAGE, particularly for oligonucleotides <50 bases in length.

Oligonucleotides Containing Trityl Groups

- ***High-performance liquid chromatography:*** Oligonucleotides carrying a trityl group may be fractionated by HPLC according to their hydrophobicity. PE Applied Biosystems supplies low-pressure, reversed-phase cartridges that specifically retain tritylated oligonucleotides. The retained oligonucleotides are released from their trityl groups, eluted with acetonitrile, and then dried to a powder. Unlike denaturing PAGE, these cartridges do not remove shorter, incomplete oligonucleotides from the preparation.
- ***Oligonucleotide purification cartridges:*** PE Applied Biosystems also manufactures a kit that can be used to desalt oligonucleotides and/or to purify rapidly oligonucleotides synthesized using the dimethoxytrityl blocking group. This group, which is attached to the 5′-hydroxyl group of nucleosides added to the growing oligonucleotide chain, is normally removed by TCA during routine syntheses (please see the information panel on **OLIGONUCLEOTIDE SYNTHESIS**). However, if the TCA cycle on the last step of a synthesis is omitted, the resulting oligonucleotide retains a dimethoxytrityl group at its 5′ end. Oligonucleotide purification cartridges (OPCs) contain a resin with a high affinity for this bulky hydrophobic group and can be used to separate the complete oligonucleotide chain from incompletely synthesized oligonucleotides that do not contain the dimethoxytrityl group. The kit contains detailed instructions for the use of OPCs.

  There are two reactions in which oligonucleotides purified by this method are less useful or contraindicated: as primers in DNA sequencing reactions and as probes (after annealing) in gel-retention assays. Use of OPC-purified oligonucleotides as primers in DNA-sequencing reactions results in a background smear at the bottom of the gel that can obscure the reading of 10–25 nucleotides immediately adjacent to the primer. Similarly, in gel-retention assays, annealed OPC-purified oligonucleotides produce smears at the bottom of the gel. If an oligonucleotide is to be used for either of these applications, then we recommend that the DNA be purified by gel electrophoresis and reversed-phase chromatography as described in Protocol 1.

Chapter 11

Preparation of cDNA Libraries and Gene Identification

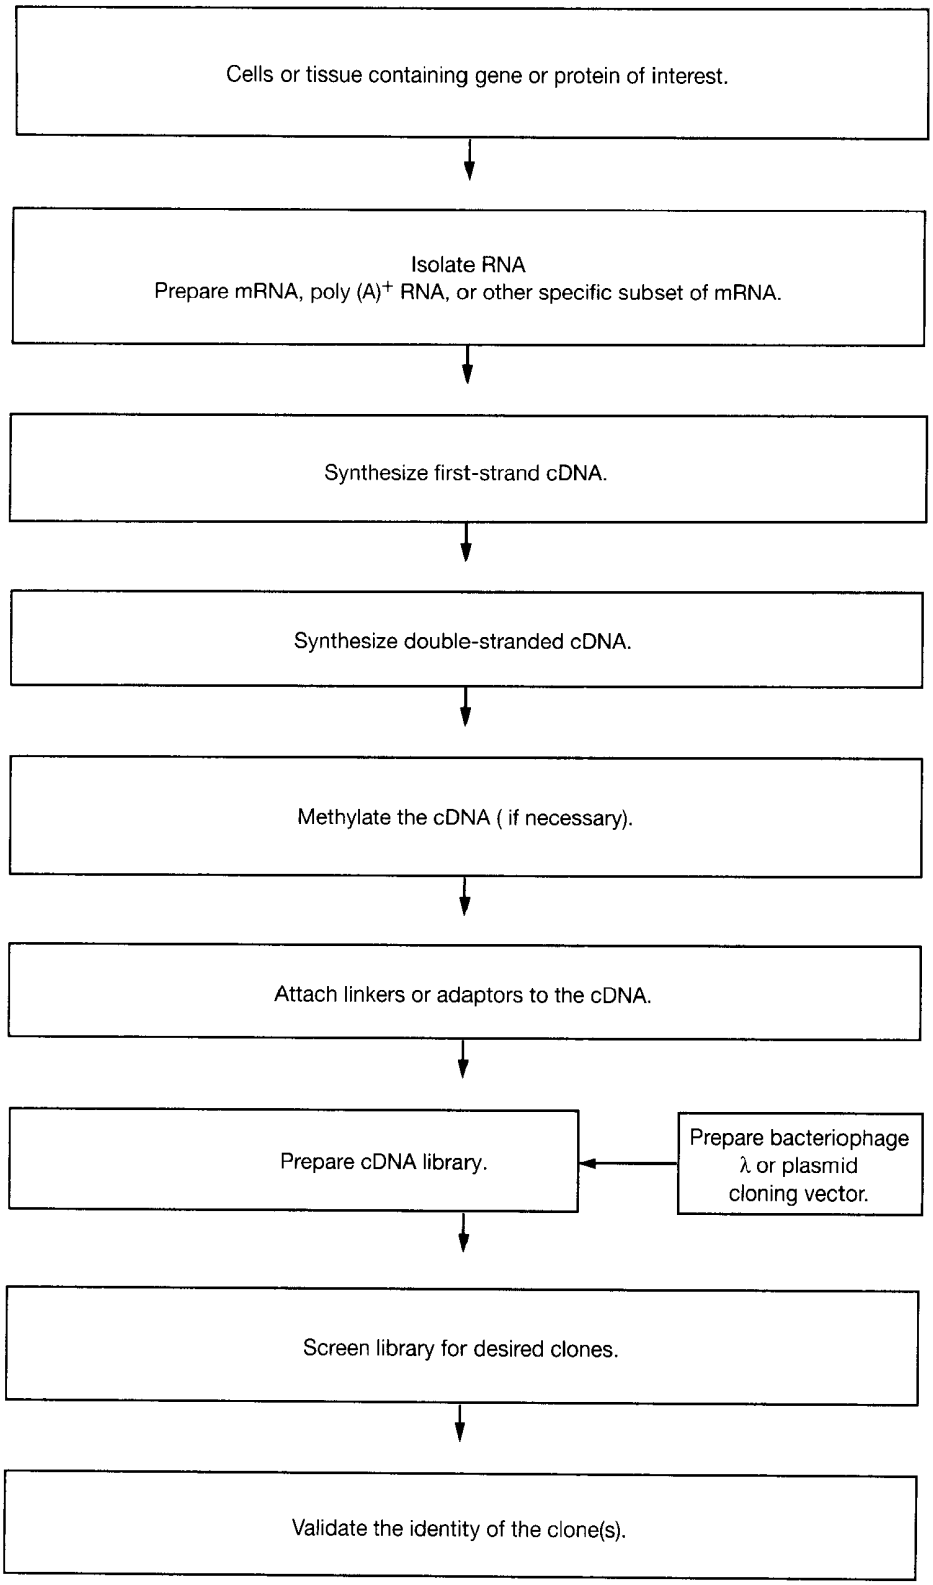

FIGURE 11-1 Flowchart: Preparing and Screening a cDNA Library

THE ENZYMATIC CONVERSION OF POLY(A)$^+$ MRNA TO DOUBLE-STRANDED DNA and the insertion of this DNA into prokaryotic and eukaryotic vectors have become fundamental tools of molecular biology. Since the first clones of complementary DNA (cDNA) were obtained in the mid 1970s, many different methods have been developed to increase the efficiency of synthesis of double-stranded cDNA and many improvements have been made to the vector systems. The first part of this introduction describes how these methods were developed and points out their advantages and disadvantages. The section on strategies for cDNA cloning outlines the major pathways by which cDNA libraries can be established from preparations of RNA. The strengths and limitations of each method are discussed, as are the options available at various stages of each pathway. Finally, we discuss the following in detail:

- preparation of mRNA for cDNA cloning
- procedures commonly used to synthesize cDNA
- vector-host systems used to construct and propagate cDNA libraries
- methods to screen cDNA libraries
- tests to validate cDNA clones
- exon amplification and trapping
- selection of cDNAs with large genomic DNA clones

The overall sequence of steps for preparing and screening a cDNA library as presented in this chapter is given in Figure 11-1. It is worth noting that the quality and number of premade cDNA libraries available from commercial sources have increased greatly in the past few years. In addition, custom-made cDNA libraries can be synthesized to order, sometimes at a reasonable price. As a consequence, fewer academic laboratories need to generate their own cDNA libraries. In most other chapters in this manual, we have been reluctant to recommend the use of kits. Here, however, we endorse them enthusiastically. For a discussion of the virtues and shortcomings of commercially available kits for cDNA synthesis and for construction of cDNA libraries, please see the information panel on **COMMERCIAL KITS FOR cDNA SYNTHESIS AND LIBRARY CONSTRUCTION** at the end of this chapter.

DEVELOPMENT OF METHODS TO SYNTHESIZE AND CLONE cDNAS

Following the discovery of reverse transcriptase by Howard Temin and David Baltimore in 1970 (Baltimore 1970; Temin and Mizutani 1970), three different groups showed that the enzyme could be used in vitro with an oligo(dT) primer to synthesize single-stranded cDNA from mRNA templates (Bank et al. 1972; Ross et al. 1972; Verma et al. 1972). However, the size of the majority of the cDNA transcripts was considerably smaller than that of the template mRNAs, and techniques for synthesis of second-strand cDNA were not yet developed. After the methods of cloning fragments of DNA in plasmid vectors had been established by Cohen and Boyer (Cohen et al. 1973), a number of groups independently attempted to establish methods for cDNA cloning, and their results were reported within a 6-month span between late 1975 and mid 1976 (Rougeon et al. 1975; Maniatis et al. 1976; Rabbitts 1976; Rougeon and Mach 1976).

All of the early cDNA cloning methods used variations of the poly(dA)–poly(dT) tailing method developed by Lobban and Kaiser (1973) and employed by other investigators to insert SV40 DNA (Jackson et al. 1972) or *Drosophila* genomic DNA (Wensink et al. 1974) into plasmid

vectors. Rougeon et al. (1975) used oligo(dT) to prime synthesis of the first strand of cDNA, added a string of dT residues to the 3′ end of the cDNA with terminal transferase, and then synthesized the second cDNA strand with *Escherichia coli* DNA polymerase I using oligo(dA) as a primer. The duplex cDNA was then tailed with oligo(dG) and joined to a plasmid that had been tailed with oligo(dC). As the authors pointed out, this approach generated only partial cDNA inserts, the transformation frequency was very low, and only one of the five clones obtained contained a short cDNA insert (Rougeon et al. 1975). Although this work demonstrated the feasibility of cloning fragments of cDNA, it did not provide a generally useful method for creating cDNA libraries.

A novel approach developed at about the same time involved the addition of homopolymeric dT tails to the ends of a plasmid vector and the use of these tails to prime the first cDNA strand synthesis from mRNA (Rabbitts 1976). The resulting molecules, which contained one cDNA at each terminus, were again treated with terminal transferase to generate dT tails and then annealed to a plasmid containing dA tails. The resulting double plasmid containing two single-stranded cDNAs was then used to transform bacteria. In this case, the second cDNA strand was synthesized in bacteria. Although cDNA recombinants were obtained by this approach, neither the size of the cDNA nor the fidelity of synthesis and propagation of the cDNA was evaluated (Rabbitts 1976).

The method of cDNA cloning most widely used from 1976 to 1985 was designed specifically to synthesize and clone full-length double-stranded cDNAs (Maniatis et al. 1976). The first step in establishing this approach was to optimize conditions for the synthesis of full-length single-stranded cDNA (Efstratiadis et al. 1975, 1976). This advance could not have been achieved without the development of high-resolution denaturing polyacrylamide gel electrophoresis and the availability of well-characterized synthetic single-stranded DNA size markers (Maniatis et al. 1975). Once this system became available, the efficiency of full-length cDNA synthesis could be monitored accurately under a variety of conditions. Routine synthesis of full-length cDNA copies of mRNA was quickly achieved by simple adjustments to the temperature and pH of the reaction and by using high concentrations of deoxynucleoside triphosphates (dNTPs) (Efstratiadis et al. 1975).

The strategy taken to synthesize the second cDNA strand was based in part on earlier observations that the reaction products of cDNA synthesis contain double-stranded regions (Leis and Hurwitz 1972). A significant portion of this double-stranded DNA rapidly regained resistance to single-strand-specific nucleases after denaturation, indicating the presence of intrastrand base-paired regions. Leis and Hurwitz (1972) speculated that this duplex DNA was produced by the generation of a hairpin structure at the 3′ terminus of the first cDNA strand that could serve as a primer for second-strand synthesis by reverse transcriptase. Their hypothesis of self-primed synthesis was confirmed by showing that the products synthesized during the second-strand reaction consisted largely of single-stranded cDNAs twice the length of the original template mRNA (Efstratiadis et al. 1976). A key advance was the finding that the hairpin loop joining the first and second cDNA strands could be specifically digested with nuclease S1 (Efstratiadis et al. 1976). The double-length cDNA could thus be converted to duplex cDNA. Detailed characterization of the duplex cDNA with restriction enzymes demonstrated convincingly that full-length double-stranded DNA copies of mRNA could be produced in vitro (Efstratiadis et al. 1976). Cloning of the duplex cDNA was soon accomplished using the poly(dA)–poly(dT) tailing method (Maniatis et al. 1976). The utility of this approach to cDNA cloning was confirmed shortly thereafter by Higuchi et al. (1976).

At the time, there was concern about the fidelity of in vitro cDNA synthesis and the faithful propagation of cloned cDNAs in *E. coli*. Almost nothing was known about the fidelity of in vitro synthesis of the first cDNA strand by reverse transcriptase, nor of the second cDNA strand by *E. coli* DNA polymerase I. Whether cDNA sequences could be faithfully replicated in bacteria seemed to be a potentially significant problem considering that all of the early cDNA cloning

methods involved transformation with constructs that required gap filling and the generation of closed circular DNA in vivo. Obviously, almost any level of base substitution during synthesis and propagation of duplex cDNA would have severely hampered the use of this cloning method. It was therefore significant that the DNA sequence of the first full-length globin cDNA clone was identical to the sequence predicted from the amino acid sequence of the protein and the sequence of RNase T1 oligonucleotides of the mRNA (Efstratiadis et al. 1977). Subsequent DNA sequence analyses of hundreds of cDNA clones since that time have revealed that mistakes in synthesis and propagation of cDNAs are exceedingly rare.

The problem of fidelity of cDNA clones has arisen again recently as a consequence of the introduction of polymerase chain reaction (PCR)-based methods to clone cDNAs from minute amounts of mRNA (e.g., please see Ennis et al. 1990). There is no doubt that cDNA clones generated by standard PCR amplification of double-stranded cDNA contain a higher number of mutations than those generated by more traditional techniques. Ennis et al. (1990) estimate that an average of 1 nucleotide in ~1500 is mutated in cDNAs that have been cloned by PCR amplification. When error rates are this high, it would be foolish to rely on the nucleotide sequence of any single clone. To obtain a workable consensus sequence of the target cDNA, it is usually necessary to sequence between three and six independent cDNA clones. Better alternatives are (1) to reduce the number of errors during PCR by using a cocktail of thermostable polymerases (please see the section on thermostable DNA polymerases in the introduction to Chapter 8) or (2) to use the PCR-generated cDNAs as probes to screen a separate cDNA library constructed without the aid of amplification. However, this option is not always available when the quantities of mRNA are limiting.

STRATEGIES FOR cDNA CLONING

As a consequence of a wide range of technical and theoretical advances, cDNA cloning is now well within the range of any competent laboratory. Comprehensive cDNA libraries can be routinely established from small quantities of mRNA, and a variety of reliable methods are available to identify cDNA clones corresponding to extremely rare species of mRNA. As the enzymatic reactions used to synthesize cDNA have improved, the sizes of cloned cDNAs have increased, and it is now possible to isolate full-length cDNAs corresponding to all but the largest mRNAs.

Before embarking on the synthesis and cloning of cDNA, it is essential to consider carefully which source material, methods, vectors, and screening procedures offer the best chance of success. The item of foremost concern is the method that will be used to screen the library. The process of screening is dictated chiefly by the information and reagents that are available — for example, whether the sequence of the protein is known or can be obtained, whether suitable antibodies are available, or whether a robust and sensitive biological assay exists to detect the target protein expressed from a cloned cDNA. The choice of vector, the steps involved in library construction, and the method by which the cDNA molecules are inserted into the vector are all factors that will be heavily influenced by the method that will be used to screen the library. Table 11-1 presents a guide to the options that are frequently used to construct and screen cDNA libraries.

PREPARATION OF mRNA FOR cDNA CLONING

Discussed below are several considerations to be taken into account for the preparation of high-quality mRNA for use in cDNA cloning and selection.

TABLE 11-1 Strategies for cDNA Cloning

Information and/or Reagents Available About the Target Protein	Recommended Method of Library Construction	Recommended Vector[a]	Recommended Method of Screening
Nucleic acid sequence of a cDNA encoding a homologous protein	Gubler-Hoffman procedure (Gubler and Hoffman 1983; Gubler 1988)	any standard plasmid, phagemid, or bacteriophage λ vector	hybridization to synthetic oligonucleotides or to segment of DNA
Protein sequence of at least 15 contiguous amino acid residues	Gubler-Hoffman procedure (Gubler and Hoffman 1983; Gubler 1988)	any standard plasmid, phagemid, or bacteriophage λ vector	hybridization to a synthetic guessmer or MOPAC probe
Protein sequence of < 15 contiguous amino acid residues	Gubler-Hoffman procedure (Gubler and Hoffman 1983; Gubler 1988)	any standard plasmid, phagemid, or bacteriophage λ vector	hybridization to synthetic oligonucleotides
Antibody to target protein	directional cloning using the primer-linker modification of the Gubler-Hoffman procedure (Gubler and Hoffman 1983; Gubler 1988)	any bacteriophage λ expression vector or plasmid expression vector	antibody-antigen recognition and complexing
Assay for expression of target protein	directional cloning using the primer-linker modification of the Gubler-Hoffman procedure (Gubler and Hoffman 1983; Gubler 1988); or plasmid priming of first-strand cDNA	expression vector tailored to the particular assay; e.g., assays for biological activity of proteins synthesized after transfection of cDNA clones into mammalian cells require that the library be constructed in an appropriate mammalian expression vector	analysis of pools of clones by biological assay

[a]For a list of vectors, please see Appendix 3.

Source of the mRNA

Clearly, the higher the concentration of the sequences of interest in the starting mRNA, the easier the task of isolating relevant cDNA clones. It is therefore worthwhile investing some effort to ensure that the richest source of mRNA available is being used. This can be achieved, for example, by preparing mRNA from different cell lines or tissues for use in cell-free translation systems. Immunoprecipitation is then used to measure the amount of protein of interest synthesized for each set of mRNAs. In addition, some investigators have found ways to increase the concentration of the relevant mRNA by using drugs to select cell lines that overexpress particular proteins. For example, Luskey et al. (1983) describe the use of the drug compactin to develop a line of Chinese hamster ovary cells that have undergone a 15-fold increase in the number of gene copies and a much greater increase in the amount of mRNA coding for 3-hydroxy-3-methylglutaryl coenzyme A reductase (HMG CoA reductase). Others have taken advantage of the observation that treatment of infected cells with inhibitors of protein synthesis causes extended transcription of the early genes of mammalian DNA viruses (e.g., please see Persson et al. 1981). In these and a number of similar cases, increased abundance of specific classes of rare mRNAs greatly facilitated their subsequent cloning.

Ideally, estimates should be obtained of the frequency with which the mRNA of interest occurs in the starting preparation. This frequency not only determines the size of the cDNA library needed, but may also influence the method used to screen it. The first cDNA clones to be isolated were derived from abundant mRNAs such as those encoding globin, immunoglobulins, and ovalbumin. In these cases, the RNA species of interest constitutes as much as 50–90% of the

total poly(A)$^+$ RNA isolated from specific types of differentiated cells. Consequently, no further purification of the particular mRNA is required before double-stranded cDNA is synthesized and cloned. The desired cDNA clones can easily be identified by nucleic acid hybridization. The probes consist either of ^{32}P-labeled single-stranded cDNA synthesized in vitro from mRNA preparations rich in the sequences of interest or of mRNA that has been partially fragmented by limited alkaline hydrolysis and end-labeled by phosphorylation. As a good approximation, the mRNA sequences of interest will be represented in both the probe and the cloned double-stranded cDNAs in proportion to their abundance in the original preparation of mRNA. In cases such as globin, immunoglobulins, and ovalbumin, the chances are high that any colony hybridizing strongly to the probe will contain the desired DNA sequences. Although used extensively in the early days of cDNA cloning, this method no longer finds wide application, since few systems remain in which interesting uncloned mRNAs represent a sufficiently high proportion of the starting population.

RNAs that represent <0.5% of the total mRNA population of the cell are classified as "low-abundance" or "rare" mRNAs. The isolation of cDNA clones for mRNAs of this type presents two major problems: (1) construction of a cDNA library whose size is sufficient to ensure that the clone of interest has a good chance of being represented and (2) identification and isolation of the clone(s) of interest.

Integrity of the mRNA

Since the cDNA library cannot be better than the mRNA from which it is derived, it is important to check the integrity of the preparation of mRNA before it is used as the template for synthesis of the first strand of cDNA. The following tests are commonly used:

- ***The ability of the mRNA to direct the synthesis of high-molecular-weight proteins in cell-free translation systems derived from reticulocytes.*** Bulk mRNA purified from mammalian cells should encode a large number of polypeptides with molecular weights ranging from <10,000 to >100,000.

- ***The ability of the mRNA to direct the synthesis of the polypeptide of interest in a cell-free system derived from reticulocytes.*** An aliquot of the translation products of the bulk mRNA is analyzed by immunoprecipitation and SDS-polyacrylamide gel electrophoresis. After autoradiography, the radioactive band can be excised from the gel and counted in a scintillation counter. The proportion of the total radioactivity contained in the band is an estimate of the relative concentration of the mRNA of interest.

- ***The size of the mRNA.*** If a sufficient quantity of mRNA is available, the mRNA should be fractionated by gel electrophoresis and stained with ethidium bromide (please see Chapter 7, Protocol 6). The mRNA should appear as a smear between ~500 bases and 8 kb. The bulk of the mRNA should lie between 1.5 kb and 2 kb. Transfer of the mRNA to a nitrocellulose or nylon membrane followed by hybridization with control cDNA probes is an additional check on the integrity of the mRNA preparation.

- ***The ability of the bulk mRNA preparation to direct the synthesis of long molecules of first-strand cDNA.*** cDNA synthesized from mammalian mRNA should run on an alkaline agarose gel as a continuous smear from ~500 bases to >5 kb. The bulk of the radioactivity should lie between 1.5 kb and 2 kb, and no specific bands of cDNA should be visible unless the mRNA was prepared from cells that express large quantities of specific mRNAs. In addition, the amount of radioactivity incorporated into the first strand of cDNA should be stimulated at least 20-fold by oligo(dT)$_{12\text{-}18}$ primers. Efficient cDNA synthesis in the absence of added

primer is a sign that the mRNA preparation may be contaminated with fragments of DNA or RNA that can bind to mRNA at random sites and serve as primers. If necessary, these fragments can be removed by denaturing the mRNA (100°C for 30 seconds in H_2O), cooling quickly in ice water, and immediately selecting poly(A)$^+$ RNA by chromatography on oligo(dT)-cellulose.

Methods of Enrichment

A typical mammalian cell contains between 10,000 and 30,000 different transcribed *sequences* (Davidson 1976; Welsh et al. 1990). However, the number of mRNA *species* per cell may be much greater because of differential splicing. Not all of these transcribed sequences are represented equally in the steady-state population of mRNA molecules. Instead, the proportional representation of each sequence depends on its rate of synthesis, half-life, and pattern of splicing: Genes that are actively transcribed into stable mRNAs make a greater contribution to the pool of mRNA molecules than genes that are transcribed sluggishly into less stable mRNAs. Some years ago, Williams (1981) determined the number of clones necessary to construct a complete cDNA library from a human fibroblast cell that contains ~12,000 different transcribed sequences. Rare mRNAs (<14 copies/cell) constitute ~30% of the mRNA, and ~11,000 different mRNAs belong to this class. The minimum number of cDNA clones required to obtain a complete representation of mRNAs of this class is therefore 11,000/0.30 or 37,000.

Of course, because of sampling variation and/or preferential cloning of certain sequences, a much larger number of recombinants must be obtained to increase the chance that any given clone will be represented in the library. The number of clones required to achieve a given probability that a low-abundance mRNA will be present in a cDNA library is:

$$N = \frac{\ln(1 - P)}{\ln(1 - [1/n])}$$

where N is the number of clones required, P is the probability desired (usually 0.99), and $1/n$ is the fraction of the total mRNA that is represented by a single type of rare mRNA. Therefore, to achieve a 99% probability of obtaining a cDNA clone of an mRNA present in human fibroblasts at a frequency of ~14 molecules/cell:

$$\begin{aligned} P &= 0.99 \\ 1/n &= 1/37{,}000 \\ N &= 170{,}000 \end{aligned}$$

Unfortunately, many mRNAs of interest are present at even lower levels (1 molecule/cell is not unusual [Toole et al. 1984; Wood et al. 1984]). Furthermore, it is often necessary to clone cDNAs from populations of mRNAs isolated from tissues that consist of several cell types. In such cases, the frequency at which the sequences of interest are represented in the initial preparation of mRNA may be reduced still further, and it then becomes necessary to construct and screen libraries that contain several million independent cDNA clones. Since 1985, the efficiency with which cDNA can be synthesized and cloned has increased steadily to the point where cDNA libraries of this size can be generated routinely from 1–5 μg or less of poly(A)$^+$ mRNA. In principle, there is no a priori reason why even the most difficult cDNA clones — those corresponding to a very rare mRNA of large size — cannot be identified in such comprehensive libraries. However, screening large numbers of cDNA clones is both tedious and expensive. Methods have therefore been devised to enrich either the starting population of mRNA molecules or double-stranded cDNA synthesized from it for sequences of interest. Enrichment allows the size of the cDNA library to be reduced and decreases the cost and labor involved in screening for the desired cDNA clones.

It is difficult to offer specific guidelines regarding the circumstances that require enrichment procedures. As a rule of thumb, fractionation of mRNA is probably unnecessary if the cDNA of interest is expected to be present at a frequency ≥1 in 10^6 in a library of cDNA clones synthesized from unfractionated mRNA. Enrichment becomes more attractive as the number of clones to be screened increases above 1 million. Consequently, when designing a scheme to clone a specific cDNA, it is important to know the approximate frequency with which the mRNA of interest occurs in the bulk, unfractionated population of mRNA molecules using one or more of the methods described previously (please see the discussion on Integrity of the mRNA, above).

Fractionation of mRNA by Size

The simplest method to enrich preparations of mRNA for sequences of interest is to fractionate them according to size. Clearly, this method works best for mRNAs that are much larger or smaller in size than the bulk mRNA of the cell. The modal size of the mRNA population extracted from most types of mammalian cells is ~1.8 kb, and mRNAs smaller in size than 700 bases or larger than 4 kb can be enriched at least tenfold by a single round of density gradient centrifugation carried out under denaturing conditions. However, it is important to remember that it is not possible to predict with certainty the size of an mRNA from the size of a protein for which it codes. There is considerable variation in the sizes of the untranslated regions of mRNAs (particularly the 3′-untranslated regions); many proteins purified from cells are cleavage products of larger precursors and many undergo extensive posttranslational modification. However, the size of the unmodified polypeptide chain provides a minimal estimate of the size of the mRNA: 10,000 daltons of an average polypeptide is encoded by ~280 bases of mRNA.

Electrophoresis through agarose gels gives the best separation of molecules of mRNA of different sizes, but the recovery of RNA from gel slices is generally poor. Sedimentation through sucrose gradients formed in nondenaturing solvents results in good recovery, but the presence of secondary structure in the RNA often confounds effective fractionation. An alternative is sucrose gradient centrifugation in the presence of an agent, such as methylmercuric hydroxide, which denatures secondary structure in RNA (Schweinfest et al. 1982). Each fraction is then assayed for the presence of the mRNA that encodes the relevant polypeptide. Typically, an aliquot of the RNA in each fraction is translated in a cell-free system, and the resulting polypeptides are analyzed by immunoprecipitation and electrophoresis through polyacrylamide gels. Alternatively, aliquots are injected into *Xenopus* oocytes (for review, please see Melton 1987) and the resulting products are assayed either for biological activity or by immunoprecipitation and gel electrophoresis. The fraction that directs the synthesis of the greatest amount of the polypeptide product is then used as the starting material for construction of a cDNA library. A major drawback of this method of mRNA fractionation is the need to work with methylmercuric hydroxide, a poisonous compound of insidious toxicity.

Fractionation of cDNA

Until the mid 1980s, fractionation of mRNA was the method of choice for cloning mRNAs that encode large proteins. However, as methods for the synthesis of cDNA have improved, fractionation of double-stranded cDNA has become a more practical alternative, and there are now many examples of extremely large cDNAs that have been cloned by fractionating cDNA, rather than the mRNA from which it was copied; for example, human factor VIII:C (Toole et al. 1984; Wood et al. 1984), human sucrase-isomaltase (Hunziker et al. 1986), and human LDL-receptor-related protein (Herz et al. 1988). Fractionation of cDNA has major advantages: DNA is less susceptible than mRNA to degradation by contaminating nucleases; it can be fractionated more accurately by electrophoresis through agarose gels or neutral sucrose gradients (Kieffer 1991); and since the

fractionation can be carried out at a late stage during the cDNA cloning protocol, the chance of subsequent mishaps is reduced and the probability of obtaining a full-length clone of cDNA is increased. Fractionation is usually carried out after all of the enzymatic reactions involved in cDNA synthesis have been completed and just before the cDNA is inserted into a vector.

Immunological Purification of Polysomes

An alternative method of enrichment, now rarely employed, uses antibodies to purify polysomes that are trapped in the act of synthesizing the polypeptide of interest. The technique described originally (Palacios et al. 1972; Schechter 1973), which involved the immunoprecipitation of polysomes, worked well for mRNAs encoding abundantly synthesized proteins such as albumin and immunoglobulin, but attempts to apply the method to mRNAs of lesser abundance were generally disappointing. However, the introduction of immunoaffinity columns (Schutz et al. 1977) and protein A–Sepharose columns (Shapiro and Young 1981) led to a brief resurgence of the technique in the mid 1980s. For example, Korman et al. (1982) used a monoclonal antibody directed against the heavy chain of the human HLA-DR histocompatibility antigen to bind polysomes synthesizing the nascent protein to protein A–Sepharose columns. The polysomes were then dissociated with EDTA (ethylenediaminetetraacetic acid) and the mRNA was isolated by oligo(dT) chromatography. The immunoaffinity-purified mRNA, which represented only 0.01–0.05% of the total mRNA, was used both to prepare cDNA probes and to construct cDNA clones. Using similar methods with polyclonal antisera, Kraus and Rosenberg (1982) obtained a 6300-fold purification of the mRNA that encodes rat liver cystathionine β-synthase, and Russell et al. (1983) isolated cDNA clones for the bovine low-density lipoprotein receptor, whose mRNA is present at ~80 copies/cell in bovine adrenal cells.

Although a powerful technique, immunoaffinity purification of polysomes cannot be applied universally. First, it clearly will not work unless a reliable source of material is available from which to isolate functional polysomes. This is not always possible, especially when the starting material is a tissue or organ that is not commonly available. Second, it has not yet been shown to work for mRNAs that are extremely rare (1 molecule/cell or less). Furthermore, the success of the method depends entirely on the specificity, avidity, and type of the particular immunoglobulin, and the results obtained with one antibody cannot always be translated directly to another. Finally, the method requires the use of relatively large quantities of antibody. Partly because of these difficulties, immunoaffinity purification of polysomes has been superseded by development of cDNA expression vectors (e.g., λgt11 and λZAPII) that allow the direct isolation of cDNA clones encoding specific antigens.

Subtractive Cloning

It is never easy to identify cDNAs corresponding to mRNAs that are expressed in low abundance. However, the problem has been ameliorated by improvements in methods used to construct subtracted cDNA libraries.

The aim of subtractive cloning is to remove sequences that are of no interest from the cDNA preparation before constructing a library. If everything works well, this results in an enrichment of the target sequences. Removal of unwanted sequences is achieved by hybridizing single-stranded cDNA prepared from mRNA extracted from the tissue of interest to a 10–20-fold excess of DNA or RNA (driver) prepared from another source that does not express the genes of interest. After hybrids containing the cDNA have been removed, the residual cDNA molecules are cloned. Until recently, subtractive cloning involved using very large amounts of poly(A)$^+$ RNA to drive small amounts of cDNA into hybrids. The DNA-RNA hybrids were then separated from unhybridized cDNA by hydroxyapatite chromatography (e.g., please see Sargent and Dawid 1983;

Hedrick et al. 1984; Sargent 1987; Travis et al. 1987; Travis and Sutcliffe 1988). Nowadays, bacteriophage promoters can be used to generate RNA drivers from populations of cloned cDNAs, PCR can be used to generate DNA drivers (Timblin et al. 1990) from cDNAs cloned in single-stranded vectors (Duguid et al. 1988; Rubenstein et al. 1990), and hybrids can be captured by biotin:avidin affinity chromatography (Duguid et al. 1988; Rubinstein et al. 1990) or on latex beads (Hara et al. 1991). For a good general review, please see Sagerstrom et al. (1997).

CURRENT METHODS OF SYNTHESIZING cDNA

The basic strategy for enzymatic conversion of mRNA to cDNA has changed little since the mid 1970s, but there have been great improvements to the efficiency of the entire process. In addition, there is now a choice among several enzymes at many steps.

Synthesis of First-strand cDNA

The first strand of cDNA is synthesized by an RNA-dependent DNA polymerase reverse transcriptase using poly(A)$^+$ RNA (or mRNA) as a template and primed by either oligo(dT) or random oligonucleotide primers.

Reverse Transcriptase

Several different forms of reverse transcriptase are available commercially:

- ***Avian reverse transcriptase,*** which is purified from particles of an avian leukemia virus (ALV).
- ***Murine reverse transcriptase,*** which is isolated from a strain of *E. coli* that expresses a cloned copy of the reverse transcriptase gene of the Moloney strain of murine leukemia virus (Mo-MLV).

Commercial preparations of both ALV and Mo-MLV are now reasonably free of contaminating RNase, which, in the past, was a major impediment to the synthesis of large cDNA. However, some preparations of the avian enzyme are contaminated by an endonuclease that cleaves DNA, although this is less of a problem today than it was in the early 1980s. The avian enzyme consists of two nonidentical polypeptide subunits that carry several enzymatic activities: RNA-dependent synthesis of DNA (reverse transcriptase), endonucleolytic cleavage of DNA (integrase), and endonucleolytic attack on the RNA moiety of DNA-RNA hybrids followed by processive exonucleolytic removal of rNTPs (RNase H) (for reviews, please see Champoux 1993; Prasad 1993; Skalka 1993). The murine enzyme consists of a single polypeptide subunit that carries out both RNA- and DNA-dependent synthesis of DNA but has a reduced capacity to degrade RNA in DNA-RNA hybrids. Murine reverse transcriptase also lacks a contaminating endonuclease activity (Gerard 1983; Kotewicz et al. 1988).

The avian enzyme available from many manufacturers is adequate for routine construction of cDNA libraries. However, the high level of RNase H activity of the avian enzyme tends both to suppress the yield of cDNA and to restrict its length. At the beginning of the reaction, the hybrids formed between the template mRNA and the primer are a substrate for RNase H. Thus, at the beginning of cDNA synthesis, there is a competition between degradation of the mRNA and initiation of DNA synthesis (for review, please see Champoux 1993). In addition, the RNase H activity can cleave the RNA template near the 3′-hydroxyl terminus of the growing DNA strand if the polymerase pauses during synthesis (Kotewicz et al. 1988). Thus, the murine enzyme, with its weaker complement of endogenous degradative activities, is a safer choice when attempting to obtain full-length cDNA copies of mRNAs larger than 2–3 kb in length. The murine and avian enzymes display different salt and temperature optima for the synthesis of cDNA from RNA tem-

plates, and it is therefore important to modify the conditions for first-strand synthesis accordingly.

Reverse transcriptases lacking RNase H activity (e.g., SuperScript from Life Technologies) are genetically engineered versions of the murine enzyme that carry mutations that drastically reduce RNase H activity without any diminution in DNA polymerase activity (Gerard et al. 1992; Gerard and D'Alessio 1993). The total yield of first-strand cDNA is substantially higher with these enzymes than with nonengineered reverse transcriptases, and the proportion of full-length cDNAs is significantly greater (Kotewicz et al. 1988; Gerard et al. 1989, 1992; Gerard and D'Alessio 1993; Telesnitsky and Goff 1993). In addition, because the polymerizing activity of the enzyme is not inhibited by high temperatures, synthesis of first-strand cDNA can be carried out at temperatures as high as 50°C. This is an advantage when the template RNA is tightly crimped into secondary structures. For further information on these enzymes, please see the information panel on **Mo-MLV REVERSE TRANSCRIPTASE.**

Primers for Synthesis of First-strand cDNA

Listed below are four types of primers used to synthesize first-strand cDNA.

- ***Oligo(dT) 12–18 nucleotides in length that binds to the poly(A) tract at the 3′ terminus of eukaryotic cellular mRNA molecules.*** The primer is added to the reaction mixture in large molar excess so that each molecule of mRNA binds several molecules of oligo(dT)$_{12\text{-}18}$. Sequencing of cloned cDNAs shows that priming of first-strand synthesis probably begins from the most proximal of these bound primers and is very efficient.

- ***Primer-adaptors that contain a homopolymeric oligo(dT) tract at the 3′ terminus and a restriction site at the 5′ terminus*** (Coleclough and Erlitz 1985; Krawinkel and Zoebelein 1986; Han et al. 1987). The oligo(dT) sequences are used to prime synthesis of the first strand, which can then be tailed with dC residues. This procedure allows the DNA to be ligated to a vector before synthesis of the second strand (Coleclough and Erlitz 1985), or it enables a second primer-adaptor to be used to prime the synthesis of second-strand cDNA (please see Figure 11-2).

- ***Primers linked to a plasmid.*** Priming of first-strand synthesis is carried out by a tract of oligo(dT) that is covalently attached to a plasmid (Okayama and Berg 1982, 1983; Okayama et al. 1987). Because it is often not possible to incorporate enough oligomerically tailed plasmid in the reaction mixture to achieve a high ratio of primer to template, priming is usually the rate-limiting step during this kind of reaction. This limitation results in less efficient utilization of mRNA templates during synthesis of the first strand of cDNA. However, the reduction in yield of the first strand of cDNA is offset, at least in part, by the increased efficiency of cloning that results from the direct covalent attachment of the cDNA to the vector. Libraries made according to the original Okayama-Berg protocol (1982, 1983) are generally moderate in complexity and have a high proportion of full-length cDNAs. The chief disadvantage of the original protocol is that it is lengthy, demanding, and involved. Newer procedures that also use asymmetrically tailed plasmid to prime synthesis of first-strand cDNA are much simpler and yield libraries of higher complexity (e.g., please see Bellemare et al. 1991; Spickofsky and Margolskee 1991).

- ***Random primers.*** Even the best cDNA libraries contain only a small proportion of full-length clones. If the synthesis of first-strand cDNA was incomplete, the clones will lack sequences from the 5′ end of the mRNA. If synthesis of second-strand cDNA was arrested or blocked, the 3′ end of the mRNA will be underrepresented in the library. These problems can be amelio-

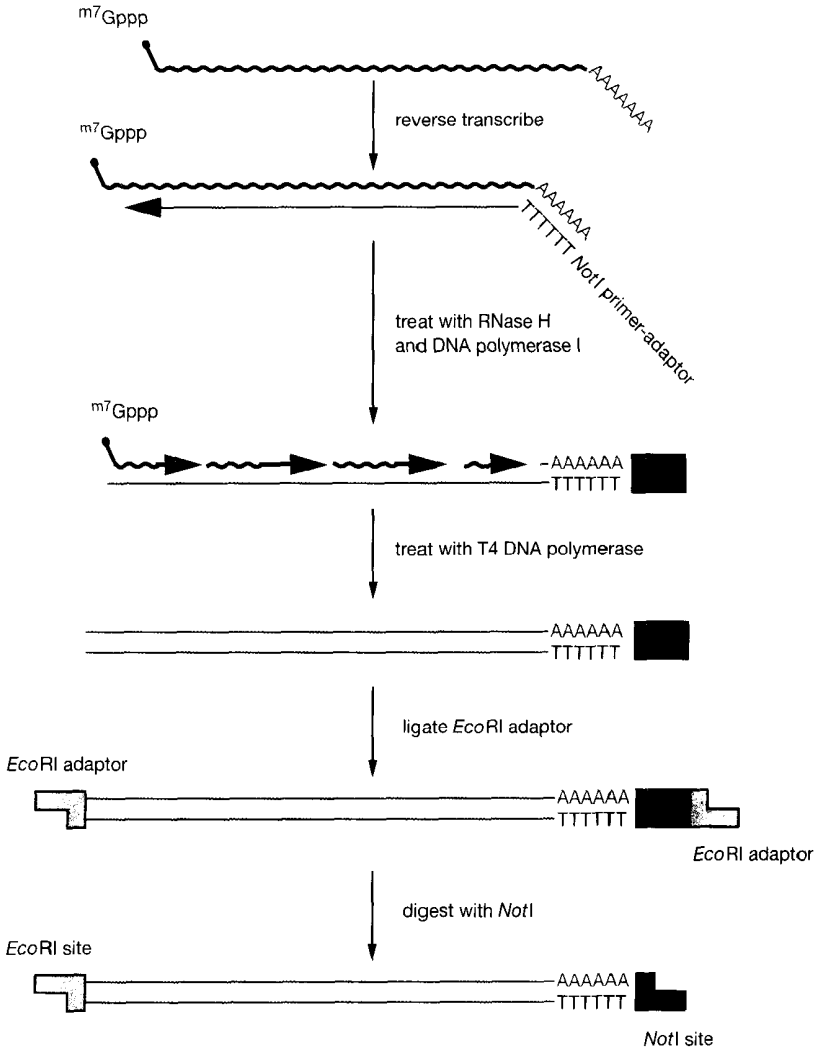

FIGURE 11-2 Priming cDNAs with an Oligo(dT) Adaptor for Directional Cloning

The first-strand reaction of cDNA synthesis is primed by oligo(dT) sequences linked to a primer-adaptor encoding a restriction endonuclease recognition site (in this case, *Not*I). The sequence of mRNA is represented by the colored (wiggly) strand, whereas the oligo(dT)-adaptor is shown in black. Treatment of the RNA-DNA hybrid with RNase H and DNA polymerase I nicks the RNA moiety, creating 3′-hydroxyl termini that are used by T4 DNA polymerase to complete the second-strand synthesis. Ligation of *Eco*RI adaptors to the double-stranded cDNA product and cleavage with *Not*I allow the product to be inserted in a directed manner into an appropriate vector.

rated by using random oligonucleotides (usually hexamers) as primers (please see Figure 11-3). However, although this strategy may solve one problem, it also creates others. cDNA clones derived from random priming of first-strand cDNA tend to be smaller than clones derived from oligo(dT) priming. In addition, the efficiency of priming varies from one RNA to another, depending on the size of the mRNA and the complexity and composition of the random oligonucleotide pool. If the use of random primers creates problems, there are alternative ways to generate cDNA clones containing 5′- and 3′-terminal regions of mRNAs, for example, 5′ RACE and 3′ RACE (please see Chapter 8, Protocols 9 and 10). For a summary of methods to synthesize first-strand cDNA, please see Table 11-2.

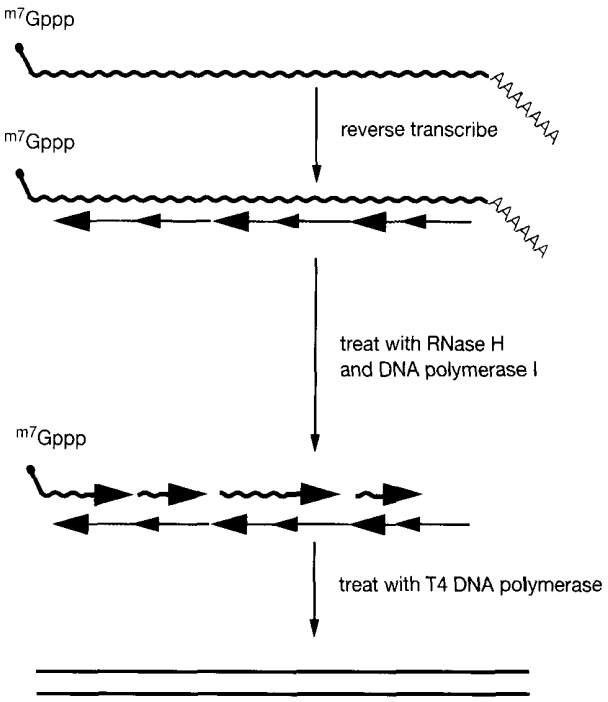

FIGURE 11-3 Random Priming of cDNAs

Synthesis of first-strand cDNA is initiated by random oligonucleotides, usually hexamers (represented as black arrows) that are extended by reverse transcriptase (extension products are shown as colored arrows). Treatment with RNase H and DNA polymerase I nicks the RNA and repairs gaps in the cDNA. Second-strand synthesis is carried out by T4 DNA polymerase.

Synthesis of Second-strand cDNA

For many years, there was no effective way other than self-priming to synthesize the second strand of cDNA, and almost all clones of cDNA made before 1982 were obtained using this enzymatic reaction (e.g., please see Efstratiadis et al. 1976; Higuchi et al. 1976; Maniatis et al. 1976; Rougeon and Mach 1976). The self-primed synthesis of the second strand of cDNA was at best a poorly controlled reaction, and the subsequent cleavage of the hairpin structure with nuclease S1 almost invariably led to the loss or rearrangement of sequences corresponding to the 5′ terminus of the mRNA (Land et al. 1981). Consequently, this scheme for synthesizing double-stranded cDNA molecules has now been largely replaced by more efficient and less destructive methods (please see below) that yield 10–100 times more cDNA clones than self-priming (Okayama and Berg 1982; Gubler and Hoffman 1983).

Today, second-strand synthesis is usually catalyzed by *E. coli* DNA polymerase I and *E. coli* RNase H. However, other enzymes including thermostable DNA polymerases such as *Tth* and *Taq* are also used, albeit rarely. The conditions used to achieve synthesis of full-length second-strand cDNA depend on the particular DNA polymerase. Reactions that use *E. coli* DNA polymerase I are usually carried out at pH 6.9 to minimize the 5′→3′ exonuclease activity of the enzyme and at 15°C to minimize the possibility of synthesizing "snapback" DNA. These problems can be completely avoided by using either reverse transcriptase or the Klenow fragment, both of which lack 5′→3′ exonuclease activity and are available in pure form from commercial sources. *E. coli* DNA ligase is sometimes included in the reaction because evidence indicates that the efficiency of

TABLE 11-2 Methods to Synthesize First-strand cDNA

Priming with Oligo(dT)

Advantages: Efficient and simple.

Allows use of the Gubler and Hoffman (1983) procedure for synthesis of the second strand of cDNA.

Because different linkers or adaptors can be added at each end of the cDNA, directional cloning is possible and there is great flexibility in choice of vectors.

Disadvantages: Linkers, tails, or adaptors must be added before the cDNA is inserted into the vector.

Many procedures require that the double-stranded cDNA be digested with a restriction enzyme(s) before cloning. This step can be risky because the cDNA of interest itself may be cleaved. Potential restriction sites can be protected by methylation of double-stranded cDNA or incorporation of methylcytosine residues during synthesis of first-strand cDNA. In either case, a strain of *E. coli* defective in the *mcr* restriction system should be used as a host. *mcr*$^+$ strains restrict DNA carrying methylcytosine residues (Raleigh et al. 1988; Woodcock et al. 1989).

The background of empty clones is generally much higher than that in plasmid-primed methods.

Most cDNA libraries constructed by oligo(dT) priming are enriched for sequences that lie at the 3′ end of the mRNAs.

Priming with Primer-Adaptors

Advantages: Synthesis of the second strand can be carried out after the homopolymerically tailed cDNA has been ligated to a vector.

Alternatively, second-strand synthesis can be carried out using the Gubler-Hoffman method (Gubler and Hoffman 1983; Gubler 1988). In this case, directional cloning of the cDNA can be achieved by the use of a linker-primer and an adaptor for the restriction enzyme *Sfi*I (Miki et al. 1989).

The background of empty clones is generally lower with primer-adaptors than with oligo(dT)-primed synthesis of the first strand. Both plasmids and bacteriophage λ vectors can be used.

Disadvantages: Many protocols require the elimination of small oligonucleotides and unused primers from the first strand of cDNA by electrophoresis through alkaline agarose gels. The recovery of DNA at this stage is often poor.

Plasmid-primed Methods

Advantages: Selects for full-length or nearly full-length clones, perhaps because long cDNAs are preferred substrates for terminal transferase.

Whereas the original protocol (Okayama and Berg 1982) generated libraries of modest complexity, more recent versions are claimed to be extremely efficient and to generate almost 10^7 to 10^9 clones/μg of linker-primer DNA (Bellemare et al. 1991; Spickofsky and Margolskee 1991).

Disadvantages: The original protocol (Okayama and Berg 1982) was difficult and lengthy. More modern versions (e.g., please see Bellemare et al. 1991; Spickofsky and Margolskee 1991) are slightly easier but remain demanding.

Restricted to plasmid vectors.

Priming with Random Populations of Oligonucleotides

Advantages: Priming of first-strand cDNA by random primers (Goelet et al. 1982; Binns et al. 1985) can sometimes improve the efficiency of cloning 5′ sequences of a particular mRNA.

Disadvantages: cDNAs generated by random priming tend to be small and must be carefully fractionated according to size to eliminate the useless population of tiny molecules. Random hexamers are usually removed between synthesis of first and second cDNA strands.

RT-PCR Methods

Advantages: "Universal primers" may be used for amplification of all mRNAs, regardless of their sequence (please see the information panel on **UNIVERSAL PRIMERS** in Chapter 8). These are used to generate cDNA libraries when only small amounts of poly(A)$^+$ RNA (<200 ng) are available. Other PCR protocols rely on gene-specific primers that are unique to or selective for particular target cDNAs (Frohman et al. 1988). For example, the 5′ RACE method allows amplification of the 5′ end of mRNAs for which some sequence near the 5′ end is known (please see Chapter 8, Protocol 9).

Disadvantages: Clones generated by standard PCR amplification are likely to contain a higher number of mutations than those produced by other means. Methods that require unique primer sequences can be used only if the partial sequence of a cDNA or its cognate protein is already available.

cloning longer cDNAs may be improved (Okayama and Berg 1982; Gubler and Hoffman 1983; D'Alessio and Gerard 1988). Frequently, T4 DNA polymerase or a thermostable polymerase such as *Pfu* is added at the end of the second-strand reaction to polish the termini of the completed double-stranded DNAs. However, generating blunt ends in this fashion sometimes results in loss of 5′-terminal sequences so that the resulting cDNA clones are 5–30 nucleotides shorter than the original mRNA (Gerard and D'Alessio 1993).

Replacement Synthesis of the Second Strand of cDNA

In this method, which was introduced by Okayama and Berg (1982) and modified by Gubler and Hoffman (1983; Gubler 1988), the product of first-strand synthesis — a cDNA-mRNA hybrid — is used as a template for a nick-translation reaction (please see Figure 11-4). RNase H produces nicks and gaps in the mRNA strand of the hybrid, creating a series of RNA primers that are used by *E. coli* DNA polymerase I during the synthesis of the second strand of cDNA. The reaction has three main virtues:

- It is very efficient.
- It can be carried out directly using the products of the first-strand reaction, which need no further treatment or purification.
- It eliminates the need to use nuclease S1 to cleave the single-stranded hairpin loop in the double-stranded cDNA, a reaction that is difficult to control and frequently results in a great loss of cDNA.

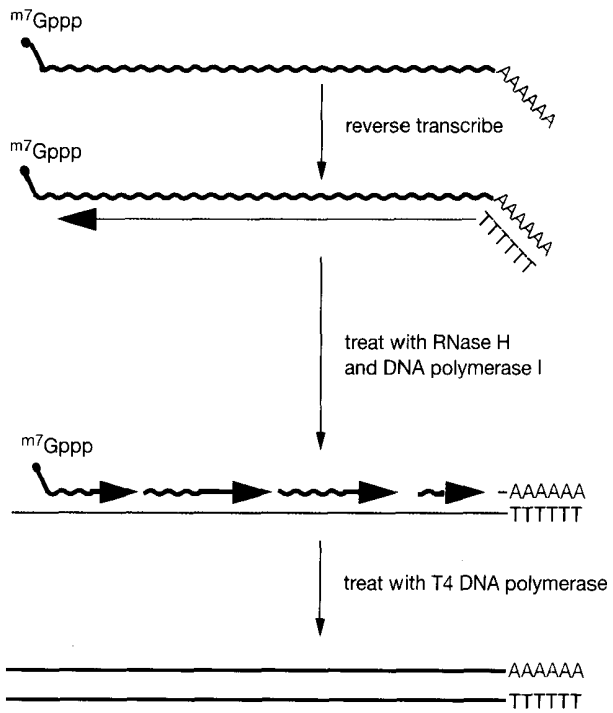

FIGURE 11-4 Schematic for Basic Gubler-Hoffman Strategy

A series of three enzymatic reactions is used to generate double-stranded cDNA. First-strand synthesis is initiated using poly(dT), the mRNA template is removed by treatment with RNase H, and second-strand synthesis is carried out using DNA polymerase I and T4 DNA polymerase. The resulting double-stranded cDNA product is left in a blunt-ended state, convenient for subsequent attachment of linkers or adaptors to facilitate cloning.

Although most cDNA libraries are now constructed using a replacement reaction to synthesize the second strand of cDNA, the reaction described by Gubler and Hoffman (1983) presents three potential problems: (1) Eukaryotic mRNAs carry "cap" structures at their 5′ termini, and it is not clear how these caps are removed so that the double-stranded cDNA can be inserted into a prokaryotic vector; (2) the replacement reaction is incapable of synthesizing the second strand of cDNA corresponding to the 5′-terminal region of the mRNA; and (3) hairpin priming of second-strand synthesis may still occur during the replacement reaction if RNase H efficiently removes the mRNA sequences immediately adjacent to the cap structure. In practice, however, these disadvantages turn out not to be serious: The products of the replacement reaction can be efficiently inserted into prokaryotic vectors without taking any special steps to remove the cap structure; the resulting cDNAs are often very nearly full-length, lacking only a few nucleotides corresponding to the 5′ terminus of the mRNA; and self-priming usually accounts for <10% of the second-strand synthesis.

Oligonucleotide-primed Synthesis of the Second Strand of cDNA

For routine construction of cDNA libraries, the simple replacement reaction described by Gubler and Hoffman (1983) is perfectly adequate. However, if the goal is to establish expression libraries (which require full-length cDNAs) or to clone the 5′-terminal sequences of eukaryotic mRNA with high efficiency, the methods outlined below offer some advantages.

- After completion of first-strand synthesis, terminal transferase can be used to add homopolymeric tails of dC residues to free 3′-hydroxyl groups (Rougeon et al. 1975; Land et al. 1981). This tail is then hybridized to oligo(dG), which serves as a primer for synthesis of the second strand of cDNA (please see Figure 11-5). The efficiency of this method seems to depend on the particular mRNA under study. In the best cases (e.g., chicken lysozyme mRNA [Land et al. 1981]), full-length clones of cDNA can be obtained with high efficiency; other mRNAs, however, have provided more variable results (Rougeon et al. 1975; Cooke et al. 1980), perhaps reflecting the relative efficiencies with which terminal transferase uses the 3′ termini of different first-strand cDNAs as substrates for homopolymeric tailing. The presence of oligomeric tails at each end of the first-strand cDNA provides an opportunity to amplify the cDNA in vitro by PCR (Belyavsky et al. 1989; Tam et al. 1989; Welsh et al. 1990). This is useful when the amount of available mRNA is too small for producing cDNA by standard procedures. However, because PCR amplification of long cDNAs is inefficient, there is a strong selection against large cDNAs.

- Okayama and Berg (1982) used a fragment of plasmid DNA carrying a short tail of dG residues as a primer for second-strand synthesis (Figure 11-6). The dG residues are annealed to a homopolymeric tract of dC residues that has been added to the 3′ terminus of the first strand of cDNA by terminal transferase. Although the protocol generally works well, it is laborious, requiring restriction endonuclease digestion of the mRNA:cDNA duplex, followed by the addition of a fragment tailed with dG to prime the second-strand repair reaction. Several modifications have been described that simplify the cloning procedure by omitting the need for the separate upstream linker that is used to prime second-strand synthesis and to join the double-stranded cDNA to the plasmid. These modifications include:

  The use of synthetic primer-adaptors that carry both homopolymeric tails for priming the synthesis of the first and second strands of cDNA and restriction sites for cloning into plasmids (Coleclough and Erlitz 1985) and bacteriophage λ vectors (Krawinkel and Zoebelein 1986; Han et al. 1987). The use of primer-adaptors has three advantages. First,

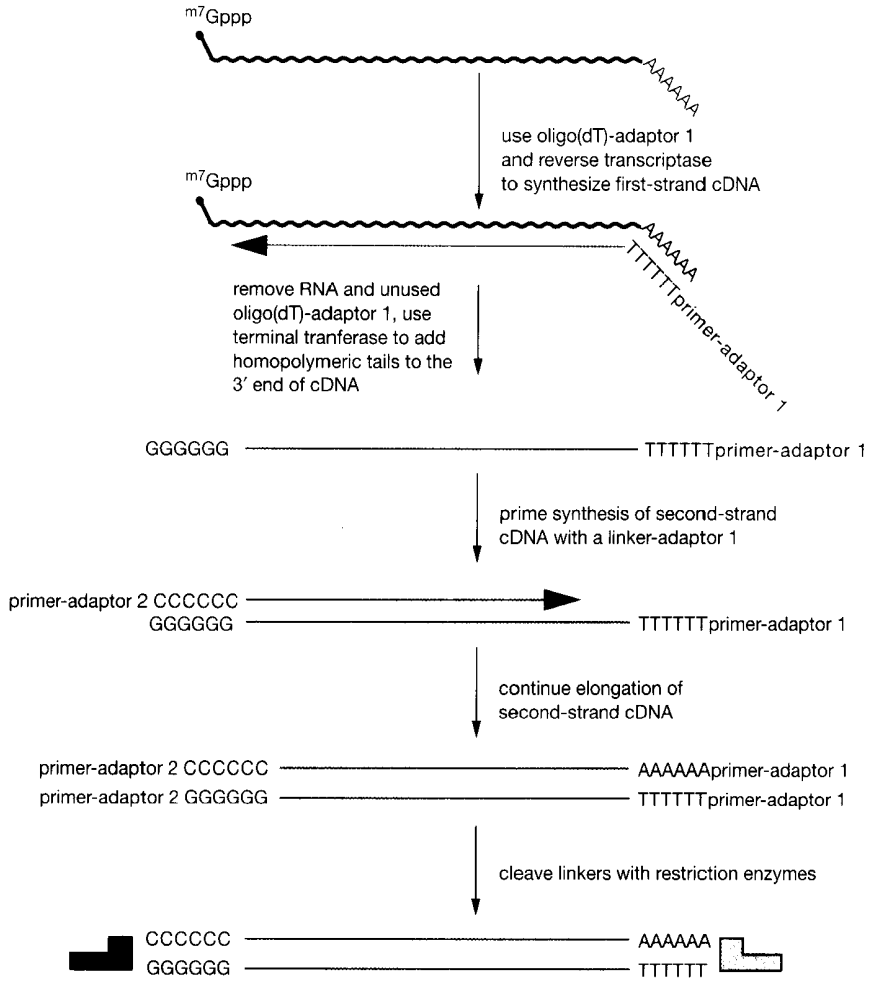

FIGURE 11-5 Homopolymeric Priming of Second-strand cDNA

First-strand synthesis is initiated with an oligo(dT) primer-linker (represented in black). After removal of the mRNA template, a homopolymeric tail is added to the single-stranded cDNA product. Second-strand synthesis is primed using an oligomeric sequence complementary to the the homopolymeric tail, and the resulting product is cleaved with restriction endonucleases whose recognition sites have been incorporated at the ends of the double-stranded cDNA molecules.

the number of steps involved in the synthesis and cloning of cDNA is reduced. For example, in the protocol described by Han et al. (1987), the cDNA-mRNA hybrid is attached to a bacteriophage λ vector by synthetic adaptors before synthesis of the second strand of cDNA. This eliminates several steps that are required when double-stranded cDNA is cloned by addition of synthetic linkers. Second, the increased efficiency of priming of second-strand synthesis yields libraries that contain a comparatively high proportion of full-length cDNA molecules. Third, the method can be adapted to allow the amplification of first-strand cDNA by PCR. However, there are also some disadvantages: All of the clones generated by homopolymeric priming of second-strand synthesis carry a tract of dG:dC residues immediately upstream of the sequences corresponding to the mRNA template. The presence of these additional sequences may inhibit transcription of DNA both in vivo and in vitro. Furthermore, they may form a barrier to the Klenow fragment of *E. coli* DNA polymerase I during DNA sequencing by the dideoxy-mediated chain-termination

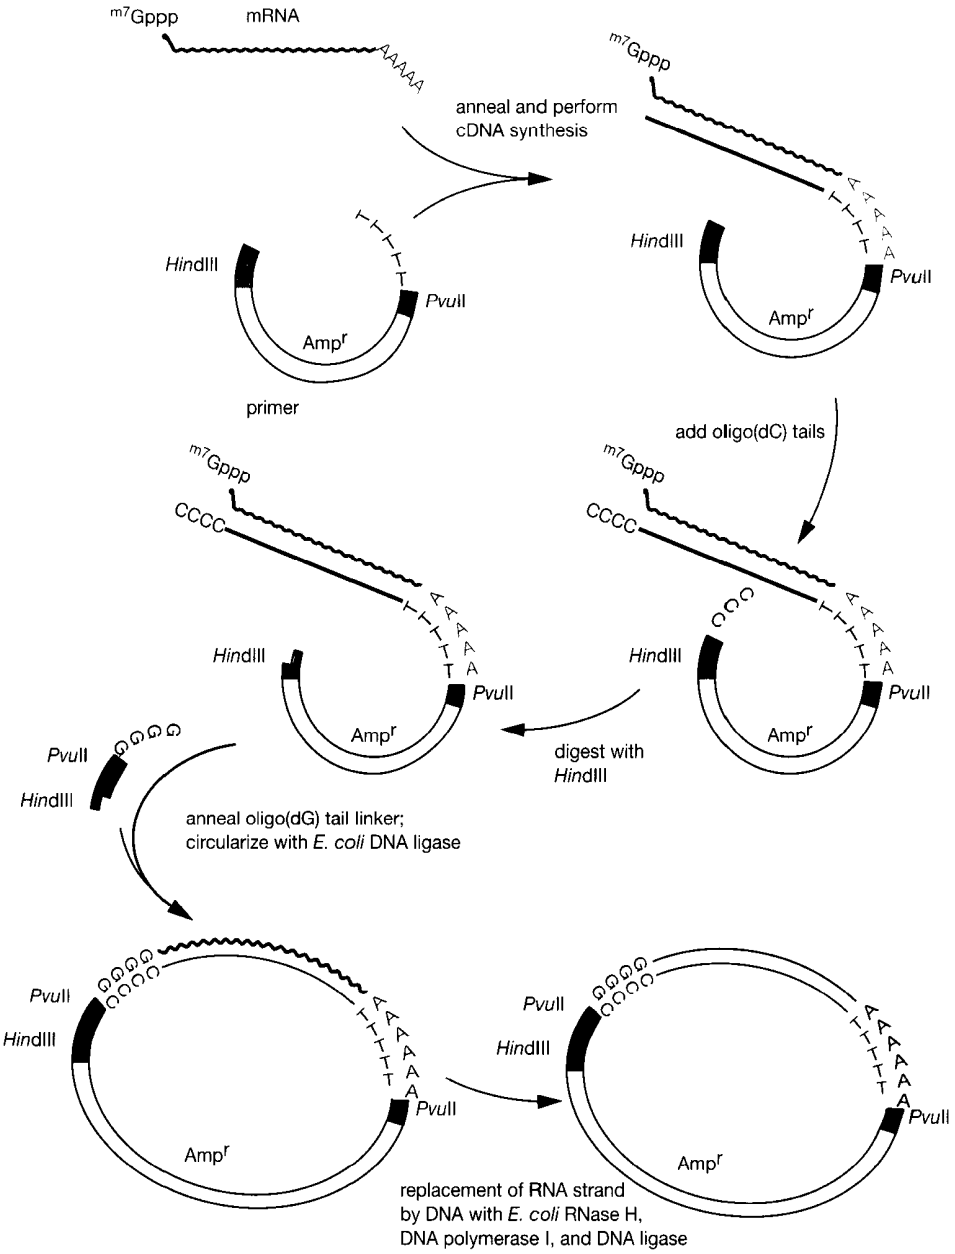

FIGURE 11-6 Schematic of the Okayama and Berg Strategy

Preparation of plasmid primer and linker DNA. The unshaded portion of each vector circle is pBR322 DNA, and the shaded segments represent the restriction endonuclease sites. Please see text for details. (Adapted, with permission, from Okayama and Berg 1982 [©American Society for Microbiology].)

method, requiring that another DNA polymerase (e.g., reverse transcriptase) be used instead and the conditions adjusted accordingly.

The use of a linearized plasmid that carries a synthetic (dT) tail at one 3′ end and a synthetic (dC) tail at the other (Spickofsky and Margolskee 1991). This construct is made by ligating adaptors bearing the appropriate homopolymeric tails to a plasmid that has been cleaved by two different restriction enzymes (e.g., *Kpn*I and *Sac*I). The dC tail carries a 3′-phosphate group to block further addition of residues at the 3′ end. After the dT tail has been used to prime synthesis of first-strand cDNA, dG residues are added to the free 3′ end

of the cDNA by terminal transferase. The blocking 3′-phosphate is then removed by alkaline phosphatase, and the second DNA strand is synthesized by the combined actions of RNase H, DNA polymerase I, and DNA ligase.

Careful consideration should be given to the method used to synthesize the second strand of cDNA, because it can determine the choice of vector and dictate the means used to link the cDNA to the vector.

MOLECULAR CLONING OF DOUBLE-STRANDED cDNA

The cloning of double-stranded cDNA into a vector is facilitated by the addition of various tails, linkers, or adaptor sequences to the ends of cDNAs.

Synthetic DNA Linkers and Adaptors

Synthetic linkers containing one or more restriction sites provide an effective method for joining double-stranded cDNA to both plasmid and bacteriophage λ vectors and have supplanted other methods for cloning cDNA populations (please see the information panel on **HOMOPOLYMERIC TAILING**). Double-stranded cDNA is treated with bacteriophage T4 DNA polymerase or *E. coli* DNA polymerase I, enzymes that remove protruding single-stranded 3′ termini with their 3′→5′ exonucleolytic activities and fill in recessed 3′-hydroxyl termini with their polymerizing activities. The combination of these activities generates blunt-ended cDNA molecules, which are then incubated with a very large molar excess of linker molecules in the presence of bacteriophage T4 DNA ligase, an enzyme capable of catalyzing the ligation of blunt-ended DNA molecules. The products of the reaction are cDNA molecules carrying polymeric linker sequences at their termini. These molecules are cleaved at a restriction site in the linker, purified, and ligated to a vector that has been cleaved with a restriction enzyme that generates cohesive termini compatible with those of the linker.

Double-stranded cDNA molecules containing the synthetic cohesive termini will of course ligate to each other, as well as to the vector DNA. It is therefore important to arrange the ligation conditions to minimize the formation of chimeric molecules, since it is extremely laborious subsequently to test whether cDNA clones that contain the particular restriction site at an internal location have been formed by end-to-end ligation of two unrelated cDNAs. The ligation mixture should therefore always contain a high molar excess of vector DNA to cDNA. However, these conditions strongly favor reformation of the vector by self-ligation, leading to unacceptably high backgrounds of nonrecombinant clones. This problem may be minimized by treating the cleaved vector with a phosphatase before ligation to cDNA.

If the double-stranded cDNA contains one or more recognition sites for the restriction enzyme, it will be cleaved and subsequently cloned as two or more DNA fragments, preventing the isolation and analysis of full-length cDNAs. Attempts to alleviate this problem have included the following:

- ***The use of restriction enzymes that cleave mammalian DNA very rarely*** (e.g., *Not*I and *Sal*I). There is no guarantee that even a small cDNA does not contain a recognition site for a particular restriction enzyme. However, if the size of the cDNA clone of interest is considerably smaller than the size of the average fragment of genomic DNA obtained by digestion with the chosen enzyme, there is a good chance that it will not contain a recognition sequence for that enzyme. For example, the odds of finding the G/C-rich octanucleotide sequence recognized by *Not*I in a 5-kb clone of cDNA are less than 1 in 200. For *Sal*I, whose sites occur, on average, once every 100 kb in mammalian DNA, the odds rise to 1 in 20, still perhaps an acceptable risk.

By contrast, the average distance between *Eco*RI sites is ~4 kb, and so there is a reasonably good probability that a cDNA of average size will be cleaved into two or more pieces. If it is essential to clone into a restriction site that occurs as frequently as *Eco*RI, it is advisable to take one of the additional precautions outlined below to avoid potential problems.

- ***The introduction of methyl groups that will modify and protect naturally occurring restriction sites in cDNAs.*** This modification can be done either by methylation of double-stranded cDNA with a methylase (e.g., M·*Eco*RI methylase) before addition of synthetic linkers, or by incorporating 5-methyl dCTP during synthesis of the first cDNA strand (Han and Rutter 1988; Huse and Hansen 1988). If the cDNA is methylated, then a strain of *E. coli* must be used that is deficient in the *mcr* restriction system, which cleaves DNA at methylcytosine residues (Raleigh et al. 1988; Woodcock et al. 1989). When constructing cDNA libraries from small amounts of RNA, many investigators simply omit the methylation step in an effort to streamline the procedure and to generate the maximum number of cDNA clones (e.g., please see McDonnell et al. 1987; Don et al. 1993).

- ***The use of synthetic adaptors rather than linkers.*** Adaptors are short, double-stranded oligonucleotides that carry one blunt end (which can be ligated to the double-stranded cDNA) and one cohesive terminus (which can be ligated to a compatible terminus in the vector). Adaptors are essentially precut linkers that do not require digestion with restriction enzymes after they have been ligated to double-stranded cDNA. However, cDNA molecules carrying phosphorylated adaptors can form covalently closed circular molecules (which cannot be cloned) or chimeric linear molecules (which are highly undesirable) during the subsequent ligation reaction in the presence of dephosphorylated vector DNA. To avoid this problem, only the shorter strand of the adaptor is phosphorylated before ligation to cDNA. The products of the ligation (cDNA molecules carrying a single adaptor at each end and dimer adaptor molecules) are separated by column chromatography. The termini of the cDNA molecules carrying adaptors are phosphorylated with bacteriophage T4 polynucleotide kinase and then ligated to a large molar excess of the appropriate dephosphorylated vector.

In addition to equipping the termini of cDNA for cloning, linkers can also be used as binding sites for primers in PCRs. By including a PCR step, large cDNA libraries can be established from very small amounts of cDNA (for methods and reviews, please see Tam et al. 1989; Hu et al. 1992; Brady and Iscove 1993; Lambert and Williamson 1993, 1997; Rothstein et al. 1993; McCarrey and Williams 1994; Revel et al. 1995).

Vectors Used for Cloning of cDNA

Until 1983, almost all cDNA cloning was carried out using plasmid vectors, and cDNA libraries were usually maintained as a collection of $>10^5$ independently transformed bacterial colonies. These colonies were sometimes pooled, amplified in liquid culture, and stored at –70°C; more frequently, they were maintained on the surfaces of nitrocellulose filters (please see Chapter 1, Protocol 31). In either case, the results were unsatisfactory. The libraries were difficult to preserve without loss of viability, and screening by hybridization with multiple radioactive probes often required painstaking replication of colonies from one nitrocellulose filter to another. This is a laborious process that can be repeated only a few times before the colonies on the master filter become smeared beyond recognition. With the advent of more efficient ways to synthesize cDNA (Gubler and Hoffman 1983) and with the growing availability of linkers, adaptors, methylases, and packaging mixtures, it became possible to use bacteriophage λ as a vector and to take advantage of the high efficiency and reproducibility of in vitro packaging of bacteriophage λ DNA into

infectious virus particles. The resulting libraries are often large enough to be screened directly without amplification. Alternatively, they can be amplified, stored indefinitely without loss of viability, and, depending on the particular vector, screened with either nucleic acid probes, antibodies, or other ligands.

The features of the most popular bacteriophage λ vectors and plasmid vectors used to construct cDNA libraries are outlined below. We recommend λZAP and its derivatives (Stratagene) or λZipLox (Life Technologies) for standard cDNA library construction. These vectors have been engineered to allow recovery of cDNA inserts as plasmids, and they thus obviate the need for tedious preparation of bacteriophage λ DNA and conventional subcloning into plasmids.

- ***λZAP*** (Short et al. 1988) carries a polycloning site embedded in the region of the *lacZ* gene coding for the α-complementation fragment of β-galactosidase. cDNAs up to 10 kb in length may be inserted into the polycloning site downstream from the *lacZ* promoter and expressed either in infected bacteria or in induced lysogens, essentially as described for λgt11. In addition, λZAP fusion proteins may be expressed from high-copy-number plasmids following excision of the DNA insert and flanking plasmid sequences from the bacteriophage λ vector. Among the advantages of λZAP are (1) the presence of six unique restriction sites within the polycloning region that may be used for directional cloning of cDNA molecules; (2) the presence of promoters from bacteriophages T3 and T7 that flank the polycloning regions; these promoters can be used to synthesize strand-specific RNA probes complementary to the cloned cDNA; and (3) the presence of bacteriophage-f1-derived sequences for in vivo conversion of the DNA insert from the bacteriophage λ vector to the Bluescript plasmid, whose sequences are contained within λZAP. Excision is facilitated by positioning bacteriophage f1 sequences that encode signals for initiation and for termination of single-stranded DNA synthesis on either side of the polycloning site (Dotto et al. 1984). When F′ cells infected with λZAP are superinfected with a filamentous helper bacteriophage (e.g., f1 R408 [Russel et al. 1986]), the gene II product synthesized by the superinfecting phage nicks one of the two strands of λZAP DNA at the initiation site. Synthesis of single-stranded DNA proceeds through the polycloning site (and any cDNA sequences inserted into it) and terminates at the downstream termination site. Some of the single-stranded progeny DNA molecules circularize and become packaged into filamentous virus particles that are secreted from the cell. When F′ bacteria are infected with these particles, the incoming single-stranded DNA is converted into a double-stranded molecule that carries a colicin E1 (colE1) origin, expresses β-lactamase, and replicates as a conventional plasmid, which can be amplified and purified by conventional methods (please see Chapter 1). Because the plasmid carries a functional origin of bacteriophage f1 replication, cells superinfected with a suitable helper bacteriophage yield progeny particles that carry single-stranded copies of the DNA lying between the initiation and termination sites in the bacteriophage λ genome.
- ***λZAPII*** is equivalent to λZAP except that a Sam100 mutation has been removed. Removal of the Sam100 mutation allows better growth of bacteriophage λ, which, in turn, causes the plaques to turn blue much sooner in the presence of IPTG (isopropyl-β-D-thiogalactopyranoside) and X-gal (5-bromo-4-chloro-3-indole-β-D-galactoside). A map of λZAPII is presented in Figure 11-7.
- ***λZAP Express*** is similar to other members of this series of vectors except that the excised plasmid carries control elements for expression of the cloned cDNA in eukaryotic cells (please see Figure 11-8). These elements include the powerful immediate early region promoter of the human cytomegalovirus positioned upstream of the multiple cloning site and an SV40 termination sequence located downstream from the cDNA insert. Excision of the expression plasmid from λZAP Express is mediated by superinfection with a filamentous helper bacteriophage. The excised plasmid carries sequences needed (1) for transcription of the cDNA in *E.*

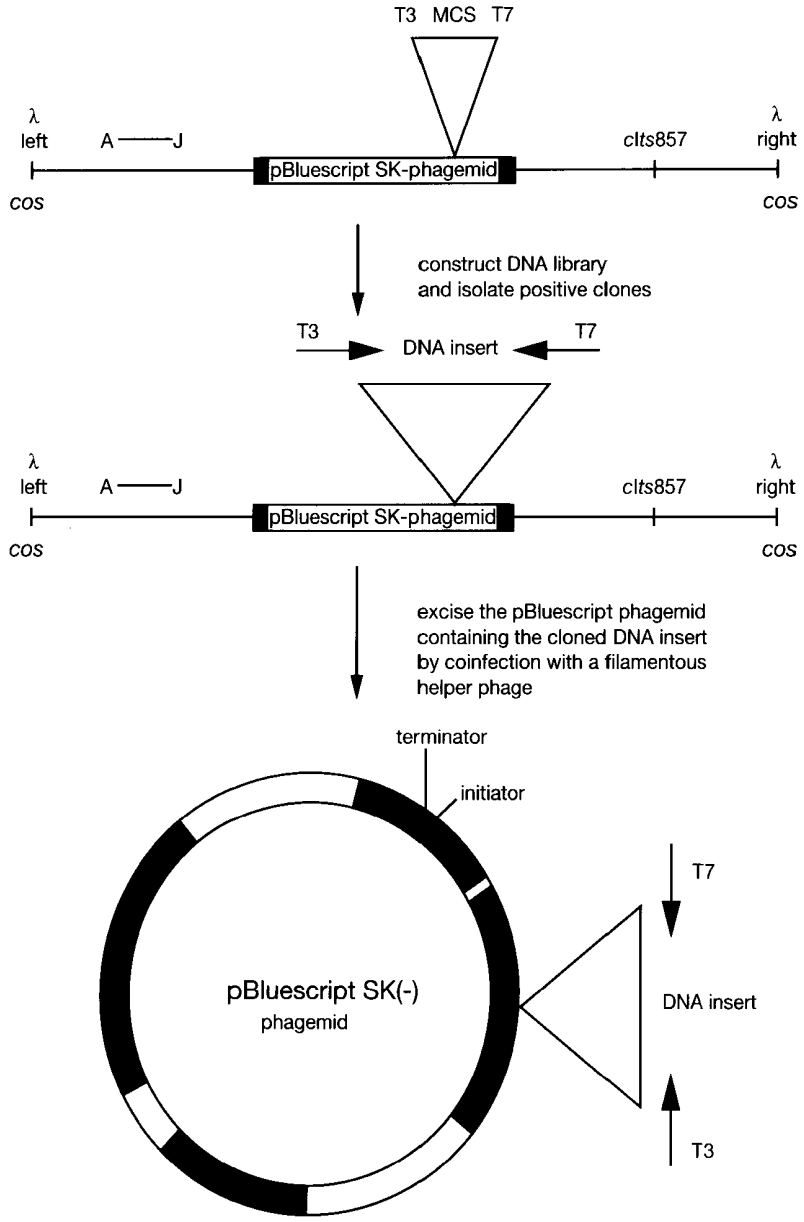

FIGURE 11-7 λZAPII

λZAPII is constructed from a fragment derived from the left arm of bacteriophage λ carrying λ genes *A–J*; a fragment derived from the right arm of λ carrying c*Its*857; the gene encoding the temperature-sensitive repressor; and pBluescript SK phagemid. The multiple cloning site (MCS) carried within the phagemid sequence is flanked by transcription initiation sites for bacteriophages T3 and T7. The vector carries the origins of replication from f1 and colE1 and the gene conferring ampicillin resistance. Individual bacteriophage λ clones or an amplified library can be used to infect *E. coli* that are coinfected with filamentous helper phages. Inside the cell, *trans*-acting proteins encoded by the helper phage recognize initiator (I) and terminator (T) domains within the λZAPII vector arms. Both signals are recognized by the helper phage gene II protein and a new DNA strand is synthesized, displacing the existing strand. The displaced strand is circularized and packaged as a filamentous phage by helper phage proteins and secreted from the cell. Circular double-stranded pBluescript phagemids are generated by infecting an F′ strain of *E. coli* with the population of recovered filamentous bacteriophages and growing small-scale cultures of infected cells in media containing ampicillin. The closed circular phagemid DNA is then isolated by standard methods (please see Chapter 1). (Adapted with permission, ©1999 Stratagene.)

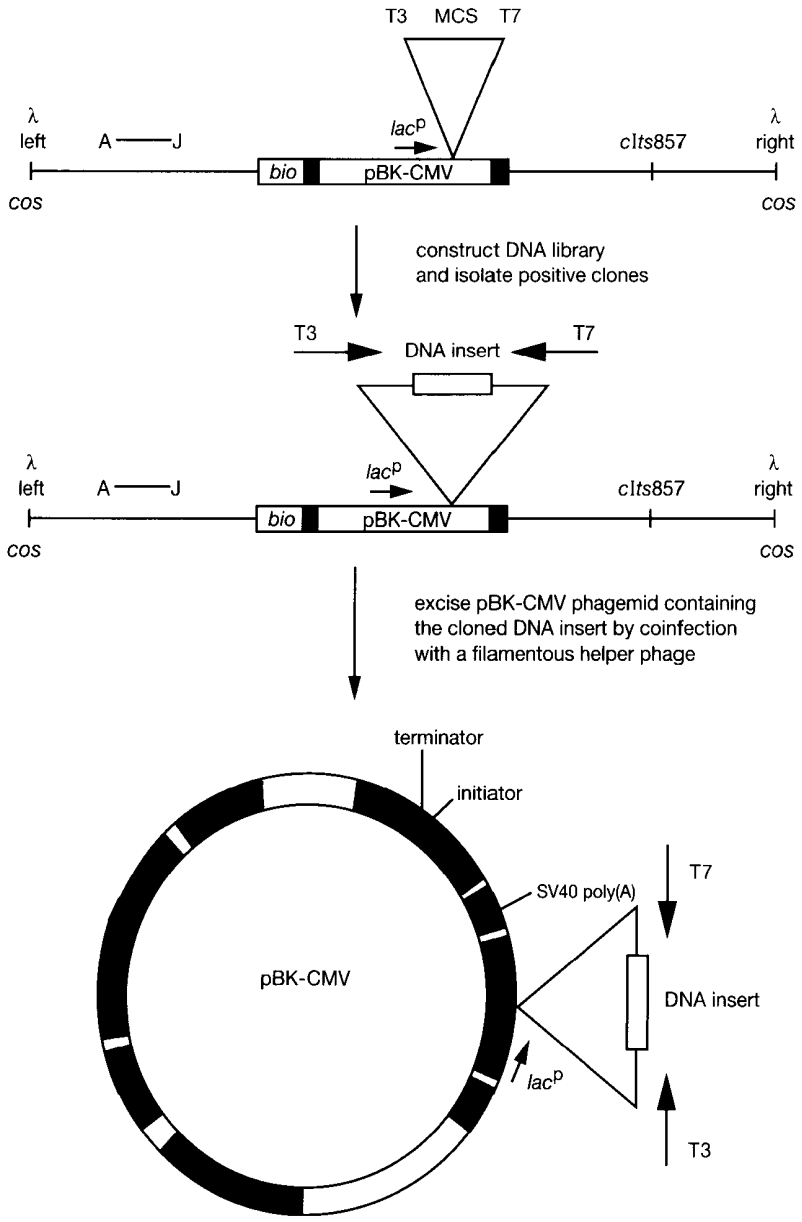

FIGURE 11-8 λZAP Express

λZAP Express is constructed from a fragment derived from the left arm of bacteriophage λ which carries λ genes *A–J*; a fragment derived from the right arm of λ carrying *cIts857*; the gene encoding the temperature-sensitive repressor; and pBK-CMV plasmid. The multiple cloning site (MCS) carried within the plasmid sequence is flanked by transcription initiation sites for bacteriophages T3 and T7. The vector carries the origins of replication from f1, colE1, and SV40; the CMV and *lac*^{p} promoters; and the gene for neomycin resistance. Individual bacteriophage λ clones or an amplified library can be used to infect *E. coli* cells that are coinfected with filamentous helper phage. Inside the cell, *trans*-acting proteins encoded by helper phage recognize initiator (I) and terminator (T) domains within the λZAP Express vector arms. Both signals are recognized by the helper phage gene II protein and a new DNA strand is synthesized, displacing the existing strand. The displaced strand is circularized and packaged as a filamentous phage by the helper phage proteins and secreted from the cell. Circular double-stranded pBK phagemids are generated by infecting an F′ strain of *E. coli* with the population of recovered filamentous bacteriophages and growing small-scale cultures of the infected cells in media containing kanamycin. The circular phagemid DNA is then isolated by standard methods (please see Chapter 1). (Adapted with permission, ©1999 Stratagene.)

coli, (2) for in vitro transcription of RNA by bacteriophage DNA-dependent RNA polymerases, and (3) for an expression cassette containing a neomycin resistance gene.

Two strains of *E. coli* are supplied by the manufacturer of λZAP (Stratagene): BB4 and XL1-Blue. The relevant genotype of *E. coli* strain BB4 is *supE supF hsdR* [F′ *proAB*$^+$ *lacI*^{q} *lacZ*ΔM15]. This strain supports growth of λZAP, λZAPII, and λZAP Express. The relevant genotype of *E. coli* strain XL1-Blue is *recA1 supE hsdR lac*$^-$ [F′ *proAB*$^+$ *lacI*^{q} *lacZ*ΔM15]. This strain supports vigorous growth of λZAPII, but not λZAP, since it does not contain the *supF* tRNA suppressor required for λZAP (Sam100) growth. The Rec$^-$ phenotype of this strain has advantages if the bacteriophage λ clone is carrying rare cDNAs with repetitive sequences that can be deleted or rearranged by recombination between homologous sequences. XL1-Blue also has the added benefit of allowing improved color discrimination between recombinant and nonrecombinant clones. A more recent derivative of strain XL1-Blue, XL1-Blue MRF′ (available from Stratagene), carries assorted mutations that should further improve the stability of repetitive sequences and other recombination-prone DNAs (please see Chapter 2).

BB4, XL1-Blue, and XL1-Blue MRF′ carry a tetracycline resistance marker on the F′ episome. It is therefore a simple matter to ensure that the bacteria are expressing F pili by growing liquid cultures from colonies grown on an agar plate containing tetracycline.

- ***λZipLox*** (D'Alessio et al. 1992) is a hybrid of λgt10 and λgt11 that contains unique *Eco*RI, *Not*I, and *Sal*I sites in the amino-terminal coding portion of a *lacZ′* gene, encoding the α-complementation fragment of β-galactosidase (please see Figure 11-9). cDNA inserts up to 7 kb in length can be identified by nucleic acid or immunochemical screening. Cloned cDNAs can be excised on a replication-competent plasmid that is integrated into the vector DNA. Excision is accomplished by a Cre/LoxP mechanism in *E. coli* strains DH10B(ZIP) or DH12S(ZIP), followed by plating on media containing ampicillin. The DH10B(ZIP) strain is used for the production of double-stranded plasmid DNA, whereas the DH12S(ZIP) strain is used to produce single-stranded plasmid DNA after superinfection with a filamentous helper bacteriophage such as M13K07 (please see Chapter 3). The excised plasmid, called pZL1, contains 19 different 6-base recognition sites for restriction enzymes, as well as promoters from bacteriophages T7 and SP6 that flank the polylinker sequence.

  The major differences between λZipLox (available from Life Technologies) and the λZAP series of vectors (available from Stratagene) relate to cDNA insert sizes and excision mechanisms. λZAP vectors can harbor cDNA inserts up to 10–12 kb in length, whereas λZipLox can accommodate cDNAs up to 7 kb in size. λZAP relies on an excision system based on the DNA replication systems of filamentous bacteriophages (please see above), whereas λZipLox relies on the Cre/LoxP recombination system of bacteriophage P1, which, in our hands, is more reproducible.

- ***λgt10 and* λgt11** (Young and Davis 1983a,b; Huynh et al. 1985). For much of the 1980s, the standard vectors for construction of cDNA libraries were λgt10 and λgt11 (please see Figure 11-10). λgt10 was used to construct libraries that were to be screened only by nucleic acid probes; cDNA libraries constructed in λgt11 could be screened with antibodies or other ligands to isolate DNA sequences encoding specific proteins. Although few investigators today would choose λgt10 or λgt11 to construct new libraries, libraries generated during the 1980s remain important resources that continue to yield valuable cDNA clones. For additional details on λgt10 and λgt11, please see the information panel on **λgt10 AND λgt11**.

- ***Plasmid vectors.*** Although the plasmids used in the 1970s to construct the first cDNA libraries are not longer in use, their derivatives are still employed to construct and propagate cDNA libraries that may be used for functional screening, expressed sequence-tagged (EST) sequencing, and the generation of subtracted libraries and probes. As the bacteriophage λ vectors have evolved, becoming more plasmid-like, the plasmid vectors, for example, pSPORT1 (Figure 11-

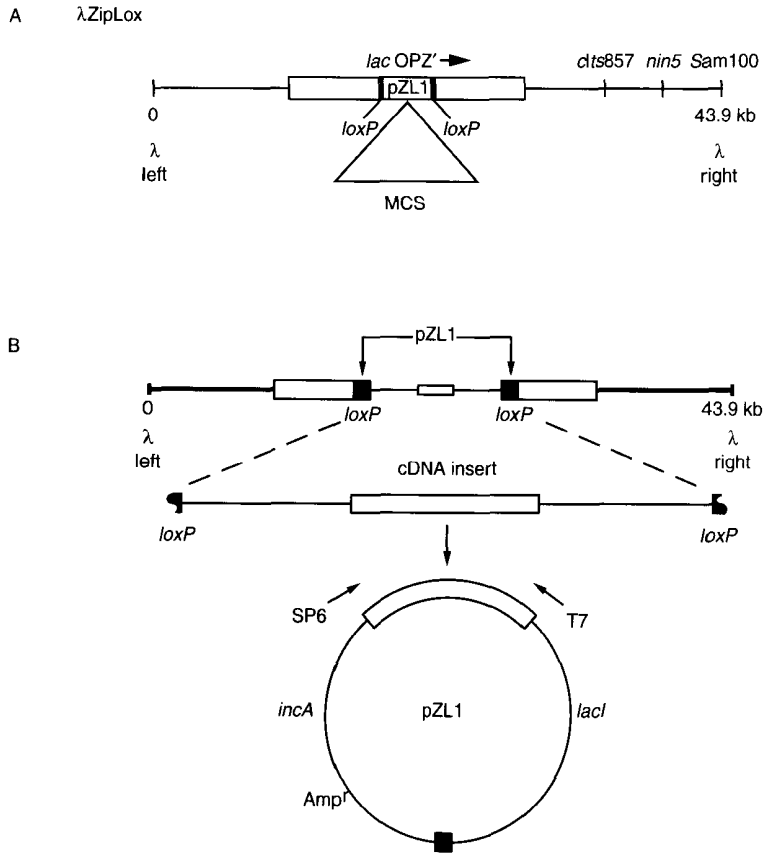

FIGURE 11-9 λZipLox

(*A*) λZipLox is constructed from an *Eco*RI fragment derived from the left arm of bacteriophage λ, an 18.3-kb *Sst*I fragment derived from the arm of a deletion mutant of λgt11, and the pZL1 plasmid, flanked by *loxP* sites to facilitate Cre-mediated recombination and excision. The multiple cloning site (MCS) carried within the pZL1 sequence contains six unique restriction sites for insertion of foreign DNA and is flanked by the promoters from bacteriophages SP6 and T7. (*B*) cDNA sequences cloned into λZipLox can be recovered in the form of a plasmid by infecting a recombinant λZipLox into a strain of *E. coli* such as DH10B(ZIP) that is lysogenic for bacteriophage λ and expresses *cre* recombinase. (Adapted with permission, from Life Technologies, Inc.)

11), pCMV-Script (Figure 11-12), and pcDNA3.1 (Figure 11-13) have also extended their utility by incorporating a variety of sequence elements, including versatile multiple cloning regions, promoters for bacteriophage T3, T7, and/or SP6 polymerase, and a filamentous f1 phage intergenic region that permits DNA to be rescued in single-stranded form.

IDENTIFICATION OF cDNA CLONES OF INTEREST

Methods of Screening

Four methods are commonly used to screen cDNA libraries for clones of interest:

- conventional nucleic acid hybridization
- using PCR to identify pools of clones containing the desired nucleic acid sequences
- binding of specific ligands (e.g., antibodies or DNA) to proteins expressed by recombinant cDNA clones
- assaying for production of biologically active molecules

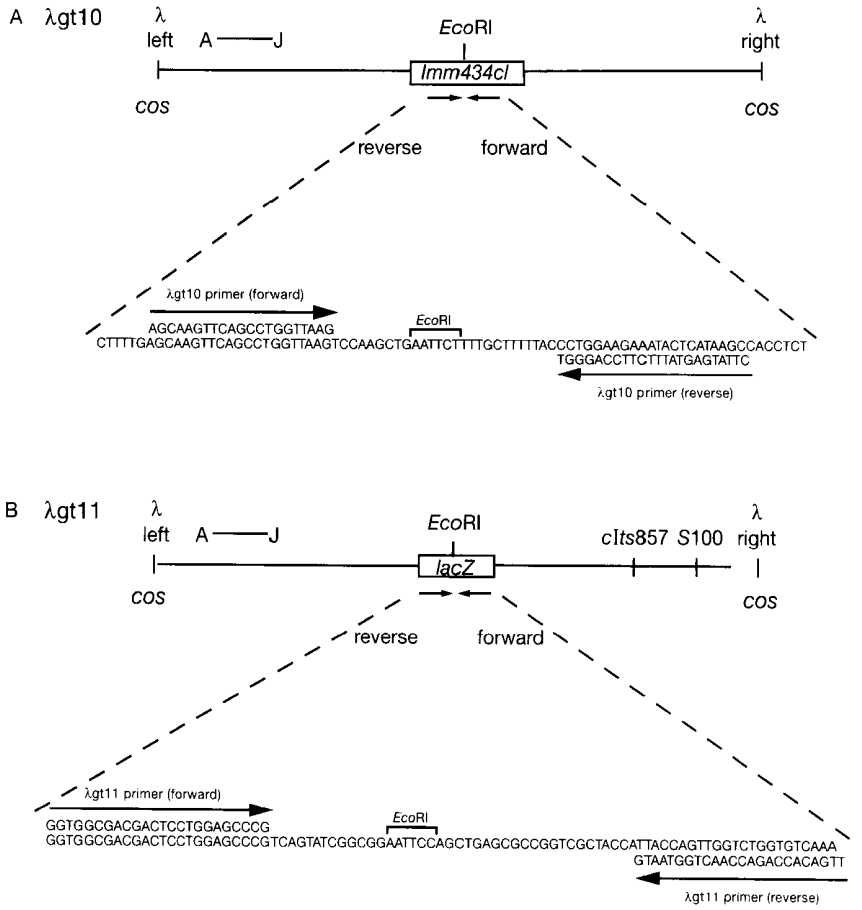

FIGURE 11-10 λgt10 and λgt11

(Adapted with permission, ©1999 Stratagene.)

Nucleic Acid Hybridization

This is the most commonly used and reliable method of screening cDNA libraries for clones of interest. None of the other methods display such an abundance of attractive features. Screening by nucleic acid hybridization allows extremely large numbers of clones to be analyzed simultaneously and rapidly, does not require that the cDNA clones be full-length (note, however, that full-length clones are required if the probe hybridizes to a region near the 5′ end of the cDNA), and does not require that an antigenically or biologically active product be synthesized in the host cell. Furthermore, as a result of more than 30 years of work, the theoretical basis of nucleic acid hybridization is well understood. This has led to the development of a large number of different techniques that can accommodate nucleic acid probes of very different lengths and specificities.

HOMOLOGOUS PROBES

These probes contain at least part of the exact nucleic acid sequence of the desired cDNA clone. They are used in a variety of circumstances, for example, when a partial clone of an existing cDNA is used to isolate a full-length clone from a cDNA library. Usually, a fragment derived from one end or the other of the existing clone is isolated, radiolabeled in vitro, and used to probe a library. Hybridization with homologous probes is always carried out under stringent conditions.

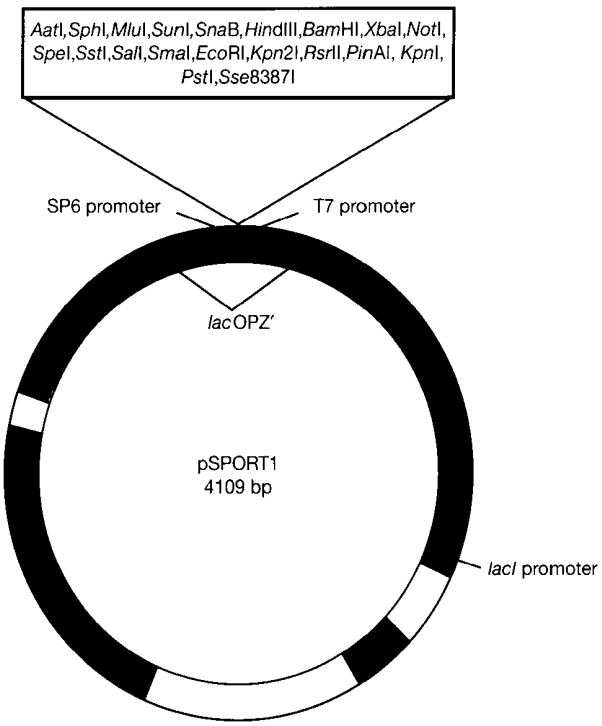

FIGURE 11-11 pSPORT1

The plasmid pSPORT1 is a multifunctional expression vector that is used for cDNA cloning, in vitro transcription, and construction of subtractive library procedures. It contains the origin of replication from the pUC series of vectors (ori), the β-lactamase gene conferring ampicillin resistance (Amp^r), and the bacteriophage f1 intergenic region for synthesis of single-stranded DNA in *E. coli*. The multiple cloning site (MCS) within the the α-peptide region of the *lacZ* gene is flanked by bacteriophage SP6 and T7 promoters to allow in vitro transcription of either strand of the inserted foreign DNA. (Adapted with permission, from Life Technologies, Inc.)

PROBES FOR SIMILAR BUT NOT IDENTICAL SEQUENCES

Probes of this type are used to detect cDNA clones that are related, but not identical, to the probe sequences, for example, the same gene cloned from another species or a related gene cloned from the same species. In such cases, it is worthwhile to carry out a series of trial experiments to determine whether there is sufficient conservation of nucleic acid sequence to allow the screening of an appropriate cDNA library by hybridization. This task is most easily accomplished by performing a series of Southern and northern hybridizations at different stringencies. The aim is to establish conditions that will allow the previously cloned gene to be used as a probe for the cDNA of interest, without undue interference from background hybridization. If the nucleic acid in hand is not sufficiently conserved to produce reliable signals on Southern and northern blots of DNAs and RNAs from the target species, two alternative strategies can be explored. First, the nucleic acid can be used to probe "zoo" blots, which contain genomic DNAs from a wide variety of species. It is often the case that a gene isolated from yeast, for example, will not cross-hybridize with the homologous gene from, say, humans. However, the yeast gene may well cross-hybridize with the homologous gene from *Drosophila* or *Xenopus*. In turn, the gene from these "intermediate" species may be close enough in sequence to the mammalian gene to be used as a probe in screens of genomic or cDNA libraries. Second, probes can sometimes be generated in PCRs primed by sets of degenerate oligonucleotides (please see Chapter 8, Protocol 11). In this case, the template for the PCR is

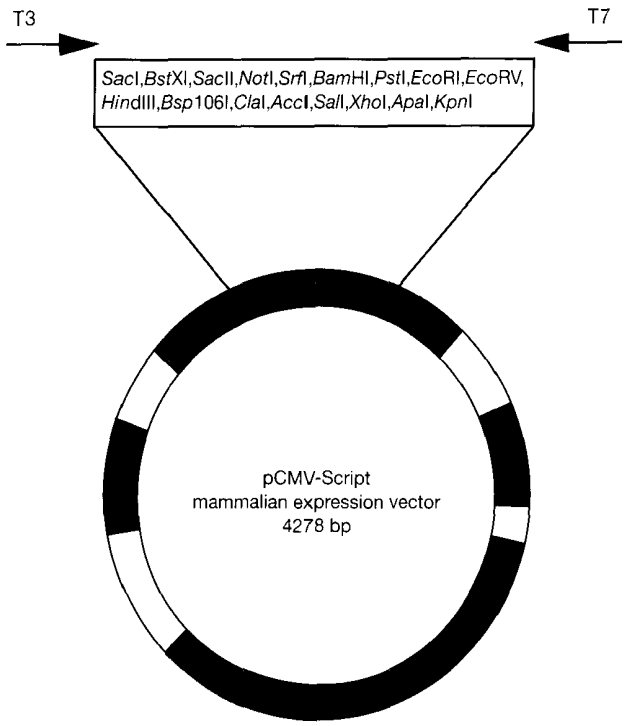

FIGURE 11-12 pCMV-Script

pCMV-Script is a vector designed to facilitate high-level expression of cloned cDNAs in mammalian cells. It contains the origin of replication of bacteriophage f1 for synthesis of single-stranded DNA in *E. coli*, the colE1 origin for replication in *E. coli*, and the SV40 origin for replication in mammalian cells and the promoters from CMV and SV40. The multiple cloning site (MCS) is flanked by bacteriophage SP6 and T7 promoters to allow in vitro transcription of either strand of the inserted foreign DNA. Expression is driven by the CMV immediate early promoter. The presence of G418, the gene conferring resistance to neomycin and kanamycin, provides for selection of stable clones in mammalian cells with expression driven by the SV40 promoter (P_{SV40}), and selection of clones in *E. coli* with expression driven by the β-lactamase promoter (P_{bla}). (Adapted with permission, ©1999 Stratagene.)

the DNA or RNA of the target or an intermediate species, and the primers are derived from regions of the amino acid sequence whose codons are nondegenerate. Wherever possible, the oligonucleotide primers should correspond to regions of the gene that are likely to be conserved between species (e.g., active sites of enzymes and highly conserved structural motifs).

TOTAL cDNA PROBES

Total cDNA probes are prepared by uniform incorporation of radiolabeled nucleotides in in vitro reactions catalyzed by reverse transcriptase and containing mRNA as templates; or by end-labeling of total or fractionated poly(A)$^+$ mRNA. The resulting probes can be used to screen cDNA libraries if the cDNA clones of interest correspond to mRNA species present in the initial population at a frequency of at least 1 in 200 (please see Gergen et al. 1979; Dworkin and Dawid 1980; Travis et al. 1987). Using total cDNA probes, it is not possible to detect cDNA clones homologous to species that are represented rarely in the mRNA preparation.

SUBTRACTED cDNA PROBES

Subtracted cDNA probes are often used to screen cDNA libraries for clones corresponding to mRNAs that are differentially regulated (please see both the information panel on **ISOLATING**

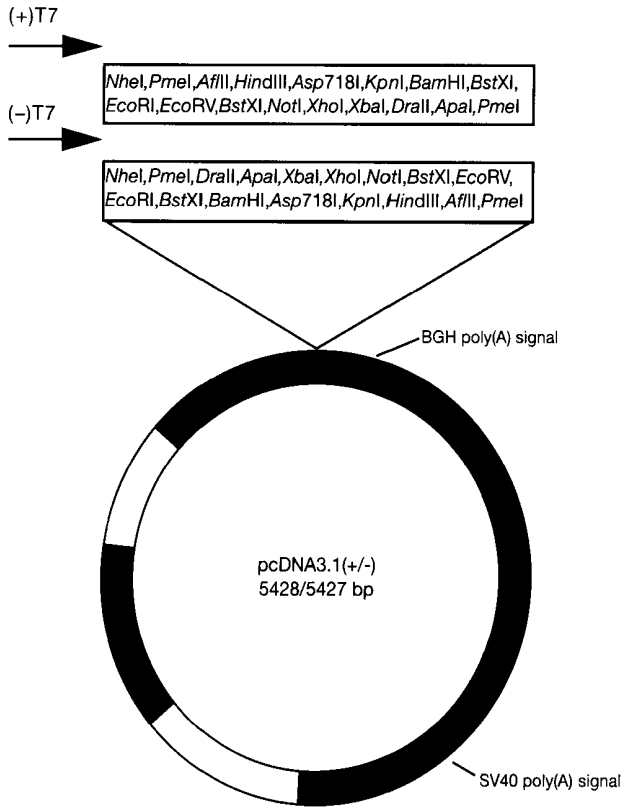

FIGURE 11-13 pcDNA3.1

pcDNA3.1 is a vector designed to facilitate high-level expression of cloned cDNAs in mammalian cells. It contains the origin of replication of bacteriophage f1 for synthesis of single-stranded DNA in *E. coli*, the pMB1 (pUC) origin for replication in *E. coli*, the SV40 origin for replication in mammalian cells, and the signals for poly(A) addition from SV40 and bovine growth hormone (BGH). The multiple cloning site (MCS) is flanked by bacteriophage T7 promoters to allow in vitro transcription of either strand of the inserted foreign DNA. Expression is driven by the CMV promoter. The G418 resistance gene is used to select clones of mammalian cells that have been stably transformed by pcDNA3.1. (Adapted with permission, ©1996–1998 Invitrogen.)

DIFFERENTIALLY EXPRESSED cDNAS BY DIFFERENTIAL SCREENING AND CLONING and Protocol 9 in Chapter 9). A labeled cDNA probe prepared from one type of mRNA is depleted of sequences that are present in a second type of mRNA (Timberlake 1980; Zimmermann et al. 1980; Wang and Brown 1991). Removal of unwanted sequences is achieved by hybridizing single-stranded cDNA prepared from mRNA extracted from the tissue of interest to a 10–20-fold excess of DNA or RNA (driver) prepared from another source that does not express the genes of interest. After hybrids containing the cDNA have been removed, the residual cDNA molecules are used to probe a cDNA library for clones containing homologous sequences. Using subtracted cDNA probes, it is possible to detect rare mRNAs that constitute as little as 0.01% of the total population of mRNAs as long as the subtraction step removes at least 95% of the original labeled cDNA (Sargent 1987).

Subtracted cDNA probes are particularly valuable when very few differences exist between the two starting mRNA preparations, i.e., when most species of mRNA are represented equally in the two preparations and a small proportion (<2%) of the mRNAs are not present at all in one preparation. cDNAs that have been cloned using subtracted cDNA probes include the murine J

immunoglobulin chain (Mather et al. 1981), the murine T-cell receptor (Hedrick et al. 1984), MyoD (Davis et al. 1987), and a porcine glucose transporter (Weiler-Guttler et al. 1989).

A slightly different approach is used when two preparations of mRNA contain different concentrations of certain sequences. Examples of such sib pairs might be mRNAs extracted from control cells and cells that have been exposed to heat shock, drugs, or hormones. cDNAs corresponding to mRNAs whose expression is altered by such treatments can sometimes be detected by differential hybridization. Labeled first-strand cDNAs are synthesized in vitro using both mRNAs as templates. Most of the cDNA sequences correspond to mRNAs whose concentrations are not appreciably changed by the treatment to which the cells were exposed. However, a minority of the cDNAs will be copied from mRNAs whose concentrations are significantly increased or decreased. The two cDNA probes are then used to screen replicas of a cDNA library constructed from mRNA extracted from control cells (when searching for mRNAs that are repressed) or treated cells (when searching for mRNAs that are induced). The clones that hybridize preferentially to one of the cDNA probes are chosen for further analysis. Among the many examples of genes cloned in this way are the galactose-inducible genes of yeast (St. John and Davis 1979), human fibroblast interferon (Taniguchi et al. 1980), the glucose-regulated proteins of mammalian cells (Lee et al. 1981), hormonally induced proteins (Buckbinder and Brown 1992; Kolm and Sive 1995), growth-related proteins (Foster et al. 1982; Cochran et al. 1983; Linzer and Nathans 1983), differentiation-specific proteins (Spiegelman et al. 1983), and a variety of heat shock proteins and stress proteins (e.g., please see Mason et al. 1986). The procedure has also been used to identify cDNA clones of developmentally regulated mRNAs from organisms of many different species, including *Xenopus* (Williams and Lloyd 1979; Weeks et al. 1985; Sive et al. 1989; Le Guellec et al. 1991; Kolm et al. 1997), *Dictyostelium* (Rowekamp and Firtel 1980; Mehdy et al. 1983), sea urchins (Lasky et al. 1980), mice (Gorman et al. 1985), and zebrafish (Sagerstrom et al. 1996; Grinblat et al. 1998).

SYNTHETIC OLIGONUCLEOTIDE PROBES

Synthetic deoxyoligonucleotide probes are tracts of defined sequence that have been synthesized in vitro. The sequences of these probes are deduced, using the genetic code, from short regions of the known amino acid sequence of the protein of interest. In the vast majority of cases, because of the degeneracy of the genetic code, the same sequence of amino acids can be specified by many different oligonucleotides. There is no way to know with certainty which of these oligonucleotides is actually used in the gene of interest. Three solutions to this problem have been found:

- A family of oligonucleotides can be synthesized which contains all possible sequences that can encode a given sequence of amino acids. The number of members in this family depends on the degree of degeneracy of the codons for the particular amino acids. However, since all possible oligonucleotide sequences are represented, at least one of the members will match perfectly with the cDNA clone of interest. To keep the size of each family within manageable proportions, short oligonucleotides (14–17 nucleotides) are generally used, the minimum size practical for hybridization. Often, more than one family of oligonucleotides is synthesized based on separate sequences of amino acids. For more details, please see the section on Degenerate Pools of Oligonucleotides in the introduction to Chapter 10.
- A longer (40–60-nucleotide) oligonucleotide of unique sequence can be synthesized using the most commonly used codon for each amino acid. Almost certainly, this oligonucleotide will not match exactly the sequence in the cDNA, but it will fit well enough to be detected by hybridization under nonstringent conditions. For more details, please see the section on Guessmers in Chapter 10.

- An oligonucleotide can be synthesized that contains a base such as inosine at positions of high potential degeneracy. Inosine can pair with all four conventional bases without seriously compromising the stability of the resulting hybrid. Families of oligonucleotides can therefore be generated that are reduced in number and yet are capable of hybridizing to virtually all cDNA clones that could encode the protein of interest. For more details, please see the section on Universal Bases in Chapter 10.

Finally, if the available protein sequence is from the amino terminus of the protein, the cDNA library that is to be screened must be of high quality to ensure that most of the 5′ terminus of the mRNA is represented.

Screening cDNA Libraries by PCR

PCR may be used in several ways to identify clones of interest in a cDNA library. For example, pools of phagemids or plasmids growing in the individual wells of 96-well plates can be screened by PCR using two oligonucleotide primers specific for the desired gene. Pools that generate a product of the appropriate size are then plated at lower concentration and rescreened. This process is repeated until individual clones containing the desired sequence are identified (Alfandari and Darribère 1994; Takumi and Lodish 1994).

PCR is also used to facilitate isolation of a full-length cDNA once a primary cDNA clone has been identified by, for example, screening by hybridization. The DNA of the primary clone is used to design two specific oligonucleotide primers, which are used in conjunction with vector-specific primers corresponding to sequences that flank the insertion site (Rosenberg et al. 1991). The products of the PCR can be cloned and used to reconstruct a full-length copy of the cDNA or they can be radiolabeled and used as probes to rescreen the library (Hamilton et al. 1991; Sang and Thompson 1994). An alternative method may be used to amplify a sequence extending from a pool if the library was not constructed by using directional cloning. In this approach, pairs of oligonucleotide primers corresponding to the flanking vector sequences or the linker-adaptors used to establish the cDNA library can be used in combination with pools of degenerate oligonucleotides to amplify and recover cDNA clones containing sequences that potentially code for the desired protein (e.g., please see Libert et al. 1989; Rasmussen et al. 1989; Cooper and Isola 1990).

Screening by Binding to Specific Ligands

DETECTION OF SPECIFIC ANTIGENS WITH IMMUNOGLOBULIN PROBES

cDNA libraries constructed in expression vectors such as λgt11, λgt18-23, λZAP, and λORF8 can be screened with antibody directed against the protein of interest. Usually, nitrocellulose filters imprinted with the detritus of bacterial lysis are soaked in a solution containing the antibody. The filter is washed and then incubated with *Staphylococcus aureus* protein A or with a second antibody directed against the species-specific epitopes of the first antibody. In the original descriptions of the method, the secondary ligand was radiolabeled with ^{125}I (Young and Davis 1983b; Huynh et al. 1985; Snyder et al. 1987). Today, the secondary ligand is covalently linked to an enzyme whose activity can be detected (e.g., alkaline phosphatase).

The key to success with this method lies in the quality of the antibody. It is essential that the antibody efficiently recognize the denatured protein (i.e., it should produce strong signals on western blots). Screening is made easier and more sensitive if, in addition, the antibody is derived from a polyclonal antiserum of high titer. Because such antisera normally react with many differ-

ent epitopes, the chance of detecting a cDNA clone that expresses a fragment of the protein of interest is increased. Polyclonal antisera often contain cross-reacting antibodies that recognize nonrecombinant components of the bacterial lysate; these must be removed before screening is undertaken.

The background of nonspecific binding is much lower when a monoclonal antibody is used as a probe. However, the number of recombinants that can be detected is also reduced, because each individual monoclonal antibody can react with only a single epitope. The ideal immunological probe might therefore consist of a cocktail of several different monoclonal antibodies, each of which reacts strongly with the denatured target protein.

DOUBLE-STRANDED DNAS AS PROBES

cDNA clones encoding proteins that bind to specific sequences of DNA (e.g., transcription factors) can be identified by screening expression libraries with double-stranded DNA probes comprising the binding site for the factor. This technique is similar in principle to screening expression libraries with immunoglobulins: cDNA libraries are constructed in expression vectors such as λgt11 and λZAP that express cloned cDNA sequences as fusion proteins with β-galactosidase after induction with IPTG. The proteins are then transferred in situ to nitrocellulose and probed with synthetic radiolabeled double-stranded oligonucleotides containing the binding site of interest. Plaques expressing protein that reacts well with the oligonucleotide probe are picked, replated, and tested again for the ability to bind to both specific and nonspecific oligonucleotide probes. The functional characteristics of a putative transcription factor expressed in a positive plaque must eventually be confirmed in biochemical assays that detect protein binding to DNA regulatory sequences and, ultimately, in a transcription assay. This approach has been used successfully to clone cDNAs encoding different transcription factors of various types (for review, please see Singh 1993). Curiously, it seems to be particularly powerful in the cloning of factors belonging to the leucine zipper family. For detailed descriptions of the technique, please see Harline et al. (1992), Cowell and Hurst (1993), and Singh (1993). For further details on screening by binding to ligands, please see the introduction to Chapter 14.

Cloning cDNAs by Expression

Several methods of screening are based on detection of the biological activity of the protein encoded by the target cDNA. In some cases, transfection with cDNA expression libraries can be used to screen for clones that express proteins capable of complementing a particular genetic defect in yeast, mammalian cells, or *E. coli* (for more information, please see Protocol 2). A very large suite of housekeeping and regulatory genes is potentially accessible by this method. However, in cases where target protein is so specialized that no genetic screen is available, it may nevertheless be possible to isolate the target cDNA by screening libraries for the production of protein molecules that display biological activity. For example, in vitro assays have been used to identify cDNA clones that express the human lymphokine colony-stimulating factor and interleukin-3 in cultures of mammalian cells (Wong et al. 1985; Yang et al. 1986); transfection of cDNAs has been used to isolate cDNA encoding cell-surface receptors (Munro and Maniatis 1989; Kluxen et al. 1992); and microinjection of synthetic RNAs transcribed from cDNA clones has been used to isolate cDNAs encoding *Xenopus* noggin (Smith and Harland 1992). This approach is usually undertaken when no other methods of screening are available and when the protein product is small enough to give reasonable assurance that the cDNA library will contain full-length clones. To increase the sensitivity of the assay, the cDNA is usually divided into a number

of pools, each consisting of between 10 and 100,000 clones. These pools are then tested for expression of the sequence of interest. The lower complexity of each pool allows methods that are relatively insensitive to be applied to a complete cDNA library. After a pool is identified that scores positively, it is subdivided into successively smaller and smaller pools, each of which is retested until the cDNA clone of interest is isolated. The process of sib selection and analysis can sometimes be performed more rapidly if during subdivision of the initial pool, the individual clones are assigned to their subpools in a matrix format (Wong et al. 1985). This expands the number of subpools by a factor of 2 or 3, but it often leads directly to the identification of the clone of interest.

Methods to Validate Clones of cDNA

cDNA libraries are usually plated at high density for screening with antibody or nucleic acid probes, and any clones that react positively in the first round require several additional cycles of plating and screening before they can be considered pure. However, the ability to react consistently with a particular probe, although an encouraging and necessary property, is not sufficient to prove that a given cDNA clone is derived from the mRNA of interest. The only absolute proof of identity is to show that the cDNA clone contains an open reading frame that encodes the entire amino acid sequence of the protein. Since this is clearly impractical for most proteins of current interest, other, less elemental, tests must be used. These include in decreasing order of rigor:

- ***Expression from the full-length cDNA in prokaryotic or eukaryotic cells*** of a protein that displays the correct biological or enzymatic activity.
- ***Correspondence between portions of the nucleotide sequence of the cDNA*** and the amino acid sequences of peptides derived from the purified protein.
- ***Correspondence between the peptide maps of the polypeptide*** synthesized in vitro by transcripts of the cDNA clone and peptide maps of the authentic protein.
- ***Immunoprecipitation of the polypeptide synthesized in vitro or in vivo*** from transcripts of the cDNA clone by antibodies raised against the protein of interest. The stringency of this test increases when it is carried out with a series of monoclonal antibodies that recognize different epitopes on the protein.
- ***Immunoprecipitation of the authentic protein with antibodies*** raised against synthetic peptides whose sequences are determined by the nucleic acid sequence of the cloned cDNA.

It is essential that the tests used to validate a cDNA clone do not use the same reagents that were used to identify the clone in the first place. If, for example, a clone is selected by screening a library with antibody, it cannot be validated in tests that rely on the same antibody (such as immunoprecipitation of polypeptides synthesized in vitro from transcripts of the clone). In addition, the cloned cDNA should hybridize to mRNA whose size, tissue, and species distribution are consistent with the structure and function of the protein. Finally, the properties of the polypeptide predicted by the nucleotide sequence of the cDNA should be in accord with those of the authentic protein. For example, the vast majority of secreted or plasma membrane proteins are derived from polypeptide precursors that carry a hydrophobic signal sequence at their amino termini. The absence of such a signal from the predicted polypeptide would therefore be cause for concern. Similarly, the predicted size of the polypeptide, its overall charge and amino acid composition, the number of potential glycosylation sites, and the presence of hydrophobic regions that could serve as transmembrane anchors should be consistent with the known properties of the authentic protein.

GENE IDENTIFICATION: EXON TRAPPING AND cDNA SELECTION

The construction of a comprehensive gene map is a key component in building the biological map of an organism and is the primary goal of most genome projects. The identification of biologically significant coding sequences is a complex task in many organisms. The identification of coding sequences is particularly difficult in mammalian genomes for two reasons: (1) It is likely that only 5% of the genome encodes genes, whereas the rest of the genome harbors structural sequences, regulatory sequences, and junk, and (2) the majority of mammalian genes are not contiguous within the genome but are interrupted by noncoding regions termed introns (Watson et al. 1987). Exon amplification exploits this latter characteristic by selecting for the ability of a piece of genomic DNA cloned into a reporter construct to splice within a heterologous system (Buckler et al. 1991) (please see Protocol 3). In addition to exon amplification, a variety of other strategies have been developed to facilitate gene identification in complex mammalian genomes. Some of the more commonly utilized methods are cDNA selection (Lovett et al. 1991; Parimoo et al. 1991; Simmons and Lovett 1999), large-scale sequence analysis of cDNA libraries (Adams et al. 1992; Deloukas et al. 1998), and computational analysis of finished genomic sequences (Uberbacher et al. 1996; Burge and Karlin 1997, 1998). Experimental evidence suggests that the most effective means for identifying all of the potential transcription units within a given region involves utilizing a combination of these methods (Yaspo et al. 1995; Pribill et al. 1997; Ruddy et al. 1997).

Direct cDNA selection can be used for targeted gene(s) identification within a large genomic interval. The technique is based on the hybridization "capture" of cDNAs using biotinylated genomic templates (Morgan et al. 1992; Simmons and Lovett 1999). The specifically selected cDNA species are subsequently enriched by amplification with PCR.

Completing a collection of expressed sequences (ESTs) over a broad genomic region is technically difficult for two reasons. First, current methods for isolating cDNAs typically favor representation of more abundant transcripts, and second, conventionally constructed cDNA libraries do not adequately represent mRNA populations present in complex tissues or organs. These difficulties can be circumvented by using direct cDNA selection which relies upon the use of high-complexity cDNA pools rather than libraries as the starting source and can be designed to yield "quasi-normalized" cDNA populations.

Protocol 4 presents a method for direct selection of cDNAs using as an example a bacterial artificial chromosome contig of 500 kb as the genomic target. The cDNA source for the example is randomly primed first-strand cDNA, ligated to an amplification cassette.

PROTOCOLS FOR THE PREPARATION AND ANALYSIS OF cDNA

The collection of protocols in this chapter is presented in four parts:

- Protocol 1 is a traditional protocol for the construction of cDNA libraries in bacteriophage λ vectors (for the investigator who does not have access to kits). This protocol, which is based on the Gubler-Hoffman method (Gubler and Hoffman 1983), is divided into six stages:

  Stage 1: Synthesis of First-strand cDNA Catalyzed by Reverse Transcriptase
  Stage 2: Second-strand cDNA Synthesis
  Stage 3: Methylation of cDNA
  Stage 4: Attachment of Linkers or Adaptors
  Stage 5: Fractionation of cDNA by Gel Filtration through Sepharose CL-4B
  Stage 6: Ligation of cDNA to Bacteriophage λ Arms

- Protocol 2 (similar to Protocol 1) is for the construction and screening of a cDNA library in eukaryotic expression vectors.

  Stage 1: Construction of cDNA Libraries in Eukaryotic Expression Vectors
  Stage 2: Screening cDNA Libraries Constructed in Eukaryotic Expression Vectors

- Protocol 3 is a method for gene identification using exon amplification.

  Stage 1: Construction of the Library
  Stage 2: Electroporation of the Library into COS-7 Cells
  Stage 3: Harvesting of the mRNA
  Stage 4: RT-PCR Analysis
  Stage 5: Clone Analysis

- Protocol 4 is used for gene identification by direct selection of cDNA.

I cannot understand what makes scientists tick. They are always wrong and always go on.

Sir Fred Hoyle

Protocol 1

Construction of cDNA Libraries

THIS TRADITIONAL PROTOCOL IS BASED ON THE GUBLER-HOFFMAN method (Gubler and Hoffman 1983) and is divided into six stages:

- Stage 1: Synthesis of First-strand cDNA Catalyzed by Reverse Transcriptase
- Stage 2: Second-strand Synthesis
- Stage 3: Methylation of cDNA
- Stage 4: Attachment of Linkers or Adaptors
- Stage 5: Fractionation of cDNA by Gel Filtration through Sepharose CL-4B
- Stage 6: Ligation of cDNA to Bacteriophage λ Arms

STAGE 1: Synthesis of First-strand cDNA Catalyzed by Reverse Transcriptase

Three different RNA-dependent DNA polymerases are currently used to catalyze synthesis of first-strand cDNA. The optimal reaction conditions for synthesis of first-strand cDNA of maximum average length differ slightly from one enzyme to the next and are summarized in Table 11-3.

For this protocol, we recommend the use of Mo-MLV reverse transcriptase (RT) that lacks RNase H activity, for example, StrataScript RT from Stratagene, SuperScript and SuperScript II from Life Technologies, and Mo-MLV RT RNase H^- from Promega. Please note that many commercially marketed cDNA synthesis and cloning kits are supplied with versions of the wild-type enzyme that carry RNase H activity (please see the information panel on **COMMERCIAL KITS FOR cDNA SYNTHESIS AND LIBRARY CONSTRUCTION** and the information panel on **HOW TO WIN THE BATTLE WITH RNASE** in Chapter 7).

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Actinomycin D

Actinomycin D is needed only when a wild-type version of Mo-MLV RT is used that possesses RNase H activity. Please see the information panel on **ACTINOMYCIN D** in Chapter 7.

Dithiothreitol (1 M)

EDTA (0.5 M, pH 8.0)

KCl (1 M)

TABLE 11-3 Optimal Reaction Conditions for First-strand Synthesis

	Enzyme		
Parameter	Mo-MLV RT	Mo-MLV H^- RT	AMV RT
pH[a]	8.0 at 37°C	8.0 at 37°C	8.0 at 42°C

Temperature[b]	37°C	37–42°C	42°C
Dithiothreitol	10 mM	10 mM	1 mM
dNTPs	500 µM	500 µM	1 mM
Actinomycin D[c]	50 µg/ml	None	50 µg/ml
Other components	RNase inhibitor (optional)	RNase inhibitor (optional)	sodium pyrophosphate (4 mM) spermidine (0.5 mM) RNase inhibitor (optional)

Modified, with permission, from Gerard and D'Allessio (1993, Humana Press).

[a] *Buffer:* The reaction is buffered by Tris-Cl at pH 8.0 (at 37°C). Because Tris buffers have a large temperature coefficient, the pH of the buffer at room temperature should be 8.3.

[b] *Temperature:* cDNA of maximum average length is synthesized by both Mo-MLV and Mo-MLV H^- at 37°C. Both enzymes catalyze the synthesis of larger quantities of cDNA of smaller average size at higher temperatures (Mo-MLV RT at 45°C; Mo-MLV H^- RT at 50°C).

[c] *Actinomycin D:* This drug is often used to suppress self-primed synthesis of second-strand cDNA in reactions catalyzed by Mo-MLV RT (please see the information panel on **ACTINOMYCIN D** in Chapter 7). Actinomycin D is not required in reactions catalyzed by Mo-MLV RNase H^-.

$MgCl_2$ (1 M)
Tris-Cl (1 M, pH 8.3 at room temperature)

Enzymes and Buffers

Reverse transcriptase

Recombinant murine reverse transcriptase is available from several manufacturers. We strongly recommend the use of a mutated form of the enzyme that lacks RNase H activity (e.g., Superscript II reverse transcriptase from Life Technologies). As discussed in the information panel on the **Mo-MLV REVERSE TRANSCRIPTASE**, the specific activity of preparations of reverse transcriptase depends on the particular cDNA clone used to express the enzyme in *E. coli*. Follow the individual manufacturer's directions (i.e., units/μg input poly(A)$^+$ RNA and incubation temperature) for the enzyme at hand. For additional information, please see the panel on **TROUBLESHOOTING: OPTIMIZING FIRST-STRAND cDNA SYNTHESIS** at the end of this protocol.

Mo-MLV RT is temperature-sensitive and should be stored at –20°C until needed at the end of Step 1.

RNase inhibitor (optional)

Protein inhibitors of RNase bind to and inhibit the activity of most RNases but do not affect the RNase H activity of Mo-MLV RT. These inhibitors are sold by several manufacturers under various trade names (e.g., RNAsin, Promega and Prime Inhibitor, 5 Prime→3 Prime). For more details, please see the information panel on **INHIBITORS OF RNASES** in Chapter 7.

Nucleic Acids and Oligonucleotides

dNTP solution containing all four dNTPs, each at 5 mM

Oligonucleotide primers for cDNA synthesis (1 mg/ml)

Synthesis of first-strand cDNA is generally primed by random hexamers, oligo$(dT)_{12\text{-}18}$, or a mixture of the two. For directional cloning, primer-adaptors of the general structure $^{5'}$p(dX)–(dR)–$(dT)_x$-$OH^{3'}$ are used, where X = a clamp composed of four nucleotides (usually GAGA), R = a recognition site for a restriction enzyme, and $(dT)_x$ = a homopolymeric run of 15 dT residues used for directional cloning.

Oligo$(dT)_{12\text{-}18}$ primers are present in the first-strand reaction mixture at a 10-fold (Mo-MLV H$^-$) to 40-fold (Mo-MLV) molar excess. Unlike random hexamers and primer-adaptors (please see below), the concentration of oligo$(dT)_{12\text{-}18}$ primers generally does not need to be optimized in the reaction mixture.

The concentration of random hexamers in the reaction mixture is critical. As the ratio of hexamers to mRNA increases, the average length of the cDNA decreases. It is therefore essential to optimize the ratio of random primers and mRNA template in a series of pilot reactions containing radiolabeled dCTP. The average size of the first-strand cDNA generated in each of the pilot reactions should be measured by alkaline agarose gel electrophoresis and autoradiography using DNA markers of known size. When setting up a large-scale reaction to synthesize first-strand cDNA, use the highest ratio of random primer to mRNA that generates cDNA of the maximum average length.

Primer-adaptors are generally less troublesome than random primers. However, it is nevertheless prudent to optimize the ratio of primer-adaptors and mRNA template in a series of pilot reactions containing radiolabeled dCTP. Measure the amount of cDNA synthesized in each reaction as outlined in Steps 5 and 6 of this protocol. When setting up a large-scale reaction to synthesize first-strand cDNA, use the lowest ratio of primer-adaptor to mRNA that generates the maximum yield of cDNA.

Prepare stock solutions of primers (1 mg/ml in 10 mM Tris-Cl [pH 7.4]). Store aliquots of the solutions at –70°C.

Poly(A)$^+$ RNA (1 mg/ml)

Approximately 5–10 μg of poly(A)$^+$ RNA is required to synthesize enough double-stranded cDNA to construct a large library. (One confluent 90-mm plate of cultured mammalian cells yields 1–2 μg of poly(A)$^+$ RNA.) The synthetic reactions will still work if less template is available, but the losses of cDNA at each stage in the protocol will be proportionately greater. For assistance when preparing a cDNA library from a limited number of cells, please see the information panel on **CONSTRUCTING cDNA LIBRARIES FROM SMALL NUMBERS OF CELLS** at the end of this chapter.

Before beginning construction of the cDNA library, the integrity of the poly(A)$^+$ RNA to be used should ideally be checked by (1) agarose gel electrophoresis and northern hybridization with a control probe (please see Chapter 7, Protocols 5 and 8), (2) translation in a cell-free system followed by SDS-polyacrylamide gel electrophoresis of the resulting polypeptides, and (3) analysis of the size of the first strand of cDNA synthesized in a pilot reaction (please see the panel on **TROUBLESHOOTING: OPTIMIZING FIRST-STRAND cDNA SYNTHESIS** at the end of this protocol).

Radioactive Compounds

[α-^{32}P]dCTP (10 mCi/ml, 400 Ci/mmole) **<!>**

[α-^{32}P]dATP and [α-^{32}P]dTTP should not be used as radioactive tracers to monitor synthesis of the first and second strands of cDNA, since they may be incorporated preferentially into cDNA derived from the poly(A)$^+$ tract at the 3′ terminus of the mRNA. Batches of [α-^{32}P]dCTP >2 weeks old should not be used in this protocol.

Thaw the [α-^{32}P]dCTP just before starting the protocol. Store the thawed radiolabeled dCTP on ice until needed in Step 2. Return the radiolabeled dCTP to the freezer immediately after use.

▲ **IMPORTANT** The Stratagene cDNA Synthesis Kit recommends the use of any label other than dCTP with its protocol. This kit includes 5-methyl dCTP in the dNTP mixes to protect the cDNA against cleavage at internal sites by *Xho*I, which is used to release *Xho*I ends for ligation. The use of radiolabeled dCTP with the Stratagene protocol could create unprotected *Xho*I sites within the cDNA sequence.

Special Equipment

Microfuge tubes, RNase-free
Water baths preset to 16°C and 70°C

Additional Reagents

Step 5 of this protocol requires the reagents listed in Chapter 5, Protocol 8.

METHOD

1. To synthesize first-strand cDNA, mix the following in a sterile microfuge tube on ice:

1 μg/μl poly(A)$^+$ RNA	10 μl
1 μg/μl oligonucleotide primer(s)	1 μl
1 M Tris-Cl (pH 8.0 at 37°C)	2.5 μl
1 M KCl	3.5 μl
250 mM $MgCl_2$	2 μl
solution of all four dNTPs, each at 5 mM	10 μl
0.1 M dithiothreitol	2 μl
RNase inhibitor (optional)	25 units
H_2O	to 48 μl

Add the manufacturer's recommended amount of Mo-MLV H$^-$ RT to the reaction. Mix the reagents well by gentle vortexing.

Try to avoid producing bubbles, although this is sometimes difficult because RT is supplied in buffers containing Triton X-100 or Nonidet P-40 and 50% glycerol. If necessary, remove bubbles by brief centrifugation in a microfuge.

Mo-MLV RT is temperature-sensitive and should be stored at –20°C until needed.

▲ **IMPORTANT** If a preparation of AMV RT is used, please see Table 11-3 for reaction conditions.

2. After all of the components of the reaction have been mixed at 0°C, transfer 2.5 μl of the reaction to a fresh 0.5-ml microfuge tube. Add 0.1 μl of [α-^{32}P]dCTP (400 Ci/mmole, 10 mCi/ml) to the small-scale reaction.

3. Incubate the large- and small-scale reactions for 1 hour at 37°C.

   Higher temperatures (up to 55°C) can be used with some mutant forms of Mo-MLV RT. Synthesis at higher temperatures can increase the yield of cDNA from mRNA templates that contain extensive secondary structure. However, the population of cDNAs synthesized at 55°C will be shorter on average than cDNA synthesized at 37°C.

4. At the end of the incubation period, add 1 µl of 0.25 M EDTA to the small-scale reaction containing the radioisotope. Transfer the small-scale reaction to ice. Heat the large-scale reaction to 70°C for 10 minutes and then transfer it to ice.

   The cDNA synthesized in the large-scale reaction can be used directly as a template in PCRs.

   If the first-strand cDNA is to be used as a template for synthesis of the second DNA strand, assemble the materials and prepare a water bath at 16°C while carrying out Steps 5 and 6.

5. Measure both the total amount of radioactivity and the amount of trichloroacetic acid (TCA)-precipitable radioactivity in 0.5 µl of the small-scale reaction, as described in Appendix 8. In addition, it is worthwhile analyzing the products of the small-scale reaction through an alkaline agarose gel using appropriate DNA markers (please see Chapter 5, Protocol 8).

   The first-strand cDNA should appear as a smear with sizes ranging from ~0.7 kb to >6 kb and a modal value of ~2 kb.

   The remainder of the small-scale reaction can be stored at –20°C.

6. Calculate the amount of first-strand cDNA synthesized as follows:

   a. Since 10 µl of a solution containing all four dNTPs at a concentration of 5 mM each was used (i.e., 10 µl of 20 mmoles/liter of total dNTP), the large-scale reaction must contain

      $$20 \text{ nmoles/µl dNTP} \times 10 \text{ µl} = 200 \text{ nmoles of dNTP}$$

   b. Because the molecular weight of each dNMP incorporated into DNA is ~330 g/mole, the reaction is capable of generating a total of

      $$200 \text{ nmoles} \times 330 \text{ ng/nmole} = 66 \text{ µg of DNA}$$

   c. Therefore, from the results of the small-scale reaction,

      $$\frac{\text{cpm incorporated}}{\text{total cpm}} \times 66 \text{ µg} = \text{µg of first strand of cDNA synthesized}$$

      If the reaction has worked well, the yield of first-strand cDNA should be 30–40% of the weight of the poly(A)$^+$ RNA in the reaction mixture.

      An alternative procedure to monitor synthesis of the first strand of cDNA is to use a small amount of [α-^{32}P]dCTP (10 µCi total) in the large-scale reaction described above and a much greater amount (100 µCi total) of radiolabeled dNTP in the subsequent reaction to synthesize the second strand of cDNA. This procedure is less desirable because it is then necessary to expose the alkaline agarose gel to X-ray film for long periods of time to obtain a suitable image of the first-strand products.

7. Proceed as soon as it is feasible to the next stage in the synthesis of the cDNA.

TROUBLESHOOTING: OPTIMIZING FIRST-STRAND cDNA SYNTHESIS

Two problems are commonly encountered during first-strand cDNA synthesis: The cDNA is short in length and/or low in yield. These problems can result from inadequacy in any of the components used for synthesis of the first strand of cDNA. However, in most cases, the culprit is the mRNA template.

- Check the integrity of the mRNA preparation by northern blotting using an antisense probe complementary to the transcript of a common housekeeping gene. If a radiolabeled band of the correct size is detected and if the band is crisp and sharp, then degradation of the RNA preparation is not the cause of the problem. These days, most protocols for synthesis of first-strand cDNA do not use a denaturation step designed to reduce secondary structure in mRNA. Although there is little effect of denaturation on the total yield or average length of cDNA, individual mRNAs differ in their amount of secondary structure and will thus be transcribed into full-length cDNA with varying efficiencies. As a precaution, some investigators heat their preparations of mRNA in H_2O or TE (pH 7.6) for 5 minutes at 68°C, followed by rapid cooling in ice water immediately before use in first-strand synthesis.

- If the yield of cDNA is low (<30% of the weight of the mRNA in the reaction), treat the mRNA preparation with proteinase K as described below. This procedure can sometimes release tightly bound proteins from RNA and remove inhibitors of first-strand cDNA synthesis. As much as 100 µg of poly(A)$^+$ RNA can be treated in a volume of 300 µl containing the following:

  5 µg/ml proteinase K
  100 mM Tris-Cl (pH 7.5)
  50 mM NaCl
  10 mM EDTA (pH 8.0)
  0.1% (w/v) SDS

  Incubate the reaction for 1–2 hours at 37°C. Remove the proteinase K by extraction with phenol:chloroform at 65°C (please see Chapter 7) and then recover the nucleic acid by precipitation with ethanol in the presence of 0.3 M sodium acetate.

- Increasing the temperature of the RT reaction to between 45°C and 55°C can sometimes improve yield of first-strand cDNA. However, this improvement is often coupled to a reduction in the average size of the cDNA population.

- If enough poly(A)$^+$ RNA is available, optimize the amount of each of the other major components in the reaction (primers and RT) to concentrations that result in the highest yields and longest cDNAs. Set up a series of small-scale reactions (each containing 0.5–1.0 µg of poly(A)$^+$ RNA) as described below using different amounts of reverse transcriptase (10–200 units/µg of RNA) and primers (10–100-fold molar excess over the amount of mRNA). For convenience, assume that the average size of the mRNA is 2 kb. Measure the yield of cDNA by precipitation with ice-cold trichloroacetic acid (please see Appendix 8) and determine its size by electrophoresis through alkaline agarose gels (please see Chapter 5, Protocol 8). For large-scale synthesis of cDNA, use the concentration of enzyme that gives the greatest yield of long cDNA.

STAGE 2: Second-strand Synthesis

If the entire Stage 1 procedure has worked according to plan, the products of that stage should be a population of perfect hybrids between the original mRNAs and full-length, first-strand cDNAs. The aim of Stage 2 is to convert these hybrids into full-length double-stranded cDNAs. The primers for synthesis of second-strand cDNA are created by RNase H, which introduces nicks into the RNA moiety of the cDNA-mRNA hybrids. *E. coli* DNA polymerase I extends the 3′-hydroxyl termini of these RNA primers, using the first-strand cDNA as a template and replacing the remaining segments of mRNA in the cDNA-mRNA hybrid with the newly synthesized second strand of DNA. Residual nicks in the DNA-DNA hybrid are then repaired by *E. coli* DNA ligase, and the frayed termini of the double-stranded cDNA are polished by a DNA polymerase such as bacteriophage T4 DNA polymerase or *Pfu*. Finally, bacteriophage T4 polynucleotide kinase is used to catalyze the phosphorylation of 5′-hydroxyl groups on the ends of the cDNAs in preparation for ligation of linkers or adaptors (Stage 4 of this protocol). After completion of these enzymatic steps, the double-stranded cDNA is precipitated with ethanol to remove Mg^{2+}, which would otherwise interfere with the methylation reaction described in Stage 3 of this protocol.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Chloroform **<!>**

EDTA (0.5 M, pH 8.0)

Ethanol

$MgCl_2$ (1 M)

$(NH_4)_2SO_4$ (1 M)

Dissolve 1.3 g of solid $(NH_4)_2SO_4$ in a final volume of 10 ml of H_2O. Filter-sterilize the solution and store the solution at room temperature.

β-Nicotinamide adenine dinucleotide (50 mM)

Make a 50 mM stock solution by dissolving 33.2 mg of β-nicotinamide adenine dinucleotide (β-NAD) in 1 ml of H_2O. Store the solution in small aliquots at –70°C. β-NAD is a cofactor for *E. coli* DNA ligase, as well as the electron acceptor; do not confuse it with α-NAD.

Phenol:chloroform (1:1, v/v) **<!>**

RNase H buffer (optional)

20 mM Tris-Cl (pH 7.6)
20 mM KCl
0.1 mM EDTA (pH 8.0)
0.1 mM dithiothreitol

Use this buffer only if carrying out the alternative to Step 1.

Sodium acetate (3 M, pH 5.2)

10x T4 polynucleotide kinase buffer

TE (pH 7.6)

Tris-Cl (2 M, pH 7.4)

Enzymes and Buffers

Bacteriophage T4 DNA polymerase (2.5 units/μl)

Bacteriophage T4 polynucleotide kinase (30 units/μl)

E. coli *DNA ligase*

E. coli *DNA polymerase I*

RNase H

The RNase H purified from *E. coli* is sold by several manufacturers and is required at a specific activity of ~1000 units/ml.

Nucleic Acids and Oligonucleotides

dNTP solution containing all four dNTPs, each at 10 mM

First-strand cDNA

Use the large-scale, first-strand reaction mixture prepared in Stage 1 of this protocol.

Markers

Please see the panel on **TROUBLESHOOTING: OPTIMIZING SECOND-STRAND cDNA SYNTHESIS** at the end of this protocol.

Radioactive Compounds

[α-^{32}P]dCTP (10 mCi/ml, 400 Ci/mmole) **<!>**

Do not use [α-^{32}P]dTTP as a radioactive tracer to monitor synthesis of the second strands of cDNA; it may be incorporated preferentially into the region of the second strand corresponding to the poly(A)$^+$ tract at the 3′ terminus of the mRNA.

Thaw the [α-^{32}P]dCTP just before starting the protocol. Store the thawed radiolabeled dCTP on ice until needed in Step 1. Return the radiolabeled dCTP to the freezer immediately after use.

Special Equipment

Sephadex G-50 spun column

Add Sephadex G-50 (medium pore) to sterile H_2O (10 g of dry powder yields 160 ml of slurry). Wash the swollen resin with sterile H_2O several times to remove soluble dextran, which can create problems by precipitating during ethanol precipitation. Finally, equilibrate the resin in TE (pH 7.6) containing 10 mM NaCl, autoclave (10 psi [0.70 kg/cm^3] for 15 minutes), and store at room temperature. Prepacked columns of Sephadex and other gel filtration resins are commercially available.

Water bath preset to 16°C

METHOD

Second-strand synthesis catalyzed by RNase H and DNA polymerase I results in loss of sequences (~20 nucleotides) from the extreme 5′ end of the mRNA template. This is because the RNase H degrades the 5′ sequences of the mRNA-DNA hybrid before DNA polymerase I can initiate synthesis of the second strand (D'Alessio and Gerard 1988). Most mammalian mRNAs carry an extensive tract of 5′-untranslated sequences, and the absence from cDNA clones of sequences corresponding to the 5′-terminal 20 nucleotides is therefore of little consequence to most investigators. However, for those who place a premium on these sequences, we have included an alternative to Step 1 that reduces the risk of losing 5′-terminal regions of cDNA clones. Unfortunately, the alternative method results in a reduced yield of double-stranded cDNA, and most investigators will therefore opt for the standard Step 1 method.

1. Add the following reagents directly to the large-scale first-strand reaction mixture (Stage 1, Step 4):

10 mM $MgCl_2$	70 µl
2 M Tris-Cl (pH 7.4)	5 µl
10 mCi/ml [α-^{32}P]dCTP (400 Ci/mmole)	10 µl
1 M $(NH_4)_2SO_4$	1.5 µl
RNase H (1000 units/ml)	1 µl
E. coli DNA polymerase I (10,000 units/ml)	4.5 µl

Mix the reagents by gently vortexing, and centrifuge the reaction mixture briefly in a microfuge to eliminate any bubbles. Incubate the reaction for 2–4 hours at 16°C.

ALTERNATIVE TO STEP 1 (D'ALESSIO AND GERARD 1988)

Incubate the second-strand synthetic reaction (above) for 2 hours at 16°C *in the absence of RNase H*. Purify the resulting double-stranded cDNA by extraction with phenol:chloroform and precipitation with ethanol in the presence of 0.3 M sodium acetate (pH 5.2). Dissolve the precipitated DNA in 20 µl of 20 mM Tris-Cl (pH 7.6), 20 mM KCl, 0.1 mM EDTA (pH 8.0), 0.1 mM dithiothreitol. Digest the DNA for 20 minutes at 37°C with RNase H (0.5 units). Proceed to Step 2.

2. At the end of the incubation, add the following reagents to the reaction mixture:

β-NAD (50 mM)	1 µl
E. coli DNA ligase (1000–4000 units/ml)	1 µl

Incubate the reaction for 15 minutes at room temperature.

3. At the end of the incubation, add 1 µl of a mixture containing all four dNTPs each at a concentration of 10 mM and 2 µl (5 units) of bacteriophage T4 DNA polymerase. Incubate the reaction mixture for 15 minutes at room temperature.

4. Remove a small aliquot (3 µl) of the reaction. Measure the mass of second-strand DNA in the aliquot as described in Steps 7 and 8.

5. To the remainder of the reaction, add 5 µl of 0.5 M EDTA (pH 8.0). Extract the mixture once with phenol:chloroform and once with chloroform. Recover the DNA by precipitation with ethanol in the presence of 0.3 M sodium acetate (pH 5.2). Dissolve the DNA in 90 µl of TE (pH 7.6).

6. To the DNA, add:

10x T4 polynucleotide kinase buffer	10 µl
T4 polynucleotide kinase (3000 units/ml)	1 µl

Incubate the reaction at room temperature for 15 minutes.

7. Use the small aliquot from Step 4 to determine the total amount of radioactivity and the TCA-precipitable counts in 1 µl of the second-strand synthesis reaction as described in Appendix 8.

8. Use the following equation to calculate the weight of the cDNA synthesized in the second-strand reaction, taking into account the amount of dNTPs already incorporated into the first strand of cDNA:

$$\frac{\text{cpm incorporated in the second-strand reaction}}{\text{total cpm}} \times (66\ \mu g - x\ \mu g)$$

$$= \mu g \text{ of second-strand cDNA synthesized}$$

where x is the weight of the first strand of cDNA (from Step 6 of Stage 1). The amount of second-strand cDNA synthesized is usually 70–80% of the weight of the first strand.

9. Extract the reaction containing phosphorylated cDNA (from Step 6) with an equal volume of phenol:chloroform.
10. Separate the unincorporated dNTPs from the cDNA by spun-column chromatography through Sephadex G-50 equilibrated in TE (pH 7.6) containing 10 mM NaCl (please see Appendix 8).
11. Precipitate the eluted cDNA by adding 0.1 volume of 3 M sodium acetate (pH 5.2) and 2 volumes of ethanol. Store the sample on ice for at least 15 minutes. Recover the precipitated DNA by centrifugation at maximum speed for 15 minutes at 4°C in a microfuge. Use a hand-held minimonitor to check that all of the radioactivity has been precipitated.
12. Wash the pellet with 70% ethanol and centrifuge again.
13. Gently aspirate all of the fluid (check to see that none of the radioactivity is in the aspirated fluid), and allow the pellet to dry in the air.
14. Dissolve the cDNA in 80 µl of TE (pH 7.6) if it is to be methylated by *Eco*RI methylase (please see Stage 3 of this protocol). Alternatively, if the cDNA is to be ligated directly to *Not*I or *Sal*I linkers, or an adaptor oligonucleotide (please see Stage 4 of this protocol), resuspend the cDNA in 29 µl of TE (pH 7.6).

    After the precipitated DNA has been redissolved, proceed as soon as it is feasible to the next stage in the synthesis of the cDNA.

    Precipitation of cDNA with ethanol is used many times in the construction of a cDNA library. Because the amounts of cDNA are usually very small (and often very precious!), special care is required to achieve maximum recovery of cDNA. For advice, please see Appendix 8.

TROUBLESHOOTING: OPTIMIZING SECOND-STRAND cDNA SYNTHESIS

The sizes of the radiolabeled first- and second-strand products should be analyzed by electrophoresis through an alkaline 1% agarose gel (please see Chapter 5, Protocol 8), using as markers end-labeled fragments of a *Hin*dIII digest of wild-type bacteriophage λ DNA (please see Chapter 9, Protocol 10). If the reactions have worked well, the population of first-strand cDNA molecules should range in size from 300 bases to >5 kb, with a modal size of ~2 kb.

The size of the products of second-strand synthesis should be similar to that of the population of first-strand molecules. The presence of large amounts of small products (<500 nucleotides) is a sure sign that synthesis of the second-strand cDNA has not worked well. Truncation of second-strand cDNA molecules is the result of gaps that are not filled by DNA polymerase and nicks that are not ligated by *E. coli* DNA ligase. If the modal distribution of the products of second-strand synthesis is significantly skewed toward molecules of lower molecular weight, it is best to abandon the preparation and reoptimize the conditions of second-strand synthesis. In most cases, efficient synthesis of long molecules of second-strand cDNA can be achieved by altering the ratio of template cDNA to RNase H and DNA polymerase in the reaction.

If the size of the first-strand cDNA is smaller than that of the second-strand cDNA, then a significant proportion of the second-strand molecules may have been generated by self-priming rather than by replacement synthesis. Self-priming generates a double-stranded or "long hairpin" cDNA molecule that contains a loop of cDNA at the 5′ end of the molecule. The covalently closed loop will prevent addition of linker-adaptor in subsequent steps. If the alkaline-agarose gel indicates that the second-strand cDNA is noticeably larger than the first, carry out the following troubleshooting experiment to diagnose the proportion of self-priming in the reaction:

a. Treat two aliquots of radiolabeled first strand and two aliquots of radiolabeled second strand with 1 mM EDTA (pH 8.0), 300 mM NaOH for 30 minutes at 60°C. This treatment hydrolyzes the RNA and denatures the DNA in the samples. Each aliquot should contain at least 10^4 cpm of TCA-precipitable material.

b. Add 0.1 volume of 3 N HCl, 0.1 M Tris-Cl (pH 7.4) to each aliquot.

c. Purify the DNAs by extraction with phenol:chloroform and standard precipitation with ethanol.

d. Dissolve the DNAs in 10 μl of H_2O. Add 1 μl of 3 M NaCl. Incubate the DNAs for 5 minutes at 68°C to allow "hairpins" to form.

e. Add 20 μl of H_2O and 3 μl of 10x nuclease S1 buffer (2 M NaCl/0.5 M sodium acetate [pH 4.5]/10 mM $ZnSO_4$/5% glycerol).

f. Add 5 units of nuclease S1 to one of the two tubes containing the first strand of cDNA and to one containing the second strand of cDNA. Incubate all four tubes for 30 minutes at 37°C.

g. Analyze the size of first- and second-strand products by electrophoresis through an alkaline 1% agarose gel (please see Chapter 5, Protocol 8), using end-labeled fragments of a *Hin*dIII digest of wild-type bacteriophage λ DNA as markers (please see Chapter 9, Protocol 10).

The first-strand molecules should be completely hydrolyzed by nuclease S1, and no more than 10–15% of the second-strand molecules should be resistant to digestion with the enzyme. If the proportion of self-primed molecules is unacceptably high, it is often helpful to adjust the amount of RNase H used during the synthesis of the second strand. In addition, self-priming may be suppressed by including actinomycin D (50 μg/ml) or 4 mM sodium pyrophosphate (Rhyner et al. 1986) in first-strand reactions catalyzed by avian reverse transcriptase. Note that sodium pyrophosphate should not be used with murine reverse transcriptase because it inhibits the polymerizing activity of the enzyme (Roth et al. 1985).

STAGE 3: Methylation of cDNA

The products of Stage 2 are phosphorylated, blunt-ended double-stranded cDNAs that are full-length, or close to it. Attaching these molecules to a vector requires the addition of adaptors or linkers to the termini of the cDNAs. If adaptors are used, omit Stage 3 and proceed directly to Stage 4. If linkers are used, Stage 3 must be carried out with great diligence.

Methylated bases protect internal restriction sites in the double-stranded cDNA against cleavage by *Eco*RI, a step required to generate cohesive termini after addition of double-stranded *Eco*RI linkers to the cDNA. There are two ways to produce methylated cDNA:

- Use 5′methyldeoxycytosine triphosphate as a precursor in place of dCTP during first-strand cDNA synthesis (Han and Rutter 1988; Huse and Hansen 1988). Second-strand synthesis is completed using the four conventional nonmethylated bases. The resulting hemimethylated double-stranded cDNA is partially resistant to cleavage by *Eco*RI. This strategy is used in cDNA synthesis kits sold by Stratagene. If the cDNA is methylated by incorporation of 5′methyldeoxycytosine, it is essential to use a strain of *E. coli* that is deficient in the *mcr* restriction system, which normally cleaves DNA at methylcytosine residues (Raleigh et al. 1988; Woodcock et al. 1989).
- Use *Eco*RI methylase to catalyze the transfer of methyl groups from a donor such as *S*-adenosylmethionine to the second of the two adenine residues in the recognition sequence of *Eco*RI. The modification of adenine to 6-methylaminopurine protects the DNA from cleavage by *Eco*RI (Greene et al. 1975). *Eco*RI methylase is an efficient enzyme and will usually methylate the vast majority of sites in the cDNA. Specific methylation generally affords the target sequence a high degree of protection against subsequent cleavage by the cognate restriction enzyme. However, because the *Eco*RI methylase is inhibited by Mg^{2+}, it is essential to precipitate the cDNA with ethanol to cleanse the preparation of Mg^{2+} before proceeding with methylation (Steps 11–14 of Stage 2).

When establishing cDNA libraries from very small amounts of mRNA, some investigators attempt to maximize the number of cDNA clones by simply omitting the methylation step (e.g., please see McDonnell et al. 1987; Don et al. 1993). This approach suffers from the disadvantage that cDNAs containing "natural" internal *Eco*RI sites are cleaved by *Eco*RI into two or more fragments and cloned separately.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Chloroform <!>

10x Eco*RI buffer*

10x Eco*RI methylase buffer (Optional)*

If desired, use in place of the Tris-Cl, NaCl, and EDTA in Step 1.

EDTA (0.5 M, pH 8.0)

Ethanol

$MgCl_2$ (1 M)
NaCl (5 M)
Phenol:chloroform <!>
S-Adenosylmethionine
Use the iodide salt, grade I. Make a stock solution (20 mM) in 5 mM H_2SO_4 and 10% ethanol. Store the solution in aliquots at –20°C. New England Biolabs provides a solution of S-adenosylmethionine when *Eco*RI methylase is purchased.
Sodium acetate (3 M, pH 5.2)
TE (pH 8.0)
Tris-Cl (2 M, pH 8.0)

Enzymes and Buffers

Eco*RI*
Eco*RI methylase*
New England Biolabs sells an enzyme isolated from a strain of *E. coli* that expresses the methylase gene from a multicopy plasmid.

Gels

Agarose gel (1%)
Please see Step 8.

Nucleic Acids and Oligonucleotides

Double-stranded cDNA
Use the cDNA prepared in Stage 2, Step 14 (p. 11.46) of this protocol.
Linearized plasmid DNA or Bacteriophage λ DNA
Either of these is used to check the efficiency of methylation of *Eco*RI sites. The linearized plasmid DNA should contain at least one *Eco*RI site located some distance from the termini. Use a bacteriophage λ DNA such as that used as a size standard for agarose gel electrophoresis (e.g., *Hin*dIII-digested λ DNA). For plasmid DNA, digest 1 µg to completion with *Pst*I. Purify the DNA by extraction with phenol:chloroform and precipitation with ethanol. Dissolve the DNA in 5 µl of TE (pH 7.6) and store it at –20°C.

Special Equipment

Water bath preset to 68°C

METHOD

1. Add to the cDNA (from Stage 2, Step 14, p. 11.46):

2 M Tris-Cl (pH 8.0)	5 µl
5 M NaCl	2 µl
0.5 M EDTA (pH 8.0)	2 µl
20 mM S-adenosylmethionine	1 µl
H_2O	to 96 µl

2. Remove two 2-µl aliquots and place each in a separate 0.5-ml microfuge tube. Number the tubes 1 and 2, and store the numbered tubes on ice.

3. Add 2 µl of *Eco*RI methylase (80,000 units/ml) to the remainder of the reaction mixture and then store the reaction mixture at 0°C until Step 4 is completed.
4. Remove two additional aliquots (2 µl each) from the large-scale reaction and place each in a separate 0.5-ml microfuge tube. Number these tubes 3 and 4.
5. To each of the four small aliquots (Steps 2 and 4), add 100 ng of plasmid DNA *or* 500 ng of bacteriophage λ DNA, prepared as described in Materials. These unmethylated DNAs are used as substrates in pilot reactions to assay the efficiency of methylation.

   ▲ **IMPORTANT** Do not add any DNA to the large-scale reaction!
6. Incubate all four pilot reactions and the large-scale reaction for 1 hour at 37°C.
7. Heat the five reactions to 68°C for 15 minutes. Extract the large-scale reaction once with phenol:chloroform and once with chloroform.
8. To the large-scale reaction add 0.1 volume of 3 M sodium acetate (pH 5.2) and 2 volumes of ethanol. Mix the reagents well and store the ethanolic solution at –20°C until the results of the pilot reactions are available.
9. Analyze the four pilot reactions as follows:
   a. To each control reaction, add:

0.1 M $MgCl_2$	2 µl
10x *Eco*RI buffer	2 µl
H_2O	to 20 µl

   b. Add 20 units of *Eco*RI to reactions 2 and 4.
   c. Incubate all four samples for 1 hour at 37°C, and analyze them by electrophoresis through a 1% agarose gel.

      After staining the agarose gel with ethidium bromide, the cDNA can often be seen as a background smear in the gel. The methylated cDNA (and the plasmid or bacteriophage λ DNA in Tubes 3 and 4) should be resistant to cleavage by *Eco*RI and show no change in size. The unmethylated cDNA and the plasmid or bacteriophage DNA in Tubes 1 and 2 should be cleaved by *Eco*RI. If both of these expectations are fulfilled, proceed to Step 10; if they are not, repeat the methylation reaction.
10. Recover the precipitated cDNA (Step 8) by centrifugation at maximum speed for 15 minutes at 4°C in a microfuge. Remove the supernatant, add 200 µl of 70% ethanol to the pellet, and centrifuge again.
11. Use a hand-held minimonitor to check that all of the radioactivity is recovered in the pellet. Remove the ethanol by gentle aspiration, dry the pellet in the air, and then dissolve the DNA in 29 µl of TE (pH 8.0).
12. Proceed as soon as is feasible to the next stage in the synthesis of the cDNA.

STAGE 4: Attachment of Linkers or Adaptors

Several different types of oligonucleotide linkers or adaptors may be used to construct cDNA libraries. The simplest of all are unadorned oligonucleotides (typically from 8 to 12 nucleotides in length), whose sequence contains a recognition site for a restriction enzyme such as *Eco*RI (5′-pCGGAATTCCG-3′). These single-stranded oligonucleotides are designed to anneal with one another to form double-stranded linkers that can be ligated to the polished ends of double-stranded cDNAs. During the ligation reaction, the linkers are assembled into progressively longer polymers on each end of the cDNA. The products of the reaction are then cleaved by the appropriate restriction enzyme (in this case *Eco*RI) to remove excess linkers and to expose cohesive termini at the ends of the cDNA (please see Figure 11-14). Clearly, any "natural" *Eco*RI sites in the cDNAs that have not been protected by methylation in Stage 3 are vulnerable to attack by the restriction enzyme. Cleavage at internal sites is undesirable because cDNAs are divided into two or more fragments, which become separated during the cloning process, and because chimeric molecules may be created from fragments of cDNAs derived from independent mRNA templates. These problems will not be bothersome if the methylation reaction (Stage 3) has gone well.

The potential complications of internal cleavage can be suppressed by using adaptors rather than linkers. Adaptors used in cDNA cloning are short double-stranded synthetic oligonucleotides that carry an internal restriction endonuclease recognition site and a protruding terminus at one end, for example:

5′-AATTCGCGGCCGCGTCGAC-3′
3′-GCGCCGGCGCAGCTGp-5′

Note that the double-stranded structure contains an *Eco*RI cohesive terminus, internal *Not*I and *Sal*I sites, and only one phosphorylated 5′ terminus. One adaptor molecule can be ligated to each end of a blunt-ended double-stranded cDNA molecule. Unlike linkers, adaptors are unable to form multimers because the protruding single-stranded cohesive terminus lacks a 5′-phosphate group. The cDNA molecules therefore become equipped with live *Eco*RI termini without the necessity for digestion by *Eco*RI. However, cDNAs modified by the addition of adaptors at both ends must be phosphorylated before ligation to a dephosphorylated plasmid or bacteriophage λ vector DNA. Because recognition sites for *Not*I and *Sal*I occur very rarely in mammalian DNA (please see Appendix 6), they are unlikely to be present within a cDNA sequence. Cleavage of the cloned DNA with one of these enzymes can therefore be used in most cases to release the intact cDNA insert from the vector.

Other types of adaptors permit excellent alternative strategies to be used when ligating cDNA molecules to their vectors. For example, the recessed 3′ termini created by digestion of a vector by *Xho*I may be partially filled by addition of a deoxythymidine residue. Phosphorylated adaptors with three-base protruding termini complementary to the partially filled *Xho*I site are attached to the cDNA. Neither the vector nor the cDNA molecules can anneal to themselves, but they can join efficiently to each other. Because the *Xho*I site is regenerated, the cloned cDNA can be recovered by digestion with *Xho*I. This strategy greatly improves the efficiency of the ligation step in cDNA cloning and eliminates the need to methylate the cDNA or to digest it with restriction enzymes before insertion into the vector (Yang et al. 1986; Elledge et al. 1991).

When joining linkers or adaptors to blunt-ended double-stranded cDNA molecules, it is important that the ligation reaction be carried out in as small a volume as possible (to maintain a

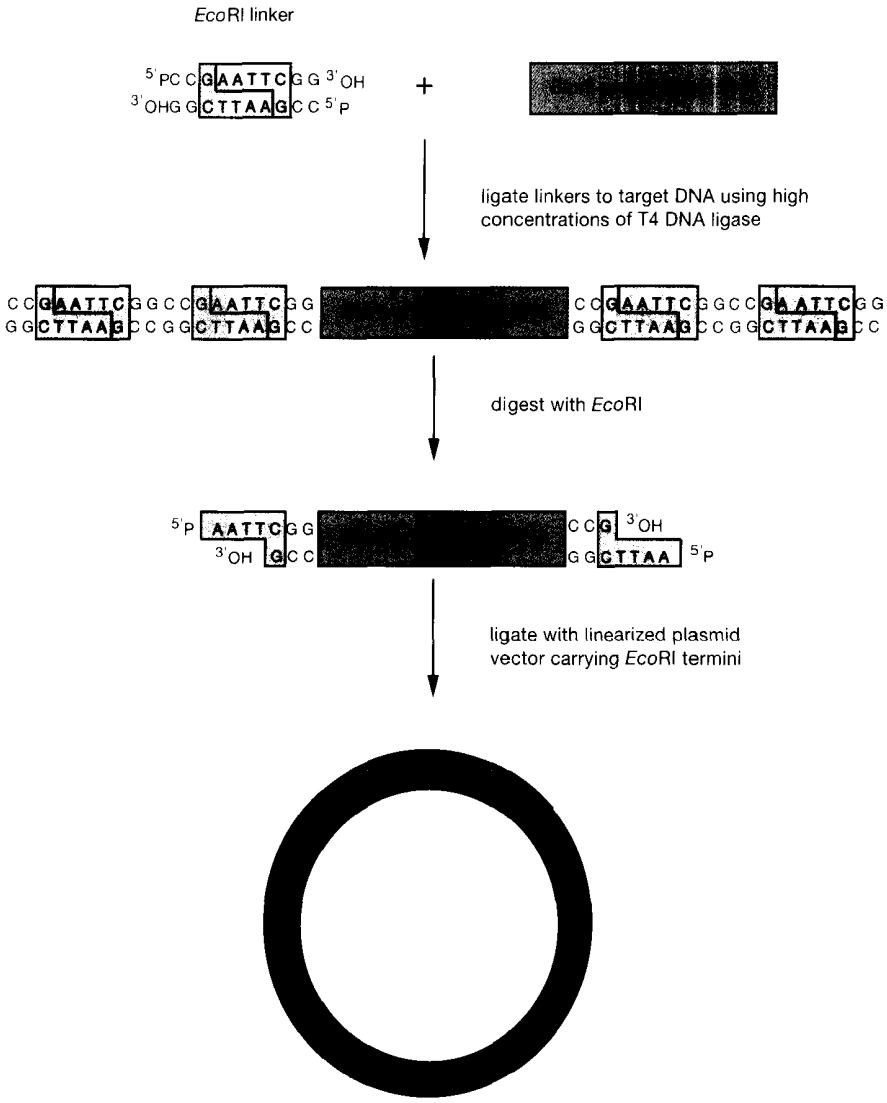

FIGURE 11-14 Addition of Linkers and Adaptors to Double-stranded cDNA Products

A phosphorylated decameric linker containing a recognition site for *Eco*RI is ligated to blunt-ended target molecules, such as a preparation of double-stranded cDNA. The target molecules are then prepared for cloning by digestion with *Eco*RI.

high concentration of linker-adaptors). The molar concentration of linker-adaptors must be at least 100 times greater than the concentration of termini of cDNA to minimize blunt-end ligation of cDNA molecules. Finally, before the cDNA is inserted into the vector, unreacted adaptors and the low-molecular-weight products created by restriction enzyme digestion of polymerized linkers must be efficiently removed by column chromatography or gel electrophoresis.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

ATP (10 mM)

5x Bacteriophage T4 DNA polymerase repair buffer

90 mM $(NH_4)_2SO_4$
0.33 M Tris-Cl (pH 8.3)
33 mM $MgCl_2$
50 mM β-mercaptoethanol **<!>**
Store the buffer in small aliquots at –20°C.

Bromophenol blue (0.25% w/v in 50% glycerol)

EDTA (0.5 M, pH 8.0)

Ethanol

Phenol:chloroform **<!>**

Sodium acetate (3 M, pH 5.2)

TE (pH 8.0)

Tris-Cl (1 M, pH 8.0)

Enzymes and Buffers

Bacteriophage T4 DNA ligase

Bacteriophage T4 DNA polymerase

Restriction enzymes

Depending on the type of linkers or adaptors used, *Eco*RI, *Not*I, *Sal*I, or other restriction enzymes are required.

Gels

Agarose gel (1%)

Please see Step 12.

Nucleic Acids and Oligonucleotides

cDNA, either unmethylated or methylated

Use the cDNA prepared in either Stage 2, Step 14 or Stage 3, Step 11 of this protocol.

Control DNA

Please see note to Step 10.

dNTP solution containing all four dNTPs, each at 5 mM

Linearized plasmid DNA or Bacteriophage λ DNA

Either of these is used to check the efficiency of digestion following linker addition. A plasmid DNA should contain at least one *Eco*RI site located some distance from the ends of the linear DNA (e.g., Xf3 or pBR322 linearized by digestion with *Pst*I). Use a bacteriophage λ DNA such as that used as a size standard for agarose gel electrophoresis (e.g., *Hin*dIII-digested λ DNA). For plasmid DNA, digest 1 μg to completion with *Pst*I. Purify the DNA by extraction with phenol:chloroform and precipitation with ethanol. Dissolve the DNA in 5 μl of TE (pH 7.6). Store at –20°C. Predigested λ DNA can be used as is.

Synthetic linkers or adaptors

Phosphorylated linkers and adaptors are sold by several manufacturers. If possible, obtain linkers that are at least 4–8 nucleotides longer than the site recognized by the restriction enzyme. Many restriction enzymes inefficiently cleave recognition sites located very close to the ends of DNA molecules (please see Appendix 6).

Special Equipment

Sephadex G-50 spun column

Add Sephadex G-50 (medium pore) to sterile H_2O (10 g of dry powder yields 160 ml of slurry). Wash the swollen resin with sterile H_2O several times to remove soluble dextran, which can create problems by precipitating during ethanol precipitation. Finally, equilibrate the resin in TE (pH 7.6), autoclave (10 psi [0.70 kg/cm^2] for 15 minutes), and store at room temperature. Prepacked columns of Sephadex and other gel filtration resins are commercially available.

Water baths preset to 16°C and 68°C

METHOD

Polishing of the cDNA Termini

1. Heat the cDNA (Step 11, p. 11.50) to 68°C for 5 minutes.

   This step denatures any double-stranded structures that may have formed from protruding single-stranded termini of the cDNA molecules.

2. Cool the cDNA to 37°C and add the following to the tube:

5x bacteriophage T4 DNA polymerase repair buffer	10 µl
5 mM dNTP solution	5 µl
H_2O	to 50 µl

3. Add 1–2 units of bacteriophage T4 DNA polymerase (500 units/ml) and incubate the reaction for 15 minutes at 37°C.

4. Stop the reaction by adding 1 µl of 0.5 M EDTA (pH 8.0).

5. Extract the sample with phenol:chloroform, and remove the unincorporated dNTPs by spun-column chromatography through Sephadex G-50 (please see Appendix 8).

6. Add 0.1 volume of 3 M sodium acetate (pH 5.2) and 2 volumes of ethanol to the column flow-through. Store the sample for at least 15 minutes at 4°C.

7. Recover the precipitated cDNA by centrifugation at maximum speed for 15 minutes at 4°C in a microfuge. Dry the pellet in the air, and then dissolve it in 13 µl of 10 mM Tris-Cl (pH 7.6).

Ligation of Linker-Adaptors to the cDNA

8. Add the following to the repaired DNA:

10x T4 DNA ligase buffer	2 µl
800–1000 ng of phosphorylated linkers or adaptors	2 µl
10^5 Weiss units/ml bacteriophage T4 DNA ligase	1 µl
10 mM ATP	2 µl

   Mix and incubate for 8–12 hours at 16°C.

   It is essential to use a vast molar excess of linkers (>100-fold) to ensure that the ends of the cDNA become ligated to a linker and not to each other.

9. Withdraw 0.5 µl from the reaction and store the aliquot at 4°C. Inactivate the ligase in the remainder of the reaction by heating for 15 minutes at 68°C.

Endonuclease Digestion of the Linker-Adaptors

If endonuclease digestion is necessary to permit ligation of the cDNA to the vector, then proceed with Steps 10–12. However, when using certain adaptor molecules, endonuclease digestion is not required. In these cases, skip to Step 13. For additional details, please see the introduction to this protocol.

When using hemiphosphorylated adaptors (please see the introduction to this protocol), an additional phosphorylation step with bacteriophage T4 polynucleotide kinase must be carried out after ligation. Phosphorylation is easily carried out by adding 30–50 units of bacteriophage T4 polynucleotide kinase directly to the heat-treated ligation products.

a. Add to the heated ligase reaction:

10x bacteriophage T4 polynucleotide kinase buffer	3 µl
bacteriophage T4 polynucleotide kinase	30–50 units
H_2O	to 30 µl

b. Incubate the reaction for 1 hour at 37°C.

c. Proceed directly to Step 13.

10. To the heated ligase reaction, add:

10x restriction enzyme buffer	20 µl
H_2O	150 µl
restriction enzyme	200 units

Mix the reagents at 0°C.

As a control, transfer 2 µl of the reaction to a 0.5-ml microfuge tube. To the 2-µl aliquot, add 100 ng (in a volume of no more than 0.5 µl) of control DNA, i.e., either a linearized plasmid or a preparation of cleaved bacteriophage λ DNA that contains an internal site for the particular restriction enzyme used.

11. Incubate the large-scale reaction and the control reaction for 2 hours at 37°C.

12. Analyze the DNA in the control sample and the 0.5-µl aliquot withdrawn at Step 9 by electrophoresis through a 1% agarose gel. Load one or two lanes of the gel with plasmid or bacteriophage λ marker DNA.

If the ligation has worked well, the ligated linkers should be visible as a smear at the bottom of the gel. If digestion with the restriction enzyme is complete, the smear of linkers should disappear and the plasmid or bacteriophage λ DNA in the control sample should be cleaved appropriately.

The size of the cDNA will not change appreciably after ligation to adaptors. Analysis of the DNA by gel electrophoresis can therefore be omitted when using adaptors.

Preparation of the cDNA for Size Fractionation

13. Purify the cDNA by extraction with phenol:chloroform and standard precipitation with ethanol. Dissolve the cDNA in 20 µl of TE (pH 8.0).

14. Add 2.5 µl of a solution of 0.25% bromophenol blue in 50% glycerol. This addition simplifies the next stage in the cDNA library — size-fractionation of the cDNA by chromatography through Sepharose CL-4B (Stage 5).

STAGE 5: Fractionation of cDNA by Gel Filtration through Sepharose CL-4B

Before insertion into a bacteriophage λ or plasmid vector (Stage 6), the preparation of cDNA is fractionated by gel filtration to remove unused linker-adaptors and low-molecular-weight products created by restriction enzyme digestion of polymerized linkers. Removing flotsam increases the number of recombinants that contain cDNAs and dramatically reduces the number of false recombinants that contain nothing more than annealed linkers. Fractionating the cDNA also creates an opportunity to discard cDNAs that are <500 bp in length. These short fragments are the unwanted products of incomplete synthesis of first- and/or second-strand cDNA synthesis and are of little use to most investigators. Eliminating these fragments from the library certainly reduces the number of recombinants that must be screened and may also increase the chance that entire sequences of the mRNAs of interest will be represented in the library. In some circumstances, there is an advantage in establishing two libraries from the fractionated preparation cDNA — one containing cDNAs whose sizes range is from 0.5 kb to 3.5 kb, and another containing larger cDNAs. Because only a small fraction of the original mRNA population is longer than 3.5 kb, the number of clones in the second library is generally ~10% of the number in the first. However, establishing and screening a library enriched for large cDNAs increases the chance and decreases the labor of isolating full-length cDNAs corresponding to rare mRNAs encoding large proteins.

Electrophoresis through agarose or polyacrylamide gels may also be used to separate unligated linker-adaptors from cDNA and to fractionate the cDNA by size. However, the recovery of cDNA from gels in a form that can be ligated efficiently to the vector can be poor, and chromatography through a long narrow column (27 x 0.3 cm) of Sepharose CL-4B is therefore the best option.

MATERIALS

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Ethanol
Sodium acetate (3 M, pH 5.2)
TE (pH 7.6)
TE (pH 7.6) containing 0.1 M NaCl
Tris-Cl (1 M, pH 8.0)

Gels

Agarose gel (1%)
Please see Step 8.

Nucleic Acids and Oligonucleotides

cDNA
Use the cDNA prepared in Stage 4, Steps 13 and 14.
Marker DNA
The marker DNA should be end-labeled fragments ranging in size from 200 bp to 5 kb.

Special Equipment

Filtered compressed air
Hemostat or equivalent hose clamp
Hypodermic needle with a bent tip
Pipette, disposable (1 ml)
Polyvinyl chloride tubing
Scissors
Sepharose CL-4B
Wash the paste supplied by the manufacturer several times in sterile TE (pH 7.6) containing 0.1 M NaCl. This washing removes inhibitors of ligation present in some batches of the gel. Prepacked columns of Sepharose CL-4B (SizeSep 400 Spun Columns) are available from Amersham Pharmacia Biotech.
Vinyl bubble tubing
Whatman 3MM paper

METHOD

Preparation of Sepharose CL-4B Column

1. Use a hypodermic needle with a bent end to pull the cotton wool pledget halfway out of the end of a sterile, disposable 1-ml pipette. Cut the pledget in half with sterile scissors. Discard the loose piece of cotton wool. Use filtered compressed air to blow the remainder of the pledget to the narrow end of the pipette.
2. Attach a piece of sterile polyvinyl chloride tubing (of the type normally used in peristaltic pumps) to the narrow end of the pipette. Dip the wide end of the pipette into a solution of TE (pH 7.6) containing 0.1 M NaCl in a beaker. Attach the tubing to an Erlenmeyer flask connected to a vacuum line. Apply gentle suction until the pipette is filled with buffer. Close the tubing with a hemostat.
3. Attach a piece of vinyl bubble tubing to the wide end of the pipette. Fill the bubble tubing with Sepharose CL-4B equilibrated with TE (pH 7.6) containing 0.1 M NaCl. Allow the slurry to settle for a few minutes and then release the hemostat. The column will form as the buffer drips from the pipette. If necessary, add more Sepharose CL-4B until the packed matrix almost fills the pipette.
The dimensions of the packed column should be ~27 x 0.3 cm.
4. Wash the column with several column volumes of TE (pH 7.6) containing 0.1 M NaCl. After washing is completed, use a hemostat to close the tubing at the bottom of the column.

Separation and Recovery of Size-selected cDNA

5. Use a Pasteur pipette to remove the fluid above the Sepharose CL-4B. Apply the cDNA (in a volume of 50 µl or less) to the column. Release the hemostat and allow the cDNA to enter the gel matrix. Wash the microfuge tube used to store the cDNA with 50 µl of TE (pH 7.6), and apply this to the column. Fill the bubble tubing with TE (pH 7.6) containing 0.1 M NaCl.
▲ **IMPORTANT** Do not allow the column to run dry at any stage!
6. Monitor the progress of the cDNA through the column using a hand-held minimonitor. Begin collecting 2-drop fractions (~60 µl) in microfuge tubes when the radioactive cDNA has

traveled two thirds the length of the column. Continue collecting fractions until all of the radioactivity has eluted from the column.

7. Measure the radioactivity in each fraction by Cerenkov counting (please see Appendix 8).

8. Analyze small aliquots of each fraction (~5 µl) by electrophoresis through a 1% agarose gel, using as markers end-labeled fragments of DNA of known size (200 bp to 5 kb). Store the remainder of the fractions at –20°C until the autoradiograph of the agarose gel is available.

   Cast the agarose gel as thin as possible to speed up the drying process at the completion of electrophoresis.

   The amount of radioactivity in the preparation of marker DNAs should be ~0.3 times the amount in the peak fractions of cDNA.

9. After electrophoresis, transfer the gel to a piece of Whatman 3MM paper. Cover the gel with Saran Wrap, and dry it on a commercial gel dryer. Heat the gel to 50°C for the first 20–30 minutes of drying and then turn off the heat. Continue drying the gel under vacuum for a further 1–2 hours.

10. Expose the dried gel to X-ray film at –70°C with an intensifying screen (please see Appendix 9).

    The autoradiograph should reveal a size-fractionated smear of radioactivity with cDNAs in the 5–7-kb range in early fractions from the column and progressively smaller cDNAs in subsequent fractions.

11. Add 0.1 volume of 3 M sodium acetate (pH 5.2) and 2 volumes of ethanol to fractions containing cDNA molecules that are ≥500 bp in length. Allow the cDNA to precipitate for at least 15 minutes at 4°C. Recover the DNA by centrifugation at maximum speed for 15 minutes at 4°C in a microfuge.

    Be very conservative in selecting these fractions. Resist all temptation to include fractions that contain any traces of cDNAs smaller than 500 bp; otherwise, the library will contain a preponderance of short clones.

12. Dissolve the DNA in a total volume of 20 µl of 10 mM Tris-Cl (pH 7.6).

13. Determine the amount of radioactivity present in a small aliquot, and calculate the total amount of cpm available in the selected fractions. Calculate the total quantity of cDNA available for ligation to bacteriophage λ arms (for calculation of second-strand cDNA data, please see Stage 2, Step 8):

$$\frac{\text{cpm available}}{\text{cpm incorporated into second strand}} \times 2x \text{ µg second-strand cDNA synthesized}$$

$$= \text{µg of cDNA available for ligation}$$

If everything has gone well, 10 µg of poly(A)$^+$ RNA should yield at least 250–400 ng, and possibly as much as 3 µg, of cDNA whose size is larger than 500 bp in length.

STAGE 6: Ligation of cDNA to Bacteriophage λ Arms

If everything up to this point has worked perfectly, all of the termini in the preparation of cDNA should be equipped with cohesive termini that can be ligated efficiently to a bacteriophage λ or plasmid vector. In practice, the situation may be far from ideal. If, for example, the frayed termini of double-stranded cDNA were inefficiently polished or phosphorylated during Stage 2, they would not carry a linker or adaptor and would be unable to ligate efficiently to the vector. The best way to estimate the concentration of competent termini in the cDNA is to carry out pilot ligations and either packaging reactions or transformations. In these reactions, a constant amount of bacteriophage λ arms or linearized, dephosphorylated plasmids are ligated to varying amounts of cDNA. The aim is to settle on an amount of cDNA that yields a mammalian cDNA library of reasonable size. Today, a library consisting of 5×10^5 recombinants is regarded as barely acceptable; because of the high quality of enzymes currently available, libraries containing 5×10^6 to 5×10^7 independent clones are now well within the reach of the average investigator.

The pilot ligation reactions are carefully arranged to minimize the chance that a single recombinant bacteriophage or plasmid will contain more than one cDNA molecule. Avoid clones containing compound cDNAs by

- using a molar ratio of phosphorylated λ arms to cDNA such that only 5% of the resulting bacteriophages are recombinant

  or

- if dephosphorylated λ arms or plasmid vectors are used, ascertaining the amount of cDNA that generates tenfold more plaques or colonies, respectively, than vector ligated in the absence of cDNA.

When constructing cDNA libraries in bacteriophage vectors such as λgt11, λgt18-23, λZipLox, and λZAP, which have no system to allow selection against nonrecombinant bacteriophages, it is sensible to use dephosphorylated arms, which reduce by ~100-fold the number of empty bacteriophages in the cDNA library. The same result can be achieved using arms with noncompatible termini produced by partial filling or addition of appropriate linker-adaptors. With some of these vectors, it is possible to estimate the ratio of empty to recombinant bacteriophages in the library by plating on strains of *E. coli* such as Y1090*hsdR*. In the presence of the inducer IPTG and the chromogenic substrate X-gal, nonrecombinant plaques are blue; recombinant plaques are colorless.

Nonrecombinant bacteriophages present less of a problem when bacteriophages such as λgt10 are used as vectors, since a single round of growth on *E. coli* strains carrying an *hfl*$^-$ mutation eliminates the vast majority of nonrecombinants from the population. Recombinants form clear plaques on the *E. coli hfl*$^-$ strain BNN102 (because insertion of the cDNA inactivates the *c*I gene, which codes for repressor). Nonrecombinant bacteriophages establish repression so effectively that their efficiency of plating is greatly reduced. The absolute number of cDNA recombinants constructed in λgt10 can therefore be obtained by counting the number of plaques formed on BNN102. The proportion of recombinants in the bacteriophage stock can be measured by counting the ratio of clear to turbid plaques on C600, an *hfl*$^+$ strain. Recombinant bacteriophages form clear plaques on this strain, whereas nonrecombinant bacteriophages, which continue to synthesize active repressor, give rise to turbid plaques. The number of clear plaques on strain C600 should equal the total number of plaques on strain BNN102. For reasons that are unclear,

this powerful genetic selection against nonrecombinant bacteriophages is used only rarely, with most investigators preferring to use dephosphorylated λgt10 DNA arms.

The main protocol provides instructions for preparing a cDNA library in a bacteriophage λ vector. An alternative protocol follows Step 8 that substitutes a plasmid vector for the bacteriophage λ arms. Plasmid vectors may be preferable when preparing a cDNA expression library that will be screened after it is transfected into cultured mammalian cells. For details on individual vectors, please see the information panel on **COMMERCIAL KITS FOR cDNA SYNTHESIS AND LIBRARY CONSTRUCTION.**

MATERIALS

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

ATP (10 mM)

SM

Enzymes and Buffers

Bacteriophage T4 DNA ligase

Gels

Agarose gel (1%)

Please see Step 8.

Nucleic Acids and Oligonucleotides

cDNA

Use the cDNA prepared in Stage 5, Step 12 (p. 11.58), of this protocol.

Control bacteriophage λ DNA

This DNA is usually provided with the commercial packaging extract and is used to determine the packaging efficiency of the extract.

Marker DNA

The marker DNA should be fragments ranging in size from 500 bp to 5 kb.

Special Equipment

Water baths preset to 16°C and 42°C

Additional Reagents

Step 4 of this protocol requires the reagents listed in Chapter 2, Protocol 1.

Step 7 of this protocol requires the reagents listed in Chapter 2, Protocol 23.

Vectors and Bacterial Strains

Bacteriophage λ arms

If making a large number of libraries, it is much less expensive to prepare arms by agarose gel electrophoresis or by sucrose density gradients (please see Chapter 2, Protocol 16) than to purchase them. For occasional users, dephosphorylated arms for some vectors (e.g., λgt10, λFix, and λZipLox) are available from Stratagene, Life Technologies, and other commercial suppliers. Whatever the source of arms, it is important to carry out a series of pilot reactions to check that the arms can be ligated to foreign DNA and packaged efficiently into infectious bacteriophage λ particles. DNAs for these controls are usually included with commercial preparations of vector arms.

E. coli *strain, freshly prepared overnight cultures*

Use strains C600 (BNN93) for growth and BNN102 (C600*hflA*) for screening of cDNA libraries constructed in bacteriophage λgt10. Use strain Y1090*hsdR* for growth and screening of cDNA libraries constructed in bacteriophage λgt11. Use strain BB4 for growth and screening of cDNA libraries construct-

ed in λZAP and λZAPII or strain XL1-Blue for λZAPII. (Strain XL1-Blue supports vigorous growth of λZAPII but not of λZAP.) For λZipLox, use strain Y1090(ZL). Please see the panel on **PLATING BACTERIOPHAGE λ ON *E. COLI* STRAINS** on the following page.

Packaging extracts for bacteriophage λ

Packaging extracts are difficult to make and should therefore be purchased commercially. Several commercial suppliers provide packaging kits with unique features. For a description of packaging extracts, please see the information panel on **IN VITRO PACKAGING.**

METHOD

1. Set up four test ligation/packaging reactions as follows:

Ligation	A	B	C	D
λ vector DNA (0.5 μg/μl)	1.0 μl	1.0 μl	1.0 μl	1.0 μl
10x T4 DNA ligase buffer	1.0 μl	1.0 μl	1.0 μl	1.0 μl
cDNA	0 ng	5 ng	10 ng	50 ng
Bacteriophage T4 DNA ligase (100 Weiss units/μl)	0.1 μl	0.1 μl	0.1 μl	0.1 μl
10 mM ATP	1.0 μl	1.0 μl	1.0 μl	1.0 μl
H_2O to a final volume of	10 μl	10 μl	10 μl	10 μl

Adding ATP as a component of the 10x ligation buffer leaves more volume for vector or foreign DNA in the reaction mixture. If using a commercial ligase buffer that contains ATP, the addition of ATP is not required.

Incubate the ligation mixtures for 4–16 hours at 16°C. Store the unused portion of the cDNA at –20°C.

2. Package 5 μl of each ligation into bacteriophage λ particles following the directions provided by the manufacturer of the packaging extract.

Because the size of the final cDNA library depends on the efficiency with which recombinant bacteriophage λ genomes are packaged into infectious bacteriophage λ particles, it is essential to use packaging mixtures of high potency that yield >5 x 10^8 pfu/μg of bacteriophage λ DNA.

Be sure to include a control λ DNA (usually provided with the packaging reaction kit) to determine the packaging efficiency of the extract on hand.

3. After the packaging reaction is complete, add 0.5 ml of SM to each mixture.

4. Use the fresh overnight cultures of the appropriate strain(s) of *E. coli* to plate 10 μl and 100 μl of a 10^{-2} dilution of each packaging mixture on each strain (please see Chapter 2, Protocol 1, and the panel on **PLATING BACTERIOPHAGE λ ON *E. COLI* STRAINS**). Incubate the plates for 8–12 hours at 37°C or 42°C.

5. Count the number of recombinant and nonrecombinant plaques. Ligation A should yield no recombinant plaques, whereas ligations B, C, and D should yield increasing numbers of recombinant plaques.

6. From the number of recombinant plaques, calculate the efficiency of cloning of cDNA (pfu/ng cDNA). If all has gone well, the efficiency should be at least 2 x 10^4 pfu/ng cDNA. The total yield of recombinants from 5 μg of poly(A)$^+$ RNA should be in excess of 5 x 10^6.

7. Pick 12 recombinant bacteriophage λ plaques, grow small-scale lysates, and prepare DNAs for digestion with the appropriate restriction enzyme.

8. Analyze the size of the cDNA inserts by electrophoresis through a 1% agarose gel, using as markers fragments of DNA 500 bp to 5 kb in length.

PLATING BACTERIOPHAGE λ ON *E. COLI* STRAINS

Different bacteriophage λ vectors require different strains of *E. coli* for plaque formation. The following are some general notes on preferences:

- ***Plaque formation with λgt10:*** Grow *E. coli* strains C600 and BNN102 in NZCYM (please see Chapter 2, Protocol 1) containing 0.2% maltose. (BNN102 grows much more slowly than C600.) Prepare stocks of plating bacteria of both strains as described in Chapter 2, Protocol 1. Note that it may be necessary to suspend the bacteria of strain BNN102 in a smaller volume of 10 mM $MgSO_4$ than usual to attain a density of ~1.5 x 10^9 cells/ml.

  Measure the number of infectious bacteriophage particles produced in the packaging mixtures as described in Chapter 2, Protocol 1, using LB agar plates and LB top agarose. Clear and turbid plaques are easily distinguished when plated at low density on confluent bacterial lawns. Plaques of recombinant λgt10 bacteriophages appear on lawns of C600 cells after 6–7 hours of incubation at 37°C; plaques on BNN102 take 1–2 hours longer to appear.

- ***Plaque formation with λgt11 and λgt18-23:*** Grow *E. coli* strain Y1090*hsdR* in NZCYM medium containing 0.2% maltose. Prepare a stock of plating bacteria in 10 mM $MgSO_4$ as described in Chapter 2.

  Measure the number of infectious bacteriophage particles produced in the packaging mixtures as described in Chapter 2, Protocol 1, using 3 ml of LB top agarose containing 40 µl of a stock solution of X-gal (20 mg/ml in dimethylformamide) and 4 µl of a solution of IPTG (200 mg/ml) for each 90-mm Petri dish. Incubate the plates for 8-10 hours at 37°C.

- ***Plaque formation with λZAP:*** Grow *E. coli* strain BB4 in NZCYM medium containing 0.2% maltose. Prepare a stock of plating bacteria in 10 mM $MgSO_4$ as described in Chapter 2, Protocol 1.

  Measure the number of infectious bacteriophage particles produced in the packaging mixtures as described in Chapter 2, Protocol 1, using 3 ml of LB top agarose containing 40 µl of a stock solution of X-gal (20 mg/ml in dimethylformamide) and 4 µl of a solution of IPTG (200 mg/ml) for each 90-mm Petri dish. Incubate the plates for 8–10 hours at 42°C to prevent the formation of lysogens. Y1090*hsdR* should not be used with the λZAP vectors, since this strain contains a plasmid (pMC9) that is homologous to the phagemid sequences within the λZAP vector. This homology can promote recombination between the bacteriophage λ vector and the plasmid.

- ***Plaque formation with λZAPII:*** Grow *E. coli* strain XL1-Blue in NZCYM medium containing 0.2% maltose. Prepare a stock of plating bacteria in 10 mM $MgSO_4$, as described in Chapter 2, Protocol 1.

  Measure the number of infectious bacteriophage particles produced in the packaging mixtures as described in Chapter 2, Protocol 1, using 3 ml of LB top agarose containing 40 µl of a stock solution of X-gal (20 mg/ml in dimethylformamide) and 4 µl of a solution of IPTG (200 mg/ml) for each 90-mm Petri dish. Incubate the plates for 8–10 hours at 42°C to prevent the formation of lysogens.

- ***Plaque formation with λZipLox:*** Grow *E. coli* strain Y1090(ZL) in NZCYM medium containing 0.2% maltose. Prepare a stock of plating bacteria in 10 mM $MgSO_4$, as described in Chapter 2, Protocol 1.

  Measure the number of infectious bacteriophage particles produced in the packaging mixtures as described in Chapter 2, Protocol 1, using LB agar plates and LB top agarose. Plaques of recombinant λZipLox bacteriophages appear on lawns of Y1090(ZL) cells after incubating for 6–7 hours at 37°C. Strain Y1090(ZL) is a derivative of strain Y1090*hsdR* that has been cured of the resident pMC9 plasmid.

- ***Use of 0.2% maltose:*** Some investigators add maltose to media used to grow and plate bacteriophage λ. The presence of 0.2% maltose leads to a substantial induction of the maltose operon including the *lamB* gene, which encodes the cell surface receptor to which bacteriophage λ binds (Schwartz 1967). This induction should theoretically increase the efficiency of infection and hence the yield of bacteriophage. The use of maltose is a double-edged sword, however, since florid growth of some strains of *E. coli* in such rich medium may lead to cell lysis and the accumulation of cellular debris laden with the LamB protein. Binding of bacteriophage particles to this debris leads to futile release of the viral DNA and an unproductive infection. In our hands, there is little difference in bacteriophage yield from cultures grown in the presence or absence of maltose.

ALTERNATIVE PROTOCOL: LIGATION OF cDNA INTO A PLASMID VECTOR

The decision to use a plasmid vector instead of a bacteriophage λ vector will depend on the method used to screen for the target DNA and on personal preference. A number of highly evolved plasmid vectors are now available, including pCMV-Script (Stratagene), pSPORT (Life Technologies), and pcDNA3.1 (Invitrogen). These versatile molecules are especially useful when preparing cDNA expression libraries.

Additional Materials

Plasmid vector
E. coli *competent for transformation*
Step 2 requires the reagents from one of the transformation protocols in Chapter 1.
Step 5 requires the reagents listed in Chapter 1, Protocol 1.

Method

1. Set up four test ligation/packaging reactions as follows:

Ligation	A	B	C	D
plasmid vector DNA (50 ng/μl)	1.0 μl	1.0 μl	1.0 μl	1.0 μl
10x T4 DNA ligase buffer	1.0 μl	1.0 μl	1.0 μl	1.0 μl
cDNA	0 ng	5 ng	10 ng	50 ng
Bacteriophage T4 DNA ligase (100 Weiss units/μl)	0.1 μl	0.1 μl	0.1 μl	0.1 μl
10 mM ATP	1.0 μl	1.0 μl	1.0 μl	1.0 μl
H_2O to a final volume of	10 μl	10 μl	10 μl	10 μl

   Incubate the ligation mixtures for 4–16 hours at 16°C. Store the unused portion of the cDNA at –20°C.

   Be sure to include a control ligation reaction using a test insert to determine the ligation and transformation efficiencies.

2. Transform an appropriate strain of competent *E. coli* bacteria using one of the transformation methods described in Chapter 1.

3. After an overnight incubation at 37°C, count the number of antibiotic-resistant colonies. Ligation A should yield few if any colonies, whereas ligations B, C, and D should yield increasing numbers of colonies containing recombinant plasmid molecules.

4. From the number of colonies, calculate the efficiency of cloning of cDNA (colony-forming units [cfu]/ng cDNA). If all has gone well, the efficiency should be at least 2×10^4 cfu/ng cDNA. The total yield of recombinants from 5 μg of poly(A)$^+$ RNA should be in excess of 5×10^6.

5. Pick 12 colonies, grow small-scale cultures, and prepare DNA for digestion with the appropriate restriction enzyme as described in Chapter 1, Protocol 1.

6. Analyze the size of the cDNA inserts by electrophoresis through a 1% agarose gel, using as markers fragments of DNA 500 bp to 5 kb in length (whether plasmid or bacteriophage λ).

If the recombinant vector molecules (whether plasmid or bacteriophage λ) contain inserts of different sizes and if the average size of the inserts is ~1 kb or greater, it is worthwhile proceeding to the generation of a complete cDNA library. If the average size of the inserts is significantly less than 1 kb, then the quality of the library is not as high as it could be. Go back and reanalyze the quality of the starting mRNA and the cDNA reactions, paying special attention to the precautions noted in Stage 1, Step 6 and the panel on **OPTIMIZING FIRST-STRAND cDNA SYNTHESIS**; Stage 2, Step 8 and the panel on **OPTIMIZING SECOND-STRAND cDNA SYNTHESIS**; *and the introduction to Stage 5. For additional assistance on improving the quality of the* library, please see the panel on **TROUBLESHOOTING** on the following page.

The trial ligation reactions will often yield sufficient recombinant molecules ($>10^5$ cfu) to begin screening for the cDNA of interest. To generate a complete library from the size-fractionated cDNA, additional ligation reactions should be set up based on the results of the trial ligations and subsequently packaged or used to transform *E. coli*. The amount of cDNA required depends in part on the estimated abundance of the desired cDNA, how the library will be used in the future, and the laboratory budget. A primary library of $>10^6$ clones should yield even rare cDNAs. If the library is to be screened several times, then as many as 10^7 recombinants may be required. However, vectors and packaging reactions are expensive, and it can cost many thousands of dollars to ligate and package every nanogram of cDNA. Such sums are usually out of the reach of all but the richest laboratories.

TROUBLESHOOTING

Several problems related to the addition of linker-adaptors to cDNA ends may become evident following restriction analysis of the recombinant bacteriophage λ or plasmid DNA.

- ***The cDNA inserts contain more sites for* NotI, SalI, *or* EcoRI *than expected.*** In mammalian DNA, *Not*I sites occur, on average, once in 1000 kb; *Sal*I sites are separated by an average of 100 kb, and *Eco*RI sites are separated by an average of 4 kb. If these sites occur more frequently than expected (e.g., if every cDNA carries an internal *Not*I site), it is likely that tandem arrays of cDNA molecules have been cloned into the vector. This problem can be avoided by decreasing the ratio of inserts to vector molecules in the ligation mixtures of Step 1.
- ***The frequency of* EcoRI *sites within the cDNA inserts is <1 site per 4 kb.*** This problem arises when methylation of *Eco*RI sites within the double-stranded cDNA is not complete. In this case, it is usually necessary to check the methylation reaction in a series of pilot reactions and then to repeat the methylation step using a fresh batch of cDNA.
- ***No cDNA inserts can be excised from the vector by digestion with the appropriate restriction enzyme.*** This problem is almost always caused by inefficiency in adding synthetic linkers or adaptors to the ends of the double-stranded cDNA. Re-treat the ends of the double-stranded cDNA with bacteriophage T4 DNA polymerase (Stage 4, Steps 2 and 3), and repeat the large-scale ligation reaction with a mixture of unlabeled, phosphorylated linkers and ^{32}P-labeled linkers. Analyze an aliquot of the reaction by polyacrylamide gel electrophoresis to check that the radiolabeled linkers have formed a series of ligation products that exhibit a ladder-like distribution. Finally, cDNA inserts that cannot be excised by digestion with the appropriate restriction enzyme can often be recovered by digesting the recombinant vector DNA with restriction enzymes that cleave the vector sequences near the site at which the cDNA is inserted. For example, *Hin*dIII and *Bgl*II cleave on either side of the single *Eco*RI site used for cloning in λgt10, generating a DNA fragment ~1 kb in length. The size of cDNA inserts in putative λgt10 recombinants can be estimated from changes in the mobility of this fragment and the appearance of novel DNA fragments. Alternatively, cDNA inserts can be directly amplified via PCR from bacteriophage λ plaques or antibiotic-resistant colonies (please see Chapter 8, Protocol 12).

ADDITIONAL PROTOCOL: AMPLIFICATION OF cDNA LIBRARIES

We strongly recommend that primary libraries be used for most cDNA screening purposes. Although amplification of a primary library can provide a near limitless source of cDNA clones to screen, even a single round of amplification distorts the representation of mRNAs in a cDNA library. However, amplification is certainly the best option when the amount of a given library begins to dwindle.

Amplification involves plating the primary library in its entirety on agar plates and then preparing a lysate from the dishes. The lysate is thereafter used as a source of recombinant bacteriophages for screening with nucleic acids, antibodies, or other ligands. Although amplification is a simple procedure, plating and growth invariably reduce the complexity of the library, i.e., the number of independent cDNA clones in the collection. This loss results from plating inefficiency, poor growth of some recombinants, and faster growth of nonrecombinant virus. A good example of this phenomenon is the relative ability of different investigators to isolate a cDNA for their favorite gene from a commercially available library. Often, one investigator can find many clones for one gene in a given library, whereas a colleague detects no isolates for another equally abundant mRNA on the same filters. Commercial libraries are invariably amplified, unless they have been custom-synthesized, and they therefore have a biased representation of the starting mRNA population.

As noted several times in this protocol, use primary libraries whenever possible. However, if the need arises, one of the two following methods can be used to amplify most bacteriophage-λ-based cDNA libraries.

METHOD 1: Amplification of Libraries Constructed in λgt10

To establish a permanent supply of the library, it should be amplified by growth on *E. coli* strain BNN102 on agar plates. The BNN102 strain contains an *hflA* mutation that selects against nonrecombinant bacteriophages (please see the panel on **PLATING BACTERIOPHAGE λ ON *E. COLI* STRAINS** [in the main protocol of Stage 6] and comments in the protocol introduction).

Additional Materials

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Chloroform **<!>**
Dimethylsulfoxide **<!>**
NZCYM agar plates and top agarose
Sorvall SS-34 rotor or equivalent

Method

1. For amplification, add 10^5 bacteriophages or 200 µl of the packaging mixture (whichever is the smaller volume) to 300 µl of plating bacteria of strain BNN102 (for methods, please see Chapter 2, Protocol 1). Incubate the infected culture for 20 minutes at 37°C. Then plate the entire culture in top agarose on a 150-mm Petri dish containing NZCYM agar, and incubate the plate for 8–10 hours at 37°C.

   In some cases, the use of large volumes of packaging mixture leads to a reduction in plating efficiency. This inhibition can be checked before amplification by a reconstruction experiment in which known numbers of bacteriophage λgt10 (e.g., 1000 pfu) are mixed with increasing amounts of packaging mixture and plated on E. coli strains C600 and BNN102. The cost of such an experiment can quickly become prohibitive if commercial packaging extracts are used.

2. Overlay the plates with 15 ml of SM. Store the plates for 2 hours at room temperature or overnight at 4°C.

3. Harvest the SM carefully, and remove cellular debris by centrifugation at 7000*g* (7700 rpm in a Sorvall SS-34 rotor) for 30 minutes at 4°C. The cDNA library will be stable for several months when stored at 4°C in small (1-ml) aliquots in tightly closed tubes, each of which contains 20–30 µl of chloroform. For longer-term storage, add dimethylsulfoxide to a final concentration of 7% (v/v) and store aliquots at –70°C.

4. Measure the titer of the library on *E. coli* strains C600 and BNN102 (please see Chapter 2, Protocol 1). The titer of clear plaques on strain C600 should be 10^{10} to 10^{11} pfu/ml and the ratio of clear to turbid plaques should be >20:1.

   In any amplification, keep in mind that the size or complexity of the library is determined by the number of independent recombinant plaques that are amplified. For example, if ten plates, each containing 100,000 plaques, are used for amplification, the resulting cDNA library can have no more than 1,000,000 members. The titer of the amplified library has nothing to do with its complexity.

METHOD 2: Amplification of Libraries Constructed in λgt11, λZAP, λZipLox, and Their Derivatives

Table 11-4 lists the strains that should be used to amplify cDNA libraries constructed in various types of bacteriophage λ vectors.

Additional Materials

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Chloroform **<!>**
Dimethylsulfoxide **<!>**
200 mg/ml IPTG (20% w/v)
LB agar plates and top agarose
NZCYM agar plates and top agarose
Sorvall SS-34 rotor or equivalent
20 mg/ml X-gal (2% w/v in dimethylformamide) **<!>**

Method

1. Mix 10^5 bacteriophages with 300 µl of plating bacteria of the appropriate *E. coli* strain. After incubating for 20 minutes at 37°C, plate the infected culture in top agarose on a 150-mm Petri dish containing NZCYM agar. Incubate for 12 hours at 37–42°C (The latter temperature is used with λgt11 libraries and libraries prepared in derivatives of λgt11 to prevent the formation of lysogens. All other viral vectors are grown at 37°C.)

2. Prepare and store the library as described above in Steps 2 and 3 of Method 1.

3. Titer the amplified library on the appropriate *E. coli* strain using LB agar plates and 3 ml of top agarose containing 40 µl of a stock solution of X-gal and 4 µl of a solution of IPTG (200 mg/ml). The ratio of blue to colorless plaques is a measure of the proportion of the library that consists of nonrecombinant bacteriophages.

TABLE 11-4 *E. coli* Strains for the Amplification of cDNA Libraries in Bacteriophage λ Vectors

Strain of Bacteriophage λ Used for Construction of cDNA Library	Strain of *E. coli* Recommended for Amplification (Genotype)	Comments
λgt11 λgt18 λgt20 λgt22	Y1090*hsdR* (*supF hsdR araD139* *Δlon ΔlacU169* *rpsL* *trpC22*::Tn*10*(*tet*^{r})pMC9)	Strain Y1090*hsdR*: • Carries a plasmid (pMC9: pBR322 *lacI*^{q}) that expresses the *lac* repressor and prevents synthesis of fusion proteins controlled by the *lacZ* promoter. • Is deficient in the *lon* protease; in *lon*$^-$ cells, β-galactosidase fusion proteins often accumulate to much higher levels than in wild-type cells. • Is *supF*, suppressing the normally defective lysis of λgt11 and leading to a high frequency of lytic plaque. • Is defective for host-controlled restriction (*hsdR*$^-$) but carries an active methylation system (*hsdM*$^+$). Potential sites for restriction by the *Eco*K system become methylated during amplification so that, if necessary, the recombinants can be used to infect a restriction-competent strain of *E. coli*.
λZAP	BB4 (*supF58 supE44 hsdR514* *galK2 galT22 trpR55* *metB1 tonA ΔlacU169* F′[*proAB*$^+$ *lacI*^{q} *lacZ*ΔM15Tn*10*(*tet*^{r})])	λZAP cannot be grown on strain Y1090*hsdR* due to the homology between the plasmid pMC9 and phagemid sequences within the λZAP vector; this homology interferes with excision of cDNA-containing plasmids from the vector; expression of toxic fusion proteins in strain BB4 strain is prevented by a *lacI*^{q} gene on an F episome. Strain BB4 is defective for host-controlled restriction (*hsdR*$^-$) but carries an active methylation system (*hsdM*$^+$); potential sites for restriction by the *Eco*K system become methylated during amplification so that, if necessary, the recombinants can be used to infect a restriction-competent strain of *E. coli*.
λZAPII λZAP Express	XL1-Blue (*supE44 hsdR17 recA1* *endA1 gyrA96 thi-1 relA1* *lac* F′[*proAB*$^+$ *lacI*^{q} *lacZ*ΔM15Tn*10*(*tet*^{r})])	XL1-Blue is defective for host-controlled restriction (*hsdR*$^-$) but carries an active methylation system (*hsdM*$^+$). Potential sites for restriction by the *Eco*K system become methylated during amplification so that, if necessary, the recombinants can be used to infect a restriction-competent strain of *E. coli*.
λZipLox	Y1090(ZL) (*ΔlacU169 proA*$^+$ *hsdR hsdM*$^+$ *Δlon araD139 strA supF* (*trpC22*::Tn*10*))	Strain Y1090(ZL): • Is deficient in the *lon* protease; in *lon*$^-$ cells, β-galactosidase fusion proteins often accumulate to much higher levels than in *lon*$^+$ cells. • Is *supF*, suppressing the normally defective lysis of λZipLox and leading to a high frequency of lytic plaques. • Is defective for host-controlled restriction (*hsdR*$^-$) but carries an active methylation system (*hsdM*$^+$); potential sites for restriction by the *Eco*K system become methylated during amplification so that, if necessary, the recombinants can be used to infect a restriction-competent strain of *E. coli*. • Is a derivative of Y1090*hsdR* that has been cured of the resident plasmid pMC9; removal of pMC9 allows the use of ampicillin selection when cDNA-containing pSPORT1 plasmids are excised from λZipLox.

Protocol 2

Construction and Screening of Eukaryotic Expression Libraries

Protocol 2, like Protocol 1, is a method for the construction and screening of a cDNA library in eukaryotic expression vectors and is divided into two stages as listed below.

- Stage 1: Construction of cDNA Libraries in Eukaryotic Expression Vectors
- Stage 2: Screening cDNA Libraries Constructed in Eukaryotic Expression Vectors

STAGE 1: Construction of cDNA Libraries in Eukaryotic Expression Vectors

Expression cloning in eukaryotic cells is a brute-force method to isolate cDNA clones that encode functional proteins for which no amino acid sequences exist. Three broad options are available, depending on the general characteristics of the target protein (for reviews, please see Aruffo 1991; Frech and Joho 1992; Simonsen and Lodish 1994; Seed 1995).

- ***For proteins such as mammalian receptors and channel and transporter proteins, whose expression on the plasma membrane can be detected by electrophysiological methods:*** A cDNA library is prepared in a plasmid or bacteriophage λ vector equipped with promoters for bacteriophage-encoded DNA-dependent RNA polymerases. Pools of cDNA clones, chosen at random from the library, are transcribed in vitro, and the resulting mRNA is injected into *Xenopus* oocytes. The individual oocytes are then scored for expression of the functional protein. Pools of cDNAs that generate a positive signal are divided into subpools and retested until a single clone encoding the target protein is identified and isolated. This type of sib-selection has been used to isolate cDNAs encoding voltage-gated and ion-gated channels for sodium, potassium, calcium, and chloride ions; G-coupled receptors for peptide hormones; and transporters for urea, peptides, and antibiotics.
- ***For cell-surface and secreted proteins:*** A cDNA library is prepared in a bacteriophage λ or plasmid vector equipped with signals for expression in mammalian cells. These signals include a promoter/enhancer, splice donor and acceptor, and addition of poly(A). Pools of cDNA clones are then transfected into a line of cultured mammalian cells. In the case of secreted proteins, the supernatant medium from the cells is assayed for the appropriate biological activity. Transfected cells expressing a target surface protein are identified by binding of a specific ligand or antibody. Individual cDNAs encoding the target proteins may be identified by sib-selection, as described above. Alternatively, cells expressing the target protein at the cell surface may be isolated by panning, the use of radiolabeled ligands, or fluorescence-activated cell sorting. The plasmid DNA is then recovered from the selected population of transfected cells and amplified in *E. coli*, yielding a population of cDNA clones that is enriched for the target gene (Aruffo and Seed 1987; Seed and Aruffo 1987; Horst et al. 1991; please see below). This method has been used to identify cDNAs encoding a variety of glycotransferases (for review, please see Fukuda et al. 1996), as well as a large number of cytokines and their receptors (for review, please see Nakayama et al. 1992).
- ***For intracellular proteins:*** Pools of cDNA clones are transfected into cultured mammalian cells. Extracts of the transiently transfected cells are then screened for an activity characteristic of the target protein. For example, Tsai et al. (1989) used a gel-retardation assay to isolate a cDNA encoding a DNA-binding protein highly expressed in the erythroid lineage, and Andersson et al. (1989), screening intact transfected cells for steroid 5α-reductase activity, were able to isolate a cDNA encoding the enzyme.

Because successful expression screening requires production of biological activity, the probability of isolating full-length cDNAs by expression screening is increased, whereas the risk of isolating truncated clones or related cDNAs is decreased.

MAMMALIAN HOST/VECTOR SYSTEMS THAT AMPLIFY TRANSFECTED cDNA CLONES

To eliminate some of the considerable labor involved in traditional sib-selection schemes, many investigators in recent years have used host/vector systems in which transfected cDNA clones replicate as episomes in mammalian cells. cDNA libraries are constructed in plasmids that carry a wild-type origin of DNA replication derived from SV40, polyomavirus. or, more rarely, Epstein-Barr virus or bovine papillomavirus (Kern and Basilico 1986; Muller et al. 1994; Shen et al. 1995). Pools of cDNA clones are then transfected into lines of mammalian cells that express all of the *trans*-acting factors required to drive replication of the transfected cDNA clones. Cells that express the target protein may be identified, for example, by immunological staining (e.g., please see Horst et al. 1991) and, in some cases, isolated by "panning" on a Petri dish coated with an appropriate ligand or antibody (for reviews, please see Aruffo 1991; Nakayama et al. 1992; Seed 1995). The cells expressing the target protein are lysed, and the episomal DNAs are isolated (Hirt 1967) and reestablished in *E. coli*. Depending on (1) the efficiency of panning, (2) the amount of amplification of the transfected cDNA clones in the mammalian host, and (3) the frequency with which the target clone is represented in the cDNA library, the gene of interest may be isolated after three to four rounds of transient expression and selection.

By far the most popular host cells for this type of cloning are permanent lines of African green monkey kidney cells that express SV40 T antigen from chromosomally integrated copies of an origin-minus mutant of SV40 (Gluzman 1981). These lines are known as COS cells (*C*V-1, *o*rigin-minus, *S*V40). Because the integrated copies of the viral DNA lack viable origins of replication, they are unable to be activated by the endogenously expressed T antigen (please see the information panel on **COS CELLS**). The yield of episomal DNA therefore consists predominantly of amplified transfected plasmids. Expression of the cloned cDNA is generally driven by a strong promoter such as an immediate early cytomegalovirus (CMV) promoter (Aruffo and Seed 1987).

The SV40 origin of replication is maximally active only in cells of simian origin and is completely inactive in murine cells, even in the presence of T antigen. A number of other mammalian host-vector systems have been constructed in an effort to extend the host range of cells that can be used for expression cloning (please see Table 11-5). For example, cDNA libraries constructed in plasmid shuttle vectors carrying the origin of replication from polyomavirus can be screened by expression in murine cell lines that express polyomavirus T antigen. However, few of these systems match the efficiency of replication routinely achieved in COS cells using shuttle vectors carrying an SV40 origin of replication.

VARIABLES THAT DETERMINE SUCCESS OR FAILURE OF EXPRESSION CLONING

Prominent among the many factors that determine the success or failure of expression cloning are the following:

- ***The assay used to detect the target protein,*** which must be robust, sensitive, and specific.
- ***The abundance and length of the target mRNA.*** The longer the mRNA and the lower its abundance, the smaller the chances of isolating clones capable of expressing an active protein.
- ***The depth of the library.*** Because most cDNAs isolated by expression cloning encode relatively rare proteins, it is usually necessary to generate a library consisting of 10^6 or more independent cDNA clones.

- ***The efficiency with which the cloned cDNAs (or mRNAs transcribed from them) can be introduced into eukaryotic cells.*** It is essential to optimize the efficiency of transfection of the host cells, using plasmids carrying reporter genes (e.g., β-galactosidase or green fluorescent protein) before embarking on expression cloning.

There is little hope of success with expression cloning if the cDNA library is not of the highest quality. The starting mRNA must be intact, the populations of first-strand cDNAs and mRNAs should match each other for size, the yields of the first- and second-strand cDNAs must be acceptable, cDNA of the required size should be recovered in sufficient quantity, and all steps in the ligation and transformation/packaging reactions must be accomplished with high efficiency. Unless success at each phase of library construction can be documented, it is best to abandon the preparation and start over again with fresh mRNA. Less work is involved in repeating the synthesis and cloning of cDNA than in screening inadequate expression libraries with a wish and a prayer.

CONTROLS

When constructing an expression cDNA library, it is essential to have internal controls that can provide evidence that the overall process — from synthesis of first-strand cDNA to the final step of identifying individual cDNA clones of interest — has worked with acceptable efficiency. The best internal control is a synthetic, polyadenylated mRNA encoding a protein with a biological activity that can be readily assayed. If possible, the control mRNA and the target mRNA should be similar in size and should encode proteins with similar but distinct characteristics. An mRNA encoding a cytoplasmic protein, for example, is not an appropriate control for an experiment whose aim is to isolate a cDNA encoding a cell surface protein. The control mRNA is seeded at an appropriate density into the mRNA preparation used to construct the cDNA expression library. The library may then be screened for the ability to express two biological activities: one encoded by the control mRNA and the other encoded by the desired target mRNA. Success in recovering appropriate numbers of cDNA clones expressing the control protein provides comforting reassurance that all has gone well in every phase of the experiment.

A less than perfect but adequate internal control is an already-cloned cDNA encoding a distinctive, biologically active protein. The cDNA can then be excised from its vector and seeded into the preparation of second-strand cDNA used to construct the library. A control of this type provides assurance that construction and screening of the expression library have gone according to plan.

Some investigators prefer to use as an internal control a cDNA that has already been cloned into an expression vector. This vector should have the same features as the expression vector used to construct the cDNA library, but it need not be identical in all respects. For example, the cDNA used as a positive control may be cloned into an expression plasmid that carries a kanamycin resistance gene, rather than an ampicillin resistance gene. Using a different antibiotic resistance gene provides an unambiguous method to distinguish between cDNA clones derived from the library and the cDNA used as a control.

In the screening phase of the experiment, it is essential to include a negative control, for example, an empty copy of the expression vector, which should be included in all experiments involving transfection of cultured mammalian cells. When using *Xenopus* oocytes as a vehicle to screen the expression library, the best negative controls are (1) an aliquot of the in vitro transcription reaction from which template DNA has been omitted and (2) an aliquot of an in vitro transcription reaction that contains empty plasmid DNA as template.

MATERIALS

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

10x Restriction endonuclease buffer(s)

Enzymes and Buffers

Restriction enzymes

Please see Step 3.

Nucleic Acids and Oligonucleotides

Poly(A)$^+$-enriched mRNA

This mRNA should be isolated from a cell line or tissue that expresses the activity of interest and purified by two-pass chromatography on oligo(dT) cellulose (please see Chapter 7, Protocol 3). Identification of the highest expressing tissue or cell line must be accomplished empirically using the biological assay that will be employed in the expression cloning screen.

Knowledge of the size of the target mRNA is very useful in expression cloning. This variable can sometimes be determined by translation of size-fractionated mRNA followed by biological assay of the translation products, by injecting size-fractionated mRNAs into oocytes and then assaying the eggs for the target protein, or possibly by transfecting size-fractionated mRNAs into cultured mammalian cells (please see Chapter 16).

Special Equipment

cDNA synthesis kit

These kits are available from several manufacturers and generally include all of the reagents required to synthesize a population of cDNAs ready for ligation into a bacteriophage or plasmid expression vector (please see the information panel on **COMMERCIAL KITS FOR cDNA SYNTHESIS AND LIBRARY CONSTRUCTION**).

Choose a kit that allows the construction of an oriented cDNA library, i.e., one in which the synthesized cDNAs have different restriction enzyme sites at their 5′ and 3′ ends. For example, by using the appropriate adaptor-linker combination, cDNAs can be synthesized with a *Sal*I site at the 5′ end and a *Not*I site at the 3′ end. Ligation of the cDNAs into a *Sal*I/*Not*I-cleaved vector in which the *Sal*I site is located closest to the promoter and the *Not*I site is located closest to the transcriptional terminator sequence of the vector will produce an oriented cDNA library. By constructing and screening an oriented cDNA library, the absolute number of clones that must be screened is reduced by a factor of 2, and problems with antisense inhibition of expression of the target protein activity are eliminated.

A possible disadvantage of this type of kit is that the positioning of a *Not*I site at the 3′ end of the cDNA is usually accomplished by use of an oligo(dT) primer to which a *Not*I sequence has been attached (e.g., 5′-pCCGCGGCCGCT$_{15}$-3′). Synthesis of cDNA by reverse transcriptase with this type of primer begins at the poly(A) tail of most mRNAs and proceeds toward the 5′ end of the mRNA template. If the target mRNA is long, the chance of obtaining a full-length cDNA and hence a positive signal in the injected or transfected cells is reduced. Options to overcoming this potential problem include (1) the use of random hexanucleotide-*Not*I primers in the reverse transcriptase reaction (e.g., 5′-pCCGCGGCCGCNNNNNN-3′), which can lead to biased priming due to the GC-rich nature of the primer or (2) the construction of size-fractionated libraries containing a preponderance of long cDNAs.

In some instances, an antisense approach to screening is taken by design (e.g., please see Lübbert et al. 1987). In this situation, orient the 3′ end of the cDNA next to the promoter and the 5′ end of the cDNA next to the transcription terminator.

TABLE 11-5 Vector Systems for Expression Cloning

Vector	Source	Promoter(s)	Expression in *Xenopus* Oocytes	Expression in Cultured Mammalian Cells
pcDNA 3.1	Invitrogen	CMV, T7		√
pcDNA 4	Invitrogen	CMV with enhancer QBI SP163		√

Additional Reagents

Step 1 of this protocol requires the reagents listed in Protocol 1, Stages 1–4.
Step 2 of this protocol requires the reagents listed in Protocol 1, Stage 5.
Steps 4 and 5 of this protocol require the reagents listed in Protocol 1, Stage 6.
Step 8 of this protocol may require the reagents listed in Chapter 1, Protocol 26.

Vectors and Bacterial Strains

Electrocompetent E. coli *cells*

If a plasmid expression vector is chosen, prepare (please see Chapter 1, Protocol 26) or purchase electrocompetent *E. coli* as hosts for the cDNA library. The titer of the electrocompetent cells should be at least 5×10^8 colonies/μg plasmid DNA. Ideally, use a single lot or preparation of cells throughout the expression cloning and screening procedure.

Packaging extracts

If a bacteriophage λ vector is chosen, then purchase (or prepare) a very high titer packaging extract with which to insert the recombinant cDNAs into the virus (please see the information panel on **IN VITRO PACKAGING**). The titer of the extract should be at least 10^9 pfu/μg viral DNA.

Plasmid or bacteriophage λ expression vector

The choice of vector is dictated by the host system used for expression. If *Xenopus* oocytes are used, the expression vector should be a bacteriophage λ DNA or a plasmid vector DNA carrying promoters for the bacteriophage SP6, T3, or T7 DNA-dependent RNA polymerases flanking the polylinker (e.g., λZAP Express, λExCell, and pSPORT). If cultured mammalian cells are used, then choose a plasmid-based expression vector that contains a powerful promoter (e.g., the immediate early region promoter of human cytomegalovirus) and a strong transcription terminator sequence (e.g., the 3′ sequences of the human growth hormone gene or the SV40 late terminator region). Examples include the pCMV series of plasmids and pcDNA 4 (please see Table 11-5 and Appendix 3).

METHOD

1. Use a commercial kit or follow the instructions in Protocol 1 (Stages 1–4) to synthesize blunt-ended, double-stranded cDNA and equip the termini with the appropriate linkers or adaptors.

2. Fractionate the double-stranded cDNA according to size, using gel-filtration chromatography. For details, please see Protocol 1, Stage 5.

   If the size of the target mRNA is known, pool the column fractions that contain double-stranded cDNAs ranging in size from 1 kb smaller than the target mRNA to 1 kb larger than the target mRNA. If the size of the target mRNA is unknown, fractionate the preparation of double-stranded cDNA into three pools containing molecules of different sizes: 500–1500 bp, 1500–3000 bp, and >3000 bp.

3. Digest 10–25 μg of the plasmid or bacteriophage λ expression vector with two restriction enzymes whose recognition sequences occur in the linker-adaptors placed at the 5′ and 3′ ends of the cDNA.

   ▲ **IMPORTANT** Take care to ensure that both restriction enzymes digest the vector DNA to completion. Carry out the digestions in sequence rather than simultaneously; purify the DNA by extraction with phenol:chloroform and precipitation with ethanol between digests, and where possible, use gel electrophoresis to check that both of the digests have gone to completion.

   To ensure complete cleavage of the expression vector before the cloning of cDNA, some investigators insert a short "stuffer" fragment of 200–300 bp between the *Sal*I and *Not*I (or other enzyme combination) sites of the polylinker. The presence of a stuffer fragment allows the efficiency of digestion to be monitored more readily and, in some cases, enhances double digestion of the vector since the two restriction sites are usually located close to each other in the polylinker sequence, and separating them by 200–300 bp removes end inhibition.

4. Set up trial ligations using different ratios of cDNA to bacteriophage λ arms or plasmid DNA. For details on optimizing ligations, please see the introduction to Stage 6 (as well as Step 1 of Stage 6) of Protocol 1 of this chapter.

   If the cDNA has been separated into fractions of different sizes (please see the note to Step 2), aliquots of each fraction must be assayed separately.

5. Package an aliquot of the products of each of the ligation reactions into bacteriophage λ particles. Determine the titer of infectious particles generated in each packaging reaction. For details, please see both the panel on **PLATING BACTERIOPHAGE λ ON *E. COLI* STRAINS** and Steps 2–6 in Protocol 1, Stage 6.

   or

   Use electroporation to transform *E. coli* with aliquots of each ligation reaction (please see Chapter 1, Protocol 26).

6. Test six bacteriophage λ or plasmid recombinants for the presence of cDNA inserts of the appropriate size and determine the ratio of cDNA to vector DNA that generates the largest number of recombinant clones. Calculate the size of the library that can be generated from the ligation reactions containing the optimum ratio of cDNA to vector.

7. Using the optimum ratio of cDNA insert to vector, ligate as much of the cDNA as possible to the bacteriophage λ or plasmid DNA.

   It is usually better to set up many small ligation reactions, rather than one large reaction.

8. Prepare and analyze the recombinants using one of the methods below:

   If a bacteriophage λ vector is used: Package the ligated cDNA into bacteriophage λ particles following the directions provided by the manufacturer of the packaging extract, measure the titer of the virus stock, and store the stock at 4°C.

   If a plasmid vector is used: Measure the number of potential recombinants in the ligation reaction by electroporating small aliquots of the ligation mixture into *E. coli* cells (please see Chapter 1, Protocol 26).

9. Proceed as soon as is feasible to the screening of the eukaryotic expression library.

STAGE 2: Screening cDNA Libraries Constructed in Eukaryotic Expression Vectors

To minimize the amount of work involved in screening expression libraries, the cDNA library is divided into a series of screening pools that contain the maximum number of cDNA clones compatible with efficient detection of the target biological activity. The complexity of the pools therefore depends almost exclusively on the sensitivity of the screening assay used to detect the target activity. For ion channel and other proteins whose activity can be detected by sensitive patch-clamping or electrophysiological assays, complex pools containing up to 300,000 cDNA clones have been used (e.g., please see Masu et al. 1987). For a steroid-metabolizing enzyme in which the assay involved adding [^{14}C]testosterone to the medium of cultured cells, followed by a thin-layer chromatography separation of substrate and product, pools of 10,000 clones were successfully screened (Andersson et al. 1989, 1991). A protein that transports mevalonate was isolated after screening pools of 1000 cDNAs (Kim et al. 1992), whereas the isolation of one of the endothelin receptors was accomplished by screening pools of 500 cDNAs (Sakurai et al. 1990). Clearly, the larger the pool size, the greater the capacity to screen large numbers of clones from the library.

In general, the sensitivity required to detect a single target cDNA in a screening increases as a linear function of the size of the pool. If there is reason to believe that the biological assay is insensitive, a large number of screening pools should be constructed, each containing no more than 1000 or 2000 clones. Whatever the number of clones in the screening pool, the aim should be to screen at least three times more recombinants than the number of individual cDNA clones in the expression library. For example, an expression library of 10^6 individual clones can be divided into ~30 screening pools, each containing 100,000 clones, or into 1000 screening pools each containing 3000 clones, or into any intermediate number of pools of proportional size. Always include a positive and negative control in each screening experiment.

MATERIALS

Buffers and Solutions

SM

Enzymes and Buffers

Restriction endonucleases

Restriction endonucleases will be required for certain procedures. Please see Steps 1 and 3.

Nucleic Acids and Oligonucleotides

cDNA library, prepared as described in Stage 1 of this protocol

Transfection/Injection controls

A cDNA that can be used as a positive control is a priceless commodity when setting up expression cloning. Whenever possible, choose a cDNA that encodes a biological activity similar to that of the

desired target cDNA. For example, if a novel potassium channel is the target cDNA, use a cDNA encoding a previously isolated K^+ channel as a positive control. The control cDNA is used to establish the optimum pool size and to check that a given transfection/injection experiment worked. The positive control cDNA should be transferred into the appropriate strain of *E. coli* (if using a plasmid expression vector) or packaged into bacteriophage λ before carrying out Step 1.

Two types of negative controls should be included in screening experiments using *Xenopus* oocytes: The plasmid vector alone and the transcription reaction without added template DNA.

In addition, Step 1 requires either an empty bacteriophage λ expression vector packaged into bacteriophage λ particles or *E. coli* transformed with the empty plasmid expression vector.

Media

Terrific agar plates containing the appropriate antibiotic
Terrific broth (or other rich medium) containing the appropriate antibiotic

Additional Reagents

Steps 1 and 2 of this protocol may require a commercial plasmid purification kit (see Chapter 1, Protocol 9).

Steps 1 and 3 of this protocol may require the reagents from one of the transfection protocols in Chapter 16.

Steps 1 and 3 of this protocol may require the reagents listed in Chapter 9, Protocol 6.

Steps 1 and 3 of this protocol may require the reagents necessary to inject mRNA molecules into Xenopus *oocytes, as described by Spector et al. (1998a).*

Step 1 of this protocol may require the reagents listed in Chapter 2, Protocol 1 or 5 and Protocol 23 or 24.

Step 1 of this protocol requires the reagents necessary to assay for the biological activity encoded by the positive control cDNA.

Step 2 of this protocol may require the reagents listed in Chapter 1, Protocol 26, and Chapter 2, Protocol 1 and Protocol 23 or 24.

Step 4 of this protocol requires the reagents necessary to assay for the biological activity encoded by the target cDNA.

Step 6 of this protocol requires the reagents listed in Chapters 7, 12, 15, and 16.

Cells and Tissues

Host cells

Xenopus oocytes are taken from female South African clawed frogs, which are available from several biological supply houses (such as Carolina Biological Supply or Kons Scientific). The ability of oocyte clutches to express injected mRNAs varies seasonally and is affected by the age and physiological state of the donor animals. Difficulties in expressing mRNAs can sometimes be overcome by switching suppliers. For methods to isolate oocytes, please see Colman (1984), Spector et al. (1998a), and Julius et al. (1988).

Simian COS cells or derivatives of the 293 line of human embryonic kidney cells are the mammalian hosts of choice for transient expression of cloned cDNAs because of their superior efficiencies of transfection (Gluzman 1981; Gorman 1990). However, many other cell lines have been used successfully (e.g., Chinese hamster ovary and NIH-3T3) (Naglich et al. 1992; Bates et al. 1993; Young et al. 1993).

Before embarking on expression cloning, test lysates of mock-injected oocytes or lysates of mock-transfected cells for the activity of target protein. It is essential to start with an expression host that has low to undetectable levels of the activity to be cloned.

METHOD

1. Set up a series of trial experiments to optimize the transfection and expression systems used to screen the library for cDNA clones of interest. This is best done by using a previously cloned cDNA encoding a biological activity for which reliable assays are available.

IF A EUKARYOTIC PLASMID EXPRESSION VECTOR AND CULTURED CELL HOST ARE USED

a. Inoculate a single colony of *E. coli* harboring a plasmid carrying the cDNA used as a positive control into 10 ml of rich medium (e.g., Terrific Broth containing a selective antibiotic) together with 10, 100, 1000, 10,000, or 100,000 colonies derived from electroporation of *E. coli* with an empty vector. Grow the cells to saturation in an overnight culture incubated with agitation at 37°C.

b. Use a commercial kit to prepare plasmid DNA of a purity sufficient for efficient transfection of cultured mammalian cells (please see Table 1-6 in Chapter 1, Protocol 9).

c. Use one or more of the methods described in Chapter 16 to transfect the various plasmid preparations into cultures of eukaryotic cells and assay for the biological activity encoded by the positive control cDNA.

When screening the cDNA library, use the transfection method that generates the maximum signal and an acceptably low level of background.

IF A BACTERIOPHAGE RNA POLYMERASE (E.G., T3, T7, OR SP6) IS USED TO TRANSCRIBE CDNAS FROM A PLASMID EXPRESSION VECTOR FOLLOWED BY *XENOPUS* OOCYTE INJECTION

a. Follow Steps a and b above.

b. Linearize the pooled, purified plasmid DNAs at the rare restriction site placed at the 3′ end of the cDNAs during library construction, and transcribe the templates in vitro into mRNA (please see Chapter 9, Protocol 6).

c. Inject the mRNA prepared from the pooled cDNAs into *Xenopus* oocytes and assay the appropriate biological activity or transfect the mRNA into the appropriate cell line.

IF A BACTERIOPHAGE λ VECTOR CONTAINING BACTERIOPHAGE-ENCODED RNA POLYMERASE PROMOTERS WAS CHOSEN AS AN EXPRESSION VECTOR

a. Generate a set of bacteriophage suspensions containing different ratios (10:1, 100:1, 1000:1, etc.) of an empty bacteriophage λ vector to a recombinant bacteriophage λ harboring the control cDNA. Infect an appropriate strain of *E. coli* with a multiplicity of bacteriophage particles that yields near-confluent lysis of bacterial lawns or complete lysis of infected cells grown in liquid culture (please see Chapter 2, Protocol 1 or 5).

b. Prepare bacteriophage λ DNA from the plates (please see Chapter 2, Protocol 23) or from the liquid cultures (please see Chapter 2, Protocol 24).

c. Linearize the bacteriophage λ DNA at the rare restriction site placed at the 3′ end of the cDNAs during library construction, and transcribe the cDNAs into mRNA as described in Chapter 9, Protocol 6.

d. Inject the prepared mRNA into *Xenopus* oocytes, and assay the mRNAs for their ability to encode the biological activity of the cDNA used as a positive control.

2. Using the results obtained in Step 1 as a rough guide, divide the cDNA library into pools of a suitable size for screening, and transform or transfect *E. coli* with the expression library pools. Prepare plasmid or bacteriophage λ DNA that will be used to screen the pools for the presence of the target cDNA.

IF THE EXPRESSION LIBRARY IS CONSTRUCTED IN A PLASMID VECTOR AND POOLS ARE GROWN ON SOLID MEDIUM

a. Withdraw a sufficient number of aliquots (e.g., 50–100 aliquots, each capable of generating ~1000 recombinants) from the ligation mixture (Stage 1, Step 8), and introduce each aliquot individually into *E. coli* by electroporation. Plate the entire contents of each electroporation cuvette onto a single dish of Terrific agar medium containing the appropriate antibiotic. Incubate the plates overnight at 37°C.

The goal is for the number of colonies on each plate to equal the desired pool size. For example, if the pool size to be screened is 50,000 colonies, then enough ligation mix should be electroporated to produce 1000 colonies on each of the 50 plates. Culture may be grown before plating as described in Step b for growth in liquid medium.

b. Estimate the number of colonies on each plate. Scrape the colonies from each plate into 5 ml of rich medium (e.g., Terrific broth containing a selectable antibiotic). Grow the bacterial suspensions to saturation, and then prepare purified plasmid DNA for screening.

IF THE EXPRESSION LIBRARY IS CONSTRUCTED IN A PLASMID VECTOR AND POOLS ARE GROWN IN LIQUID MEDIUM

The advantages of this procedure are that the plating step is omitted, thus saving time and effort, and there is less chance that any individual cDNA will be lost because of poor growth on agar, or because of mechanical damage.

a. Withdraw a sufficient number of aliquots (e.g., 50–100 aliquots, each capable of generating ~1000 recombinants) from the ligation mixture (Stage 1, Step 8), and introduce them individually into separate cultures of *E. coli* by electroporation. The number of transformants should equal the desired pool size in each culture.

b. Add 1 ml of rich medium (e.g., SOC or Terrific broth) without antibiotics to each bacterial culture immediately after electroporation. Incubate the culture for 1 hour at 37°C with very gentle agitation.

The short period of incubation allows the plasmid-encoded antibiotic resistance gene to be expressed to a level that will protect the transformed bacteria.

c. Use an aliquot of each bacterial culture to inoculate separate 5-ml cultures. After growing the bacterial cultures to saturation, prepare purified plasmid DNA for screening.

IF THE EXPRESSION LIBRARY IS CONSTRUCTED IN A BACTERIOPHAGE λ VECTOR AND POOLS ARE TO CONTAIN 10,000 TO 100,000 CDNAS

a. Plate an appropriate volume of packaging mixture to produce a semiconfluent lawn of recombinant bacteriophage plaques. Alternatively, use a sufficient amount of packaging mixture to obtain complete lysis of *E. coli* cells grown in liquid culture.

b. Isolate bacteriophage λ DNA by a plate lysis procedure or a liquid culture procedure (please see Chapter 2, Protocol 23 or 24).

IF THE EXPRESSION LIBRARY IS CONSTRUCTED IN A BACTERIOPHAGE λ VECTOR AND POOLS ARE TO CONTAIN 10,000 OR FEWER CDNAS

a. Plate recombinant bacteriophages, equal in number to the pool size, at a density of 1000 pfu per 100-mm dish.

b. When plaque formation is complete, overlay each dish with 2–3 ml of SM to produce a low-titer plate lysate. Calculate the titer of the lysate.

c. From the low-titer plate lysate, produce a high-titer stock in liquid culture.

d. Purify bacteriophage λ DNA by a liquid culture procedure (please see Chapter 2, Protocol 24).

3. Transfer the purified clone into the appropriate background to analyze for expression:

If the clone is purified plasmid DNA: Either transfect into cultured mammalian cells or use as a template for in vitro synthesis of RNA by a bacteriophage-encoded RNA polymerase, followed by injection into *Xenopus* oocytes.

If the clone is purified bacteriophage λ DNA: Linearize the DNA and use as a template for in vitro synthesis of RNA, followed by injection into *Xenopus* oocytes.

A typical transfection experiment using 50–100 dishes of cultured mammalian cells permits 50,000–100,000 cDNA clones (from pools containing 1000 clones each) to be screened for their ability to express the desired biological activity. A typical *Xenopus* experiment involves injection of mRNAs transcribed from each pool of plasmid DNA into five *Xenopus* oocytes. For pools containing 1000 clones each, 250–500 oocytes are therefore required to screen 50,000–100,000 cDNAs for biological activity.

4. Assay for the biological activity encoded by the target cDNA.

5. After a positive pool(s) of cDNAs has been identified, subdivide and rescreen it in an iterative fashion until a single cDNA encoding the target activity has been identified. Carry out this goal, which is most easily accomplished using the preparation of purified plasmid or bacteriophage λ DNA corresponding to the positive pool(s) of recombinants, as follows:

a. Divide the positive (primary) pool of plasmid or bacteriophage λ DNA into aliquots that generate approximately one tenth of the original number of transformed colonies or plaques.

A primary pool containing a total of 10,000 individual recombinant DNAs should be divided into ~30 aliquots, each of which generates ~1000 colonies or plaques.

b. Repeat Steps 3 and 4 above. Include the original positive pool as a positive control in the rescreening assay.

c. Repeat the process of subdivision until a single recombinant is obtained that encodes the desired activity. Make sure that only single well-isolated plaques or bacterial colonies are used to prepare bacteriophage or plasmid DNA for the ultimate screen.

6. Characterize the single isolate that encodes the target activity by DNA sequencing (Chapter 12), expression (Chapter 15 or Chapter 16), and RNA blotting (Chapter 7).

If the recombinant does not encompass the entire coding region of the cDNA, additional recombinants should be isolated by screening the cDNA library by hybridization at high stringency, using cDNA isolated from the first isolate as a probe.

Protocol 3

Exon Trapping and Amplification

Deanna M. Church
National Institutes of Health, Bethesda, Maryland

EXON AMPLIFICATION SELECTS FOR THE PRESENCE OF FUNCTIONAL splice donor and acceptor sites within a fragment of genomic DNA. This process has been used successfully with genomic DNA from a variety of sources, including cosmids, bacterial artificial chromosomes, yeast artificial chromosomes, and total genomic DNA (North et al. 1993; Church et al. 1994). An unforeseen difficulty with the original vector (pSPL1) used for exon amplification is the production of an unacceptable level of a particular mRNA artifact that occurs due to the presence of a cryptic splice site within the intron of the vector. Three additional problems arise as a result of the use of pSPL1 and the current experimental design. First, the majority of genomic fragments cloned into the vector do not contain an exon; thus, the major splice product will be an empty vector. Second, restriction enzymes used for library production can interrupt the sequence of an exon, thus preventing or interfering with splicing. Third, transcription units consisting of less than three exons will not be identified in this scheme. The use of an improved vector, pSPL3, ameliorates or eliminates the first three of these problems. However, transcription units consisting of less than three exons must still be identified using alternative methods (Church et al. 1993; Church and Buckler 1999). The inclusion of *Bst*XI sites within the multiple cloning site of the vector (Figure 11-16) allows for the elimination of most of the cryptic splice products. The presence of a multiple cloning site expands the choices of different enzymes that may be used for library design, thus reducing the likelihood of cutting within an exon. Finally, to eliminate the vector-only splice product, *Bst*XI half-sites now flank the vector splice sites. Vector-only splicing will reconstitute this restriction site, and subsequent digestion with *Bst*XI will virtually eliminate this product (Figure 11-16). However, because the protocol involves PCR amplification of spliced gene products, any molecules that result from aberrant splicing will be amplified and contribute to the background.

This protocol presents a method to amplify exons, using the mammalian shuttle vector pSPL3, and is divided into five stages as listed below (please see Figure 11-15).

- Stage 1: Construction of the Library
- Stage 2: Electroporation of the Library into COS-7 Cells
- Stage 3: Harvesting the mRNA
- Stage 4: Reverse Transcriptase–PCR
- Stage 5: Analysis of Clones

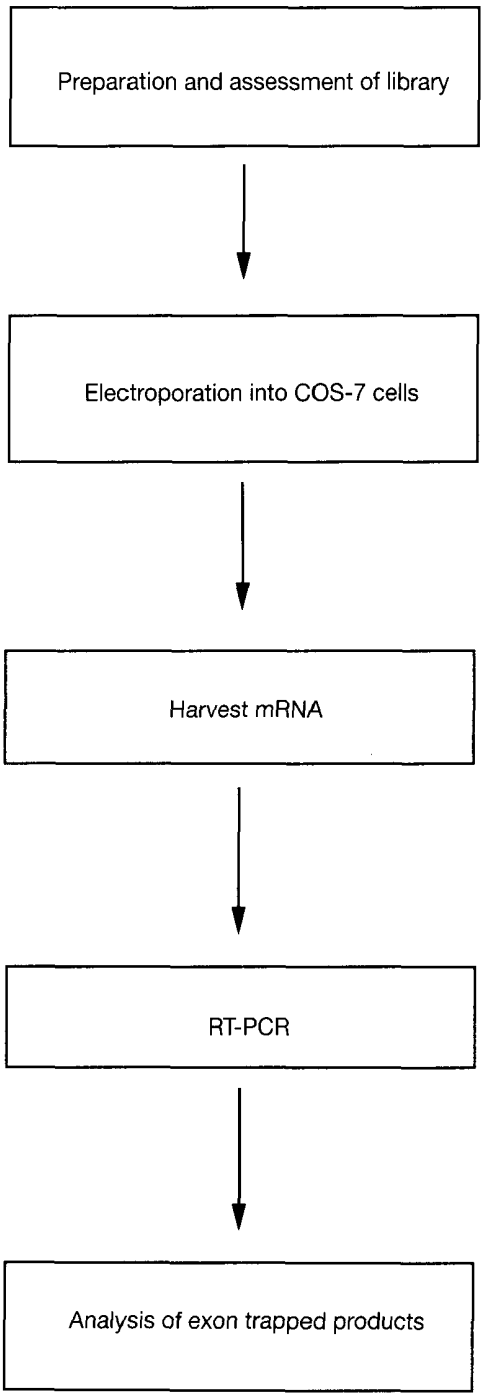

FIGURE 11-15 Flowchart of the Experimental Steps in Exon Amplification

(Adapted, with permission, from D.M. Church.)

STAGE 1: Construction of the Library

An important aspect of exon amplification is the construction of a highly representative library of genomic DNA. In this protocol, the library is constructed in the vector pSPL3 (Figure 11-16), which contains features that improve the efficiency of library construction and exon trapping. For additional details on these features, please see the discussion on Amplification and Trapping of Exons in the introduction to this chapter. Great care should be taken in preparing the DNA, because any contaminating material from the host used to propagate recombinants can contribute to the background. Although splicing is unknown in bacteria, and is a rare event in yeast, both types of genomes contain sequences capable of undergoing splicing in this heterologous system (D.M. Church and A. Buckler, unpubl.).

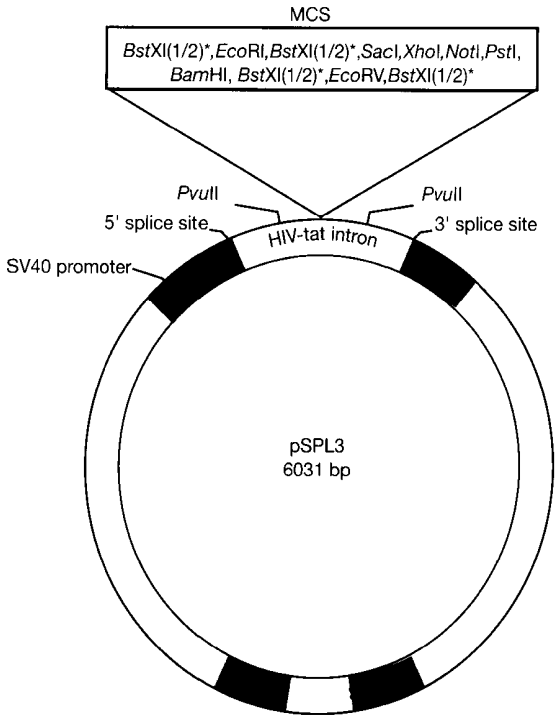

FIGURE 11-16 pSPL3

The SV40 promoter drives the transcription of a heterologous minigene. Two exons are interrupted by an intron derived from the HIV *tat* gene. A multiple cloning site (MCS) has been inserted into the intron. The vector carries the SV40 promoter and the origins of replication from pUC (pUC ori) and from SV40 (SV40 ori). An enlarged view of the MCS reveals possible cloning sites for library construction. The presence of half sites of *Bst*XI (*Bst*XI [1/2]) decreases the background from cloned sequences that do not contain exons. An expanded view of the minigene within pSPL3 is shown in Figure 11-18. (Adapted, with permission, from D.M. Church.)

Media

LB agar plates containing 50 μg/ml ampicillin
Please see Step 8 to determine the appropriate size plates to use.
LB broth containing 50 μg/ml ampicillin
SOC medium

Special Equipment

Water baths preset to 15°C and 65°C

Additional Reagents

Step 1 of this protocol requires the reagents listed in Chapter 1, Protocol 20.
Step 6 of this protocol requires the reagents required for transformation listed in Chapter 1, Protocol 23, 24, or 25.
Steps 10 and 12 of this protocol require the reagents listed in Chapter 1, Protocol 1 or 9.

Vectors and Bacterial Strains

E. coli *strain HB101, competent for transformation*
Prepare as described in Chapter 1, Protocols 23, 24, or 25.
pSPL3
The vector pSPL3 is available separately or as part of a kit from Life Technologies.

METHOD

1. Digest pSPL3 with a restriction enzyme(s) that will permit insertion of the genomic DNA (for the map of the pSPL3 multiple cloning site, please see Figure 11-16). Dephosphorylate the ends of the linearized vector, and purify the vector by gel electrophoresis.

   It is important that the vector DNA be completely digested into a single fragment of ~6 kb.

2. Digest 1–2 µg of genomic DNA or recombinant vector carrying genomic target DNA with a restriction enzyme(s) that is compatible with the enzyme used to prepare pSPL3 in Step 1.

3. Analyze 10% of the digested genomic DNA on a 0.9% agarose gel cast and run in TAE.

   The genomic DNA should be completely digested and undegraded. When examining the genomic DNA in the agarose gel, also look for the presence of contaminating bacterial (or yeast) DNA, which will appear as a generalized haze in the background.

4. Inactivate the restriction enzyme from the digested genomic DNA by heating the reaction mixture to 65°C for 15 minutes. Extract the reaction mixture with phenol:chloroform and recover the DNA by standard ethanol precipitation. Resuspend the DNA at a concentration of 100 µg/ml in TE (pH 8.0).

5. Ligate the genomic DNA to the vector by combining the following:

digested genomic DNA	150 ng
digested, dephosphorylated pSPL3 vector	50 ng
10x ligation buffer	1 µl
bacteriophage T4 DNA ligase	10 Weiss units
H_2O	to 10 µl

   Incubate the reaction mixture for 2–3 hours at room temperature or overnight at 15°C.

   Adding ATP as a component of the 10x ligation buffer leaves more volume for vector or foreign DNA in the reaction mixture. If using a commercial ligase buffer that contains ATP, the addition of ATP is no longer required.

   Be sure to include a control containing only the vector DNA. This control is important for assessing the quality of the library.

6. Transform 40 µl of competent HB101 cells with the ligation reaction.

   Be sure to include positive (vector alone DNA) and negative (no DNA) transformation controls to assess efficiency.

   ▲ **IMPORTANT** It is imperative that HB101 be used to propagate the library and the vector, because pSPL3 is unstable in other bacterial strains (Church and Buckler 1999).

7. After transformation, add 800 µl of SOC medium to the cells and incubate the culture for 30–45 minutes at 37°C to allow expression of the antibiotic resistance marker encoded on the plasmid.

8. Amplify the library by growing the bacteria overnight at 37°C in the presence of ampicillin.

   If using a single cosmid: Plate 100 µl of the transformation mixture onto an LB agar plate containing 50 µg/ml ampicillin. Grow the remainder of the transformation in a 2-ml liquid culture of LB broth containing 50 µg/ml ampicillin.

   Growth on the small LB plate allows the transformation efficiency to be assessed.

   If using a BAC, PAC, or pools of cosmids: Plate the entire contents of the transformation onto separate 150-mm LB agar plates containing 50 µg/ml ampicillin.

   Plating these complex libraries on 150-mm plates helps eliminate the preferential growth of certain clones by reducing competition for nutrients, thus allowing for the construction of a more representative library.

9. Estimate the efficiency of ligation by comparing the number of recombinant and nonrecombinant clones (i.e., colonies arising from the transformation of HB101 with the ligation mixture containing only pSPL3).

   The recombinant clones should be anywhere from 500-fold to 1000-fold in excess of the nonrecombinant clones.

10. If the library was amplified on a 150-mm LB agar plate, proceed to Step 11. If the genomic library was amplified in liquid culture, purify plasmid DNA from the bacteria using a standard alkaline lysis procedure (please see Chapter 1, Protocol 1) or use a commercial plasmid purification kit. Proceed to Step 13.

11. If the entire library was plated onto a large LB agar plate, flood the plate with 10 ml of LB broth, and gently scrape the colonies from the surface of the agar. Minimize the amount of agar that is scraped into the LB broth.

12. Purify the plasmid DNA using a modification of the standard alkaline lysis minipreparation: triple the amounts of Alkaline lysis solutions I (300 µl), II (600 µl), and III (450 µl) added to the bacterial pellet. To simplify the procedure, after addition of Alkaline lysis solution I, transfer the bacterial slush to a 2-ml microfuge tube. The rest of the procedure can be carried out in 2-ml tubes. After adding Alkaline lysis solution III and centrifuging, divide the recovered, crude nucleic acid supernatant into two 1.5-ml tubes. Extract the resulting supernatant with phenol:chloroform and with chloroform. Precipitate the supernatant with isopropanol and combine the two dissolved DNA pellets. Alternatively, use a commercial plasmid purification kit (Chapter 1, Protocol 9).

13. Digest an aliquot of the purified DNA with *Pvu*II to determine the quality of the library.

    *Pvu*II sites flank the multiple cloning site in the vector. The digestion of empty vector with *Pvu*II produces 4-kb and 2-kb bands. Recombinant clones should still produce a prominent 4-kb band, but little or no 2-kb band. A clearly visible 2-kb band suggests that the library is of poor quality or, less probably, that a 2-kb *Pvu*II fragment is highly represented in the genomic DNA (Figure 11-17). If the library is of acceptable quality, it can be used for the next stage.

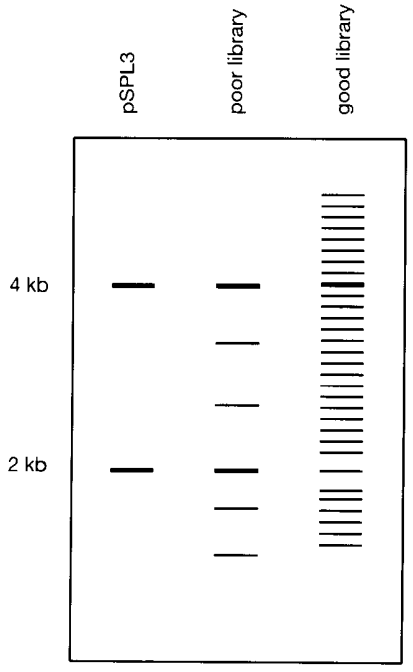

FIGURE 11-17 Representation of a Gel Demonstrating Good Library Construction

*Pvu*II digestion of the library constructed in pSPL3 is a good indicator of the quality of the library. (Lane *1*) *Pvu*II digest of pSPL3; note the 2-kb and 4-kb bands. (Lane *2*) Example of a poor library; note the strong 2-kb band, indicating a substantial vector religation. (Lane *3*) Example of a good library; note the reduction in the amount of the 2-kb band, and the large number of fragments released by the *Pvu*II digestion. (Adapted, with permission, from D.M. Church.)

STAGE 2: Electroporation of the Library into COS-7 Cells

In this stage of the exon amplification protocol, COS-7 cells are transfected with recombinant pSPL3 plasmids containing the genomic DNA of interest. COS-7 cells were originally derived from the African green monkey kidney cell line CV-1 by transformation with a replication-deficient SV40 that encodes wild-type large T antigen (Gluzman 1981; please see the information panel on **COS CELLS**). The large T antigen drives replication of the transfected plasmid by activating the SV40 origin of replication. The resulting high-copy number of the transfected plasmid allows for vigorous transcription, initiating at the SV40 promoter of pSPL3, of the heterologous minigene (please see Figure 11-16).

Other transfection techniques, such as lipofection, have been used with success in exon amplification (e.g., please see Nisson et al. 1994).

MATERIALS

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Phosphate-buffered saline (PBS) without divalent cations

Enzymes and Buffers

Trypsin-EDTA solution

Nucleic Acids and Oligonucleotides

DNA

The plasmid DNA to be transfected was prepared in Stage 1 of this protocol, Steps 10–12.

Plasmid vector for use as control (Step 3)

Media

Dulbecco's modified Eagle's medium (DMEM) containing 10% heat-inactivated fetal calf serum

Centrifuges and Rotors

Sorvall H1000B rotor or equivalent

Special Equipment

Electroporation device and cuvettes fitted with electrodes spaced 0.4-cm apart
Tissue culture dishes (100 mm)
Wide-bore pipettes

Cells and Tissues

COS-7 cells

COS-7 cells are grown to a confluency of 75–85% in DMEM containing 10% heat-inactivated fetal calf serum. For details of dealing with cells in culture, including trypsinizing, please see Spector et al. (1998b).

METHOD

1. Wash the monolayer of COS-7 cells with phosphate-buffered saline lacking divalent cations. Remove the cells from the surface of the dishes by treatment with trypsin-EDTA. Collect the cells by centrifugation at 250*g* (1100 rpm in a Sorvall H1000B rotor) for 10 minutes at 4°C.

   ▲ **IMPORTANT** Keep the COS-7 cells cold throughout the procedure.

   For details on trypsinizing cells, please see Spector et al. (1998b).

2. Adjust the volume of the DNA sample to be used for transfection to a total volume of 100 µl in PBS without divalent cations.

   The amount of DNA required for transfection must be optimized as described in Chapter 16, Protocol 5.

3. Resuspend 4×10^6 COS-7 cells in a volume of 700 µl of PBS without divalent cations. Mix the cells with the DNA in a cooled electroporation cuvette (0.4-cm chamber). Incubate the mixture for 10 minutes on ice.

   Use of PBS with divalent cations can lead to arcing during electroporation, which can ruin the electroporator.

   Be sure to perform a transfection with vector-only DNA as a control.

4. Gently resuspend the cells and introduce the DNA into the cells by electroporation at 1.2 kV (3 kV/cm) and 25 µF. Immediately return the cuvettes to ice, and store them for 10 minutes.

   The conditions for electroporation may need to be optimized as described in Chapter 16, Protocol 5.

5. Use a wide-bore pipette to transfer 1×10^6 of the electroporated cells into a series of 100-mm tissue culture dishes that contain 10 ml of DMEM containing 10% heat-inactivated fetal calf serum that has been warmed to 37°C. Incubate the cultures for 48–72 hours at 37°C in a humidified incubator with an atmosphere of 5–7% CO_2.

STAGE 3: Harvesting the mRNA

RNA is isolated from the transfected COS-7 cells by differential centrifugation, followed by precipitation of nucleic acids from the cytoplasmic component. A 100-mm tissue culture dish, nearly confluent with transfected COS-7 cells, will provide RNA for several experiments.

MATERIALS

▲ **IMPORTANT** Prepare all reagents used in this protocol with DEPC-treated H_2O (please see the information panel on **HOW TO WIN THE BATTLE WITH RNASES** in Chapter 7).

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

DEPC-treated H_2O **<!>**
Ethanol
NaCl (5 M)
Phenol **<!>**
Phenol:chloroform **<!>**
Phosphate-buffered saline (PBS) without divalent cations
SDS (5% w/v)
TKM buffer
- 10 mM Tris-Cl (pH 7.5)
- 10 mM KCl
- 1 mM $MgCl_2$

Triton X-100 (10% v/v) or Nonidet P-40 (4% v/v)

Centrifuges and Rotors

Sorvall H1000B rotor or equivalent

Special Equipment

Cell scrapers or Rubber policemen
Polystyrene tubes (15 ml), chilled to 0°C in ice

Cells and Tissues

COS-7 cells transfected with the recombinant and nonrecombinant forms of pSPL3

METHOD

1. Rinse the tissue culture plates of transfected COS-7 cells three times with ice-cold PBS lacking calcium and magnesium ions. Keep plates on a bed of ice between rinses.
2. Add 10 ml of ice-cold PBS to each plate. Place the plate on the bed of ice, and gently scrape the cells off the plate.
3. Transfer the cell suspensions to chilled 15-ml polystyrene tubes.

   The use of polystyrene tubes, which are transparent, will facilitate recovery of cytoplasm free of nuclei in Steps 8 and 9.
4. Recover the cells by centrifugation at 300*g* (1200 rpm in a Sorvall H1000B rotor) for 8 minutes at 4°C.
5. Decant as much of the supernatant as possible. Remove the residual supernatant with a pipette.
6. Resuspend the cell pellet from 1×10^6 to 2×10^6 COS cells in 300 µl of TKM buffer and store the suspension on ice for 5 minutes.
7. Add 15 µl of 10% Triton X-100 or 4% Nonidet P-40 and store the cell suspension on ice for a further 5 minutes.

   Addition of nonionic detergent gently lyses the plasma membrane while leaving the nuclear membrane intact.
8. Recover the nuclei by centrifugation at 500*g* (1500 rpm in a Sorvall H1000B rotor) for 5 minutes at 4°C.
9. Transfer the supernatant to a chilled 1.5-ml microfuge tube.

   ▲ **IMPORTANT** Use extreme care when removing the supernatant. Do not touch the nuclear pellet. If the nuclear membranes burst, the sample will become too viscous to pipette due to the contamination with genomic DNA.
10. Add 20 µl of 5% SDS and 300 µl of phenol. Vortex the mixture vigorously and separate the organic and aqueous phases by centrifugation at maximum speed for 5 minutes at 4°C in a microfuge.
11. Transfer the aqueous layer to a 1.5-ml microfuge tube containing 300 µl of phenol:chloroform. Vortex the suspension vigorously and then separate the organic and aqueous phases by centrifugation at maximum speed for 3 minutes at room temperature in a microfuge.
12. Transfer the aqueous (upper) layer to a chilled 1.5-ml microfuge tube containing 12 µl of 5 M NaCl and 750 µl of ethanol. Allow the RNA to precipitate for 2–3 hours at –20°C or for 30 minutes at –80°C.

    Nucleic acids are more stable in ethanol than in H_2O. For long-term storage, store the RNA in ethanol at –80°C (please see the panel on **STORAGE OF RNA** at the end of Protocol 1 in Chapter 7).
13. Recover the RNA by centrifugation at maximum speed for 10 minutes at 4°C in a microfuge.
14. Discard the supernatant and wash the pellet with 70% ethanol. Dry the pellet in air and redissolve it in 20 µl of DEPC-treated H_2O.

Stage 4: Reverse Transcriptase–PCR

In this stage of the protocol, cDNA molecules are generated from the RNA isolated in Stage 3. Molecules of pSPL3-derived cDNA lacking genomic DNA sequences and those containing genomic DNA sequences harboring cryptic splice sites are eliminated by digestion with *Bst*XI (please see Figure 11-18). The digestion products are cloned into a Bluescript vector (Stratagene) to facilitate identification of the exon-trapped products.

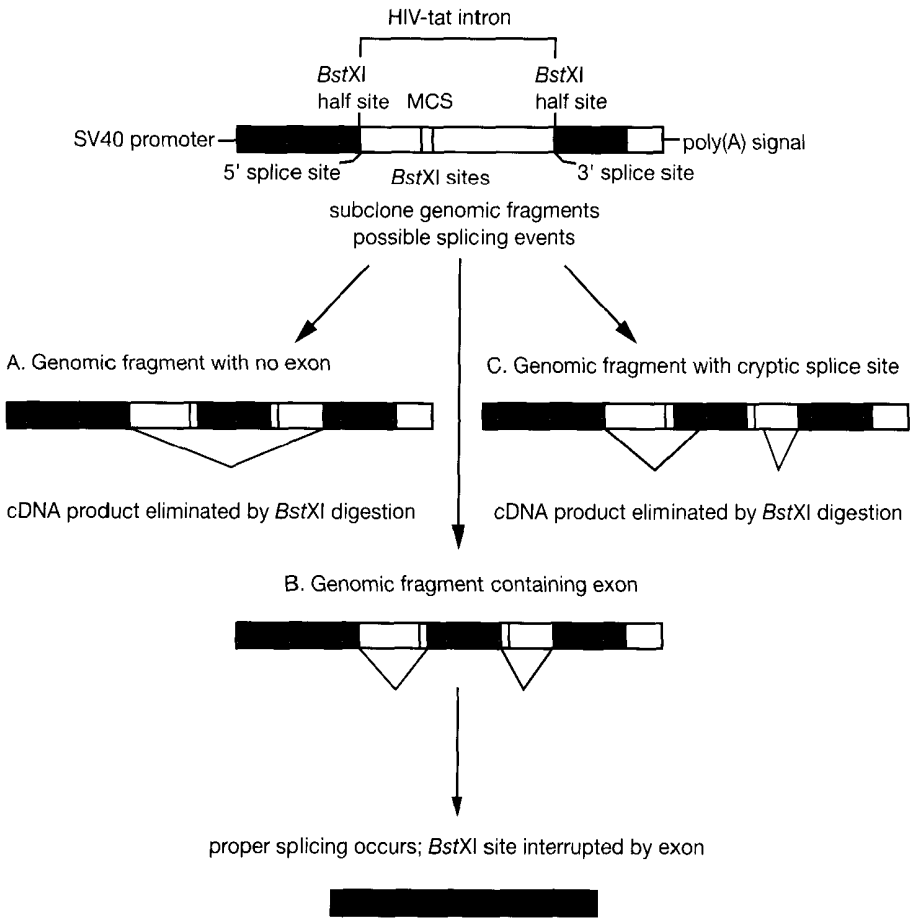

FIGURE 11-18 Linear View of the Minigene of pSPL3

The SV40 promoter sequence (*shaded box*) and poly(A) addition signal (*open box*) are shown at either ends of the linear scheme. (*Shaded pattern*) Vector-derived exons; (*open box*) intronic sequences; (*narrow open box*) multiple cloning site (MCS). Note the inclusion of *Bst*XI half-sites at the vector splice donor and splice acceptor sites. Three possible splicing classes can be derived from this experiment: (*A*) The genomic fragment does not contain an intact exon or the fragment is cloned in the wrong orientation; vector-only splicing occurs. This product is virtually eliminated by *Bst*XI digestion prior to cloning of the products. (*B*) The genomic fragment contains an intact exon, cloned in the proper orientation; proper splicing occurs between the vector sequences and the exon sequences found in the genomic DNA. The *Bst*XI half-sites are not reconstituted. (*C*) The genomic sequence contains a cryptic splice site that activates a cryptic splice site found in the intron of pSPL3. In this case, improper splicing occurs between the vector sequences and the genomic fragment. However, this product will retain a portion of the MCS. The MCS is flanked by *Bst*XI sites, allowing this product to be eliminated by *Bst*XI digestion before cloning. (Adapted, with permission, from D.M. Church.)

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

10x Amplification buffer
Chloroform <!>
DEPC-treated H_2O <!>
Dithiothreitol (1 M)
dNTP solution containing all four dNTPs, each at a concentration of 1.25 mM
Phenol <!>
RNase inhibitor

Enzymes and Buffers

Bst*XI*
Eco*RV*
Mo-MLV reverse transcriptase
Taq *DNA polymerase*
Uracil DNA glycosylase (1 unit/μl)

Gels

Agarose gel (1.5% w/v) in TBE buffer

Nucleic Acids and Oligonucleotides

Oligonucleotides primers (20 mM in TE [pH 8.0]):

SA2	5′ ATC TCA GTG GTA TTT GTG AGC 3′
SD6	5′ TCT GAG TCA CCT GGA CCA CC 3′
SDDU	5′ AUA AGC UUG AUC UCA CAA GCT GCA CGC TCT AG 3′
SADU	5′ UUC GAG UAG UAC UTT CTA TTC CTT CGG GCC TGT 3′
BSD-U	5′ GAU CAA GCU UAU CGA TAC CGT CGA CCT 3′
BSA-U	5′ AGU ACU ACU CGA AUT CCT GCA GCC 3′

Please note that the 5′ ends of oligonucleotides SDDU, SADU, BSD-U, and BSA-U contain uracil residues to facilitate ligation-independent cloning (please see the information panel on **LIGATION-INDEPENDENT CLONING**; Rashtchian 1995). SADU and SDDU are nested primers.

RNA isolated from COS-7 cells transfected with control and recombinant vectors (Stage 3)

Media

LB agar plates containing 50 μg/ml ampicillin

Special Equipment

Barrier tips for automatic micropipettes
Microfuge tubes (0.5-ml thin-walled for amplification reactions, RNase-free)
Positive-displacement pipette
Thermal cycler programmed with desired amplification protocol

If the thermal cycler is not equipped with a heated lid, use either mineral oil or paraffin wax to prevent evaporation of liquid from the reaction mixture during PCR. Paraffin wax may be used not only to prevent evaporation, but also to maintain separation between components (e.g., primer and template) until the reaction mixture is heated. This prevents nonspecific binding of primers during the initial phase of the reaction (please see the information panel on **HOT START PCR** in Chapter 8).

Water baths preset to 42°C, 55°C, and 65°C

Additional Reagents

Step 14 of this protocol requires the reagents listed in Chapter 1, Protocol 25.

Vectors and Bacterial Strains

E. coli *strain DH5α (or another strain that permits α-complementation)*
pBluescript II (KS or SK) (Stratagene)

METHOD

Synthesis of the cDNA

1. Generate the first-strand cDNA from the cytoplasmic RNAs isolated in the previous stage (Stage 3), using the SA2 oligonucleotide as a primer. In an RNase-free 0.5-ml tube combine:

RNA	3 µl
10x amplification buffer	2.5 µl
dNTP solution at 1.25 mM	4 µl
0.1 M dithiothreitol	1 µl
3′ oligo (SA2, 20 µM)	1.25 µl
DEPC-treated H_2O	11.25 µl

Heat the reaction mixture to 65°C for 5 minutes.

▲ **IMPORTANT** To reduce formation of secondary structures in the RNAs, do not place the reaction mixture on ice!

Then add:

RNase inhibitor	1 µl
Mo-MLV reverse transcriptase (200 units)	1 µl

Incubate the reactions for 90 minutes at 42°C.

2. Use both the SA2 oligonucleotide primer and the SD6 oligonucleotide primer to carry out a limited second-strand synthesis. Combine the following in a sterile thin-walled amplification tube:

reverse transcriptase reaction (Step 1)	12.5 µl
10x amplification buffer	4 µl
dNTP solution at 1.25 mM	6 µl
SA2 oligonucleotide primer (20 µM)	2 µl
SD6 oligonucleotide primer (20 µM)	2.5 µl
Taq DNA polymerase	1–2 units
DEPC-treated H_2O	to 40 µl

Process the vector-only control in the same way. This will serve as an important control during the PCR analysis.

3. If the thermal cycler is not fitted with a heated lid, overlay the reaction mixtures with 1 drop (~50 µl) of light mineral oil. Alternatively, place a bead of paraffin wax into the tube if using a hot start PCR. Place the tubes in the thermal cycler.

4. Amplify the nucleic acids using the denaturation, annealing, and polymerization times and temperatures listed in the table.

Cycle Number	Denaturation	Annealing	Polymerization
1	5 min at 94°C		
5–6	30 sec at 94°C	30 sec at 62°C	3 min at 72°C
Last cycle			5 min at 72°C

These times are suitable for 40-µl reactions assembled in thin-walled 0.5-ml tubes and incubated in thermal cyclers such as the Perkin-Elmer 9600 or 9700, Master Cycler (Eppendorf), and PTC 100 (MJ Research). Times and temperatures may need to be adapted to suit other types of equipment and reaction volumes.

The purpose of this PCR is to generate double-stranded material for *Bst*XI digestion.

Three-minute extensions are used in this initial PCR to increase the efficiency of capture of longer cDNA products. Limited cycling time is used to minimize the possibility of generating PCR artifacts.

Continue to process the material amplified from COS cells transfected with vector DNA alone (Stage 2).

Preparation of the cDNA and Vector for Cloning

5. Add 30 units of *Bst*XI to the PCRs. Overlay the reaction mixtures with light mineral oil (if not already on the reaction) and incubate the mixtures overnight at 55°C.

   *Bst*XI digestion greatly reduces vector-only splice products and false positives generated by a cryptic splice site within the vector intron.

   The vector pSPL3 contains several cryptic splice sites. The molecules generated by aberrant splicing at these sites are generally a minor component of the amplified products, and generally appear only (i) in the reaction tube containing empty vector, (ii) in a reaction in which the pSPL3 library is of poor quality, or (iii) when the genomic DNA contains no transcripts that can be identified with this method.

6. Add an additional 20 units of *Bst*XI to the PCR and incubate the reaction for an additional 2–3 hours at 55°C.

7. Meanwhile, digest 1 µg of pBSII(KS or SK) to completion with *Eco*RV. Purify the DNA by extraction with phenol and precipitation with ethanol. Dissolve the digested DNA in H_2O at a concentration of 2 ng/µl.

8. In a 0.5-ml amplification tube, mix the following:

*Bst*XI-digested RT-PCR (Step 6)	5–10 µl
10x amplification buffer	4.5 µl
dNTP solution at 1.25 mM	7.5 µl
SADU oligonucleotide primer (20 µM)	2.5 µl
SDDU oligonucleotide primer (20 µM)	2.5 µl
Taq DNA polymerase	10–20 units
H_2O	to 45 µl

9. In another 0.5-ml amplification tube, mix the following:

pBSII(KS or SK) digested with *Eco*RV (2 ng/µl)	10 µl
10x amplification buffer	10 µl
dNTP solution at 1.25 mM	16 µl
BSD-U oligonucleotide primer (20 µM)	5 µl
BSA-U oligonucleotide primer (20 µM)	5 µl
Taq DNA polymerase	2–4 units
H_2O	to 100 µl

10. If the thermal cycler is not fitted with a heated lid, overlay the reaction mixtures (Steps 8 and 9) with 1 drop (~50 µl) of light mineral oil. Alternatively, place a bead of paraffin wax into the tubes if using a hot start PCR. Place the tubes in the thermal cycler.

11. Amplify the nucleic acids using the denaturation, annealing, and polymerization times and temperatures listed in the table.

Cycle Number	Denaturation	Annealing	Polymerization
1	5 min at 94°C		
25–30	30 sec at 94°C	30 sec at 62°C	3 min at 72°C
Last cycle			5 min at 72°C

These times are suitable for reactions assembled in thin-walled 0.5-ml tubes and incubated in thermal cyclers such as the Perkin-Elmer 9600 or 9700, Master Cycler (Eppendorf), and PTC 100 (MJ Research). Times and temperatures may need to be adapted to suit other types of equipment.

The 5′ ends of the primers used in the second round of PCR amplification contain dUTP rather than dTTP. This facilitates ligation-independent cloning (Rashtchian 1995). The 5′ ends of BSD-U and BSA-U are complementary to the 5′ ends of SADU and SDDU.

It is best to perform the uracil DNA glycosylase reaction (Step 13) the same day as the amplification. If this is not possible, purify the amplification reactions by extraction with phenol:chloroform, followed by ethanol precipitation, and store them at –20°C until ready for use. The dU-amplified vector (Step 9) can be stored for several weeks at –20°C.

12. Run an aliquot of the PCR on a 1.5% agarose gel in TBE to assess the quality of the reaction. There should be a smear representing several amplification products (Figure 11-19).

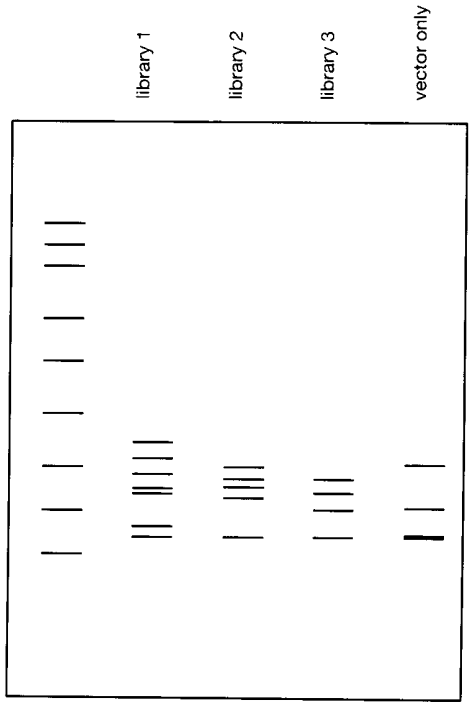

FIGURE 11-19 Representation of a Gel Demonstrating Possible Products Seen after Amplification of the Exon-trapped Products with SADU and SDDU, before Cloning

Amplification of nonrecombinant pSPL3 is shown in the right-hand lane (vector only). The lowest band represents the vector-only splice product, whereas the other two bands are derived from additional cryptic splice sites in the vector. The other three lanes (library 1, 2, 3) show representations of three typical amplification reactions. The vector-only band is present in all other lanes, but it is reduced in intensity. (Adapted, with permission, from D.M. Church.)

Cloning the Exon-trapped Products

13. In a 0.5-ml microfuge tube, mix the following:

*Bst*XI-digested cDNA (Step 8) amplified in Step 11	3 µl
*Eco*RV-digested pBSII DNA (Step 9) amplified in Step 11	1 µl
10x amplification buffer	1 µl
uracil DNA glycosylase (UDG; 1 unit/µl)	1 µl
H_2O	to 10 µl

Incubate the reaction mixture for at least 30 minutes at 37°C.

▲ **IMPORTANT** During this reaction, DNA containing dU residues is digested by uracil DNA glycosylase. In addition, the complementary termini of the plasmid and the amplifed cDNA anneal to form recombinant molecules. To prevent nonspecific annealing of the vector and PCR product, do not place the reaction on ice after the 37°C incubation. If Steps 14 and 15 cannot be carried out immediately, leave the reaction at 37°C or store it at –20°C.

14. Use the entire UDG reaction mixture to transform 30–50 µl of DH5α *E. coli* cells using a $CaCl_2$ transformation procedure (please see Chapter 1, Protocol 25).

15. Plate 100–500 µl of the transformation reaction onto LB agar plates containing 50 µg/ml ampicillin, and incubate them overnight at 37°C.

STAGE 5: Analysis of Clones

The final stage of this protocol outlines a strategy for the initial analysis of amplified and exon-trapped products (ETPs). By amplifying the ETPs with the –20 and REV primers of pBSII, promoters for bacteriophages T3 and T7 remain intact. The amplicons can therefore be sequenced using oligonucleotide primers complementary to the promoter sequences. Direct sequencing of the amplicons using these internal primers can then be easily performed.

Sequence analysis and comparison to public databases will allow quick elimination of clones derived from splicing artifacts that escaped *Bst*XI digestion. Sequences other than authentic exons that can be captured in this system, such as the *Alu*, *Line*, and *HERV* repetitive elements, can be identified by comparing the ETP sequences with those in public databases. In addition, contamination of the genomic DNA with DNA from *E. coli* or yeast can be readily identified by sequence analysis, as the genomes of both organisms have been sequenced completely.

Once false positives have been eliminated, further analysis is required of the reduced ETP set. A critical goal is to determine the map locations of the ETPs. If an ETP fails to map to a region of interest, it may be because the original DNA was chimeric or because chimeras formed during amplification.

After the initial analysis has been performed and a minimal set of ETPs has been validated, these reagents become ideal starting materials for other analyses, including northern hybridization, RNase protection, and in situ hybridization (Church et al. 1993; D.M. Church et al., unpubl.). ETPs are also the starting point for the identification of full-length RNAs. They can be used to probe cDNA libraries (Church et al. 1993), or oligonucleotide primers can be synthesized from their sequences and used in other protocols, such as rapid amplification of cDNA ends (RACE; please see Chapter 8, Protocols 9 and 10), or PCR-based cDNA screening (Frohman 1993; Munroe et al. 1995).

MATERIALS

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

10x Amplification buffer

Enzymes and Buffers

Taq *DNA polymerase*

Gels

Agarose gel (1.5%) cast in TAE buffer
Please see Step 7.

Nucleic Acids and Oligonucleotides

dNTP solution containing all four dNTPs, each at 1.25 mM
Exon-trapped products cloned into a pBSII vector
Clones are in the form of recombinant DH5α colonies prepared in Stage 4.

T3	5′ AAT TAA CCC TCA CTA AAG GG 3′
T7	5′ GTA ATA CGA CTC ACT ATA GGG C 3′
–20	5′ GTA AAA CGA CGG CCA GT 3′
REV	5′ AGC GGA TAA CAA TTT CAC ACA GG 3′

Media

LB broth containing 50 µg/ml ampicillin
LB broth containing 30% (v/v) glycerol

Special Equipment

Microtiter plates (96 well) for PCR
Multichannel pipettor or insulating manifold/frogger (e.g., Dank or Scientific)
Thermal cycler capable of accepting 96-well microtiter dishes

Additional Reagents

Step 8 of this protocol requires the reagents listed in Chapter 12, Protocol 3, 4 or 5.

METHOD

1. Dispense 100 µl of LB broth containing 50 µg/ml ampicillin into each well of a 96-well microtiter plate. Transfer one transformed bacterial colony (from Step 15 of Stage 4) at a time into individual wells. Cover the plate with Parafilm, and grow the colonies for 3–4 hours at 37°C. It is not necessary to agitate the plate.

2. Prepare a master mix (sufficient for 100 wells) of PCRs by combining the following components together:

10x amplification buffer	250 µl
dNTP solution at 1.25 mM	400 µl
–20 oligonucleotide primer (20 µM)	125 µl
REV oligonucleotide primer(20 µM)	125 µl
H_2O	1475 µl
Taq DNA polymerase	75 units

   Aliquot 24 µl of the master mix into each well of fresh 96-well PCR plates.

3. Use a 96-prong replicating device to transfer bacterial cultures from the plate in Step 1 to the plate containing the PCR master mix.

4. If the thermal cycler is not fitted with a heated lid, overlay the reaction mixtures with 1 drop (~50 µl) of light mineral oil. Alternatively, place a bead of paraffin wax into the wells if using a hot start PCR. Place the 96-well plates in the thermal cycler.

5. Amplify the nucleic acids using the denaturation, annealing, and polymerization times and temperatures listed in the table.

Cycle Number	Denaturation	Annealing	Polymerization
1	5 min at 94°C		
25–30	30 sec at 94°C	30 sec at 62°C	30 sec at 72°C
Last cycle	30 sec at 94°C	30 sec at 62°C	5 min 72°C

6. Use a multichannel pipettor to make a replica of the 96-well plate (from Step 1) containing the bacterial colonies and allow them to grow overnight at 37°C. The next day, add to each well 100 µl of LB broth containing 30% glycerol. Seal the plate with Parafilm, and store it at –80°C.

7. Analyze the amplification products from Step 5 by gel electrophoresis on a 1.5% agarose gel.

   There should be a variety of different size bands on the gel. It is not productive to determine ETP redundancy based on size, because the PCR products typically cluster around 120 bp.

8. Determine the sequence of each of the ETPs (please see Chapter 12, Protocol 3, 4, or 5).

   If pBSIISK$^-$ was used for cloning, sequencing with T7 will produce sequence from the 5′ end of the ETP. The ETP will be flanked by the following pSPL3-derived sequence:

   5′ GTCGACCCAGCA ETP sequence ACCTGGAGATCC 3′

Procotol 4

Direct Selection of cDNAs with Large Genomic DNA Clones

Michael Lovett
Washington University, St. Louis, Missouri

THIS TECHNIQUE IS USED TO DERIVE PARTS OF CANDIDATE GENES from large genomic regions. It is based on the hybridization capture of cDNAs using biotinylated genomic templates (Morgan et al. 1992; Simmons and Lovett 1999). The starting template is a genomic contiguous sequence (contig) carried in bacterial (cosmid, P1, PAC, or BAC) and/or yeast (YAC) vectors. These genomic DNA clones, which can cover a region as short as a few kilobases or as large as 100 Mb (Del Mastro et al. 1995) are labeled with biotin and then hybridized in solution to PCR-amplifiable cDNA pools. After washing, the genomic DNAs and hybridizing cDNAs are captured using streptavidin beads. The cDNAs are eluted, amplified by PCR, and recycled through a second round of direct selection, after which they are again amplified and then cloned (please see Figure 11-20).

Whereas in the first cycle of selection, the genomic DNA is in molar excess relative to the concentration of rare cDNA species, in the second round of selection, the concentration of genomic DNA is limiting. This sequence results in large increases in the relative abundance of the more prevalent cDNA species in the first round of selection. During the second round, insufficient genomic target is present to capture all of the abundant cDNAs, which become reduced in abundance. However, the genomic target is still in excess relative to the low-abundance species of cDNAs, whose relative abundance is increased, leading to a quasi-normalized final library of selected cDNAs.

The efficiency of each round of the selection procedure is monitored using reporter genes. This is accomplished by hybridizing gene-specific DNA probes to a Southern blot containing the amplified starting cDNA, cDNAs from the first round of selection, and cDNAs from the second round of selection. Enrichments of 10^3-fold to 10^4-fold are routinely achieved when genomic targets of ~1 Mb are used.

Efficient labeling of the genomic template with biotin is a critical step in this procedure and is indirectly monitored using trace amounts of [α-^{32}P]dCTP in the labeling reaction in addition to the biotin-labeled nucleoside triphosphate. Part of the labeling reaction is then tested for its ability to bind to streptavidin-coated beads. The ratio of bound to unbound counts on the beads provides an estimate of the biotin incorporation. The labeling reactions are also performed using a 1:10 molar ratio of biotin-16-dUTP to dTTP to reduce steric hindrance during the hybridization reactions. For further details on labeling with biotin and subsequent detection using streptavidin-coated beads, please see the information panels on **BIOTIN** and **MAGNETIC BEADS.**

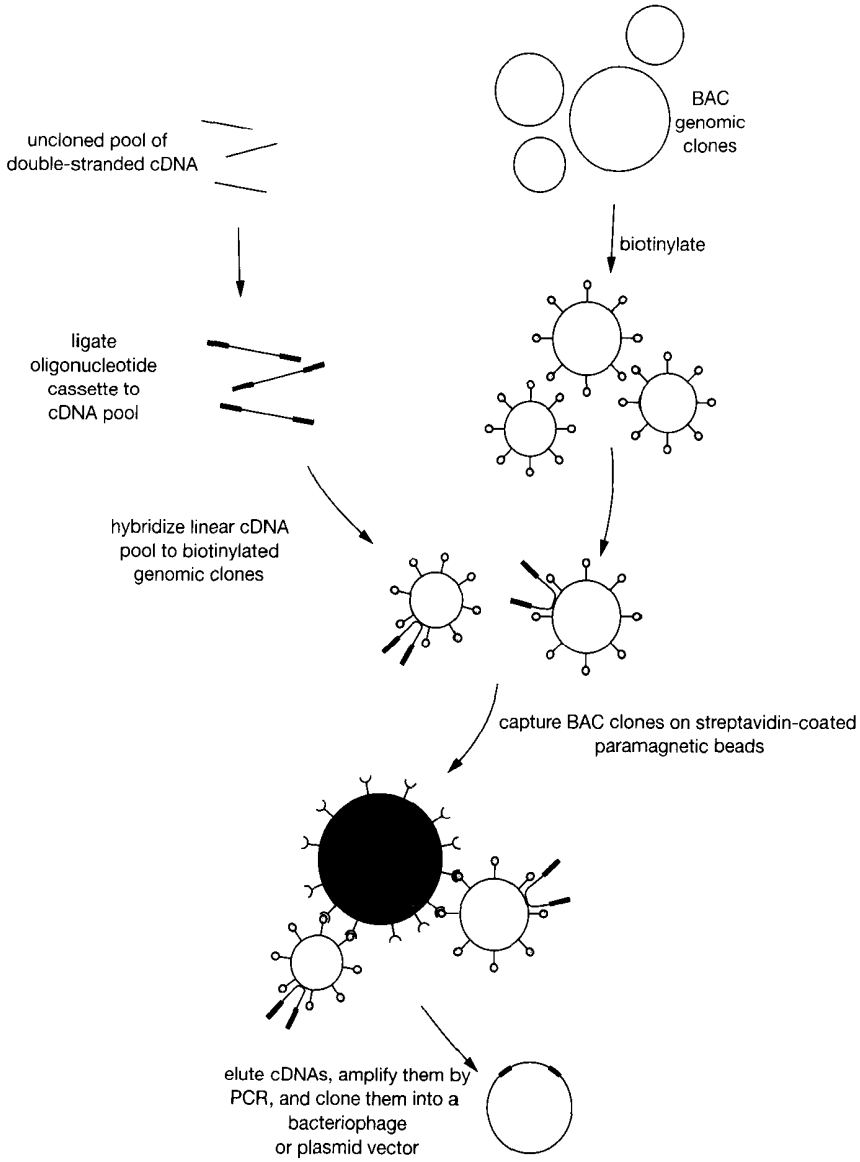

FIGURE 11-20 Scheme for Direct Selection of cDNAs

For details of the reaction, please see text. (Adapted, with permission, from Simmons and Lovett 1999 [©Academic Press].)

The best source of cDNA for direct selections is an uncloned pool of PCR-amplifiable cDNA (Reyes and Kim 1991; Reyes et al. 1992). Conventional cDNA libraries contain only a subset of the transcripts expressed in a complex tissue source, and their average insert lengths are usually not optimal for en masse PCR amplification of all the inserts. By contrast, uncloned cDNA pools represent the entire mRNA complexity of the source tissue, and they can be constructed by random priming to have a mean length of ~500 bp, which is optimal for all the PCR steps. For the cleanest results, it is advisable to use cytoplasmic RNA purified from mammalian cells or tissues to reduce the possibility of selecting heterogeneous nuclear RNA and/or genomic DNA (Clemens 1984). Polyadenylated RNA is purified by two rounds of oligo(dT)-cellulose chromatography (please see Chapter 7, Protocol 3). Synthesis of double-stranded cDNA can be performed using a combination of oligo(dT) and random hexamer primers (please see Protocol 1,

Stage 2). It is advisable to select cDNA products that are at least 500 bp in length by either column chromatography or gel electrophoresis, before adding linkers. The linker cassettes contain a 2-bp overhang at the 3′ end, which forces the cassette to be ligated in only one orientation and also prevents the formation of large oligomers of the cassette. Direct selections are often performed with multiplexed cDNA pools from several different tissues. These can be amplified separately by PCR and cloned after the two rounds of selection are completed (Simmons et al. 1995).

This protocol describes direct selection of cDNAs complementary to a 500-kb human genomic DNA contig cloned in a BAC vector, but it can be adapted to any size of genomic target. The cDNA source for the example is random-primed cDNA, which is ligated to an amplification cassette. If a cDNA library is used instead of primary cDNA, then vector primers for PCR must be substituted in these steps. It is important to change the relative ratios of cloned genomic DNA to cDNA as the total length of the contig changes and to recalculate the $C_0t_{1/2}$ of the reaction using all of the nucleic acid components that are added to the mixture.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

10x Amplification buffer
Include 0.01% (w/v) gelatin in the buffer.

ATP (10 mM)

2x Hybridization solution
1.5 M NaCl
40 mM Na phosphate buffer (pH 7.2)
10 mM EDTA (pH 8.0)
10X Denhardt's solution
0.2% SDS

NaOH (0.1 M) **<!>**

10x Nick translation buffer
500 mM Tris-HCl (pH 7.5)
100 mM $MgCl_2$
50 mM dithiothreitol

SDS (10%)

20x SSC

Streptavidin bead-binding buffer
10 mM Tris-HCl (pH 7.5)
1 mM EDTA (pH 8.0)
1 M NaCl

Tris-HCl (1 M, pH 7.5)

Enzymes and Buffers

DNA polymerase/DNase I (5 units/μl; Boehringer Mannheim)
Restriction endonucleases
T4 DNA ligase
Thermostable DNA polymerase

Gels

Agarose gels (1%) cast in 0.5x TBE
Please see Steps 18, 19, 24, and 25.

Nucleic Acids and Oligonucleotides

BAC DNA encompassing the target genomic region
Purify as described in Chapter 4, Protocol 8 or 9.

Blunt-ended, random-primed cDNAs
Please see Protocol 1, Stage 1.

C_0t1 genomic DNA
Purchased from Life Technologies.

Cytoplasmic poly(A)$^+$ RNA, purified from tissue or cell line of interest
Please see Protocol 1, Stage 1.

Please see the introduction to this protocol for recommendations of purifying RNA to be used in this protocol.

DNA size markers

dNTP solution for nick translation containing all four dNTPs, each at 0.4 mM (pH 8.0)

dNTP solution for PCR containing all four dNTPs, each at 2.5 mM (pH 8.0)

Oligonucleotides (10 mM in TE [pH 8.0]):
Oligo3 5′-CTCGAGAATTCTGGATCCTC-3′
Oligo4 5′-GAGGATCCAGAATTCTCGAGTT-3′

Positive-control DNA
The positive-control DNA should be a part of a gene or expressed sequence tag (EST) known to be present in the starting segment of DNA. If no genes are known, then a single-copy control DNA can be seeded into the genomic target before labeling (at a 1:1 molar ratio) and diluted into the cDNA (at a 1:10^6 molar ratio). Label the DNA sample using one of the protocols given in Chapter 9; the choice of labeling protocol is determined by the experimental goal (for a discussion of options, please see the introduction to Chapter 9).

Labeled Compounds

[α-^{32}P]dCTP (3000Ci/mmole) **<!>**

Biotin-16-dUTP (0.4 mmole)

Special Equipment

Barrier tips for automatic pipettes

Geiger counter or Cerenkov counter

Heating blocks preset to 14°C and 100°C

Hybridization oven with rotating spindle, or shaking water bath

Magnetic separator for removing streptavidin beads (Dynal)

Microfuge tubes (0.5-ml thin-walled for amplification)

Positive displacement pipettes

Sephadex G-50 spun column, equilibrated in TE (pH 7.6)
Prepacked columns of Sephadex and other gel filtration resins are commercially available.

Streptavidin-coated paramagnetic beads

Thermal cycler programmed with desired amplification protocol
If the thermal cycler is not equipped with a heated lid, use either mineral oil or paraffin wax to prevent evaporation of liquid from the reaction mixture during PCR. Paraffin wax may be used not only to prevent evaporation, but also to maintain separation between components (e.g., primer and template) until the reaction mixture is heated. This prevents nonspecific binding of primers during the initial phase of the reaction (please see the information panel on **HOT START PCR** in Chapter 8).

Water bath preset to 65°C

Additional Reagents

Step 1 of this protocol requires reagents listed in Chapter 10, Protocol 2.

Step 2 of this protocol requires reagents for the synthesis of random primed double-stranded cDNAs or PCR-amplified inserts from a cDNA library listed in Protocol 1, Stages 1 and 2.

Step 2 of this protocol requires reagents for labeling listed in Chapter 9, Protocols 3, 5, and 6.

Steps 19 and 20 require reagents listed in Chapter 6, Protocols 8 and 10.

METHOD

Preparation of the Linkered cDNA Pools

1. Label oligonucleotides 3 and 4 separately by phosphorylation at their 5′ termini using polynucleotide kinase, as described in Chapter 10, Protocol 2. Mix the labeled complementary oligos in equal molar ratios (~2 µg of each), denature them for 10 minutes at 100°C, and slowly cool them to room temperature. During this process, the oligonucleotides anneal to form an adaptor. Adjust the concentration of the adaptor to 1 µg/ml.

2. Prepare at least 2 µg of double-stranded cDNA from cytoplasmic polyadenylated RNA by random priming (please see Protocol 1).

3. Prepare the following ligation reaction in a sterile 0.5-ml microfuge tube:

double-stranded blunt-ended cDNA (Step 2)	2 µg
oligonucleotide amplification cassette mixture at 1 µg/µl, from Step 1	3 µl
10x T4 DNA ligase buffer	3 µl
10 mM ATP	3 µl
T4 DNA ligase at 1 unit/µl	3 µl
H_2O	to 30 µl

Incubate the ligation for 16 hours at 14°C. Inactivate the T4 DNA ligase by a 10-minute incubation at 65°C.

Adding ATP as a component of the 10x ligation buffer leaves more volume for vector or foreign DNA in the reaction mixture. If using a commercial ligase buffer that contains ATP, the addition of ATP is no longer required.

4. Purify the products of the ligation reaction by phenol:chloroform extraction, by spun-column chromatography through Sephadex G-50 (please see Appendix 8), and by standard ethanol precipitation. Dry the pellet and resuspend it in 10 µl TE (pH 7.6).

Biotin Labeling of the Genomic Clones

5. Incorporate biotinylated residues into the BAC genomic DNA clone using nick translation. Prepare the following nick translation reaction in a sterile 0.5-ml microfuge tube (label each BAC DNA separately):

purified BAC DNA (0.1 mg/ml)	1 µl
biotin-16-dUTP (0.04 mM)	1 µl
10x nick translation buffer	2 µl
dNTP mix for nick translation (0.4 mM)	1 µl
[α-^{32}P]dCTP (3000 Ci/mmole)	1 µl
DNA polymerase/DNase I (5 units/µl)	1 µl
H_2O	to 20 µl

Incubate the reaction for 2 hours at 4°C.

6. Purify the radiolabeled and biotinylated products of the nick translation reaction by spun-column chromatography through Sephadex G-50 (please see Appendix 8) and standard ethanol precipitation. Resuspend the pellet in 10 µl of TE and store it at –20°C.

Prepare Streptavidin-coated Paramagnetic Beads

7. In a 1.5-ml sterile microfuge tube, wash 3 mg (300 µl) of beads with 500 µl of streptavidin bead-binding buffer three times. Following each wash, remove the beads from the binding buffer using a magnetic separator. Resuspend the beads at a concentration of 10 mg/ml in streptavidin bead-binding buffer.

8. Test an aliquot of each labeling reaction (from Step 6) for the ability to bind to streptavidin beads. Prepare the following binding reaction in a sterile 0.5-ml microfuge tube:

washed streptavidin-coated beads (Step 7)	20 µl
labeled genomic DNA contig* (Step 6)	1 µl
streptavidin bead-binding buffer	29 µl

*Mix equimolar amounts of each separately labeled BAC in the contig to yield a mixture at a concentration of 10 ng/µl.

Incubate the reaction for 15 minutes at room temperature with occasional gentle mixing. Remove the beads from the binding buffer using a magnetic separator, and transfer the supernatant to a fresh sterile 0.5-ml microfuge tube. Use a Geiger counter or Cerenkov counter to measure the radioactivity present on the beads and in the supernatant. If the ratio of bound to free cpm is >8:1, then proceed with the selection.

If the ratio of bound to free cpm is <8:1, it is likely that the DNA was resistant to proper labeling in Step 5. Before labeling, try purifying the BAC DNA further by several rounds of extraction with phenol:chloroform and passing it through a Sephadex G-50 spun column.

Direct cDNA Selection (Primary Selection)

9. Block or "repeat suppress" repetitive sequences in the pool of cDNA (from Step 4) using C_0t1 DNA as follows:

   a. Prepare the following annealing reaction in a sterile 0.5-ml microfuge tube:

cDNA carrying linkers (Step 4)	5 µl (1 µg)
human genomic C_0t1 DNA	5 µl (1 µg)

   b. Overlay the reaction mixture with light mineral oil (~50 µl) to prevent evaporation, and denature the DNA by heating for 10 minutes at 100°C. Cool the reaction mixture to 65°C, deliver 10 µl of 2x hybridization solution under the oil. Mix the components gently. Incubate the reaction mixture for 4 hours at 65°C.

If YAC DNAs are used as the genomic target, the DNA may be contaminated with host (yeast) ribosomal sequences. Block these sequences by using at least 100 ng of cDNA derived from rRNA (please see the panel on **TROUBLESHOOTING** at the end of this protocol).

10. After hybridization of the cDNA pools to the C_0t1 DNA is complete, set up the primary direct selection. Deliver 5 µl (50 ng) of biotinylated BAC DNAs from Step 6 into a fresh microfuge tube, and overlay the solution with light mineral oil (~50 µl) to prevent evaporation. Denature the BAC DNA by heating to 100°C for 10 minutes. Cool the reaction to 65°C.

11. Prepare the following annealing reaction in a sterile 0.5-ml microfuge tube:

biotinylated BAC DNA from Step 10	5 µl (50 ng)
blocked cDNA from Step 9 (1 µg cDNA plus 1 µg C_0t1 DNA)	20 µl
2x hybridization solution	5 µl

Mix the reagents gently, and incubate the reaction for >54 hours at 65°C in a rotating hybridization oven or shaking water bath.

12. To capture and wash the genomic DNA and hybridized cDNAs, prepare the following in a sterile 1.5-ml microfuge tube:

washed streptavidin-coated beads	100 µl
annealing reaction from Step 11	30 µl
streptavidin bead-binding buffer	100 µl

Incubate the mixture for 15 minutes at room temperature with occasional gentle mixing. Remove the beads from the binding buffer using a magnetic separator, and then remove and discard the supernatant. Wash the beads twice, for 15 minutes each time, in 1 ml of 1x SSC/0.1% SDS at room temperature followed by three washes, 15 minutes each, in 1 ml of 0.1x SSC/0.1% SDS at 65°C. After the final wash, transfer the beads to a fresh microfuge tube.

13. To elute the hybridizing cDNAs from the beads in Step 12:

a. Add 100 µl of 0.1 M NaOH, and incubate the reaction mixture for 10 minutes at room temperature.

b. Add 100 µl of 1 M Tris-Cl (pH 7.5).

c. Desalt the mixture by spun-column chromatography through Sephadex G-50 (please see Appendix 8).

Amplification of the Primary Selected cDNAs

14. Transfer three aliquots (1 µl, 5 µl, and 10 µl, respectively) from the 200 µl of eluted cDNA (Step 13) to 0.5-ml sterile amplification tubes.

15. To each tube, add the following:

primer oligo3 (10 mM)	5 µl
10x amplification buffer	2.5 µl
dNTP mixture for PCR (2.5 mM)	2.5 µl
Taq DNA polymerase (Perkin Elmer 5 units/µl)	0.2 µl
H_2O	to 25 µl

Set up two control reactions at the same time as the above test reactions. For the negative control, include all of the components listed above, but omit the template cDNA. For the second control, include 10 ng of the starting cDNA (Step 4).

16. If the thermal cycler is not fitted with a heated lid, overlay the reaction mixtures with 1 drop (~50 µl) of light mineral oil to prevent evaporation. Alternatively, place a bead of wax into the tube if using a hot start PCR. Place the tubes in the thermocycler.

17. Amplify the nucleic acids using the denaturation, annealing, and polymerization times and temperatures listed below.

Cycle Number	Denaturation	Annealing	Polymerization
30 cycles	30 sec at 94°C	30 sec at 55°C	1 min at 72°C

These times are suitable for 25-µl or 50-µl reactions assembled in thin-walled 0.5-ml tubes and incubated in thermal cyclers such as the Perkin-Elmer 9600 or 9700, Master Cycler (Eppendorf), and PTC 100 (MJ Research). Times and temperatures may need to be adapted to suit other types of equipment and reaction volumes.

18. Analyze 10% of each amplification reaction on a 1% agarose gel cast and run in 0.5x TBE, including DNA markers of an appropriate size. Stain the gel with ethidium bromide or SYBR Gold to visualize the DNAs, estimate the concentration of the amplified cDNA, and determine which input cDNA concentration produces the highest yield of cDNA.

    A successful reaction should yield a visible smear of amplified cDNA fragments and may contain some distinct bands.

19. Onto a second 1% agarose gel, load the same amounts (~0.5 µg per lane) of the amplifiied products of each PCR, as well as the appropriate size markers. Also load 0.5 µg of randomly primed cDNA from Step 4.

20. Transfer the separated DNA species to a membrane by Southern blotting (Chapter 6, Protocol 8) and hybridize with the radiolabeled, positive control cDNA.

    The intensity of hybridization to the selected cDNA should be ~1000-fold greater than to the randomly primed cDNA (Step 4).

21. Once the positive control enrichment is confirmed, scale up the optimal amplification reaction to yield at least 1.5 µg of selected cDNAs. Extract the pooled reactions with phenol:chloroform and recover the DNA by standard ethanol precipitation. Resuspend the dried cDNA pellet in 7.5 µl of TE (200 µg/ml).

Direct cDNA Selection (Secondary Selection)

Carry out the secondary selection under the same conditions as the primary selection, using 1 µg of the primary selected cDNA and 50 ng of the target DNA (total length 500 kb in this example).

22. Block repetitive sequences in the primary selected cDNA as described in Step 9 (with 1 µg of cDNA being used and 0.5 µg of cDNA being held in reserve for later analysis).

23. Set up the secondary selection as described in Steps 9 through 13.

24. Analyze the products of the second amplification by electrophoresis through a 1% agarose gel as in Step 18, including a lane with 0.5 µg of primary cDNA (held in reserve) and a lane with 0.5 µg of the starting cDNA.

25. Analyze the gel by Southern blotting and hybridization with the radiolabeled reporter probe as described in Step 20.

    In general, the result of this analysis should reveal a large increase in abundance of the reporter probe between the starting and primary cDNAs and a more modest (~10-fold) increase between the primary and secondary cDNAs.

26. Once enrichment of the control is confirmed, clone the selected cDNAs into the appropriate vector(s). The restriction enzyme sites in the amplification cassette facilitate the cloning of the secondary selected cDNAs into bacteriophage or plasmid vectors.

    A useful alternative is to use one of several ligation-independent cloning systems now commercially available (e.g., the UDG system from Life Technologies or the CLONEAMP pAMP vector system from Life Technologies). If one of these alternatives is used, then use the oligo3 primer with a modified 5′ extension (see manufacturers for details). For further discussion of this strategy, please see the information panel on **LIGATION-INDEPENDENT CLONING**.

TROUBLESHOOTING

- ***Poor labeling of the genomic target with biotin*** is the most common cause of failure in direct selection. It is very important not to proceed with the selection if the test binding (Step 8) fails to yield the correct ratio of bound to unbound genomic DNAs. If the DNA is resistant to labeling, it may be purified by several extractions with phenol:chloroform and passage over a Sephadex G-50 spun column.
- ***High frequency of background sequences in the final cloned selected cDNAs.*** These sequences usually fall into four classes.

  Plasmid vector sequences can be a problem when using commericial cDNA libraries that are frequently contaminated with these "inserts." The best way to eliminate these inserts is to block the cDNA with linearized vector DNA during the selection. Blocking by the vector should be used whenever a cDNA library, rather than primary cDNA, is used in the selection.

  Mitochondrial cDNA is sometimes present because the yeast mitochondrial genome is contaminating a YAC DNA preparation. This contaminant can easily be identified and discarded by screening colonies by hybridization to a mitochondrial DNA probe.

  Whether or not ribosomal sequences are blocked in YAC direct selection, they tend to sneak through to the final set of clones. This contaminant can be counterscreened with an rDNA probe. A ribosomal probe can be generated by first-strand cDNA synthesis from the poly(A)$^-$ fraction of total RNA.

  The final common "contaminants" are cDNAs containing repetitive sequences. Approximately 10% of mRNAs contain repetitive elements within their untranslated regions. Although repeat-containing cDNAs are usually not analyzed due to the technical problems in manipulating these clones, these clones may in fact be bone fide parts of a transcript that is encoded by the target region. Fortunately, if cDNAs synthesized by random priming are used in the selection, then another nonrepetitive part of the same transcription unit is likely to be identified. The clones containing repetitive sequences can then be identified by colony screening with labeled C_0t1 DNA and then discarded.

COMMERCIAL KITS FOR cDNA SYNTHESIS AND LIBRARY CONSTRUCTION

Between 1975, when the first cDNA clones were isolated, and the late 1980s, when methods to generate large cDNA libraries became routine, virtually all of the advances in cDNA cloning flowed from academic laboratories. Since then, however, most of the progress in both synthesis of cDNA and establishment of cDNA libraries has come from commercial companies. Very few of these improvements have been described in the formal scientific literature. Some have been published in the house journals of commercial companies, whereas others appear in advertising and technical literature and on Web pages. However, many of the significant improvements are simply incorporated into kits marketed by commercial suppliers.

The quality and number of premade cDNA libraries available from commercial sources have increased greatly in the past few years. In addition, custom-made cDNA libraries can be synthesized to order, sometimes at a reasonable price. Consequently, fewer academic laboratories now need to generate their own cDNA libraries. Establishing such a library is a lengthy process, requiring many specialized enzymes and reagents, most of which need to be tested and optimized. Laboratories that need to generate their own cDNA libraries should therefore consider the advantages of using a commercial kit. Enzymes, buffers, reagents, and in many cases vectors and host cells are provided; each of the steps in the protocol has been optimized, a task that might otherwise require several weeks' work by an academic scientist; control mRNAs and DNAs are often provided; some of the improvements in cDNA cloning are available only in kit form; and finally, although kits are expensive, the true cost of generating a cDNA library the old-fashioned way may be far greater.

Commercial kits are now available in such number and variety (for a sampling, please see Table 11-6) that at least one of them is likely to fit the needs of a particular project. Wherever possible, choose a kit containing a versatile vector, for example, one that contains control elements for both prokaryotic and eukaryotic expression and, in the case of bacteriophage λ, allows the cDNA to be rescued as a plasmid or phagemid. When faced with a choice of kits produced by different companies, look on the Web to see which company provides better support if something should go wrong and try to obtain a copy of the protocol that accompanies the kit (many of these are available on the Web). Read the protocol thoroughly to ensure that the individual steps make sense and are described and explained in sufficient detail. Pay particular attention to the troubleshooting section of the technical literature because it often gives clues to places in the protocol that might prove difficult. See if individual components of the kit can be replaced as they are used up. Check carefully to determine which items are provided in the kit and which are the responsibility of the investigator to provide. Do not order the kit until all of the necessary solutions and materials have been prepared locally and, if possible, tested.

Mo-MLV REVERSE TRANSCRIPTASE

Early work on copying mammalian mRNA into DNA (Kacian et al. 1972; Ross et al. 1972; Verma et al. 1972), which predated cDNA cloning by several years, used reverse transcriptase extracted from particles of avian myeloblastosis virus (AMV). Throughout the 1970s, Dr. J.W. Beard of the University of Florida was contracted by the National Cancer Institute to supply AMV particles harvested from the blood of leukemic chickens, and later, reverse transcriptase prepared from the virus particles, to the research community in the United States. This work was beyond the reach of most laboratories since it involved infecting day-old male chicks with AMV and processing large volumes of chick blood. Beard's skill and hard work provided the foundation for synthesis and cloning of cDNAs as well as the means to purify the enzyme to homogeneity and to define its chief biochemical features. However, it was not until 1988 that the cDNAs encoding the two chains of avian reverse transcriptase were cloned, independently expressed in *E. coli* (Soltis and Skalka 1988; Terry et al. 1988), and marketed commercially. Perhaps because the active enzyme consisted of several monomeric and heterodimeric forms (for review, please see Skalka 1993), the quality of these early recombinant preparations varied quite dramatically from one manufacturer to another. In addition, the powerful RNase H activity associated with both subunits of the enzyme was a liability when using avian reverse transcriptase to copy populations of mRNA into full-length double-stranded cDNAs. Yields of cDNA rarely exceeded 50%, probably because the hybrid formed between the oligo(dT) primer and the 3′-terminal poly(A) tract of the mRNA template was efficiently degraded by the endogenous RNase H activity of the avian enzyme. In addition, the endonucleolytic and exonucleolytic degradation of the RNA moiety of the hybrid between the first-strand cDNA and the mRNA increased the difficulty of synthesizing and cloning double-stranded cDNA copies of long mRNAs.

In 1985, cDNA encoding the reverse transcriptase of the Moloney strain of murine leukemia virus (Mo-MLV) was cloned and expressed in an enzymatically active form in *E. coli* (Kotewicz et al. 1985; Roth et al. 1985). The enzyme has been expressed both as a fusion protein with the bacterial gene *trpE* product (Tanese et al. 1985) and the bacteriophage λ*c*II (Hu et al. 1986) and in a form where the amino terminus of the protein more closely resembles that of the authentic enzyme (Hizi and Hughes 1988; Kotewicz et al. 1988). Most, if not all, of the commercially available enzyme preparations are from genes encoded by plasmid pB6B15.23 (Roth et al. 1985) or pRT601 (Kotewicz et al. 1985; Gerard et al. 1986). The specific activities of the enzymes encoded by these plasmids differ by a factor of ~10, with the reverse transcriptase encoded by pRT601 being the greater. On the face of it, this may seem to be an advantage. However, maximum yields of cDNA are obtained with both enzymes when the molar ratio of reverse transcriptase to mRNA is ~5. Since all manufacturers of the enzyme use the same units of activity, ~10 times as many units of the enzyme encoded by pRT601 are required to obtain equal efficiency of copying of mRNA into cDNA (Gerard and D'Alessio 1993).

Mo-MLV reverse transcriptase contains two independently functional, nonoverlapping domains (Tanese et al. 1985; Tanese and Goff 1988; for review, please see Prasad 1993). The larger amino-terminal domain (~450 residues) contains the DNA polymerase activity, whereas the RNase H activity is encompassed within the carboxy-terminal domain (~220 residues). The DNA polymerase is rather sluggish and prone to pausing at regions of the RNA template rich in secondary structure (Matson et al. 1980; Gerard et al. 1989). In addition, the RNase H activity has the capacity to hydrolyze the RNA template near the point of chain growth, which can result in dissociation of the DNA-RNA hybrid and termination of the first-strand cDNA. Up to 50% of the first-strand cDNA molecules initiated by Mo-MLV reverse transcriptase may be prematurely terminated by one or the other of these mechanisms (Berger et al. 1983).

Solving the three-dimensional structure of Mo-MLV reverse transcriptase in the early 1990s (Arnold et al. 1992; Kohlstaedt et al. 1992; Georgiadis et al. 1995) was an important step forward since it opened the way to rational genetic engineering of the enzyme. However, by then, one of the chief problems had already been solved by the creation of a mutant of Mo-MLV that retained DNA polymerase activity but lacked RNase H activity (Kotewicz et al. 1988). Surprisingly, inactivation of the RNase H domain by deletion or point mutation led to a dramatic increase in the ability of the enzyme to catalyze the synthesis of cDNA at elevated temperature (Gerard et al. 1989, 1992). Until this serendipitous discovery, Mo-MLV had been used at temperatures no greater than 42°C. However, certain mutants of Mo-MLV deficient in RNase H can efficiently catalyze the synthesis of cDNA at temperatures as high as 50°C (Gerard et al. 1989, 1992), whereas RNase H^- forms of the avian enzyme can be safely used at 60°C (for review, please see Gerard 1998).

The elimination of the RNase H activity from reverse transcriptase increases the ability of the enzyme to generate full-length cDNA molecules at standard temperatures. Various commercially marketed forms of this variant include a mutant of Mo-MLV reverse transcriptase that lacks RNase H activity expressed from a modified version of pRT601 encoding 497 residues of Mo-MLV reverse transcriptase plus five additional residues at the carboxyl terminus. Other commercial forms of Mo-MLV reverse transcriptase lacking RNase H activity include StrataScript RT from Stratagene, SuperScript and SuperScript II from Life Technologies, and two versions from Promega. SuperScript carries a deletion that eliminates RNase H activity, and the Stratagene enzyme SuperScript II and an enzyme from Promega are point mutants.

HOMOPOLYMERIC TAILING

Until 1981, most cDNAs were cloned by adding complementary homopolymeric tracts to the double-stranded cDNA and to a plasmid vector. The vector and the double-stranded cDNA were then joined by hydrogen bonding between the complementary homopolymers to form open circular hybrid molecules capable of transforming *E. coli*. Although it was used with success for many years, cloning of homopolymerically tailed cDNAs into homopolymerically tailed vectors suffers from several of the following drawbacks and is no longer used with any regularity.

- The method can be used effectively only with plasmid vectors, which yield cDNA libraries that are much more difficult to store and replicate than those constructed in bacteriophage λ vectors.
- For optimal efficiency of cloning, the number of homopolymeric residues on the plasmid and the cDNA should be approximately equal, with ~100 dA/dT residues or 20 dC/dG residues being added to each end of the DNAs (Peacock et al. 1981). However, the addition of dNTPs often proceeds asynchronously, so that different termini of DNA molecules carry homopolymeric tails of very different lengths. This problem can be alleviated, but not completely solved, by using plasmids carrying homopolymeric tails of defined size, which are available from a number of commercial suppliers.
- Different strains of *E. coli* are transformed at different efficiencies with plasmid:cDNA molecules that are held together by complementary homopolymeric tails. For example, *E. coli* strain RR1, which is *recA*$^+$, yields ten times as more recombinant cDNA clones made by the dA:dT tailing procedure than the *recA*$^-$ strain HB101 (Peacock et al. 1981). Untreated plasmid DNA transforms the two strains at equal efficiency. These results indicate that the bacterial RecA system may be involved in repairing open circular hybrid DNA molecules that contain homopolymeric tails. Whether other bacterial genes are involved is unknown. However, the fact that the genetic background of the recipient strain of *E. coli* can markedly influence the efficiency of transformation by DNA molecules containing unligated homopolymeric tails raises the possibility of systematic selection for or against specific classes of plasmid-cDNA hybrids.

Homopolymeric tailing capitalized on the ability of calf thymus terminal transferase to catalyze the addition of dNTPs to the 3′-hydroxyl termini of single- or double-stranded DNA. It was first used by Wensink et al. (1974) to introduce recombinant DNA into *E. coli* by pairing between dA:dT homopolymers (Jackson et al. 1972; Lobban and Kaiser 1973). In the original procedure, a small number of nucleotides were removed from the 5′ termini of the double-stranded DNAs to leave protruding single-stranded 3′-hydroxyl termini, which served as efficient templates for terminal transferase. The need for this step was obviated when it was shown that terminal transferase could utilize recessed 3′ termini in the presence of cobalt ions (Roychoudhury et al. 1976). Usually, between 50 and 150 dA residues were added to the linearized vector DNA, and a corresponding number of dT residues were added to the double-stranded cDNA. However, homopolymeric dA:dT tailing was used only rarely for cDNA cloning, chiefly because there was no satisfactory way to excise cDNA inserted into plasmids by dA:dT tailing. The methods described in the literature (Hofstetter et al. 1976; Goff and Berg 1978) are inefficient and not routinely reproducible. For many years, therefore, almost all cloning of cDNA was carried out by homopolymeric dC:dG tailing: dC residues were added to the double-stranded cDNA, and complementary dG residues were added to a plasmid vector that had been digested with *Pst*I (Villa-Komaroff et al. 1978; Rowekamp and Firtel 1980). This enzyme creates protruding 3′ termini that are ideal substrates for addition of homopolymeric tails. cDNA

clones carrying dC:dG tails can easily be removed from the plasmid vector because the addition of a short stretch of dG residues to the linearized plasmid DNA results in regeneration of a *PstI* site at each end of the dC-tailed insert. In practice, the efficiency of regeneration of the *PstI* site depends on the quality of the restriction enzyme used to linearize the plasmid and on the quality of the terminal transferase. Contamination of either enzyme preparation with exonuclease or single-strand-specific nuclease prevents regeneration of the site.

A variation of this strategy is to insert the double-stranded cDNA into a site that is closely flanked by two hexanucleotide restriction sites. In pUC18, for example, the *PstI* site is flanked by *SalI* and *SphI* sites, which occur only rarely in mammalian DNA. In most cases, cDNAs inserted into the *PstI* site by homopolymeric tailing can be recovered intact by cleavage with *SalI* and *SphI*.

λgt10 AND λgt11

Bacteriophage λgt10 (Young and Davis 1983a) is a member of a family of immunity insertion vectors (Murray et al. 1977) designed to accept foreign segments of DNA in the region of the bacteriophage genome that encodes the repressor (*cI*) gene (please see map of λgt10 in Appendix 3). These vectors carry a functional *cI* gene and, like wild-type bacteriophage λ, form turbid plaques on most strains of *E. coli*. λgt10 DNA contains a single *Eco*RI cleavage site located within the coding region of the *cI* gene into which DNA fragments can be inserted. Insertion causes the *cI* gene to be inactivated, generating recombinant cI^- bacteriophages that give rise to clear plaques which are readily distinguishable from the turbid plaques formed by the parental (i.e., nonrecombinant) λgt10.

Parental λgt10 DNA is ~43 kb in length and thus can accept inserts of foreign DNA up to 7.6 kb in length. However, the vector does not require a fragment of foreign DNA to be inserted to generate a genome of packageable size. Thus, cDNA libraries constructed in λgt10 always consist of a mixture of nonrecombinant and recombinant bacteriophages. These two types of bacteriophages can be distinguished phenotypically by their ability to form clear (recombinant) or turbid (nonrecombinant) plaques. More importantly, however, the proportion of recombinants in these libraries can be greatly increased by plating on a strain of *E. coli* that carries an *hfl* mutation. The *cII* gene of bacteriophage λ is a positive activator of synthesis of *cI*. The stability of the *cII* gene product is controlled by the products of the host *hflA* gene and the *cIII* gene of the bacteriophage. Mutation of the *hflA* gene enhances the stability of the *cII* gene product, resulting in an increased production of the *cI* gene product and a high frequency of lysogenization. The growth of parental bacteriophages that carry an intact *cI* gene is therefore suppressed on strains of *E. coli* that carry an hfl^- mutation. By contrast, the growth of recombinant bacteriophages that cannot synthesize an active *cI* gene product is not inhibited (for a discussion of the interactions of the *cI*, *cII*, *cIII*, and *hflA* gene products, please see Hoyt et al. [1982] and for a method to plate bacteriophage λgt10, please see Chapter 2).

λgt11 (Young and Davis 1983a,b, 1991) is an expression vector that carries a copy of the *E. coli lacZ* gene, with a single *Eco*RI cleavage site located 53 bp upstream of the translational termination codon of the *lacZ* gene (please see the map of λgt11 in Appendix 3). Approximately 7.2 kb of foreign DNA can be accommodated at this site. Coding sequences inserted in the correct reading frame and orientation will be expressed to yield fusion proteins whose amino termini consist of β-galactosidase sequences and whose carboxyl termini consist of a foreign polypeptide. Some of these fusion proteins will display antigenic or ligand-binding epitopes that can be detected by their ability to react with specific antibodies or other ligands.

Libraries constructed in λgt11, like those constructed in λgt10, can be screened with nucleic acid probes. However, libraries constructed in λgt10 are far better suited for this purpose. An efficient method is available to select against nonrecombinant λgt10 bacteriophages (please see above), and both the parental and recombinant λgt10 bacteriophages grow to higher titer than λgt11 and its derivatives. Furthermore, during amplification of libraries constructed in λgt11, some recombinants may express low levels of fusion proteins that either are toxic to the host cell or suppress growth of the infecting bacteriophage. Passage of cDNA libraries constructed in λgt11 can therefore result in loss of some classes of recombinants and selective amplification of others. For these reasons, λgt11 should be used to construct cDNA libraries that will be screened only with immunological or double-stranded DNA-binding site probes.

CONSTRUCTING cDNA LIBRARIES FROM SMALL NUMBERS OF CELLS

Mammalian tissues contain different cell types, none of which express exactly the same sets of genes. cDNA libraries established from tissues therefore consist of a melange of sequences, some common to all cells, others unique to a particular population. mRNAs can sometimes be extracted from homogeneous populations of cells obtained by microdissection of fixed tissues, harvesting of oocytes, sorting of cells with specific surface properties, or individual colonies of specific types of differentiated cells. A somatic diploid mammalian cell contains ~10^6 mRNA molecules (1 pg), whereas a mammalian oocyte contains 7–35-fold more. The scarcity of the starting material therefore demands that special techniques and precautions be required to establish cDNA libraries of useful size. The chance of establishing a fruitful library is increased by the following:

- ***Use freshly harvested material and extract the RNA immediately.*** A less desirable alternative involves storing the cells or tissue at –70°C in lysis buffer containing an inhibitor of RNase until sufficient material has been harvested.
- ***Use a scaled-down version of standard protocols to isolate the RNA*** (e.g., please see Belyavsky et al. 1989; Weng et al. 1989; Brady et al. 1990; Hahnel et al. 1990; Revel et al. 1995).
- ***Use carriers to reduce loss of material onto surfaces and to improve the efficiency and speed of precipitation of the mRNA with ethanol.*** Recommended carriers (McCarrey and Williams 1994) include tRNA, poly(I), and poly (I:C). Be aware, however, that using a carrier may decrease the fraction of DNA clones in the library that correspond to the target mRNA population.
- ***Use total RNA rather than poly(A)$^+$ mRNA as a template for first-strand cDNA synthesis.*** Most methods used to purify small amounts of poly(A)$^+$ RNA result in significant loss of material on surfaces and yield preparations that are too dilute to allow the mRNA to be recovered efficiently. The use of total mRNA as template means that synthesis of first-strand cDNA must be primed by oligo(dT) rather than random primers (Domec et al. 1990; Urven et al. 1993). Oligo(dT) priming can be carried out in solution or by using oligo(dT) tethered to paramagnetic beads (Lambert and Williamson 1993).
- ***Use a single buffer for synthesis of first-strand cDNA, second-strand cDNA, and addition of linkers or homopolymeric tails*** (Brady et al. 1990; Don et al. 1993; Aatsinki et al. 1994).
- ***Use PCR to amplify either first-strand or double-stranded cDNA*** (e.g., please see Belyavsky et al. 1989; Brady et al. 1990; Ennis et al. 1990; McCarrey and Willams 1994; Revel et al. 1995). To provide binding sites for oligonucleotide primers, the 3′ terminus of first-strand cDNA is modified by addition of a homopolymer tail (Belyavsky et al. 1989). Alternatively, both termini of blunt-ended double-stranded cDNA can be modified by addition of linkers, 18–20 bp in length (Tam et al. 1989; Don et al. 1993). First-strand cDNA can then be amplified using primers complementary to the poly(dT) tract at the 3′ end and the homopolymer tail (usually oligo[dG]) at the 5′ end. Double-stranded cDNA can be amplified using primers complementary to the linkers. In each case, long extension times improve the yield of clones containing cDNAs >2 kb in length (Domec et al. 1990; Seeber et al. 1993; Aatsinki 1997). cDNA libraries have been established by PCR methods from as few as ten oocytes and by modified versions of conventional cloning from 10^5 somatic mammalian cells.
- ***Omit the methylation step in the interest of streamlining the procedure and maximizing the size of the cDNA library*** (McDonnell et al. 1987; Don et al. 1993). The double-stranded cDNA can be prepared for ligation to the vector by addition of adaptors or by using linkers containing recognition sites (such as *Not*I) that are rarely found in cDNAs.
- ***Use column chromatography rather than gel electrophoresis to fractionate the cDNAs according to size*** (Weng et al. 1989; Urven et al. 1993).
- ***Use pilot reactions to ascertain the optimum ratio of cDNA to vector in the ligation reactions.***

When potent packaging mixtures became commercially available, bacteriophage λ vectors were preferred to plasmids for establishment and propagation of cDNA libraries constructed from limiting amounts of material. However, since the development of strains of *E. coli* that can be efficiently transformed by electroporation, construction of cDNA libraries in plasmid vectors is once again a viable option (Gruber 1995). Libraries constructed in bacteriophage λ are easier to maintain, amplify, and screen; on the other hand, plasmids are available in greater variety and may be the vectors of choice when the library, or individual cDNA clones, are to be used for transfection of mammalian cells.

IN VITRO PACKAGING

Packaging of bacteriophage λ DNA in vitro was initially developed by Becker and Gold (1975) using mixtures of extracts prepared from bacteria infected with strains of bacteriophage λ carrying mutations in genes required for the assembly of bacteriophage particles. The procedure has been modified and improved to the point where 2×10^9 pfu can be generated routinely in packaging reactions containing 1.0 μg of intact bacteriophage λ DNA. This high efficiency of packaging, coupled with the development of a large stable of bacteriophage λ vectors and the ability to screen libraries by hybridization or immunochemical methods, led to the dominance of these vectors in cDNA library construction in the 1980s. The increased use of bacteriophage λ as a cloning vector also led to the development of commercial packaging reactions. Today, the preparation of packaging reactions as described in the Second Edition of this manual is almost a lost art, even in the laboratories of experienced bacteriophage investigators. Commercial packaging reactions work exceedingly well and are so reasonably priced that they have replaced home-made extracts in most routine cloning tasks. However, for specialized applications such as the construction of linking and jumping genomic DNA libraries (which use huge numbers of packaging reactions), it is worth taking the time to prepare home-brewed packaging extracts (Poustka 1993). Packaging extracts are prepared by one of two general strategies:

- Expression of bacteriophage λ genes is induced in two separate lysogens that provide complementing components of the packaging reaction (e.g., please see Scalenghe et al. 1981). As a consequence of mutations in the prophage genomes, neither lysogen alone is capable of packaging exogenously added bacteriophage DNA. Extracts of each culture are prepared separately and blended at the bench into a mixture that contains all of the components necessary for packaging. The resulting packaging mixtures are efficient, typically yielding in excess of 10^9 pfu/μg of bacteriophage λ DNA and essentially free from background (when assayed on appropriate host strains). Examples of commercially available, two-component systems are Gigapack II Gold (Stratagene), and the λ packaging system available from Life Technologies.
- A single *E. coli* C bacteriophage λ lysogen is used to prepare an extract that contains all of the components necessary to package exogenously added viral DNA (Rosenberg 1987). One lysogen can be used to prepare packaging extracts for two reasons. First, the prophage carried in the lysogenic strain encodes all of the proteins needed for packaging. Second, the *cos* site of the prophage has been deleted. These features work together in the following manner. Induction of the lysogen results in the intracellular accumulation of all protein components needed for packaging, and complete preheads are formed. However, the next steps in the packaging process are the recognition of the *cos* sites on concatenated bacteriophage λ DNA by the bacteriophage A protein and the insertion of the bacteriophage λ genome into the prehead. The lack of the *cos* site in the prophage DNA prevents this step from occurring, and packaging is thus effectively halted at the prehead stage, even though all necessary components that are used later in the process are present. However, exogenous DNA with an active *cos* site can be inserted into the prehead, and the packaging process then leads to the production of an infectious bacteriophage particle. Extracts made in this way usually have a lower background of plaques than the classical binary mixtures, because the deletion of the *cos* site blocks packaging of endogenous bacteriophage λ DNA more completely than do the mutations present in the binary strains. *E. coli* C was chosen as the lysogenic host to lessen the probability of recombination between cryptic bacteriophage λ prophages, which are known to be present in the genome of *E. coli* K, and the *cos*-deleted prophage. Furthermore, *E. coli* C lacks the *Eco*K restriction system (Rosenberg 1985). This system, like other restriction systems, cuts unmodified DNA in a sequence-specific manner and is also functional in packaging reactions in vitro. Thus, extracts prepared from cells of *E. coli* K have the potential to select against DNA that contains an unmodified *Eco*K recognition site. Because eukaryotic DNA used to construct libraries will not be protected from cleavage, clones that by chance contain an *Eco*K recognition site may be lost from the population during packaging. Reconstruction experiments show that bacteriophage λ DNA carrying an *Eco*K recognition site is packaged two- to sevenfold less efficiently in extracts derived from *E. coli* K than in extracts prepared from *E. coli* C (Rosenberg 1985).

E. coli C encodes restriction-modification systems that contain components (*mcrA*/*mcrB* and *mrr*) that digest DNA carrying methyl groups on cytosine and adenine residues (e.g., please see Kretz et al. 1989;

Kohler et al. 1990). Because most eukaryotic DNAs are methylated on these residues, packaging extracts from strains of *E. coli* carrying intact *mcr* and *mrr* systems select against methylated eukaryotic DNA sequences. However, the use of packaging extracts prepared from bacterial cells deficient in the *Eco*K, *mcr*, and *mrr* genes (genotype Δ[*mrr-hsd*RMS-*mcr*B]) effectively eliminates this problem (Kretz et al. 1989). For good measure, the *mcrF*- and *mrr*-encoded restriction systems have also been eliminated from the *E. coli* strains used to prepare some commercially available in vitro packaging extracts. Examples of single component bacteriophage λ packaging extracts that are commercially available are the Gigapack III Gold (Stratagene), the MaxPlax packaging extract from Epicentre Technologies, and the Packagene extract from Promega.

COS CELLS

COS cells are a stable line of African green monkey kidney cells that carry integrated copies of the SV40 genome and constitutively express biochemically active, SV40-encoded large T antigen. Because large T antigen is the only virally encoded product required to activate the SV40 origin of DNA replication, COS cells are able to support the replication of any plasmid that contains an intact SV40 origin. Transfection of COS cells with recombinant plasmids containing an SV40 origin and a functional transcription unit leads to efficient amplification of the transfecting DNA and an enhanced level of transient expression of the cloned DNA segment. Since their construction in 1980, COS cells have proven to be invaluable for studying different aspects of eukaryotic gene regulation, for expressing cloned genes in sufficient quantity for biochemical analysis, for analyzing the intracellular transport and properties of wild-type and mutant proteins, and for cloning cDNAs for which no protein sequences are available.

COS cells did not arise by accident but were the result of several years of steady effort by Yasha Gluzman to develop a line of SV40-transformed cells that were permissive to superinfection by SV40. In the mid 1970s, when he was a graduate student at the Weizmann Institute, Gluzman exposed simian cells to UV-irradiated SV40 and isolated three lines of morphological transformants that were fully permissive to superinfection by wild-type SV40 (Gluzman et al. 1977). Unfortunately, none of the cell lines could support the replication of SV40 mutants that expressed defective T antigen. Several years later, Gluzman showed that the cells that had been transformed by SV40 had acquired a mutation affecting a function required for viral DNA synthesis (Manos and Gluzman 1985).

When he went to Cold Spring Harbor Laboratory as a postdoctoral fellow, Gluzman decided to try again — this time using mutants of SV40 (Gluzman et al. 1980a,b) that carried a defective origin of replication but expressed wild-type T antigen. He isolated three lines of transformed simian (CV-1) cells that were completely permissive for lytic growth of SV40 and could support the replication of both temperature-sensitive and deletion mutants of T antigen (Gluzman 1981). These cells were called COS-1, COS-3, and COS-7, COS being an acronym for *C*V-1 *o*rigin, *S*V40. Gluzman thought of seeking a patent but was advised that COS cells were unlikely to be of use to commercial companies. He immediately began to distribute the cells to investigators who wanted to express cloned genes from plasmids carrying an SV40 origin of replication. The first of the many papers using COS cells for this purpose was published a few months later (Mellon et al. 1981).

Two of the original three lines of COS cells (COS-1 and COS-7) are still used extensively in both commercial and academic laboratories. However, many people are confused about which line they carry. This is because Gluzman, who was born in Russia, used a flamboyant writing style in which the numeral 1 is easily confused with numeral 7. Many of the people who received COS-1 cells from him interpreted the label as COS-7 and vice versa. However, the two cells lines can easily be distinguished on the basis of their pattern of integration of SV40 DNA: authentic COS-7 cells contain SV40 DNA sequences integrated at several sites (Rio et al. 1985), whereas COS-1 cells contain only two integrated copies of the viral DNA (Gluzman 1981). Despite these differences, both cell lines amplify plasmids containing an SV40 origin to approximately the same extent and express genes carried on the plasmids with approximately equal efficiency.

BIOTIN

Biotin (vitamin H, coenzyme R [FW = 244.31]) (please see Figure 11-21 for the chemical structure) is a water-soluble vitamin that binds with high affinity to avidin, a tetrameric basic glycoprotein, abundant in raw egg white (for review, please see Green 1975). Because each subunit of avidin can bind one biotin molecule, 1 mg of avidin can bind ~14.8 µg of biotin. The dissociation constant of the complex is ~1.0×10^{-15} M, which corresponds to a free energy of association of 21 kcal/mole. With such a tight association, the off-rate is extremely slow and the half-life of the complex is 200 days at pH 7.0 (Green and Toms 1973). For all practical purposes, therefore, the interaction between avidin and biotin is essentially irreversible. In addition, the avidin-biotin complex is resistant to chaotropic agents (3 M guanidine hydrochloride) and to extremes of pH and ionic strength (Green and Toms 1972).

Biotin can be attached to a variety of proteins and nucleic acids, often without altering their properties. Similarly, avidin (or streptavidin, its nonglycosylated prokaryotic equivalent) can be joined to reporter enzymes whose activity can be used to locate and/or quantitate avidin-biotin-target complexes. For example, in enzyme immunoassays, a biotinylated antibody bound to an immobilized antigen or primary antibody is often assayed by an enzyme, such as horseradish peroxidase or alkaline phosphatase, that has been coupled to avidin (Young et al. 1985; French et al. 1986). In addition, in nucleic acid hybridization, biotinylated probes can be detected by avidin-conjugated enzymes or fluorochromes. Derivatives of biotin are used to biotinylate proteins, peptides, and other molecules (for review and references, please see Wilchek and Bayer 1990). These derivatives include:

- ***Various* N-*hydroxysuccinimide esters of biotin,*** which react with free amino groups of proteins or peptides to form amides. *N*-hydroxysuccinimide is released as a by-product (please see Figure 11-22).
- ***Photoreactivable biotin (photobiotin),*** which upon activation with a mercury vapor lamp (350 nm) reacts via an aryl nitrene intermediate and binds indiscriminantly to proteins, oligosaccharides, lipids, and nucleic acids.
- ***Iodoacetyl biotin,*** which reacts specifically with thiol groups, generating a stable thioether bond.
- ***Biotin hydrazide,*** which reacts with aldehydes generated by mild oxidation of carbohydrates.
- ***Derivatives of biotin equipped with extended spacer arms*** (e.g., biotinyl-ε-aminocaproyl-*N*-hydroxysuccinimide ester). These arms improve the interaction between avidin and biotinylated macromolecules.

The strength of the interaction between biotin and avidin provides a bridging system to bring molecules with no natural affinity for one another into close contact (please see Figure 11-23).

Biotinylation of Proteins

Biotinyl-*N*-succinimide ester, the most commonly used agent for biotinylation of proteins, reacts with primary amine groups, which are located at the amino terminus of the protein and in lysyl side chains. Being highly charged, lysine residues are usually located on the solvent-accessible surfaces of the protein. Most of the attached biotin residues therefore decorate the outer surface of the protein, where they generally cause little disturbance to structure and function. Nevertheless, it is essential to use appropriate biological and enzymatic tests to confirm that the biotinylated protein has (1) retained its activity and (2) can bind to avidin-reporter molecules.

Protein biotinylation kits are available from many manufacturers, including Pierce and Life Technologies. Using the manufacturer's instructions as a guideline, optimal conditions for biotinylation can be established by setting up a series of reactions containing different ratios of biotinylating reagent and target protein. The biotin content of the resulting conjugates are assayed in an avidin/HABA assay. HABA (2-[4′-hydroxyazobenzene]) benzoic acid is a yellow dye that adsorbs strongly at 350 nm. When avidin is added to saturating concentrations of HABA, a spectral change occurs and the absorbance at 500 nm increases (Green 1975). The absorbance at 500 nm decreases with addition of biotin, which competes with HABA for binding sites on avidin. The change in absorbance at 500 nm is directly proportional to the amount of biotin in the system. The amount of biotin attached to the target protein can therefore be calculated from a standard curve constructed with known quantities of biotin (Wilchek and Bayer 1990). (The HABA system is accurate but not very sensitive. Each assay requires between 50 and 100 µg of biotinylated conjugate at a concentration of ~1 mg/ml.)

The biotinylated protein produced in each reaction can then be checked for activity and for its ability to bind to avidin-Sepharose columns. The specificity of biotinylated antibodies and their level of nonspecific binding can be checked by dot-blots and western blots that have been "spiked" with varying quantities of the antigen.

Biotinylation of Nucleic Acids

Biotinylated nucleotides, which are available commercially, are effective substrates for a variety of polymerases including the DNA polymerases of *E. coli, Thermus aquaticus*, bacteriophage T4, and the RNA polymerases of bacteriophages T3 and T7. Biotinylated nucleic acids can therefore be generated in vitro by almost all of the procedures (nick translation, end-filling PCR, random priming, and transcription) that are used to generate radiolabeled probes (please see Table 11-7). In addition, biotin adducts can be introduced into nucleic acids and oligonucleotides by a number of chemical methods, including attachment to a 5′ amine group. This group is added during the final step of conventional cyanoethyl phosphoroamidite synthesis of oligonucleotides. The amino-oligonucleotide can then be labeled with commercially available biotinyl-*N*-succinimide ester.

As long as their content of biotinylated nucleotide does not exceed a few percent, the resulting probes hybridize to target sequences at approximately the same rate as unsubstituted probes. Incorporation of additional biotin residues is unlikely to increase the sensitivity of detection given that a typical avidin-linked reporter molecule (e.g., avidin-alkaline phosphatase) bound to a single biotin residue will cover between 50 and 100 nucleotides of nucleic acid.

The efficiency of detection of biotinylated probes by avidin-linked reporter systems is greatly improved if the length of the linker between the biotin moiety and the nucleotide is sufficient to overcome steric hindrance and to allow the biotinyl group to penetrate effectively into the binding sites of avidin. A number of companies sell biotinylated nucleotides with linkers containing six or more carbon atoms.

Biotin can also be introduced into nucleic acids simply by mixing photoactivatable biotin with double- or single-stranded DNA or RNA and then irradiating the mixture with visible light (350 nm) (Forster et al. 1985). The usual protocol yields a nucleic acid that contains an average of one biotin residue per 200 or so residues. Modification at this modest level certainly does not interfere with the ability of the probe to hybridize to its target and yet is sufficient to allow detection of single-copy sequences in Southern hybridization of mammalian DNA (McInnes and Symons 1989). The following are advantages of biotinylated probes.

- They can be stored for long periods of time without loss of activity.
- They need no special method of disposal.
- Signals from a biotinylated probe can be detected with a variety of avidin-reporter molecules, including those that can be detected by chemiluminescence and fluorescence. This means that a single probe can be used for a variety of different purposes (e.g., Southern blotting and in situ hybridization).
- The biotinylated nucleic acid can be recovered by affinity purification on avidin columns or on avidin-coated magnetic beads.

Note that the incorporation of bulky biotin groups reduces the electrophoretic mobility of nucleic acids. For example, each addition of biotin-14-dCTP is equivalent to increasing the mass of the nucleic acid by 1.75 cytosine residues (Mertz et al. 1994).

Despite these advantages, biotinylated probes have not displaced conventional radiolabeled probes from their preeminent position in molecular cloning. In part, this may be because the first-generation biotinylated probes were not as sensitive as claimed to be and sometimes failed the litmus test of detecting single-copy sequences in Southern hybridizations of mammalian DNA. In addition, one set of circumstances in which biotinylated probes are at a particular disadvantage is when screening for partially homologous sequences by cross-species hybridization. Here, there is a possibility that the presence of bulky biotinyl groups may lower the stability of mismatched hybrids to the point where no signal can be observed. Biotinylated probes are nevertheless likely to grow greatly in importance during the next few years as the difficulties and cost of disposal of radioactive waste increase dramatically.

Useful information about avidin-biotin chemistry and avidin-biotin techniques is available in *Methods in Enzymology* (volume *184* [ed. M. Wilchek and E.A. Bayer] 1990). In addition, Pierce Chemical Company sells a handbook (*Avidin-Biotin Chemistry: A Handbook*) that contains much practical advice.

MAGNETIC BEADS

Since their introduction to molecular cloning in 1989 (Hultman et al. 1989), magnetic beads (also known as microspheres) have been used for a variety of purposes, including purification and sequencing of PCR products, construction of subtractive probes and cDNA libraries, affinity purification of DNA-binding proteins, rescue of shuttle vectors from transfected cells, and hybridization of covalently attached oligonucleotides. Although such tasks can be accomplished by more traditional techniques, these older methods are almost invariably more tedious and less efficient. Among the advantages offered by magnetic beads are speed of operation and the possibility of working at kinetic rates close to those occurring in free solution. Binding of ligand takes only a few minutes, magnetic separation takes seconds, and washing or elution can be completed in <15 minutes in most cases.

Magnetic beads are nonporous, monodisperse, superparamagnetic particles of polystyrene and divinyl benzene with a magnetite core ($8 \pm 2 \times 10^{-3}$ cgs units) and a diameter of ~2.8 μm. Different types of beads carry different active groups on their surfaces (OH, NH_2, OH[NH_2], COOH, etc.), which can be used for covalent attachment of protein and nucleic acid ligands (e.g., please see Lund et al. 1988). However, most investigators prefer to purchase magnetic beads that are preloaded with covalently bound streptavidin (Lea et al. 1988), which can then be used to tether any biotin-labeled nucleic acid or protein to the surface of the bead (for review, please see Haukanes and Kvam 1993). *Note that the binding capacity varies with bead size, bead composition, and the size of the binding ligand. Different brands of beads carry different amounts of covalently attached streptavidin so that the binding capacities of beads supplied by different manufacturers are not necessarily equivalent. In addition, some brands of beads can be reused, whereas others must be discarded after a single use.* Once attached, the tethered ligand can be used for affinity capture and purification of target molecules from solution. Because the surface area of the particles is very large (5–8 m^2/g), streptavidin-coated beads have a very high biotin-binding capacity (>200 pmoles/mg). Furthermore, because of the high affinity of streptavidin for biotin ($K_{ass} = 10^{15}\ M^{-1}$; Wilcheck and Bayer 1988), complexes between biotin and streptavidin form very rapidly and once formed are resistant to extremes of pH, organic solvents, and many denaturing agents (Green 1975). Stringent washing does not cause leaching of tethered ligand from the surface of the bead, and enrichment factors of 100,000 can be attained during a single round of affinity capture. Perhaps the major disadvantages of magnetic beads are (1) their high cost and (2) the need for an efficient magnetic particle separator. The best of these devices contain one or more neodymium-iron-boron permanent magnets and are available in a number of formats from several commercial suppliers.

Figure 11-24 illustrates a generic procedure for affinity capture of a specific DNA-binding protein by a biotin-labeled oligonucleotide ligand tethered to magnetic beads. However, many other applications have been described, some of which are listed in Table 11-8. Further information may be found in the review by Jakobsen et al. (1994) and in the literature published by manufacturers of magnetic beads (e.g., Dynal http://www.dynal.net/DynalWeb/DynalWeb.nsf/htmlmedia/molecular_biology.html).

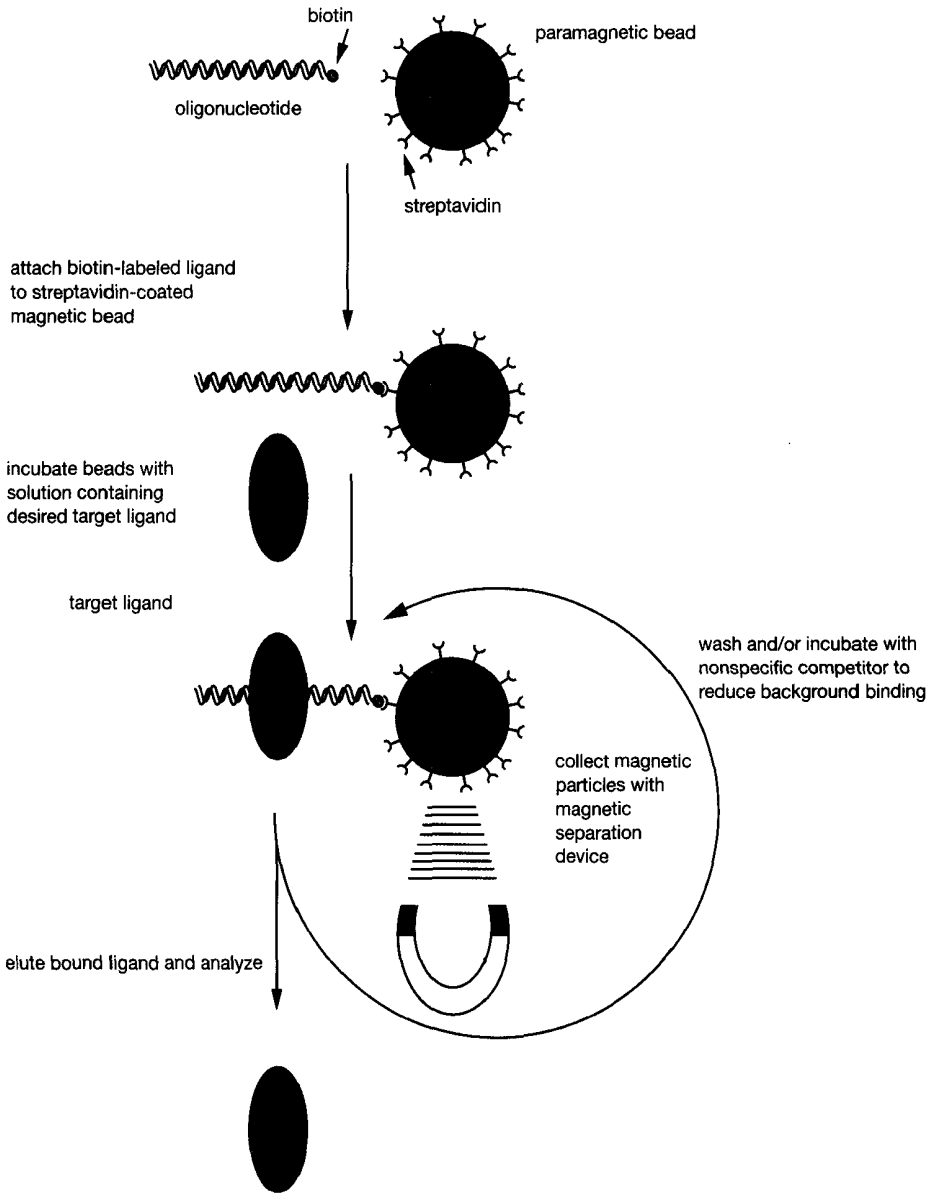

FIGURE 11-24 Affinity Purification Using Magnetic Beads

A generic approach is illustrated here for the capture of a specific target ligand, using as an example a DNA-binding protein. The biotin-labeled ligand, in this case, an oligonucleotide encoding the putative binding site for the target protein, is attached to streptavidin-coated magnetic beads and incubated in a solution containing the desired target protein. The bound particles are collected with a magnetic separation device and washed repeatedly with a solution containing a nonspecific competitor. Finally, the bound target ligand is eluted from the oligonucleotide and analyzed.

LIGATION-INDEPENDENT CLONING

Ligation-independent cloning (LIC-PCR) (also known as enzyme-free cloning) increases both the efficiency and speed of cloning of PCR products. LIC-PCR eliminates the need to ligate PCR products to a vector, does not rely on restriction sites, and avoids problems caused by extra bases that are added by the extendase activity of thermostable DNA polymerases at the 3′ termini of PCR products (Clark 1988; Hu 1993). By allowing direct cloning of a PCR product into a particular site of a plasmid vector, LIC-PCR eliminates complex constructions that arise when a vector lacks suitable cloning sites, or a genetic basis for screening for recombinants (Aslandis and de Jong 1990; Haun et al. 1992; Hsiao 1993; Yang et al. 1993; Kaluz and Flint 1994). Several variants of LIC-PCR have been described:

- ***Amplification of the target with primers that carry at least 24 extra bases at their 5′ end.*** These bases correspond to sequences at the end of a linearized plasmid vector. Amplification with these primers therefore generates PCR products whose 5′ ends are complementary to the 3′ ends of the recipient linearized plasmid. The PCR product and the linearized plasmid are then spliced together in a second PCR which extends the overlapping complementary 3′ ends (Shuldiner et al. 1990).
- ***Generation of PCR products that carry 3′-protruding termini, 12 or more bases in length,*** that are annealed to complementary single-stranded sequences at the 3′ termini of a linearized vector. Base pairing between the two sets of protruding tails creates a chimeric molecule that can be introduced into *E. coli* by transformation (Aslandis and de Jong 1990).

Methods to generate complementary single-stranded tails at the 3′ termini of the vector and the PCR product include:

- ***Exonuclease resection of 3′ termini.*** The sequences of the vector and the PCR product are designed so that one of the four bases does not occur within the first 12 nucleotides of the end of the 3′ strand. Complementary tails of defined length can therefore be produced by the 3′-5′ exonuclease activity of T4 DNA polymerase in the presence of a single dNTP. The enzyme removes nucleotides in the 3′-5′ direction until it reaches the first nucleotide that corresponds to the dNTP included in the reaction mix. Further exonucleolytic digestion by T4 DNA polymerase is neutralized by incorporation of the dNTP at the 3′-hydroxyl terminus of the recessed strand. After the enzyme has been inactivated by heat, the PCR product is annealed to a vector that has been prepared in a similar way (Aslandis and de Jong 1990; Haun et al. 1992). When the chimeric molecule is used to transform *E. coli*, the ligase of the bacterial cells seals the single-stranded nicks and generates a covalently closed circular molecule.

  In a variation of this method, overlapping sequences are designed into the PCR primers used to amplify the target DNA and the vector. Controlled digestion of the PCR product and the vector with either exonuclease III (Hsiao 1993; Li and Evans 1997) or λ exonuclease is used to generate complementary protruding 3′ termini (Tseng 1999). Because the overhangs created by the action of the exonucleases are slightly longer than the complementary sequence, after hybrid formation, a stretch of single-strand gap remains, which can be repaired in vivo (in the case of exonuclease III) or in vitro by the Klenow fragment of *E. coli* DNA polymerase I (in the case of λ exonuclease).
- ***Uracil DNA glycosylase (UDG) cloning.*** In this method, the primers used in PCR contain dUMP in their 5′-terminal regions. Digestion of the PCR products with UDG results in cleavage of the *N*-glycosidic bond between the deoxyribose residue and uracil. This cleavage generates abasic residues and destroys the base-pairing ability of the 5′-terminal sequences of the PCR products (Duncan 1981; Friedberg et al. 1981). In this method, both the vector and the insert are amplified in reactions primed by uracil-containing primers and then treated with UDG. Thus, when the insert and vector are mixed, only one strand of insert is available for annealing with the complementary strand of the vector (please see Figure 11-25) (Nisson et al. 1991; Rashtchian 1995). Several linearized vectors are commercially available (Life Technologies) that carry defined 3′-protruding termini, 12 nucleotides in length.
- ***Primers containing nonbase residues*** (Kaluz and Flint 1994). In this method, a nonbase residue (1,3-propanediol) is incorporated at defined positions in the oligonucleotide primers used to amplify the insert DNA. This modification does not affect the priming ability of oligonucleotides. However, during the amplification reaction, the DNA polymerase stops when it encounters the abasic site, resulting in products that carry 3′-protruding termini, 12 bp in length (please see Figure 11-26), which in this case

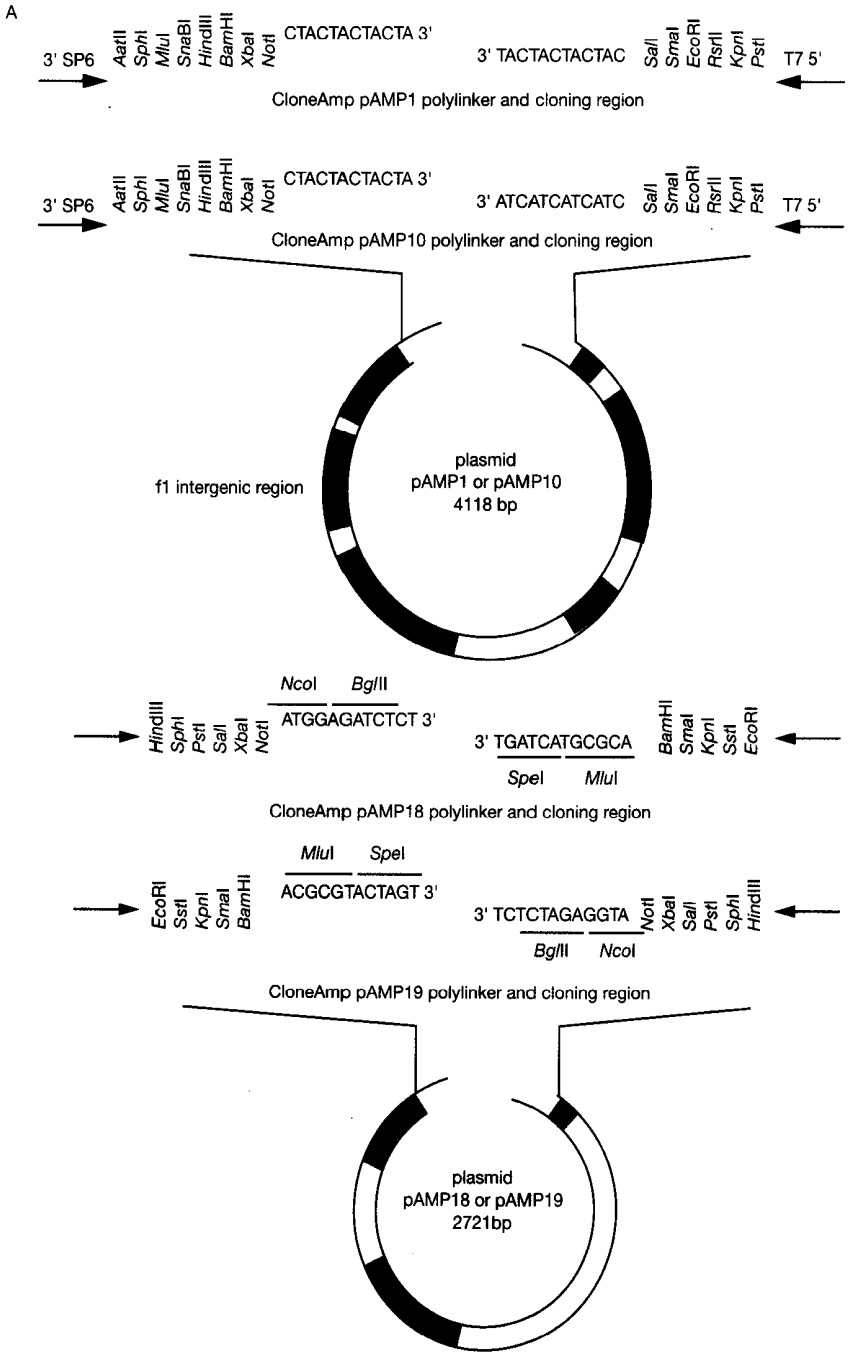

FIGURE 11-25 CloneAmp pAMP Vectors and the UDG Cloning Strategy

(*A*) Schematic maps of pAMP vectors. pAMP1 and pAMP10 are identical vectors except for the sequence of the single-stranded region (shown here, and described in the text) required for annealing with insert DNA. pAMP1 is for unidirectional cloning of insert DNA and pAMP10 is for bidirectional cloning. pAMP1 and pAMP10 contain a bacterial origin of replication, the ampicillin resistance gene for the selection of transformed bacteria, and the f1 intergenic region from M13 bacteriophage for the production of single-stranded DNAs. The polylinker is within the *lacZ* gene, permitting color selection of positive colonies. Vectors pAMP18 and pAMP19 are modified pUC18 and pUC19 vectors. They have a single-stranded region added in the polylinker of the original vectors for annealing to complementary PCR product inserts. The single-stranded cloning region contains the restriction endonuclease sites *Nco*I and *Bgl*II on one strand, and *Mlu*I and *Spe*I on the other strand. The two plasmids are identical except for the orientation of the polylinker region (shown here), which is inverted. The single-stranded tails are the same for both

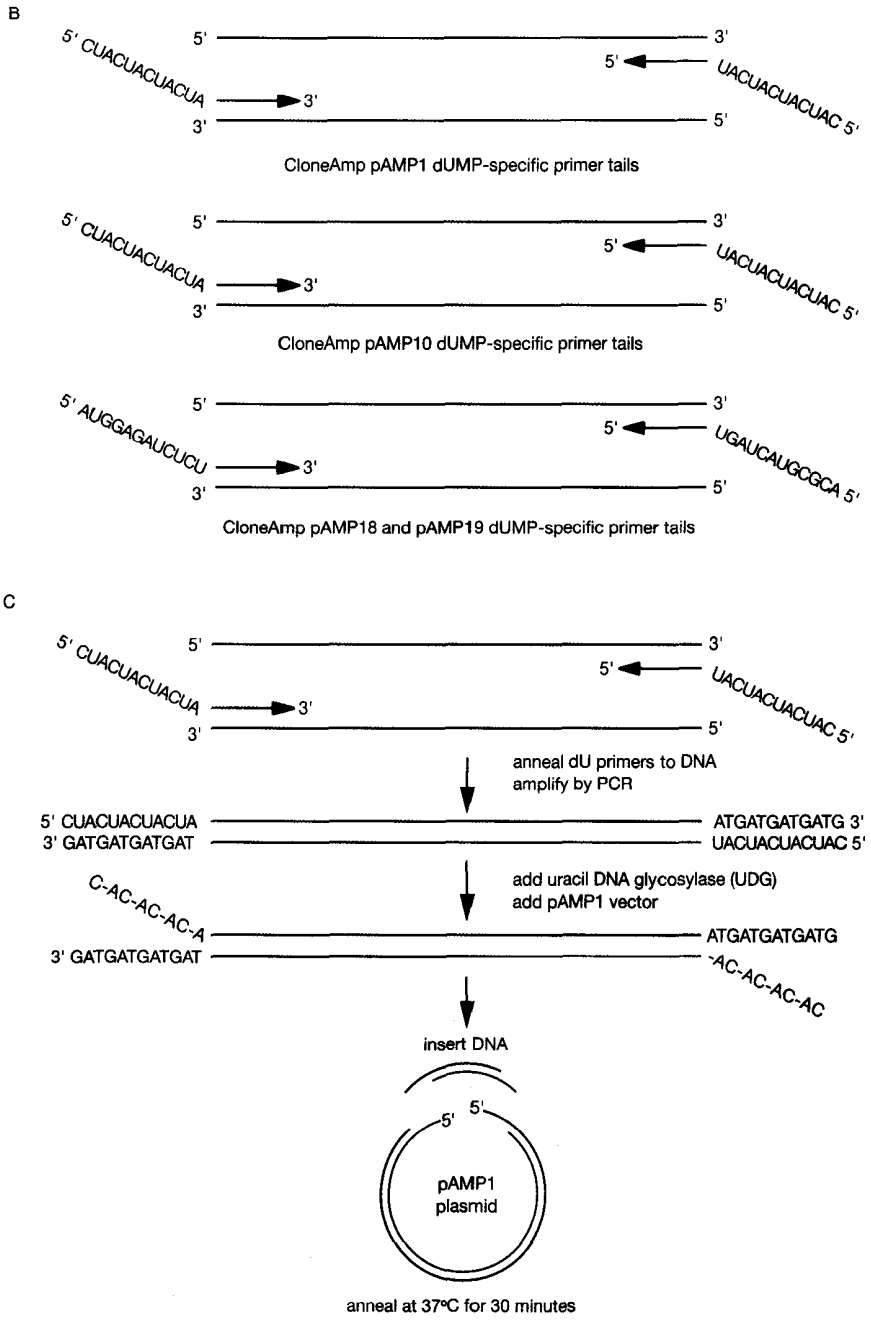

FIGURE 11-25 ***(continued)***

clones and can be used for directional cloning of an insert. The vectors contain a bacterial origin of replication and the ampicillin resistance gene for the selection of transformed bacteria. The polylinker, within the *lacZ* gene, permits color selection of positive colonies. (*B*) dUMP PCR primer tails for pAMP1, pAMP10, pAMP18, and pAMP19. The sequences shown for each clone are required at the 5′ end of oligonucleotide primers to be used for PCR amplification. (*C*) pAMP cloning protocol. PCR primers with pAMP-specific sequences at the 5′ end are used to amplify DNA. PCR products are treated with UDG in the presence of a compatible pAMP vector (supplied as a linear molecule). The vector and the insert are then annealed, and the recombinant plasmid is transformed into competent bacteria. Primer-specific sequences for pAMP1 are shown in this diagram. The protocol is identical for all of the pAMP clones. (Adapted, with permission, from Life Technologies, Inc.)

FIGURE 11-26 Generation of PCR Products Carrying Protruding 3′ Termini in PCRs with Primers Containing the Nonbase 1,3-Propanediol

The location and use or primers containing the nonbase 1,3-propanediol are indicated with an *X*. (Modified, with permission, from Kaluz and Flint (1994 [Oxford University Press].)

are complementary to the 12-nucleotide regions flanking the *Not*I site of the Bluescript vector. The insert is annealed to a *Not*I linearized and exonuclease-III-treated vector, and the resulting chimera is used to transform *E. coli*. Abasic residues are removed and gaps are repaired by the repair machinery of bacterial cells, which results in restoration of the *Not*I site.

- ***Use of multiple primers to create complementary staggered overhangs on both insert and vector by a post-PCR denaturation-hybridization reaction*** (Liu 1996; Tillett and Neilan 1999). Eight sets of primers and four separate PCRs are required to generate two PCR products (target DNA and vector) that can be denatured and annealed to yield nicked circular recombinants that can be used, without further manipulation, to transform *E. coli*.

Chapter 12

DNA Sequencing

When the war finally came to an end, I was at a loss as to what to do... . I took stock of my qualifications. A not-very-good degree, redeemed somewhat by my achievements at the Admiralty. A knowledge of certain restricted parts of magnetism and hydrodynamics, neither of them subjects for which I felt the least bit of enthusiasm. No published papers at all... . Only gradually did I realize that this lack of qualification could be an advantage. By the time most scientists have reached age thirty they are trapped by their own expertise. They have invested so much effort in one particular field that it is often extremely difficult, at that time in their careers, to make a radical change. I, on the other hand, knew nothing, except for a basic training in somewhat old-fashioned physics and mathematics and an ability to turn my hand to new things... . Since I essentially knew nothing, I had an almost completely free choice... .

Francis Crick, *What Mad Pursuit.*

THE POWER OF DNA SEQUENCING IS ITS ABILITY to reduce genes and genomes to chemical entities of defined structure. Few other techniques provide biologists with such certainty and comfort. All molecular cloners must therefore be fluent DNA sequencers — not necessarily on a grand scale, but at least on a level that dissolves doubts, confirms hopes, and pinpoints problems.

In molecular cloning laboratories, DNA sequencing today is used chiefly to characterize newly cloned cDNAs; to confirm the identity of a clone or mutation; to check the fidelity of a newly created mutation, ligation junction, or product of a polymerase chain reaction (PCR); and, in some cases, as a screening tool to identify polymorphisms and mutations in genes of particular interest. Until a few years ago, these tasks were achieved by manual labor: Virtually all steps in sequencing protocols were carried out locally and with radioactive labels. Nowadays, however, most laboratories have access to sequencing facilities equipped with oligonucleotide synthesizers and automated machines that utilize fluorescent detection systems rather than autoradiography to vizualize the products of DNA-sequencing reactions. The sequences are captured automatically and transferred to computers. These machines have taken much of the grunt work out of sequencing and have greatly increased its power and accessibility. Old timers may reminisce about the joy of running a great sequencing gel and of the pleasure in deciphering its sharp bands one by one. Do not believe them, it was not that much fun.

THE BEGINNING OF DNA SEQUENCING

In the mid 1970s, when molecular cloning techniques in general were rapidly improving, simple methods were also developed to determine the nucleotide sequence of DNA. The first attempts mirrored techniques developed 10 years earlier by Robert Holley's group to sequence tRNAs (Holley et al. 1964, 1965). Holley's method involved digesting RNAs with sequence-specific RNases, fractionating the resulting oligoribonucleotides by ion-exchange chromatography or two-dimensional homochromatography (Sanger et al. 1965; Brownlee and Sanger 1967), and establishing the order of bases within each fragment by exonuclease digestion. By using two different methods of fragmentation, Holley was able to establish overlaps between fragments and hence to assemble the entire 77-nucleotide sequence of a yeast alanine tRNA.

Several attempts were made to apply this method to DNA sequencing by cleaving DNA into smaller fragments with endonuclease IV or chemicals (pyrimidine tract analysis; Robertson et al. 1973; Ziff et al. 1973). However, none of these methods proved to be equal to the magnitude of the task. Indeed, the problems were so intractable that in some cases, DNA was transcribed with *Escherichia coli* RNA polymerase and then sequenced as RNA (Gilbert and Maxam 1973). Within 10 years, however, as a consequence of work in the Gilbert laboratory at Harvard University and in the Sanger laboratory at Cambridge, England, DNA sequencing was to become a routine matter, well within the range of any molecular biology laboratory.

The best-known DNA-sequencing techniques are the enzymatic method of Sanger et al. (1977a) and the chemical degradation method of Maxam and Gilbert (1977). Although very different in principle, these two methods both generate populations of oligonucleotides that begin from a fixed point and terminate at a particular type of residue. In the simplest case, four populations are created that terminate at A, G, C, and T residues, respectively. The termination points are nucleotide-specific but occur randomly along the length of the target DNA. Each of the four populations therefore consists of a nested set of fragments whose lengths are determined by the distribution of a particular base along the length of the original DNA. These populations of fragments are resolved by electrophoresis under conditions that discriminate between individual

DNAs differing in length by as little as one nucleotide (Sanger and Coulson 1978). When the four populations are loaded into adjacent lanes of a sequencing gel, the order of nucleotides along the DNA can be read directly from an image of the gel.

The Dideoxy Method of DNA Sequencing

The Sanger technique uses controlled synthesis of DNA to generate fragments that terminate at specific points along the target sequence. This idea originated with Ray Wu of Cornell University, who used partial repair in the presence of one, two, or three deoxynucleoside triphosphates (dNTPs) to sequence the 12-nucleotide cohesive termini of bacteriophage λ DNA (Wu and Taylor 1971; Tu and Wu 1980). Wu's idea of partial repair is formally equivalent to the "minus" arm of a short-lived technique known as the "plus and minus" sequencing technique (Sanger et al. 1973; Sanger and Coulson 1975), which was the immediate forerunner of the current dideoxy-mediated chain-termination method. In the course of in vitro experiments to prepare DNA copies of high specific radioactivity, Sanger and his colleagues noticed that the size of newly synthesized DNA chains was frequently less than unit length. Premature termination generally occurred at the residue immediately upstream of the site at which a radioactive nucleotide should have been incorporated. This anomaly occurred because the concentration of the radiolabeled nucleotide in the reaction was far lower than that of the other three unlabeled nucleotides. The 3′ ends of the resulting mixture of products therefore corresponded to the position of the nucleotide whose concentration was limiting. By carrying out four separate reactions in which each of the nucleotides was limiting in turn and separating the four sets of truncated fragments according to their size, Sanger and his colleagues were able to generate a readable DNA sequence (Sanger et al. 1977a). Although the plus and minus technique was slow and inaccurate, it was used successfully to determine almost all of the 5386-nucleotide sequence of bacteriophage ϕX174 DNA (Sanger et al. 1977b). The plus and minus system was an important advance because it first described (1) the use of a specific primer for extension by DNA polymerase, (2) base-specific chain termination, and (3) the use of polyacrylamide gels to discriminate between single-stranded DNA chains differing in length by a single nucleotide. However, the plus and the minus reactions were notoriously unreliable, and it was always difficult to get all four of them to work simultaneously, as the method required. Clearly, a further advance was required if nucleotide sequencing by controlled synthesis of DNA was to become practical.

The breakthrough came with the introduction of dideoxynucleoside triphosphates (ddNTPs) — nucleoside analogs that (1) could be substituted for deoxynucleotides at random positions during template-directed copying of a DNA strand by a DNA polymerase and (2) could efficiently terminate DNA synthesis in a base-specific manner (please see Figure 12-1) (Sanger et al. 1977a). By using ddNTPs corresponding to the conventional nucleotide bases in separate synthetic reactions, four populations of oligonucleotides could be generated that terminate at every position in the template strand. The DNA bands in the reactions could be displayed by gel electrophoresis and the DNA sequence deduced from the order of bands in the four lanes. So well did these chain terminators work that by the beginning of the 1980s, the Sanger method had become the method of choice for DNA sequencing — a position it still occupies.

The Chemical Method of DNA Sequencing

Whereas the dideoxy-mediated chain-termination method grew logically from Sanger's earlier work on protein and RNA sequencing, the chemical method of DNA sequencing was discovered accidentally in Walter Gilbert's laboratory (please see Gilbert 1981). In the late 1960s, and early 1970s, Gilbert's work focused on the interaction between the *lac* repressor and the *lac* operator in

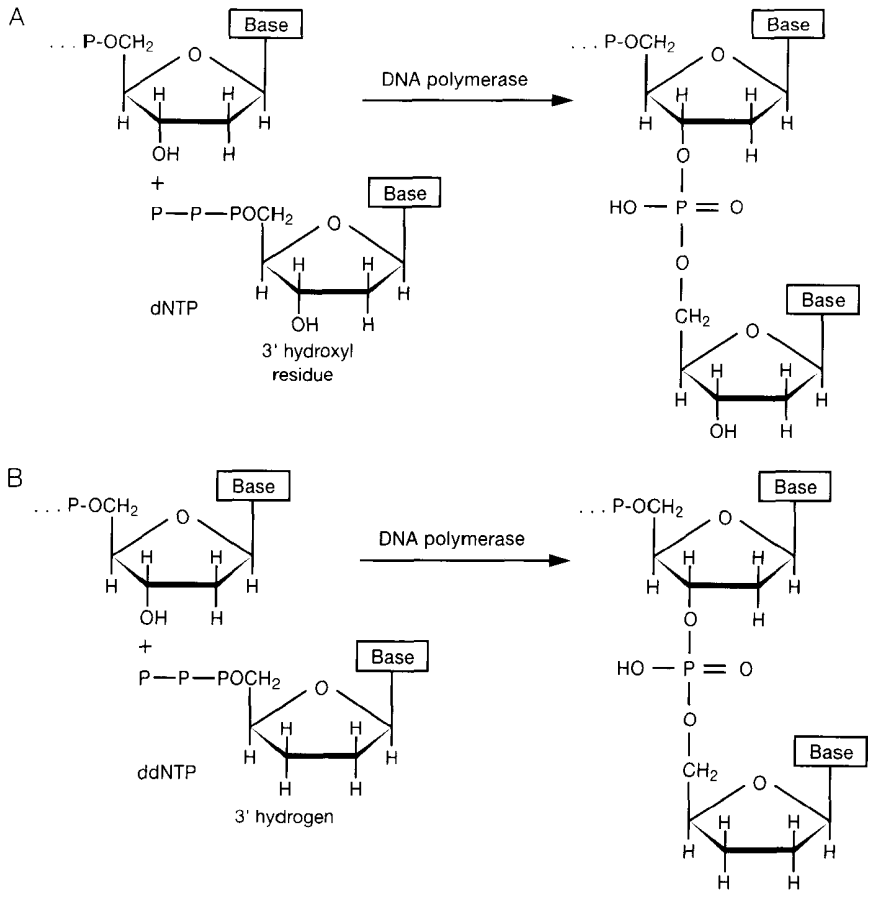

FIGURE 12-1 Termination of DNA Synthesis by Incorporation of ddNTPs

(*A*) DNA polymerase-catalyzed esterification of the normal dNTP with the 3′-terminal nucleotide of DNA. The reaction, which extends the length of the primer by a single nucleotide, can be recapitulated until all of the bases in the template strand (not shown) are paired with the newly synthesized strand. (*B*) Corresponding reaction with a ddNTP, which lacks a 3′-hydroxyl residue. The ddNTP can be incorporated into the growing chain by DNA polymerase, where it acts as a terminator because it lacks the 3′-hydroxyl group required for formation of further 5′→3′ phosphodiester bonds.

vitro. He isolated the fragment of DNA protected by the repressor and worked out its sequence by copying the DNA into RNA and then applying the techniques of RNA sequencing developed in Sanger's laboratory (Gilbert and Maxam 1973). This approach was transformed when Andre Mirzabekov, a Russian scientist, visited Harvard in 1975. Working at the Institute of Molecular Biology, Academy of Science of the U.S.S.R. in Moscow, Mirzabekov had shown that binding of histones and antibiotics to DNA could inhibit methylation of purines by dimethylsulfate. He urged Gilbert to find out whether binding of the repressor could block methylation of the operator DNA and to identify which bases in the sequence were protected. During discussion of this problem with Mirzabekov, Alan Maxam, and Jay Gralla over a lunch, Gilbert had the idea that ultimately became the basis of the chemical sequencing technique. If a DNA fragment could be labeled at one end with a radioactive phosphate group and then subjected to partial degradation with base-specific chemical reactions, the position of each base in the chain could be determined by measuring the distance between the labeled end and the point of breakage. By 1976, it was clear that the method could be used to locate adenine and guanine residues in short fragments (~40 nucleotides) of DNA. Knowing the locations of the two purine bases on each of the two comple-

mentary strands of DNA, one could, in principle, deduce a complete DNA sequence. The next year was spent in developing differential methods to cleave cytosine and thymine residues and thus to position two pyrimidine bases in a DNA sequence. By 1977, Maxam and Gilbert were able to publish a description of the complete sequencing technique (Maxam and Gilbert 1977).

From the date of this first publication until today, the chemical method of sequencing has undergone a continuous series of refinement and improvements. The number of base-specific cleavage reactions has increased, and their efficiency and discrimination have gradually improved to the point where 200–400 bases may be routinely read from the point of labeling. However, none of these improvements have been sufficient to save chemical sequencing from decline. Toxic chemicals, large amounts of radioactivity, sequencing gels that were sometimes ambiguous and all too often ugly, and most recently, the lack of automated methods to prepare end-labeled templates have all contributed significantly to the eclipse of the method by the chain-termination technique.

THE SANGER METHOD OF DNA SEQUENCING BY DIDEOXY-MEDIATED CHAIN TERMINATION

The first group of protocols in this chapter deals with the practical aspects of the chain-termination method of DNA sequencing. This introduction describes the general principles of the method and the strategies commonly used to bring sequencing projects to fruition.

General Principles

A synthetic oligonucleotide primer is annealed to a single-stranded DNA template. Four different sequencing reactions are set up each containing a DNA polymerase and the four normal dNTPs. One of the precursors or, in some cases, the primer is labeled radioactively with ^{32}P, ^{33}P, or ^{35}S or with a nonradioactive fluorescent tag. The four reactions also contain a small proportion of a 2′,3′-ddNTP that carries a 3′-H atom on the deoxyribose moiety, rather than the conventional 3′-OH group. If a ddNTP molecule is incorporated into a growing DNA chain, the absence of a 3′-OH group prevents formation of a phosphodiester bond with the succeeding dNTP: Further extension of the growing chain is impossible. Thus, when a small amount of one of the ddNTPs is included with the four conventional dNTPs in a reaction mixture for DNA synthesis, there is competition between extension of the chain and infrequent, but base-specific, termination (please see Figure 12-1). The products of the reaction are a population of oligonucleotide chains whose lengths are determined by the distance between the 5′ terminus of the primer used to initiate DNA synthesis and the sites of chain termination. In a sequencing reaction containing ddA, for example, the termination points correspond to all positions normally occupied by a deoxyadenosyl residue. By using the four different ddNTPs in four separate enzymatic reactions, populations of oligonucleotides are generated that terminate at positions occupied by every A, C, G, or T in the template strand. These populations of oligonucleotides can be separated by electrophoresis, and the locations of each band can be ascertained by autoradiography or the emission of fluorescence. When the four populations are loaded into adjacent lanes of a sequencing gel, the sequence of the newly synthesized strand can be read in a 5′-3′ orientation by calling the order of bands from the bottom to the top of the gel.

Primers

In enzymatic sequencing reactions, priming of DNA synthesis is achieved by the use of a synthetic oligonucleotide complementary to a specific sequence on the template strand. In many cases, this

template is obtained as a single-stranded DNA molecule by cloning the target DNA fragment into a bacteriophage M13 or phagemid vector (please see Chapter 3). However, it is also possible to use the Sanger method, albeit with some loss of efficiency, to sequence denatured, double-stranded DNA molecules (e.g., denatured plasmid DNA). In either case, the problem of obtaining primers that are complementary to an unknown sequence of DNA is then solved by using a "universal" primer that anneals to vector sequences flanking the target DNA. Universal primers are typically 15–30 nucleotides in length and are available from a large number of commercial companies. In addition, many companies sell primers that have been designed to allow sequencing of target DNAs cloned into a variety of restriction sites in different vectors. For details of primers that are commercially available, please see Appendix 6.

Templates and Strategies

One of the virtues of the Sanger method of sequencing is its ability to accommodate many different types of DNA templates and many types of sequencing strategies. For example, templates can be:

- ***Single-stranded DNA isolated from recombinant M13 bacteriophages*** (please see Chapter 3 and Protocol 1). Alternatively, single-stranded templates can be generated synthetically in asymmetric PCRs (Innis et al. 1988; Wilson et al. 1990) (please see Chapter 8).
- ***Double-stranded plasmid DNA that has been denatured by heat or alkali*** (Chen and Seeburg 1985) (please see Protocol 2).
- ***Double-stranded PCR-amplified DNA denatured by heat or alkali*** (Gyllensten and Allen 1993; Rao 1994) (please see Protocol 2).
- ***Double-stranded DNA digested with an exonuclease to expose a single-stranded template*** (Higuchi and Ochman 1989; E. Lee et al. 1992).
- ***Double-stranded DNA denatured by heat during cycle sequencing*** (Murray 1989) (please see Protocol 6).

Faced with these possibilities, it is important to develop an overall strategy that takes into account the size of the region to be sequenced, the accuracy required of the sequence, the nature and amount of the template required, and the resources available. PCR-based methods have the advantage of by-passing time-consuming steps of cloning and purification of template DNA and allowing nucleotide sequences to be determined from crude templates, for example, lysates of cultured cells, viruses, bacteriophages, and bacteria. These methods are therefore ideal to determine the sequence of a specific region of genomic DNA (e.g., an individual exon of a mammalian gene). On the other hand, shotgun libraries constructed in bacteriophage M13 are preferred for large-scale projects where the goal is to accumulate long tracts of virgin sequence. Virtually all of these large-scale projects are carried out in sequencing factories equipped with assembly lines of robotic devices and automated machines to perform each stage of the process, from preparation of single-stranded templates to harvesting of the nucleotide sequence. By contrast, confirmatory sequencing (e.g., of mutants generated by oligonucleotide-mediated mutagenesis) often requires no more than one set of sequencing reactions to verify the order of nucleotides in a local region of one of the two strands of DNA. Although sequencing on this small scale can be simple and enjoyable, most laboratories today buy DNA-sequencing kits and use automated machines maintained in institutional core facilities to carry out their DNA sequencing. As a consequence, the laboratory often has little more to do than settle a monthly account in order to establish a nucleotide sequence.

Choosing a Sequencing System

The majority of double- and single-stranded DNA templates can be sequenced without great difficulty at moderate temperatures (37°C) by enzymes specially tailored to the task (e.g., Sequenase). About 10% of templates, however, present problems that result for the most part from:

- ***The base composition of the template.*** The higher the GC content of the template, the higher its potential to form knotty secondary structures that obstruct the passage of DNA polymerases. Because secondary structures are less stable at high temperature, cycle sequencing or high-temperature isothermal sequencing is the preferred technique for GC-rich templates.
- ***The base sequence of the template.*** Cycle-sequencing reactions should not be used to sequence template DNAs suspected of containing a repeating sequence, for example, a dinucleotide repeat. Such regions often produce bands that are highly variable in intensity in all four channels of sequencing gels. This problem can sometimes be alleviated by using 5′ ^{32}P-labeled oligonucleotides to prime high-temperature isothermal or cycle-sequencing reactions. Frequently, repetitive tracts yield cleaner sequences in reactions catalyzed at low temperature by enzymes such as Sequenase or the Klenow fragment of *E. coli* DNA polymerase I.
- ***The amount of template.*** Cycle sequencing with its in-built amplification of signal is the method of choice when the template DNA is in short supply.

End Labeling or Internal Radiolabeling?

End-labeled oligonucleotide primers reduce the frequency and intensity of sequencing artifacts, most of which are caused by nonspecific priming by fragments of contaminating DNA or RNA. These terminally labeled primers are preferred when sequencing DNA templates that tend to generate messy sequencing ladders, for example, sequencing impure DNA preparations from bacterial colonies or bacteriophage M13 plaques, or large DNAs, such as bacteriophage λ and cosmids. When using end-labeled primers, all DNA chains become labeled to an equal extent regardless of their length. The intensity of the bands is therefore equal throughout the whole length of the gel. Sequencing ladders obtained from reactions primed by labeled oligonucleotides are therefore far easier to read than ladders produced in conventional sequencing reactions containing unlabeled primers and radiolabeled dNTPs.

Primers can be labeled at their 5′ ends by transfer of the γ-phosphate from [γ-^{32}P]ATP or [γ-^{33}P]ATP in a reaction catalyzed by bacteriophage T4 polynucleotide kinase. Labeling with ^{32}P results in shorter exposure times and costs less per reaction than ^{33}P. However, the weaker β particles emitted from ^{33}P generate sharper bands during autoradiography, which is an advantage when longer reads are required. In addition, primers and sequencing products labeled with ^{33}P suffer less radiolytic damage and can be stored for several weeks at –20°C.

[α-^{35}S]dATP is an analog of dATP in which a sulfur atom replaces a nonbridge oxygen atom on the α-phosphate. The lower energy of the β particles emitted by ^{35}S sharpens the image of bands on sequencing gels (Biggin et al. 1983). As with ^{33}P, the longer half-life of ^{35}S allows the radioisotope and the completed sequencing reactions to be stored for several weeks without damage. ([γ-^{35}S]ATP is not a good substrate for polynucleotide kinase and is transferred inefficiently to 5′-hydroxyl groups.)

Which Enzyme? Which Protocol? Which Kit?

A first-time sequencer who wants to use low-temperature isothermal DNA sequencing with radioactive dNTPs or radiolabeled primers should probably look no further than the kits sold by U.S. Biochemicals containing Sequenase, version 2.0. Like kits supplied by manufacturers of other enzymes, Sequenase kits contain almost everything required for isothermal sequencing, from a template DNA for use as a positive control to sets of comprehensive didactic instructions. A method to sequence using Sequenase is described in Protocol 3.

Kits provide a fast and easy way to gain some experience and confidence, but they are too expensive for routine use. Therefore, the casual sequencer who generates small numbers of templates from time to time should consider replacing the various components of the kit with homemade reagents and buying in bulk the enzyme(s) used to catalyze sequencing reactions.

At some point, when preparation of templates becomes a chore, the sequencer may want to switch to cycle sequencing (Protocol 6), again beginning with a kit. Here the choices are many and varied, but the decision among them depends on the available detection facilities. If a traditional radioactive detection system is used, a kit containing a thermostable enzyme engineered to remove 5′–3′ exonuclease activity should be adequate. Obviously, it would be better to use an enzyme carrying a mutation that abolishes the preference for incorporation of dNTPs over ddNTPs (for examples of these modified enzymes, please see Table 12-9 in Protocol 5). However, these enzymes are at present significantly more expensive. All of the enzymes listed in Table 12-9 can be obtained in kit form. Some also contain a thermostable pyrophosphatase to suppress pyrophosphorolysis and thereby reduce variation in band intensity.

Finally, the more serious sequencer will need to use some form of automated DNA-sequencing facility using fluorescent detection methods. The services offered by these facilities vary widely. In some, the users bring (or mail) their completed sequencing reactions to the facility for separation by electrophoresis and capture of data on automated machines. In others, the facility carries out all steps of the sequencing process from template preparation to analysis of results. Whatever the arrangement, the sequencing protocols will almost certainly be defined by the facility, based on the expertise and the equipment available. Many facilities provide a range of kits (homemade and/or commercial) at reduced prices to their users.

This chapter is a compendium of information about DNA sequencing. The first section of the chapter deals chiefly with the enzymatic method of sequencing and contains protocols describing the production of templates and primers and the assembly of sequencing reactions. The second part focuses on the chemical method of sequencing, whereas the third and final section deals with the pouring and running of DNA sequencing gels. Computational and robotic aspects of sequencing are discussed in the information panels at the end of this chapter.

Protocol 1

Generation of a Library of Randomly Overlapping DNA Inserts

ALMOST ALL MOLECULAR BIOLOGISTS ARE FACED at some time in their career with the challenge of sequencing a large segment of DNA that has been cloned into a high-capacity vector such as a cosmid, bacterial artificial chromosome, or bacteriophage P1 artificial chromosome. Efficient sequencing of a cloned DNA fragment more than a few kilobases in size requires access to a high-throughput, automated DNA sequencing facility. If such a facility is available, sequencing projects of this magnitude, which until a few years ago were beyond the reach of most laboratories, are now within the capacity of any competent group.

Most large-scale sequencing projects rely on a shotgun strategy, which involves random fragmentation of the target region into small segments that can be subcloned into a bacteriophage M13 vector (Anderson 1981; Deininger 1983; Messing 1983; Baer et al. 1984; Bankier et al. 1987). The goal is to create a library of overlapping clones that provide at least fivefold sequence redundancy over the entire target fragment. Each of these clones contains a random segment of target DNA located next to a primer-binding site that can be used repeatedly to derive, on automated DNA sequencers, 600–800 nucleotides of DNA sequence. Clones chosen at random from the library are used as templates until the nucleotide sequence of at least 95% of both strands of the target DNA has been captured. Where gaps and ambiguities remain, directed sequencing is used to complete the sequence (e.g., please see Edwards et al. 1990). The accumulated data are stored managed and assembled with the aid of computer programs (e.g., please see Dear and Staden 1991; Bonfield et al. 1995; Huang 1996; Dear et al. 1998). Please also see the collection of electronic resources in Appendix 11. Two methods are used to cleave double-stranded DNA into fragments of a suitable size for shotgun sequencing.

- ***Hydrodynamic shearing.*** Hydrodynamic forces are generated in a number of different ways, a few of which are listed in Table 12-1. In each case, breakage of DNA results from drag forces that first stretch and then break the phosphodiester backbone in the central regions of double-stranded DNA molecules (for discussion, please see Oefner et al. 1996). Because breakage tends to occur in the center of DNA molecules, the ends of the original DNA molecule are underrepresented in shotgun libraries generated by hydrodynamic shearing. This problem can be alleviated by ligating the DNA into concatemers before exposing it to hydrodynamic shear.
- ***Enzymatic Cleavage.*** In the presence of Mn^{2+}, or when very high concentrations of the enzyme are used in the absence of monovalent cations, DNase I breaks both strands of double-stranded DNA simultaneously at approximately the same site (Melgar and Goldthwait 1968; Campbell

and Jackson 1980). Under these conditions, the enzyme displays very little sequence specificity and cleaves all regions of the molecule (except for the terminal nucleotides) at an equal rate. As a consequence, the fragments generated by DNase I digestion have a relatively broad size distribution. Only a small fraction of the fragments are useful for cloning and sequencing.

Until recently, restriction enzymes were seldom used to generate fragments for shotgun sequencing. Because complete digestion of DNA with a single restriction enzyme results in nonoverlapping fragments, separate libraries constructed from digests generated by several different restriction enzymes would be necessary to provide overlap between fragments. Partial digestion has been an unattractive option because regions of DNA with very few restriction sites would be underrepresented in shotgun libraries. However, this problem has been solved by the discovery of conditions under which the enzyme *CviJI* cuts DNA at the sequences PyGCPy and PuGCPu, generating blunt-ended fragments (Xia et al. 1987; Fitzgerald et al. 1992). Under these "relaxed" conditions, the enzyme finds a potential cleavage site every 16–64 bases in DNA. DNA fragments of ~1 kb obtained by partial digestion of cosmid-sized DNAs with *CviJI* contain many potential sites and show little representational bias (Gingrich et al. 1996). Table 12-1 summarizes the strengths and weaknesses of the various methods used to generate overlapping fragments for shotgun sequencing.

TABLE 12-1 Methods Currently Used to Fragment DNA for Shotgun Sequencing

METHOD		PROS AND CONS	REFERENCES
Hydrodynamic shear	sonication	Requires relatively large amounts of DNA (10–100 μg); fragments of DNA distributed over a broad range of sizes; only a small fraction of the fragments are of a length suitable for cloning and sequencing. Requires ligation of DNA before sonication and end-repair afterward; DNA may be damaged by hydroxyl radicals generated during cavitation (McKee et al. 1977).	Deininger (1983)
	nebulization	Easy and quick; requires only small amounts of DNA (0.5–5 μg) and large volumes of DNA solution; no preference for AT-rich regions. Size of fragments easily controlled by altering the pressure of the gas blowing through the nebulizer; fragments of DNA distributed over a narrow range of sizes (700–1330 bp); requires ligation of DNA before nebulization and end-repair afterward.	Bodenteich et al. (1994); Hengen (1997)
	circulation through an HPLC pump	Requires expensive apparatus, ligation of DNA before sonication, and 1–100 μg of DNA; fragments of DNA distributed over a narrow range of sizes that can be adjusted by changing the flow rate; end-repair of fragments before cloning not necessary.	Oefner et al. (1996)
	passage through the orifice of a 28-gauge hypodermic needle	Cheap, easy, and requires only small amounts of DNA; however, the fragments are a little larger (1.5–2.0 kb) than required for shotgun sequencing; requires ligation of DNA before cleavage and end-repair afterward.	Davidson (1959, 1960); Schriefer et al. (1990)
Enzymatic cleavage	partial digestion with the restriction enzyme *CviJ1*	Cheap, easy, and requires no special equipment; only small amounts of DNA necessary (0.5–5 μg); ligation of DNA before digestion desirable but end-repair of digested DNA unnecessary. Variable rate of digestion from experiment to experiment; each new batch of *CviJ1* must be calibrated.	Fitzgerald et al. (1992); Gingrich et al. (1996)
	cleavage by DNase I in the presence of Mn^{2+}	Like sonication, generates fragments with a wide distribution of sizes; only a small fraction of the fragments are of a suitable length for cloning and sequencing; requires end-repair after cleavage. Variable rate of digestion from experiment to experiment; each new batch of DNase I must be calibrated.	Anderson (1981)

Many aspects of DNA sequencing have been automated, for example, the use of robotic workstations to assemble dideoxy-mediated sequencing reactions and the automatic reading and transfer of fluorescently tagged sequence to computers. For a review of these advances, please see the information panel on **AUTOMATED DNA SEQUENCING.**

The following protocol describes the initial stages of shotgun sequencing, from shearing of the target DNA to establishment of a library of fragments in a bacteriophage M13 vector, and outlines two methods — sonication and nebulization — to break a double-stranded target DNA into overlapping pieces and to polish the ragged ends with DNA polymerases. The fragments are then fractionated according to size by agarose gel electrophoresis. After recovery from the gel, the fragments are ligated with the DNA of a bacteriophage M13 cloning vector. The products of the ligation reaction are introduced into a suitable strain of *E. coli*, and a library of recombinant bacteriophage M13 clones is established. Single-stranded DNA templates are then prepared from individual clones grown in a 96-well format, essentially as described by Zollo and Chen (1994). Figure 12-2 illustrates the steps involved in random sequencing. Subsequent protocols describe how clones selected at random from this library are used as templates in dideoxy-mediated chain-termination sequencing reactions and how the DNA sequence is completed and assembled.

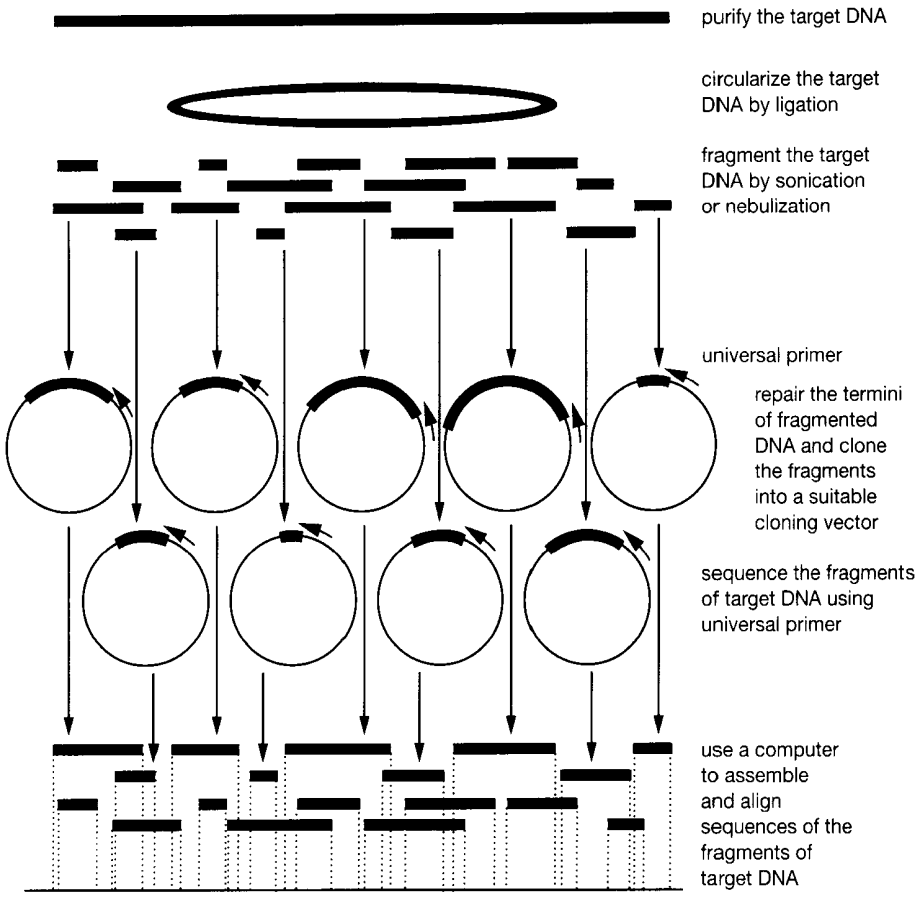

FIGURE 12-2 The Strategy for Random Sequencing

Please see text for details.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Ammonium acetate (10 M)

ATP

Optional, please see Step 1.

Ethanol

Glycerol (sterile, 100%)

H_2O (deionized distilled)

IPTG

$MgCl_2$

NaCl

Phenol (saturated with Tris at pH 7.6) <!>

Phenol:chloroform (1:1, v/v) <!>

Polyethylene glycol (30% w/v PEG 8000) <!>

Optional, please see note to Step 1.

Polyethylene glycol (20% w/v PEG 8000) in 2.5 M NaCl

TE (pH 7.6)

10x TM buffer

0.5 M Tris-Cl (pH 8.0)

150 mM $MgCl_2$

TTE buffer

0.5% Triton X-100 in TE (pH 8.0)

X-gal

Enzymes and Buffers

Bacteriophage T4 DNA ligase

Bacteriophage T4 DNA polymerase

Bacteriophage T4 polynucleotide kinase

Klenow fragment of E. coli *DNA polymerase I*

Gels

Agarose gels (two 1% and one 0.7%)

Polyacrylamide gel (neutral, 5% polyacrylamide) <!> or *Agarose gel (0.8% low-melting-point agarose)*

Nucleic Acids and Oligonucleotides

Bacteriophage λ or ϕX174 DNA, cleaved to completion with AluI *(1 μg in a volume of 20 μl of TE (pH 7.6)*

After digestion, remove the restriction enzyme from the DNA by extraction with phenol:chloroform. Recover the DNA by precipitation with ethanol and dissolve in TE (pH 7.6). The digested DNA will be used to check the efficiency of ligation of the dephosphorylated, linearized vector as described in Step 13. The digested DNA is not required if commercial preparations of vector are used.

DNA size markers

Appropriate size markers are, for example, fragments generated by digestion of pUC18 or pUC19 DNA with *Sau*3AI, or the 123-bp ladder sold by Life Technologies, or ϕX174 DNA digested with *Hae*III (New England Biolabs).

dNTP solution containing all four dNTPs, each at 2.0 mM

Target DNA

Target DNA is usually prepared by digesting a recombinant constructed in a high-capacity vector (e.g., cosmid, BAC, PAC, or P1) with a restriction enzyme that does not cleave within the cloned sequences. Wherever possible, use a restriction enzyme that generates cohesive termini. This simplifies ligation of the purified target DNA into concatemers (Step 1). After release from the vector, purify the target DNA by electrophoresis through a gel cast with low-melting-temperature agarose (please see Chapter 5, Protocol 6 or 7). Dissolve the purified DNA in TE (pH 7.6) at a concentration of 1 mg/ml. Check the integrity and recovery of the purified DNA by analyzing an aliquot (50 ng) by agarose gel electrophoresis.

Media

LB or 2x YT medium containing 5 mM $MgCl_2$

Top agarose

YT agar plates

Centrifuges and Rotors

Centrifuge capable of spinning deep-well microplates and standard microtiter plates at 3000 rpm

For example, Beckman GPR centrifuge equipped with a "Microplus" carrier or a Jouan Model CR 422 equipped with a swing-out rotor (M4 type) and microplate adaptors.

Special Equipment

Deep-well microplates, lids, and caps

The wells should have a 1–1.2-ml capacity and be capable of withstanding centrifugation at 3000 rpm. An example is 96-well flat-bottomed Bioblock (DBM Scientific, San Fernando, California) and caps (V3-Verl-Tips-Cover, Ulster Scientific; order through Baxter Inc., McGaw Park, Illinois). An alternative is the Beckman 96-tube box equipped with tubes fitted with a one-piece lid and a cap. Two boxes with lids and one cap are required to prepare 96 M13 templates.

Microtiter plates (96-well, fitted with lids)

Please see the information panel on **MICROTITER PLATES**.

Multichannel pipettor (8 or 12 channels)

Multitube vortex mixer

Silver tape (3M Corporation) or equivalent

The tape must be capable of effecting a watertight seal across the 96-tube box. The R.S. Hughes Co. (http://www.rshughes.com) distributes this 3M silver tape in the United States and Mexico.

Sonicator or Nebulizer

Please see Appendix 8.

For sonication, use either a microtip probe sonicator or a cup-horn sonicator. In this protocol, we recommend a cup horn sonicator (e.g., Heat Systems model XL2015 with a CL4 cup horn probe) for two reasons: (1) The DNA is contained in a small volume (20–25 µl) within a microfuge tube and (2) there is no contamination by a metal probe because the probe of the cup horn sonicator does not touch the DNA solution.

For nebulization, modify a disposable therapeutic nebulizer (IPI Medical Products, model 4207) as described in Appendix 8.

Toothpicks

Water baths preset to 16°C, 37°C, 68°C, and 80°C

Vectors and Bacterial Strains

Bacteriophage M13 vector DNA, equipped for blue-white screening, linearized, blunt-ended, and dephosphorylated

Vector DNAs of this type may be purchased ready-made from several commercial vendors. Otherwise, prepare the vector DNA as described in the additional protocols at the end of this protocol.

E. coli *competent cells of an appropriate strain (e.g., XL1F′-Blue, DH5αF′)*

To obtain a library that covers the target DNA to the greatest depth, it is important that the efficiency of transfection of *E. coli* be as high as possible (>10^9 transfectants/µg of closed circular vector DNA). Preparations of competent *E. coli* that can be transformed with high efficiency may be purchased ready-made from several commercial vendors or may be prepared as described in Chapter 1, Protocols 23–26. If an electroporation apparatus is available, we recommend using preparations of electrocompetent *E. coli*, because of their higher efficiencies of transformation.

METHOD

Self-ligation of the Target DNA

Self-ligation is required to ensure that sequences at the ends of the target DNA are adequately represented in the population of fragments used to construct the library.

1. Transfer 5–10 µg of the purified target DNA (see Materials) to a fresh microfuge tube and add:

10X bacteriophage T4 DNA ligase buffer	2.5 µl
5 mM ATP	2.5 µl
30% w/v PEG 8000 (*optional*)	5.0 µl
bacteriophage T4 DNA ligase	0.5–2.0 Weiss units
H_2O	to 25 µl

Incubate the mixture for 4 hours at 16°C, and then inactivate the ligase by heating the mixture for 15 minutes at 68°C.

If the target DNA is blunt-ended, include PEG in the reaction to increase the efficiency of ligation.

Use 0.5 Weiss unit for cohesive termini, and 2.0 Weiss units for blunt termini.

Some commercial ligase buffers contain ATP. When using such buffers, the addition of ATP is not required.

2. Add 175 µl of TE (pH 7.6), and purify the ligated DNA by extraction with phenol:chloroform. Recover the ligated DNA by precipitation with 3 volumes of ethanol in the presence of 2.0 M ammonium acetate. After centrifugation at maximum speed for 5 minutes in a microfuge, wash the pellet with 0.5 ml of 70% ethanol at room temperature and centrifuge again.

3. Remove as much of the supernatant as possible and allow the last traces of ethanol to evaporate at room temperature. Dissolve the DNA in 25 µl of TE (pH 7.6) in a microfuge tube.

Fragmentation of the Target DNA

This step was adapted from Birren et al. (1997, pp. 419–422 with permission).

4. Fragment the target DNA into segments 0.8–1.5 kb in length by sonication or nebulization (please see Table 12-1).

TO FRAGMENT THE DNA BY SONICATION (PLEASE SEE FIGURE 12-3)

a. Place ice water in the cup horn of the sonicator. Set the sonicator power switch to on, the timer to hold, and the power setting to 10. Apply two 40-second pulses, and allow the sonicator to warm up.

The ice water helps prevent denaturation of the DNA. It is advisable to replace the ice water in the cup horn before each sample is sonicated.

b. Place the tube containing the DNA in the ice water such that the bottom of the tube is 1–2 mm above the hole in the center of the cup horn probe (please see Figure 12-3), and sonicate the DNA.

Establish the appropriate conditions for sonication (the power setting and the number and duration of pulses) by sonicating a test sample of DNA and analyzing the results as described in Step d. For most DNA samples, two 6-second pulses at a power setting of 3 typically produce fragments of 500–2000 bp.

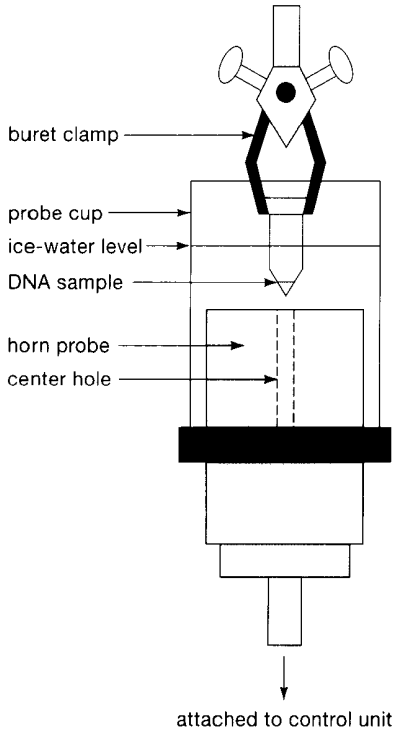

FIGURE 12-3 Cup Horn Sonicator for Random Fragmentation of DNA

The cup horn attachment for a Heat Systems sonicator is depicted with a sample tube in place. The cup horn unit, which contains a large horn probe, is attached to the sonicator control unit and filled with ice water before the sample is sonicated. Typically, the sample tube is held in place from above by using a buret clamp and a ring stand. Alternatively, a tube holder can be fabricated from 1/4-inch plastic and used to hold up to eight tubes for simultaneous processing. (Redrawn, with permission, from Birren et al. 1997.)

c. Centrifuge the tube briefly to collect the sonicated DNA sample at the bottom of the tube and place it on ice.

d. Analyze 1 µl of the sonicated DNA sample with the appropriate molecular-weight markers by electrophoresis through a 0.7% agarose gel. Keep the remainder of the DNA on ice while the gel is running.

If the desired size range of sheared DNA has not been obtained, sonicate the sample again using altered conditions. If the size range is acceptable, proceed with end-repair of the DNA as described in Step 5.

TO FRAGMENT THE DNA BY NEBULIZATION (PLEASE SEE FIGURE 12-4)

a. Prepare the following DNA solution and place it in the nebulizer cup.

DNA sample (from Step 3)	5–10 µg
10x TM buffer (pH 8.0)	200 µl
sterile 100% glycerol	1 ml
sterile H_2O	to a final volume of 2 ml

b. Place the DNA sample in an ice-water bath and nebulize using the empirically determined optimal conditions.

The size of the DNA fragments is determined primarily by the pressure of the nitrogen gas. For example, a pressure of 8 psi (0.56 kg/cm^2) typically shears cosmid DNA into fragments of 1000–2500 bp. The optimal pressure and length of time for nebulization should be established empirically for each type of target DNA when this method is first used.

As with sonication, the use of an ice-water bath prevents degradation of the DNA and is therefore important for generating an even distribution of DNA fragment sizes.

c. Place the nebulizer in a suitable centrifuge rotor and cushion it with pieces of styrofoam. Centrifuge at 2000*g* (1000 rpm in a centrifuge equipped with a microplate adaptor) briefly at 4°C to collect the DNA sample at the bottom of the nebulizer cup.

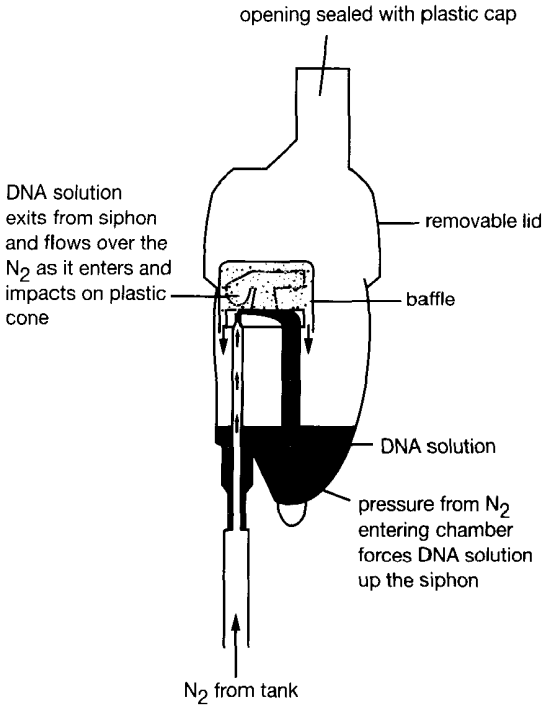

FIGURE 12-4 Nebulizer for DNA Fragmentation

A viscous DNA solution containing glycerol is placed in the nebulizer. The nebulizer is attached to a nitrogen tank. Pressure from the nitrogen entering the chamber syphons the DNA solution from the bottom of the chamber to the top. The solution exits the siphon and impacts on a small plastic cone suspended near the top of the chamber, thus shearing the DNA.

d. Divide the DNA sample into four equal aliquots in 1.5-ml microfuge tubes, carry out standard ethanol precipitation of the DNA, and dry the DNA pellets under vacuum.

e. Dissolve each DNA pellet in 35 µl of TE (pH 7.6), and analyze 1 µl of the sheared DNA with appropriate molecular-weight markers by electrophoresis through a 0.7% agarose gel. Keep the remainder of the DNA at 4°C while the gel is running.

If the desired size range of sheared DNA has not been obtained, fragment the sample again using altered conditions. If the size range is acceptable, proceed with end-repair of the DNA as described in Step 5.

Repair, Phosphorylation, and Size Selection of DNA

The termini produced by nebulization and sonication are highly heterogeneous, consisting of blunt-ended and frayed ends, with and without phosphate residues. Because only a fraction of these molecules can be repaired by DNA polymerases, the efficiency with which hydrostatically sheared DNA can be cloned in bacteriophage M13 vectors is generally low. However, 5–10 µg of sonicated, repaired, and size-selected target DNA generally yields several thousand recombinant clones.

5. To the fragmented DNA (~25 µl) add:

10x bacteriophage T4 DNA polymerase buffer	4.0 µl
2.0 mM solution of four dNTPs	4.0 µl
bacteriophage T4 DNA polymerase	5 units
H_2O	to 40 µl

Incubate the reaction for 15 minutes at room temperature, and then add ~5 units of the Klenow fragment. Continue incubation for a further 15 minutes at room temperature.

This reaction uses two DNA polymerases to repair the frayed ends of the DNA fragments generated during hydrodynamic shearing. Bacteriophage T4 DNA polymerase catalyzes filling of recessed 3′ termini and the exonucleolytic removal of protruding 3′ termini: The Klenow fragment provides a second means to fill recessed 3′ termini. Please see the information panel on **THE KLENOW FRAGMENT OF *E. COLI* DNA POLYMERASE I.**

6. Purify the DNA by extraction with phenol:chloroform. Transfer the aqueous (upper) phase to a fresh tube, and adjust the solution to 0.1 M NaCl. Recover the DNA by precipitation with 2 volumes of ethanol. Wash the pellet with 70% ethanol.
7. Redissolve the precipitated DNA in 25 µl of TE (pH 7.6).
8. Combine the following in a microfuge tube:

fragmented DNA	23 µl
10x polynucleotide kinase buffer	3 µl
20 mM ATP	3 µl
bacteriophage T4 polynucleotide kinase	1 unit

Bacteriophage T4 polynucleotide kinase catalyzes the phosphorylation of the 5′ termini of the blunt-ended DNA fragments. This step is not mandatory, but, in most cases, leads to more efficient ligation of the fragments to the vector.

9. Incubate the reaction for 30 minutes at 37°C.
10. Purify the fragments of DNA of the desired size (0.8–1.5 kb) by electrophoresis through a low-melting-temperature agarose gel (0.8%) or 5% neutral polyacrylamide gel (see Chapter 5).

To minimize the possibility of contamination, leave several lanes empty between the fragmented target DNA and the molecular-weight markers. This is especially important when using blunt-ended DNAs as markers since these are ligated to the vector DNA with much higher efficiency than the sheared target DNA.

11. Recover the target DNA from the gel by one of the methods described in Chapter 5. Dissolve the purified DNA in 25 µl of TE (pH 7.6).
12. Check the integrity and recovery of the purified DNA by analyzing an aliquot (1.0 µl) by electrophoresis through a 1% agarose gel.

Ligation to Vector DNA

13. Set up a series of test ligations containing 50 ng (~0.01 pmole) of linearized and dephosphorylated vector DNA and increasing concentrations of fragmented, blunt-ended, phosphorylated target DNA (please see Table 12-2).

TABLE 12-2 Test Ligation Reactions of Dephosphorylated Vector DNA

Tube	Type of DNA[a] A	B	C	H_2O (µl)	10x Ligation Buffer (µl)	ATP (5 mM) (µl)[b]	T4 DNA Ligase (Weiss Units)	30% PEG (Optional)[c] (µl)
1	+			5.0	1.0	1.0	2.0	1.6
2	+			6.0	1.0	1.0	–	1.6
3	+	+		3.0	1.0	1.0	2.0	1.6
4	+		+	3.0	1.0	1.0	2.0	1.6
5	+		+	3.0	1.0	1.0	2.0	1.6
6	+		+	3.0	1.0	1.0	2.0	1.6
7	+		+	3.0	1.0	1.0	2.0	1.6

[a] A = 50 ng of linearized, dephosphorylated vector (in a volume of 2 µl); B = 20 ng of bacteriophage λ DNA or ϕX174 RF DNA cleaved to completion with *Alu*I (in a volume of 2 µl); C = fragmented, blunt-ended, phosphorylated target DNA. Tubes 4, 5, 6, and 7 should contain 10, 20, 50, and 100 ng of size-selected, fragmented target DNA, respectively (100 ng of size-selected fragments = ~0.1 pmole).

[b] Some commercial ligase buffers contain ATP. When using such buffers, omit the ATP.

[c] The efficiency of ligation can be increased by adding PEG 8000 (30% w/v) to a concentration of 5% in the final ligation mixture (see Chapter 1, Protocol 19). It is important to warm the stock solution of PEG 8000 to room temperature before adding it as the last component of the ligation reactions. DNA can precipitate at cold temperatures from solutions containing PEG 8000.

14. Introduce aliquots of the test ligations into competent *E. coli* of the appropriate strain by electroporation or transformation (please see Chapter 1, Protocols 23–26). Plate the bacteria on media containing IPTG and X-gal. Incubate the plates overnight at 37°C.

    The purpose of this step is to find a concentration of fragmented target DNA that minimizes the number of recombinants containing artificially fused target fragments, which can complicate assembly of the final DNA sequence. When setting up a large-scale ligation reaction (Step 16), avoid using saturating quantities of target DNA; instead, use an amount of target DNA that produces a modest increase (~5-fold) in the number of recombinant clones over background.

15. The following day, count the number of blue and colorless plaques.

    The number of recombinants obtained with fragmented, blunt-ended target DNA should be ~10-fold lower than the number obtained with an equivalent amount of blunt-ended DNA prepared by restriction digestion (e.g., the *Alu*I-digested λ or ϕX174 DNA used in the initial test ligations).

    If the yield of clones is low, treat the preparation of DNA fragments successively with calf alkaline phosphatase and mung bean nuclease, and then repeat Steps 5–15 of this protocol. For protocols on treating DNA with CIP and mung bean nuclease, please see Chapter 1, Protocol 20.

16. Set up a large-scale ligation reaction using the minimum amount of fragmented, blunt-ended target that will yield sufficient recombinant clones to complete the sequencing project and transform *E. coli* with the ligated DNA. Incubate the plates overnight at 37°C.

    The goal is to cover the target fragment with at least a fivefold redundancy of recombinant clones. Figure 12-5 shows graphical plots of the approximate number of clones that must be sequenced to achieve 95% coverage of a double-stranded target DNA.

17. The following day, collect the plates and store the resulting transformants under the appropriate conditions until required. Prepare template DNAs from a series of individual colorless plaques as described in Chapter 3, Protocol 4.

    Pick and propagate recombinant bacteriophage M13 plaques as soon as possible (please see the panel on **PICKING PLAQUES** in Chapter 3, Protocol 2). Since the bacteriophage particles diffuse considerable distances through the top agar, plaques grown for extended periods of time (>12–16 hours) at 37°C or stored for a few days at 4°C frequently become contaminated. Both the intensity and number of background bands increase when single-stranded DNAs prepared from old plaques are used in sequencing reactions.

Growth of Recombinant Clones of Bacteriophage M13 in a 96-tube Format

Individual colorless plaques, picked as described in Chapter 3, Protocol 2, may be grown in 2-ml bacterial cultures in 15-ml tubes. The recombinant virus particles can then be recovered and DNA purified from each individual culture (Chapter 3, Protocols 3 and 4). The template purification procedure is slow and unwieldy, since only one or two dozen clones can be processed at a time. Large-scale sequencing projects typically require many thousands of DNA templates. Preparations of single-stranded DNA simply cannot be produced in a timely and economic fashion by methods that require extraction with organic solvents and multiple centrifugation steps. Instead, mass production of bacteriophage M13 templates for large-scale sequencing generally involves purification of bacteriophage particles or single-stranded DNAs using filtration (Eperon 1986), magnetic beads (Alderton et al. 1992; Wahlberg et al. 1992; Hawkins et al. 1994), or paramagnetic particles (Fry et al. 1992; Wilson 1993) in conjunction with robotic devices (e.g., please see Mardis and Roe 1989; Smith et al. 1990). The equipment and personnel required to feed and manage these devices are beyond the reach of most academic laboratories. However, Zollo and Chen (1994) have described a robust and reproducible method for the growth and preparation of single-stranded DNAs from bacteriophage M13 clones grown in a 96-well format. The templates are required in large numbers to satisfy the appetites of fluorescence-based automated DNA sequencing machines.

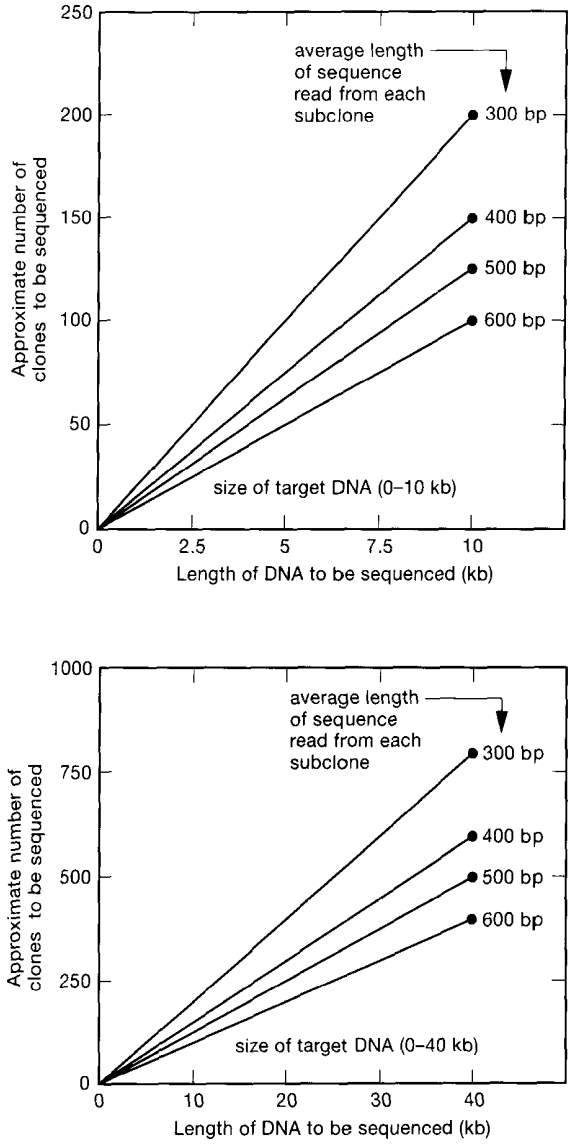

FIGURE 12-5 Approximate Number of Sequences That Must Be Read from Randomly Selected Subclones to Achieve 95% Coverage of a Double-stranded Sequence

The theoretical number of sequences that must be read from randomly selected subclones to achieve 95% coverage of both strands of a sequence (i.e., four- to sixfold sequence redundancy) in a shotgun sequencing project is depicted for 0–10-kb targets (*top*) and 0–40-kb targets (*bottom*). These rough estimates are shown for reading sequences with various average lengths. Project requirements will vary with the sequence composition and complexity of the target DNA and with the presence of repeated sequences. Note that the number of subclones required is based on obtaining sequencing data from subclones that actually contain segments of the target DNA — not from those containing vector DNA or contaminating DNA. (Adapted, with permission, from Birren et al. 1997.)

For shotgun sequencing projects, it is much more efficient to grow the bacteriophage M13 recombinants, 96 at a time, in small-scale bacterial cultures grown in flat-bottomed wells in disposable trays or in disposable tubes arrayed in boxes. All of the subsequent steps involved in preparation of single-stranded DNA templates can be carried out in the same format. Minimizing the work involved in transfer of clones from one step to the next allows one investigator to prepare 960 or more DNA templates in 1 day (please see Zollo and Chen 1994).

18. For each set of 96 clones, inoculate 100 ml of LB medium or 2x YT medium in a 500-ml flask with a single colony of a suitable F′ strain of *E. coli* (e.g. XL1-Blue, XL1-Blue MRF′, or DH5αF′). Incubate the culture for 6–8 hours at 37°C with agitation at 300 rpm or until it enters the early log phase of growth.

19. Add $MgSO_4$ to the culture to a final concentration of 5 mM.

    To maintain balance and symmetry during centrifugation, it is best to grow bacteriophage M13 clones in even-numbered multiples of 96.

    Mg^{2+} increases the yield of bacteriophage M13 and eliminates much of the asynchrony between the growth rate of different clones (Reddy and McKenney 1996).

    Approximately 80 ml of cells are required to grow each set of 96 bacteriophage M13 clones.

20. Use a multichannel pipettor to transfer 0.8-ml aliquots of the cells to individual tubes in a 96-tube box.

21. Wearing gloves, use sterile toothpicks to transfer individual well-separated, colorless bacteriophage M13 plaques into each tube of the 96-tube arrays. Stab the toothpick into the middle of a plaque and then drop the toothpick into the culture tube.

22. To avoid confusion, leave the toothpicks in the tubes until all 96 tubes in the box have been inoculated.

23. When the last plaque has been picked, remove the toothpicks, and seal the box. Label the box and place it in an orbital shaker set at 250–300 rpm and 37°C. Repeat Steps 20 and 21 as needed. Incubate the infected cultures for 8–12 hours.

    If the cultures are incubated for >12 hours, the preparations of single-stranded templates may be contaminated to a significant extent by bacteriophage M13 double-stranded replicative form DNA and/or chromosomal DNA. These DNAs, which originate from lysed bacterial cells, increase the opportunity for mispriming during the dideoxy-sequencing reaction. Longer incubation times also provide opportunities for deletion and for rearrangement of cloned segments of DNA. Short incubation periods are therefore the key to success with this method.

Purification of M13 DNAs

24. Remove the boxes from the incubator and pellet the bacterial cells by centrifugation at 2400*g* (3000–3250 rpm in a centrifuge equipped with a microplate adaptor) for 20 minutes.

    A master stock of bacteriophage M13 clones can be made by mixing 25 µl of 80% glycerol with 50 µl of each of the supernatants. Mix the solutions well by pipetting up and down and store the archival plates at –80°C. These plates serve as a source of infectious bacteriophage if additional preparations of template DNAs are required. This is the last point in the protocol at which archival stocks can be safely made. From this point on in the protocol, there is a high probability of cross-contamination between tubes. This does not matter for DNA sequencing but is unacceptable for archival stocks.

25. Use a multichannel pipettor to transfer 120 µl of 20% PEG 8000 in 2.5 M NaCl to individual tubes in a fresh 96-tube box.

26. Carefully remove the tubes from the centrifuge; use the multichannel pipettor to transfer 0.6 ml of each supernatant to a tube containing the PEG/NaCl solution.

    ▲ **IMPORTANT** Do not disturb the pellet of bacterial cells during this step. Inclusion of bacteria will drastically reduce the quality of DNA sequence obtained.

27. Place a 96-tube cap over the tubes containing the bacteriophage suspensions and PEG/NaCl solution. Make sure that a liquid-tight seal has formed, and then mix the solutions by invert-

ing the box several times. Incubate the box for 30 minutes at room temperature, followed by a 30–60-minute incubation on ice.

28. Collect the precipitated bacteriophage by centrifugation of the boxes at 2400*g* (3000–3250 rpm in a centrifuge equipped with a microplate adaptor) for 30 minutes. Remove a row of tubes and drain the supernatant by inversion over a sink. A small white pellet should be visible on the bottom of each tube. Return the row of tubes to the box.

29. When all of the tubes have been emptied, invert the boxes on a paper towel and allow the last traces of supernatants to drain for a few minutes. Keeping the box in an upside-down position, replace the wet paper towel with a fresh dry towel. Transfer the inverted box-towel combinations to the centrifuge. Remove the last traces of PEG/NaCl solution from the bacteriophage M13 pellets by centrifugation at 300 rpm for 3–5 minutes.

30. Remove the boxes from the centrifuge, check that the pellets have remained in place, and add 20 µl of TTE buffer to each tube.

    If the recombinant bacteriophages have grown well, the pellets should be white and opaque; if grown less well, they should be bluish and opaque. If the pellets have a brownish hue, it is likely that bacterial cells have been accidentally transferred in significant numbers at Step 26. Templates prepared from brown pellets yield poor-quality sequencing data.

31. Seal the tubes with 3M silver foil tape and shake the boxes vigorously on a multitube vortexer for 15–30 minutes.

32. Centrifuge the boxes briefly to bring the solution to the bottom of the tubes. Pry the base from each of the 96-tube boxes and place the tubes in an 80°C water bath for 10 minutes.

    This step lyses the bacteriophage M13 particles. Removing the base of the box ensures that all tubes are incubated at 80°C for the full 10 minutes.

33. Remove the tubes from the water bath and allow them to cool to room temperature. Replace the bottoms of the boxes and briefly centrifuge each unit to bring the solutions to the bottom of the tubes.

34. Use a multichannel pipettor to transfer 70 µl of sterile H_2O to the individual wells of 96-well microtiter plates. Transfer the bacteriophage lysates from the tubes in Step 33 to the microtiter plate wells. Mix the two solutions by pipetting up and down. Seal the plates with a strip of 3M silver foil tape or with the plate lid if sequencing is to be carried out within the next 24–48 hours. Label each plate and store it at –20°C.

    The yield of single-stranded bacteriophage M13 DNA should be 2.5–5 µg per starting culture.

35. Examine aliquots (5 µl) of DNA selected at random from a few wells by electrophoresis through a 1% agarose gel.

    If everything has worked well, there should be little variation in yield from tube to tube. Between 2 µl and 7.5 µl of each DNA preparation should be used in cycle sequencing reactions (see Protocol 6).

ALTERNATIVE PROTOCOL: PREPARATION OF SMALL NUMBERS OF SINGLE-STRANDED DNA TEMPLATES FROM BACTERIOPHAGE M13

This protocol is an abbreviated version of Protocol 4 in Chapter 3. Please refer to Protocol 4 for required materials.

Method

1. Inoculate 5 ml of 2x YT medium in a 17 x 100-mm tube with a single colony of an appropriate F´ strain of *E. coli* (e.g., XL Blue-1, DH5αF′). Incubate the culture overnight at 37°C with agitation at 300 rpm.
2. Transfer 0.1 ml of the culture into 5 ml of 2x YT medium containing 5 mM $MgSO_4$ in a disposable 30-ml centrifuge tube. Incubate for 2 hours at 37°C with vigorous agitation.
3. Dilute the 5-ml culture into 45 ml of 2x YT medium containing 5 mM $MgSO_4$ and dispense 1.5-ml aliquots into as many sterile 13 x 100-mm tubes as there are plaques to grow.
4. Use sterile toothpicks or a sterile needle to inoculate each tube with a separate bacteriophage M13 plaque. Incubate the tubes for 8–12 hours at 37°C with vigorous agitation.
5. Transfer ~1.2 ml of each culture to a separate microfuge tube and centrifuge the tubes at maximum speed for 5 minutes at room temperature.

   The remainder of each culture can be stored and used as a master stock.
6. Transfer exactly 1 ml of each supernatant to a fresh microfuge tube containing 200 µl of 20% PEG 8000 in 2.5 M NaCl. Mix the suspensions by inverting the tubes several times. *DO NOT VORTEX!* Incubate the tubes for 15–30 minutes at room temperature.
7. Recover the precipitated virus particles by centrifugation at maximum speed for 10 minutes. Remove *every last drop* of the supernatant from each tube by careful aspiration.
8. Resuspend the small white pellets of bacteriophage particles in 100 µl of TE (pH 8.0) by vortexing. Do not proceed until the pellets have completely dispersed.
9. Add 100 µl of phenol equilibrated in TE (pH 8.0). Mix the phases by vortexing twice for 30 seconds. Separate the phases by centrifugation for 3 minutes at room temperature in a microfuge.
10. Transfer the upper, aqueous phase to a fresh microfuge tube and recover the single-stranded DNA by precipitation (15–30 minutes at room temperature) with 2 volumes of ethanol in the presence of 0.3 M sodium acetate (pH 5.2). Recover the precipitate of DNA by centrifugation at maximum speed for 5 minutes at 4°C.
11. Carefully wash the precipitate of DNA with 70% ethanol and centrifuge again. Remove the supernatant by careful aspiration and allow the pellet of DNA to dry at room temperature.
12. Dissolve the DNA in 40 µl of TE (pH 8.0).

    The yield of single-stranded DNA is usually 5–10 µg/ml of the original infected culture. Usually 2–3 µl of the DNA preparation is required for each set of four DNA sequencing reactions using dye primers. The integrity and amount of DNA in each preparation can be estimated by analyzing 2–4-µl aliquots by electrophoresis through a 1.0% agarose gel containing ethidium bromide.

ADDITIONAL PROTOCOL: PREPARATION OF DEPHOSPHORYLATED BLUNT-ENDED BACTERIOPHAGE M13 VECTOR DNA FOR SHOTGUN CLONING

Method

1. Set up two tubes, A and B, each containing 5 µg of the replicative form of the DNA of the desired bacteriophage M13 vector. Adjust the volume of each tube to 44 µl with H_2O and then add 5 µl of the appropriate 10x restriction buffer. Digest both aliquots of DNA with a restriction enzyme that cleaves once within the polycloning site and generates blunt termini (e.g., digest M13mp18 and/or M13mp19 with *Hin*cII).
2. Analyze aliquots of the two digests by agarose gel electrophoresis in parallel with a sample of undigested DNA, to be sure that no circular forms of the DNA remain. Continue incubating the remainder of the digestion mixtures at the appropriate temperature while the gel is running.
3. Meanwhile, digest 1 µg of bacteriophage λ DNA or other high-molecular-weight DNA of defined size to completion with *Alu*I. At the end of the digestion, extract the reaction with phenol:chloroform and precipitate the DNA with ethanol. Redissolve the precipitated DNA in 20 µl of TE (pH 7.6). Store the dissolved DNA on ice until needed in Step 9 of this protocol.
4. When the M13 restriction digestions are complete, add 10 µl of 10x CIP buffer to both tubes. Add 5 units of CIP to Tube A, and incubate the reactions for 15 minutes at 37°C.
5. To each tube add 2 µl of 0.5 M EDTA (pH 8.0) and 5 µl of 10% SDS. Add proteinase K to a final concentration of 50 µg/ml. Incubate the reactions for 30 minutes at 56°C.

   It is important to treat the vector DNA with proteinase K at this stage to remove all traces of restriction enzyme and CIP. Subsequent ligation reactions will not work efficiently if residual enzymes are active. Although some investigators rely on heat inactivation (65°C for 1 hour, or 75°C for 10 minutes) and a single extraction with phenol:chloroform to accomplish this purification, treatment with proteinase K ensures maximum purity of the vector DNA and efficient ligation.
6. Extract the reaction mixtures once with phenol and once with phenol:chloroform. Transfer the aqueous phase to a fresh microfuge tube, and add 2 µl of 5 M NaCl. Add 2 volumes of ice-cold ethanol, and store the tube on ice for 10 minutes.

   NaCl is used instead of sodium acetate (pH 5.2) to prevent precipitation of EDTA at this step.
7. Recover the DNA by centrifugation at maximum speed for 5 minutes at 4°C in a microfuge. Remove the supernatant by aspiration, and add 1 ml of 70% ethanol at room temperature to the tube. Centrifuge again for a further 5 minutes. Carefully discard the supernatant, and store the open tube on the bench until the last traces of ethanol have evaporated. Dissolve the DNA in 100 µl of TE (pH 7.6).
8. Check the recovery and integrity of the vector DNA by analyzing an aliquot (2 µl) by electrophoresis through a 0.8% agarose gel.
9. Carry out a series of test ligations to determine the effectiveness of the phosphatase treatment. Set up five reactions as detailed in Table 12-3.
10. Incubate the ligation reactions for 12–16 hours at 16°C.
11. Transfect competent *E. coli* of an appropriate strain (see Chapters 1 and 3) using 10^{-2}, 10^{-1}, and 1 µl of each of the ligation reactions.
12. Plate the bacteria on media containing IPTG and X-gal. Incubate the plates at 37°C.
13. The following day, count the numbers of blue and colorless plaques. If the results of the test ligations are satisfactory, dispense the dephosphorylated vector DNA into aliquots and store them at –20°C.

    Dephosphorylation should reduce the number of plaques by a factor of 50–100 (Reaction 3 vs. Reaction 1 in Table 12-3). Ligation of dephosphorylated vector to a standard preparation of blunt-ended fragments should result in a 10–50-fold increase in colorless plaques (Reaction 3 vs. Reaction 5).

TABLE 12-3 Test Ligation Reactions of Dephosphorylated M13 Vector DNA

Tube	Type of DNA[a] A	B	C	H_2O (µl)	10× Ligation Buffer (µl)	ATP (5 mM) (µl)[b]	T4 DNA Ligase (Weiss Units)	30% PEG (Optional)[c] (µl)
1	+			5.0	1.0	1.0	2.0	1.6
2	+			6.0	1.0	1.0	–	1.6
3		+		5.0	1.0	1.0	2.0	1.6
4		+		6.0	1.0	1.0	–	1.6
5		+	+	3.0	1.0	1.0	2.0	1.6

[a]A = 50 ng (~0.01 pmole) of linearized, nonphosphatase-treated vector (in a volume of 2 µl); B = 50 ng of linearized, phosphatase-treated vector (in a volume of 2 µl); C = 20 ng of bacteriophage λ DNA or ϕX174 RF DNA cleaved to completion with *Alu*I (in a volume of 2 µl).

[b]Some commercial ligase buffers contain ATP. When using such buffers, the addition of ATP is no longer required.

[c]The efficiency of ligation can be increased by adding PEG 8000 (30% w/v) to a concentration of 5% in the final ligation mixture (see Chapter 1, Protocol 19). It is important to warm the stock solution of PEG 8000 to room temperature before adding it as the last component of the ligation reactions. DNA can precipitate at cold temperatures from solutions containing PEG 8000.

Protocol 2

Preparing Denatured Templates for Sequencing by Dideoxy-mediated Chain Termination

IN THEORY, SEQUENCING OF DENATURED DOUBLE-STRANDED PLASMID DNA templates should work well; in practice, the results have been a little disappointing. The simultaneous isolation and purification of large numbers of plasmids has been difficult to automate, but preparing them in smaller batches by conventional techniques is obviously a deeply inefficient way to attack a DNA sequence longer than a kilobase or two. Furthermore, the results of the sequencing reactions themselves have often been less than ideal: Blank images, weak banding patterns, short read-lengths, premature termination of sequencing products, and strong stops causing bands across all lanes of the gel have all been common complaints. More recently, however, with the availability of improved DNA polymerases and the advent of cycle sequencing, the quality of DNA sequence obtained from denatured double-stranded templates has greatly improved. If care is taken with the preparation of the template, it is now possible to obtain sequences approaching the quality, if not the read-length, routinely obtained from single-stranded DNA templates.

PREPARATION OF TEMPLATE DNA

The key factor that determines success or failure of sequencing of double-stranded plasmid DNAs is the quality of the template. The goal is to use a method of purification that eliminates salt and other small molecules that inhibit DNA polymerases, and to get rid of small fragments of nucleic acid that may serve as unwanted primers. In most cases, the methods used for isolation of sequencing-grade plasmid DNA from transformed bacterial cultures are based on the standard alkaline lysis procedure of Birnboim and Doly (1979). The best results, however, are obtained from large-scale preparations of plasmid DNAs that have been purified extensively by equilibrium centrifugation in CsCl-ethidium bromide gradients or by column chromatography (see Chapter 1, Protocols 9, 10, and 11). The final preparations of plasmid DNA should contain a very high proportion of closed circular molecules. Nicked circular molecules provide a source of 3′-hydroxyl termini that can be extended by DNA polymerases. In sequencing reactions that use internal labeling, the unbidden products of unwanted extension reactions can generate a band at every position of a sequencing ladder.

Plasmid templates suitable for sequencing can also be prepared from small-scale cultures. Several high-throughput methods have been described, (e.g., please see Huang et al. 1994; Mohler and Blau 1997), but, as yet, these have not been widely adopted. Commercial kits such as GENECLEAN (Q•BIOgene), QIAprep Turbo Miniprep (Qiagen), Wizard (Magic) Minipreps (Promega), PERFECTprep (Eppendorf-5 Prime) are always an option, but they are relatively expensive and/or are limited in throughput. For routine sequencing, we recommend purifying plasmid DNA from small-scale cultures by precipitation with PEG (please see the panel on **ADDITIONAL PROTOCOL: PURIFICATION OF PLASMID DNA FROM SMALL-SCALE CULTURES BY PRECIPITATION WITH PEG** at the end of this protocol). In our hands, this method, although lengthy, consistently yields preparations of plasmid DNA of very high quality.

Dideoxy-mediated sequencing is performed on denatured plasmid DNA using gene-specific primers or universal primers that are complementary to sequences flanking restriction sites commonly used for cloning (e.g., please see Chen and Seeburg 1985; Hattori and Sakaki 1986; Mierendorf and Pfeffer 1987) (please see the information panel on **UNIVERSAL PRIMERS** in Chapter 8). Denaturation is generally achieved by exposing the closed circular plasmid DNA to alkali followed by neutralization (e.g, please see Chen and Seeburg 1985; Hsiao 1991). Alternatively, heat may be used to denature linearized preparations of double-stranded plasmid (e.g., please see Wang and Sodja 1991). However, the details of these procedures vary greatly from one paper to the next as authors seek to find conditions that prevent rapid renaturation of the template. In this protocol, we use a denaturation procedure that is thorough and reproducible, but lengthy. More rapid alternative methods of denaturation are discussed in an additional protocol at the end of this protocol.

In sequencing methods that use thermolabile DNA polymerases such as Sequenase, denaturation of the template DNA is carried out before the sequencing reaction is assembled.

The following protocol to denature plasmid DNA by alkali should be used in conjunction with Protocol 3, in which dideoxy-sequencing reactions are catalyzed by Sequenase. For cycle-sequencing reactions, which are catalyzed by a thermostable DNA polymerase, template DNA is denatured by heating the sequencing reaction to ~94°C for 3–5 minutes before beginning the thermal cycling protocol (please see Protocol 6). Table 12-4 presents the amounts of double-stranded DNA typically required for dideoxy sequencing.

TABLE 12-4 Amounts of Double-stranded DNA Required for Dideoxy-mediated Sequencing Reactions

Amount of Template Required (fmoles)	Size of Double-stranded DNA (Vector + Insert) in kbp				
	1 kb	**2.5 kb**	**5 kb**	**10 kb**	**20 kb**
10	6.6 ng	16.5 ng	33 ng	66 ng	132 ng
25	16.5 ng	41 ng	82.5 ng	165 ng	330 ng
50	33 ng	82.5 ng	165 ng	330 ng	660 ng
100	66 ng	165 ng	330 ng	660 ng	1.33 µg
150	100 ng	250 ng	475 ng	1.0 µg	2.0 µg
200	133 ng	330 ng	660 ng	1. 33 µg	2.66 µg
250	166 ng	410 ng	850 ng	1.66 µg	3.33 µg
500	330 ng	825 ng	1.65 µg	3.33 µg	6.66 µg

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Ammonium acetate (5 M, unbuffered, pH ~7.4)

Chloroform:isoamyl alcohol (24:1, v/v) **<!>**

DMSO **<!>**

Optional, please see Step 10.

Ethanol

NaOH (2 N)/EDTA (2 mM) **<!>**

Prepare by appropriate dilution of a 10 N concentrated stock solution of NaOH just before use.

Phenol, equilibrated with H_2O or TE (pH 7.6) **<!>**

Sequenase reaction buffer

Gels

Agarose gel (0.8% w/v)

Nucleic Acids and Oligonucleotides

Oligonucleotide primers

Oligonucleotide primers used to sequence denatured double-stranded DNA templates are frequently longer (20–30 nucleotides) than primers normally used for sequencing single-stranded templates. Longer primers give rise to fewer artifactual bands when used with denatured double-stranded DNA templates.

For a list of "universal" primers that bind to vector sequences upstream of the target region, please see the information panel on **UNIVERSAL PRIMERS** in Chapter 8. Please also see the information panel on **PREPARATION OF STOCK SOLUTIONS OF OLIGONUCLEOTIDE PRIMERS FOR DNA SEQUENCING** at the end of this chapter.

Plasmid DNA, closed circular, double-stranded

Prepare plasmid DNA from small- or large-scale cultures of bacteria (see Chapter 1) or according to the additional protocol at the end of this protocol; 5 µg of DNA is required for each set of four sequencing reactions (ddA, ddG, ddC, and ddT).

Special Equipment

Dry ice–ethanol bath **<!>**

Water bath preset to 65°C

METHOD

1. Transfer ~5 µg of purified plasmid DNA to a 1.5-ml microfuge tube. Adjust the volume to 50 µl with H_2O. Add 10 µl of freshly prepared 2 N NaOH/2 mM EDTA solution. Incubate the mixture for 5 minutes at room temperature.
2. Add 30 µl of 5 M ammonium acetate and mix the contents of the tube by vortexing.
3. Add 45 µl of equilibrated phenol and mix the contents of the tube by vortexing.
4. Add 135 µl of chloroform:isoamyl alcohol, mix the contents of the tube by vortexing, and then separate the phases by centrifugation at maximum speed for 15 minutes at room temperature in a microfuge.

5. Carefully remove the upper aqueous phase to a fresh microfuge tube and precipitate the DNA by the addition of 330 µl of ice-cold ethanol. Mix the contents of the tube and place it in a dry ice–ethanol bath for 15 minutes.

6. Recover the denatured DNA by centrifugation at maximum speed for 15 minutes at 4°C in a microfuge.

7. Very carefully decant the supernatant without disturbing the DNA pellet, which may or may not be visible on the side of the tube.

8. Recentrifuge the tube for 2 seconds and remove the last traces of ethanol with a drawn-out pipette tip without disturbing the DNA precipitate.

9. Allow the precipitate to dry at room temperature and resuspend the DNA in H_2O at a concentration of 1 µg/µl.

10. Anneal the primer DNA to the denatured template, using 5 µg (5 µl) of alkali-denatured plasmid DNA for each set of four DNA sequencing reactions (i.e., 1.25 µg denatured DNA for the reaction containing the ddA reaction, 1.25 µg for the reaction containing ddG, etc.). Set up annealing reactions as follows:

alkali-denatured DNA	5.0 µg (in 5 µl H_2O)
DMSO (**optional*)	2.0 µl
Sequenase reaction buffer	2.0 µl
sequencing primer	1.0 µl (10 ng)
H_2O	to 11.0 µl

*Please see the panel on **TROUBLESHOOTING** in Protocol 4.

Heat the mixture to 65°C for 2 minutes and then allow it to cool slowly to room temperature. Store the annealed samples on ice until the elongation/chain termination reactions are set up.

11. Proceed to Step 3 in Protocol 3.

TROUBLESHOOTING

A problem commonly encountered in sequencing double-stranded plasmid DNA templates is the appearance of bands at the same position in two or more lanes of the sequencing gel. These bands are frequently more intense than the bands in the authentic sequencing ladder and are usually caused by contamination of the DNA template with short DNA and RNA oligonucleotides that act as nonspecific primers in the DNA-sequencing reactions. This problem can be solved by rigorous purification of the plasmid DNA prior to denaturation. More rarely, these bands, some times called BAFLs (bands in all four lanes), result from problems with denaturation. BAFLs can sometimes be reduced in intensity and frequency by (1) switching to the faster denaturation protocol (please see the panel on **ADDITIONAL PROTOCOL: RAPID DENATURATION OF DOUBLE-STRANDED DNA**) and (2) converting the closed circular superhelical plasmid DNA to linear molecules by digestion with a restriction enzyme (Wang and Sodja 1991). Another solution to this problem is to use a ^{32}P-labeled primer in the DNA-sequencing reactions in place of a radiolabeled dNTP (see Protocol 3).

BACTERIOPHAGE λ TEMPLATES FOR DNA SEQUENCING

DNAs cloned in bacteriophage λ can be sequenced essentially as described in this protocol. However, improved results are obtained if the bacteriophage DNA is first cleaved with restriction enzymes that release the target DNA from the vector sequences. The cloned DNA is then purified by gel electrophoresis, extraction with phenol, and precipitation with ethanol (see Chapter 5, Protocol 3). Approximately 3 µg of DNA insert is used for each set of sequencing reactions. Alternatively, small (<3–4 kb) inserts can be amplified from a bacteriophage λ vector by PCR using oligonucleotide primers that flank the insertion site. The amplified product can be purified and subjected to DNA sequencing.

ADDITIONAL PROTOCOL: RAPID DENATURATION OF DOUBLE-STRANDED DNA

The standard protocol for denaturing double-stranded plasmid DNAs works well almost all of the time, but it is quite lengthy. The following protocol is easier and less demanding. However, the length of DNA sequence that can be read is slightly shorter than the several hundred nucleotides routinely obtained from double-stranded DNA denatured at alkaline pH.

Additional Materials

Ammonium acetate (4 M)
NaOH (2 N) containing 1 mM EDTA

Method

1. Resuspend 5 µg of double-stranded closed circular plasmid DNA in 18 µl of H_2O.
2. Add 2 µl of freshly prepared 2 N NaOH containing 1 mM EDTA.
3. Incubate the alkaline solution for 5 minutes at room temperature.
4. Add 10 µl of 4 M ammonium acetate and 20 µl of H_2O. Mix the contents of the tube by vortexing.
5. Precipitate the denatured DNA with 125 µl of ice-cold ethanol and collect the precipitated DNA by centrifugation at maximum speed for 15 minutes at room temperature in a microfuge.
6. Remove the supernatant by careful aspiration and rinse the pellet with 0.5 ml of ice-cold 70% ethanol. Recover the DNA pellet by centrifugation for 2 minutes and then carefully remove the supernatant. Allow the pellet to dry in the air for a few minutes.
7. Redissolve the denatured DNA in H_2O at a concentration of ~1 µg/µl. Anneal the primer to the template DNA as described in Steps 10 and 11 of the main protocol.

ADDITIONAL PROTOCOL: PURIFICATION OF PLASMID DNA FROM SMALL-SCALE CULTURES BY PRECIPITATION WITH PEG

CAUTION:Please see Appendix 12 for appropriate handling of materials marked with <!>.

Additional Materials

Alkaline lysis solution I
Alkaline lysis solution II
Alkaline lysis solution II should be freshly prepared and used at room temperature.
Alkaline lysis solution III, ice cold
Ammonium acetate (7.5 M)
DNase-free RNase
Isopropanol
NaCl (4 M)
Phenol:chloroform **<!>**
Polyethylene glycol (13% w/v PEG 8000) **<!>**
Proteinase K (10 mg/ml)
TE (pH 8.0)
Terrific Broth

Method

1. Grow 5-ml cultures of transformed bacteria in Terrific Broth plus the appropriate antibiotic (see Appendix 2) overnight at 37°C with vigorous aeration.
   E. coli strains DH5α and XL1-Blue are the preferred hosts.
2. Transfer 1.5 ml of the overnight culture to a microfuge tube and recover the bacteria by centrifugation at maximum speed for 1 minute. Remove the supernatant and replace it with another 1.5-ml aliquot of the overnight culture. Centrifuge at maximum speed for 1 minute.
3. Remove all of the supernatant by aspiration and resuspend the bacterial pellet in 200 µl of Alkaline lysis solution I containing 5 mg/ml lysozyme.
4. Add 300 µl of a freshly prepared solution of Alkaline lysis solution II and mix by inverting the tube several times. The solution should clear to transparency. *DO NOT VORTEX.* Store the tube in ice for 5 minutes.
5. Add 300 µl of Alkaline lysis solution III and mix by inverting the tube several times.
6. Centrifuge the tube at maximum speed for 10 minutes at room temperature. Taking care not to disturb the pellet of bacterial debris, transfer the supernatant to a fresh microfuge tube.
7. Add DNase-free RNase to a final concentration of 25 µg/ml. Incubate the tube for 20 minutes at 37°C.
8. Extract the preparation with 400 µl of chloroform:isoamyl alcohol (24:1), transferring the aqueous phases to fresh tubes between each extraction. Continue the extractions until no more material is visible at the interface.
9. Add an equal volume of isopropanol, mix by vortexing, and then recover the precipitated DNA by centrifugation at maximum speed for 10 minutes at room temperature.
10. Remove the supernatant by aspiration and then wash the pellet of plasmid DNA and the sides of the tube with 70% ethanol. After centrifugation at maximum speed for 3 minutes at room temperature, remove the supernatant by aspiration and then allow the remaining ethanol to evaporate at room temperature.
11. *(Optional: Use only if the length or quality of sequence obtained from recent minipreparations of plasmid DNA has been unsatisfactory)* Dissolve the pellet in 100 µl of TE (pH 8.0), add 1 µl of proteinase K (10 mg/ml), and incubate the reaction for 20 minutes at 37°C. Extract the solution with phenol:chloroform and recover the DNA by adding 50 µl of 7.5 M ammonium actetate and 300 µl of ethanol. Remove the supernatant and allow the last traces of ethanol to evaporate at room temperature.
12. Dissolve the pellet in 32 µl of H_2O and then precipitate the DNA by adding 8.0 µl of 4 M NaCl and 40 µl of 13% PEG 8000. Mix the contents of the tube by inverting it several times and then store the tube for 1 hour on ice.
13. Recover the plasmid DNA by centrifugation at maximum speed for 15 minutes at 4°C.
14. Carefully remove the supernatant by aspiration and then wash the pellet of DNA with 500 µl of 70% ethanol. After centrifugation at maximum speed for 3 minutes at room temperature, remove the supernatant by aspiration and then allow the remaining ethanol to evaporate at room temperature.
15. Dissolve the pellet of DNA in 20 µl of H_2O. Analyze 1.0 µl of the preparation by agarose gel electrophoresis and store the remainder of the preparation at –20°C.

Protocol 3

Dideoxy-mediated Sequencing Reactions Using Bacteriophage T7 DNA Polymerase (Sequenase)

SEQUENASE, A MODIFIED VERSION OF BACTERIOPHAGE T7 DNA polymerase, is the enzyme of choice to catalyze automated or manual dideoxy-mediated isothermal DNA-sequencing reactions. Like the classical sequencing enzyme, the Klenow fragment of *E. coli* DNA polymerase I, Sequenase lacks 3′-5′ exonuclease activity. However, by sharp contrast to the bacterial enzyme, Sequenase is capable of generating DNA ladders that are strikingly beautiful, where every band is of similar intensity and readable DNA sequence extends over the full length of the gel. Since its introduction (Tabor and Richardson 1987a), Sequenase has almost completely replaced the Klenow fragment, with consequent benefit to sequencing projects, large or small, manual, or robotic.

Of the several versions of Sequenase that are available (please see the information panel on **SEQUENASE**), most DNA sequencing is carried out with version 2.0. The reaction is carried out in the following three steps.

- ***Denaturation of double-stranded DNA templates*** (if necessary) and annealing of primer to its complementary sequence.
- ***A brief polymerization reaction*** in which the primer is elongated by 20–100 nucleotides. This step is performed under conditions where DNA polymerase is present in excess and the concentrations of the four dNTPs are limiting. A radiolabeled dNTP is included in the reaction so that the short elongation products become radiolabeled at multiple sites. During this preliminary polymerization reaction, most of the available dNTPs, including the radiolabeled dNTP, are incorporated into DNA.
- ***Extension and termination reactions*** of the elongated radiolabeled primers. This step is carried out in four reactions that contain high concentrations of unlabeled dNTPs and a single unlabeled ddNTP (ddA, ddG, ddC, or ddT).

Sequenase version 2.0 produces excellent DNA sequences using either single-stranded templates or denatured double-stranded DNA templates. This protocol, adapted from Tabor and Richardson (1987a, 1989b, 1990), describes DNA sequencing with single-stranded DNA templates (for production of single-stranded bacteriophage M13 or phagemid DNAs, please see Chapter 3, Protocols 4 and 8, and Chapter 12, Protocol 1). A method for denaturing double-stranded DNA templates in preparation for sequencing with Sequenase is described in Chapter 12, Protocol 2. For further details on sequencing PCR-amplified DNA, please see the information panel on **CONVENTIONAL CHAIN-TERMINATION SEQUENCING OF PCR-AMPLIFIED DNA.**

MATERIALS

▲ **IMPORTANT** All the materials required for sequencing with Sequenase version 2.0 are contained in kits, sold by USB/Amersham Life Science, which include a detailed protocol describing the reagents and steps used in the sequencing reaction. This kit is invaluable for first-time or occasional sequencers, but it is expensive. After gaining experience, it may turn out to be more economical to purchase Sequenase version 2.0 in bulk and then assemble the remaining reagents locally.

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Deionized distilled H_2O (ice cold)

Dithiothreitol (100 mM)

dNTPs and ddNTPs, stock solutions (0.5 mM) of each of the four dNTPs and ddNTPs

Please see the information panel on **PREPARATION OF STOCK SOLUTIONS OF dNTPs AND ddNTPs FOR DNA SEQUENCING.**

5x Labeling mixture and ddNTP extension/termination mixtures (ddCTP, ddTTP, ddATP, and ddGTP)

These reaction mixtures can be assembled by mixing the volumes of the solutions shown in Table 12-5.

Formamide-loading buffer **<!>**

Sequenase dilution buffer

10 mM Tris-Cl (pH 7.5)
5 mM dithiothreitol
0.50 mg/ml bovine serum albumin

Store at –20°C

5x Sequenase reaction buffer with $MgCl_2$

200 mM Tris-Cl (pH 7.5)
100 mM $MgCl_2$
125 mM NaCl

Store at –20°C.

TABLE 12-5 5x Labeling Mixture and ddNTP Extension/Termination Mixtures for Sequenase Reactions

	Stock Solutions of dNTPs and ddNTPs (All Volumes in µl)								Other Reagents	
Reaction Mixture	dCTP 0.5 mM	dTTP 0.5 mM	dATP 0.5 mM	dGTP 0.5 mM	ddCTP 0.5 mM	ddTTP 0.5 mM	ddATP 0.5 mM	ddGTP 0.5 mM	5 M NaCl	H_2O
Labeling	15	15	–	15	–	–	–	–	–	955
ddCTP	160	160	160	160	16	–	–	–	10	334
ddTTP	160	160	160	160	–	16	–	–	10	334
ddATP	160	160	160	160	–	–	16	–	10	334
ddGTP	160	160	160	160	–	–	–	16	10	334

The 5x labeling mixture contains unlabeled dGTP, dCTP, and dTTP, each at a concentration of 7.5 mM. Radiolabeled dATP is added at Step 7 to a final concentration of ~30 µM. Each of the ddNTP extension/termination mixtures contains all four dNTPs at a concentration of 160 µM and a single ddNTP at a concentration of 0.16 µM. The 5x labeling mixture and extension/termination mixtures should be dispensed in 50-µl aliquots and stored frozen at –20°C.

When sequencing templates that are rich in GC structure, use base analogs such as 7-deaza-2′-dGTP or dITP in place of dGTP. If using 7-deaza-dGTP, simply replace the GTP in all the ddNTP extension/termination mixtures with an equimolar amount of the base analog.

If using dITP, substitute 30 µl of a 0.5 mM stock solution of dITP for dGTP in the 5x labeling mixture and decrease the amount of H_2O to 940 µl. In the ddNTP extension/termination mixtures containing ddCTP, ddTTP, and ddATP, substitute 160 µl of a 0.5 mM stock dITP solution for dGTP. In the extension/termination mixture containing ddGTP, substitute 320 µl of 0.5 mM stock solution of dITP for dGTP, decrease the amount of ddGTP to 3.2 µl, and decrease the volume of H_2O to 187 µl.

5x Sequenase reaction buffer with $MnCl_2$

200 mM Tris-Cl (pH 7.5)
25 mM $MnCl_2$
125 mM NaCl
Store at –20°C.

The presence of Mn^{2+} in the Sequenase reaction buffer increases the efficiency with which Sequenase will utilize ddNTPs, even if Mg^{2+} is also present (Tabor and Richardson 1989b). The net result is a more efficient termination of sequencing reactions closer to the starting primer. This modification is useful for improving the strength of the bands that run close to the oligonucleotide primer or when using a base analog such as dITP to iron out compressions in GC-rich regions of sequence.

To use Mn^{2+}, add 1 µl of 5x Sequenase reaction buffer with $MnCl_2$ to the labeling reaction before adding Sequenase (Fuller et al. 1996). Alternatively, add 0.01 volume of 1 M $MnCl_2$ to the dideoxy-dNTP extension/termination mixtures (Kristensen et al. 1990). Do not use manganese-containing buffers that develop a slight yellowish color or that contain a yellow-brown precipitate.

TE (pH 7.6)

Enzymes and Buffers

Sequenase (version 2.0)

Sequenase is supplied by the manufacturer at a concentration of ~13 units/µl (~1 mg/ml). Store at –20°C (not in a frost-free freezer).

Yeast inorganic pyrophosphatase

Optional, please see Step 6. This is supplied by the manufacturer (USB/Amersham Life Science) at a concentration of 5 units/ml; it catalyzes the hydrolysis of pyrophosphate to two molecules of orthophosphate.

Pyrophosphatase can be mixed with Sequenase at a ratio of 1 unit of pyrophosphatase to 3 units of Sequenase. This is best done by mixing equal volumes of the two enzyme preparations and diluting the mixture with 6 volumes of enzyme dilution buffer. This dilutes Sequenase to its working concentration of ~1.6 units/µl and adds enough pyrophosphatase to prevent build-up of pyrophosphate; 2 µl of the mixture of diluted enzymes is required for each sequencing reaction.

Nucleic Acids and Oligonucleotides

Oligonucleotide primer

Use at a concentration of 0.5 pmole/µl (~3.3 ng/µl) in H_2O or TE (pH 7.6).

Please see the information panel on **PREPARATION OF STOCK SOLUTIONS OF OLIGONUCLEOTIDE PRIMERS FOR DNA SEQUENCING**. For a list of universal primers that bind to vector sequences upstream of the target region, please see the information panel on **UNIVERSAL PRIMERS** in Chapter 8.

Template DNAs (1 µg) in TE (pH 7.6)

Single-stranded DNA (1 µg) or 2.0 µg of denatured double-stranded plasmid DNA is required for each set of four sequencing reactions. Linear double-stranded DNA can be denatured and annealed to the primer by mixing the template with an excess of primer and heating the mixture in a boiling water bath for ~2 minutes and then plunging the tube into an ice-water bath. The mixture should not be allowed to warm up and should be used without delay.

The concentration of single-stranded DNA in small-scale preparations of bacteriophage M13 recombinants varies from 0.05 µg/ml to 0.5 µg/ml, depending on the growth rate of the particular bacteriophage. Under the conditions normally used for sequencing, the template DNA is present in excess. Small variations in the amounts of template added to different sets of sequencing reactions do not generally affect the quality of the results; however, please see Table 12-6 at the end of this protocol.

Radioactive Compounds

[α-^{35}S]dATP (1000 Ci/mmole, 10 mCi/ml) **<!>**

or

[α-^{33}P]dATP (1000–3000 Ci/mmole, ~20 mCi/ml) **<!>**

or

[α-^{32}P]dATP (1000 Ci/mmole, 10 mCi/ml) **<!>**

Instead of internal labeling with [^{32}P]dATP, carry out sequencing with a 5′ ^{32}P-labeled oligonuclotide primer. In this case, 2 µl (~5 x 10^5 cpm; ~0.5 ng) of the radiolabeled primer and 2 µl of H_2O are included in the reaction mixture in place of the unlabeled primer (Step 1) and [^{32}P]dATP (Step 7). All other steps remain the same. The 5′ termini of oligonucleotides are generally labeled by transfer of [γ-^{32}P] from [γ-^{32}P]ATP in a reaction catalyzed by polynucleotide kinase. For details of the labeling reaction, please see Chapter 10, Protocol 2.

Centrifuges and Rotors

Microfuge rotor or adaptors for use with 0.5-ml microfuge tubes or Swing-out rotor and microtiter-plate holder (e.g., Sorvall), lined with polystyrene foam or rubber pads

Special Equipment

Microfuge tubes (0.5 ml) or Microtiter plates (flexible, heat-stable, with 96 U-shaped wells of ~300 µl capacity)

Please see the information panel on **MICROTITER PLATES.**

Water baths or heating blocks preheated to 37°C and 65°C

METHOD

▲ **IMPORTANT** When sequencing double-stranded plasmid DNAs that have already been denatured and annealed to a sequencing primer (Protocol 2), ignore the first two steps of this protocol and begin at Step 3.

1. To a 0.5-ml microfuge tube or well of a microtiter plate, add:

single-stranded template DNA (~1 µg/µl)	1 µl
oligonucleotide primer (~1 ng/µl)	3 µl
5x Sequenase reaction buffer containing $MgCl_2$ or $MnCl_2$	2 µl
H_2O	to 10 µl

2. Incubate the tightly closed tube for 2 minutes at 65°C. Remove the tube from the water bath and allow it to cool to room temperature over the course of 3–5 minutes.

   Some investigators prefer to cool the annealing reactions more slowly over the course of 30 minutes in a small heating block or beaker of water. In our hands, both slow- and fast-cooling regimens yield sequence of the same quality.

3. While the primer and template are cooling, thaw the 5x labeling and ddNTP extension/termination mixtures and radiolabeled dATP. Store the thawed solutions on ice.

4. Transfer 2.5 µl of each ddNTP extension/termination mixture into separate 0.5-ml microfuge tubes or into individual wells of a microtiter plate color-coded or labeled C, T, A, and G.

   The fluid should be deposited as a droplet on the wall of the tubes or wells, near the rim.

5. Make a fivefold dilution of the 5x labeling mixture in ice-cold H_2O. A volume of 2 µl of the diluted labeling mixture is required for each template sequenced.

6. Dilute Sequenase in ice-cold Sequenase dilution buffer, with or without addition of yeast pyrophosphatase, as described above in Materials.

   A volume of 2.0 µl, containing ~3.0 units of Sequenase enzyme, is required for each template sequenced. Store the diluted enzyme on ice at all times.

Pyrophosphatase is used to prevent reduction in band intensity during prolonged incubation of sequencing reactions. This reduction occurs because DNA polymerases (including Sequenase) can catalyze a reaction between the base at the 3′ terminus of a DNA chain and pyrophosphate ions in solution. The products of the pyrophosphorolytic reaction are a free dNTP molecule and a DNA chain that is now one base shorter. Pyrophosphorolysis, which is the reverse of polymerization, occurs at an insignificant rate in most DNA-sequencing reactions. However, when the reactions are incubated for a long time or when dITP is used in place of dGTP, pyrophosphorolysis may become a problem. Since the efficiency of pyrophosphorolysis varies according to the nucleotide sequence at the 3′ end of DNA chains, the intensities of some sequencing bands are reduced while others are unaffected. The consequent variation in band intensity can be prevented by using high concentrations of dNTPs or by including yeast pyrophosphatase in the reaction mixture (Tabor and Richardson 1990; Patel et al. 1991; Fuller 1992).

7. To carry out the labeling reaction, add the following to the 10-µl annealing reaction of Step 2:

diluted labeling mixture (from Step 5)	2 µl
0.1 M dithiothreitol	1 µl
[α-^{33}P]dATP, [α-^{32}P]dATP, or [α-^{35}S]dATP	0.5 µl
diluted Sequenase (~1.6 units/µl)	2.0 µl

Mix the components of the reaction by gently tapping the sides of the tube or microtiter plate and then incubate the reaction for 2–5 minutes at 20°C.

Store the diluted Sequenase in ice; do not allow it to warm to ambient room temperature. Store the concentrated stock of enzyme supplied by the manufacturer at –20°C. It may lose activity if stored in an ice bucket for hours.

8. Toward the end of the labeling reaction, prepare to set up the termination reactions by prewarming the labeled microfuge tubes or microtiter plates to 37°C. *This step is important!* Then transfer the 3.5 µl of the labeling reaction to the walls of each of the prewarmed labeled microfuge tubes or to the sides of prewarmed microtiter wells containing the appropriate dideoxy terminator mixtures (Step 4 above).

9. Place the microfuge tubes in a microfuge *at room temperature* (use appropriate rotor or adaptors for 0.5-ml tubes or place inside decapitated 1.5-ml tubes), or place the microtiter plates in a centrifuge *at room temperature* equipped with an appropriate adaptor. Centrifuge the C, T, A, and G tubes or plates for a few seconds at 2000 rpm to mix the components of the reactions. Immediately transfer the reactions to a heating block or a water bath for 3–5 minutes at 37°C.

10. Stop the reactions by adding 4 µl of formamide-loading buffer.

11. The reactions may be stored for up to 5 days at –20°C or analyzed directly by denaturing gel electrophoresis (Protocols 8, 9, or 10, 11, and 12). After heat denaturation (2 minutes at 100°C) and quick cooling on ice, load 3 µl of each of the C, T, A, and G reactions into individual wells of a sequencing gel.

SEQUENCING RANGE

The reaction conditions in this protocol have been optimized to obtain the sequence of DNA lying up to 300–400 nucleotides from the 5′ terminus of the primer. Reading of the sequence closer to or further away from the primer can be facilitated by the following modifications:

Distance of target DNA from 5′ terminus of primer (in nucleotides)	Modification of basic procedure
20–100	Dilute labeling mixture, prepared at Step 5 above, by a factor of 10. Halve the time for incubation of both labeling and extension/termination reactions. Use $MnCl_2$ in polymerization reaction.
10–300	Use primer labeled at its 5′ terminus with [^{32}P]ATP or [^{33}P]ATP (please see Chapter 10, Protocol 2).
100–400	Normal reaction conditions.
>400	Use four times the normal concentrations of unlabeled dNTPs and radioisotope in the labeling reaction. Double the time of incubation of the labeling reaction.

TABLE 12-6 Problems That Commonly Arise during Dideoxy-mediated DNA Sequencing Using Sequenase

SYMPTOM	POSSIBLE CAUSE	POSSIBLE REMEDIES
Bands are faint at the bottom of gel.	The number of primer:template complexes in the reaction is too low, which could be due to a shortage of template DNA, primer DNA, or both. In each case, the result is synthesis of a few long extension products during the labeling reaction, rather than many short products.	Optimize the amounts and ratios of primer and template DNAs in the reaction. Use a primer more distant from the target site. Decrease the concentration of dNTPs in the labeling reaction by a factor of 3.
Bands are faint at the top of the gel.	The concentration of dNTP, most probably dATP, is limiting.	Check that the specific activity of [^{35}S]dATP is 1000 Ci/mmole. Increase the amount of [^{33}P]dATP or [^{35}S]dATP in the labeling reaction to 1 µl (Step 7).
Bands are smeary at the top of the gel.	Excess glycerol is present in the samples loaded onto the gel.	Use a glycerol-tolerant electrophoresis buffer or reduce the amount of glycerol in the samples. Please see the information panel on **GLYCEROL IN DNA SEQUENCING REACTIONS.**
Bands in all four tracks of sequencing reactions are at the bottom of the gel.	Sequenase is inactivated during elongation reaction.	Do not incubate the labeling reaction at temperatures >20°C or longer than 5 minutes, unless glycerol has been included in the reaction. Glycerol can be added at the labeling step by replacing Sequenase dilution buffer with glycerol enzyme dilution buffer (20 mM Tris-HCl [pH 7.5] 2 mM DTT, 0.1 mM EDTA, 50% glycerol). This will allow incubations of up to 30 minutes at 20°C, and 5 minutes at 37°C. Note that addition of glycerol necessitates the use of a glycerol-tolerant sequencing gel. Please see the information panel on **GLYCEROL IN DNA SEQUENCING REACTIONS.**
Bands in all four tracks of sequencing reactions are at the top of the gel.	The termination reaction is working inefficiently because either the template DNA contains impurities or the termination reaction was not incubated at the correct temperature.	Repurify template DNA by digestion with proteinase K, extraction with phenol, and precipitation with ethanol. The termination reactions must be incubated at a temperature of at least 37°C. Sequenase can be used at temperatures as high as 50°C. Please see the information panel on **GLYCEROL IN DNA SEQUENCING REACTIONS.**

The intensity of bands is uneven.	Pyrophosphorolysis is catalyzed by Sequenase. The termination reaction may have been incubated for too long.	Use yeast pyrophosphatase in the extension reaction (please see Step 6 of the main protocol). Reduce the termination reaction time to 2 minutes.
Background bands (weak bands) in all four tracks.	Multiple priming events due to less than optimal primer to template ratios. Possible secondary structure formation in the template.	If the amount of template can be readily quantified, adjust this ratio to 5–10:1. If the input mass of primer or template is not known, vary the volume of primer or template to determine empirically the optimum ratio for sequencing. The use of DMSO in sequencing reactions can also reduce background bands (Winship 1989). This solvent, which is thought to decrease secondary structure formation in the template, is included at a concentration of 10% (v/v) and can be conveniently added to the tubes containing the dideoxynucleotides before addition of the denatured template DNA.
Bands in all four tracks in particular regions of sequence (strong stops).	Secondary structure or unusual base composition in template.	Sequence the complementary strand of the DNA. Incubate the termination reactions at elevated temperature (up to 50°C). Add organic solvents such as DMSO to the reaction buffer. Sequenase works well in buffers containing as much as 11% (v/v) DMSO. Add the nonionic detergent Nonidet P-40 to the termination reactions. Sequenase is active in buffers containing 0.05% (v/v) of this detergent. "Chase" the DNA sequencing reactions with a different DNA polymerase. Typically, this is accomplished by adding an aliquot of a different DNA polymerase at the end of the normal incubation time. When using Sequenase, addition of 0.5–1.0 unit of the Klenow fragment to each sequencing reaction at the end of Step 8 in Protocol 3, followed by an incubation of 1–2 minutes at room temperature or 37°C, overcomes many strong stops. Other DNA polymerases such as reverse transcriptase or a thermostable DNA polymerase may also be used. Substitute 7-deaza-dGTP or dITP for dGTP, or 7-deaza-dATP for dATP in *Taq* ddNTP mixes (please see the information panel on **COMPRESSIONS IN DNA SEQUENCING GELS**).

Protocol 4

Dideoxy-mediated Sequencing Reactions Using the Klenow Fragment of *E. coli* DNA Polymerase I and Single-stranded DNA Templates

WHEN THE FIRST CHAIN-TERMINATING DNA SEQUENCING METHODS were developed by Sanger and colleagues (Sanger et al. 1977b, 1980), only one suitable DNA polymerase was available — the Klenow fragment of *E. coli* DNA polymerase I. This enzyme retains the ability to polymerize dNTPs in a template-specific manner but lacks the potent 5′-3′ exonuclease of complete polymerase I (please see the information panel on **THE KLENOW FRAGMENT OF *E. COLI* POLYMERASE I**). Although extensive tracts of DNA sequence were determined using the Klenow fragment, it soon became obvious that the enzyme was far from ideal as a catalyst for sequencing reactions: It was not highly processive, could not traverse regions of the template that were rich in secondary structure, greatly preferred to use dNTPs rather than ddNTPs as substrates, was adversely affected by the contaminants that frequently adulterated the DNA preparations of the time, and could work efficiently only on single-stranded DNA templates. With such a set of handicaps, it is hardly surprising that large-scale sequencing projects no longer rely on the Klenow enzyme. Today, these projects are increasingly carried out using thermostable DNA polymerases and modified versions of bacteriophage T7 DNA polymerase.

Nevertheless, the Klenow fragment is still very useful for many small-scale sequencing projects where single-stranded DNA templates are available and long reads are not required. Such projects include verification of mutations, confirmation of constructs, and pinpointing the termini of deletions. The Klenow fragment still has a faithful, but aging, coterie of supporters who believe that the enzyme has an ability to capture sequences from regions of cloned DNAs that are difficult to sequence with other DNA polymerases. Why this should be is unknown, but differences in template requirement and differential sensitivity to secondary structure are possibilities.

The enzyme works best on single-stranded DNA templates, where read-lengths of ~300–400 bases can be expected. Denatured, double-stranded DNA templates are a far more doubtful proposition. There is no good reason to use the Klenow fragment to sequence denatured plasmid DNA when so many better alternatives are available.

The following protocol, adapted from Sanger et al. (1977a, 1980), describes how to use the Klenow enzyme to sequence single-stranded DNA templates.

TABLE 12-7 ddNTP Extension/Termination Mixtures and Chase Mixtures for Klenow Sequencing

Reaction Mixture	Stock Solutions of dNTPs (1 mM) (All Volumes in µl)				Stock Solutions of ddNTPs (5 mM) (All Volumes in µl)				Other Reagents		
	dCTP	dTTP	dATP	dGTP	ddCTP	ddTTP	ddATP	ddGTP	Tris-Cl (1 M, pH 8.0)	EDTA (10 mM, pH 8.0)	H_2O
ddCTP	5	100	–	100	30	–	–	–	10	10	745
ddTTP	100	5	–	100	–	25	–	–	10	10	675
ddATP	100	100	–	100	–	–	5	–	10	10	580
ddGTP	100	100	–	5	–	–	–	25	10	10	750
Chase	245	245	245	245	–	–	–	–	10	10	–
dATP	–	–	100	–	–	–	–	–	10	10	880

The ratios of ddNTP:dNTP in the extension/termination mixtures are 30:1, 25:1, and 25:1 for dCTP, dTTP, and dGTP respectively. In the assembled sequencing reaction, the ratio of ddATP:dATP is ~45:1.

Dispense mixtures as 50-µl aliquots and store frozen at –20°C.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

dATP (0.1 mM)

Optional, please Step 4.

Deionized distilled H_2O

EDTA (10 mM, pH 8.0)

Extension/termination mixtures and chase mixture

These reaction mixtures can be assembled by mixing the volumes (in µl) of the stock solutions of dNTPs and ddNTPs, as shown in Table 12-7.

Formamide-loading buffer **<!>**

TM buffer

100 mM Tris-Cl (pH 8.5)

50 mM $MgCl_2$

Tris-Cl (1 M, pH 8.0)

Enzymes and Buffers

Klenow fragment of E. coli DNA polymerase I (5 units/µl)

Approximately 2.5 units of enzyme are required for each set of four dideoxy sequencing reactions.

The Klenow fragment is generally supplied in a buffer containing 50% glycerol. The overenthusiastic use of the enzyme in sequencing reactions may cause distortions in sequencing gels, because of interactions between glycerol and borate ions in TBE, and the standard buffer used to pour and run DNA sequencing gels (please see the panel on **TROUBLESHOOTING** at the end of this protocol).

Nucleic Acids and Oligonucleotides

dNTPs, ddNTPs, stock solutions of dNTPs (1 mM) and ddNTPs (5 mM) in H_2O

Oligonucleotide primer

Use at a concentration of ~0.5 pmole/µl (~3.3 µg/ml) in H_2O.

For a list of universal primers that bind to vector sequences upstream of the target region, please see the information panel on **UNIVERSAL PRIMERS** in Chapter 8 and the information panel on **PREPARATION OF STOCK SOLUTIONS OF OLIGONUCLEOTIDE PRIMERS FOR DNA SEQUENCING** at the end of this chapter.

Template DNA, single-stranded

Use at a concentration of ~0.05 pmole/µl, which is equivalent to ~0.15 µg/µl of bacteriophage M13 single-stranded DNA.

The concentration of single-stranded DNA in small-scale preparations of bacteriophage M13 recombinants varies from 0.05 to 0.5 µg/ml, depending on the growth rate of the particular bacteriophage. Under the conditions normally used for sequencing, the template DNA is present in excess. Therefore, small variations in the amounts of template added to different sets of sequencing reactions do not generally affect the quality of the results; however, please see the panel on **TROUBLESHOOTING** at the end of the protocol.

Radioactive Compounds

[α-^{32}P]dATP (3000 Ci/mmole, 10 mCi/ml) **<!>**

or

[α-^{33}P]dATP (3000 Ci/mmole, 10 mCi/ml) **<!>**

or

[α-^{35}S]dATP (1000 Ci/mmole, 10 mCi/ml **<!>**

or

5′ ^{32}P-labeled oligonucleotide primer **<!>**

Instead of internal labeling with [^{32}P]dATP, sequencing may be carried out with a 5′ ^{32}P-labeled oligonucleotide primer. In this case, 2 µl (~5 x 10^5 cpm; ~0.5 ng) of the radiolabeled primer and 2 µl of H_2O are included in the reaction mixture in place of the unlabeled primer (Step 1) and [^{32}P]dATP (Step 4). All other steps remain the same. The 5′ termini of oligonucleotides are generally labeled by transfer of [γ-^{32}P]- from [γ-^{32}P]ATP in a reaction catalyzed by polynucleotide kinase. For details of the kinasing reaction, please see Chapter 10, Protocol 2.

Centrifuges and Rotors

Microfuge rotor or adaptors for use with 0.5-ml microfuge tubes, or Swing-out rotor and microtiter-plate holder (e.g., Sorvall) lined with polystyrene foam or rubber pads

Special Equipment

Microfuge tubes (0.5 ml) or Microtiter plates (flexible, heat-stable, with 96 U-shaped wells of ~300 µl capacity.

Please see the information panel on **MICROTITER PLATES**.

METHOD

1. Transfer the following to a 0.5-ml microfuge tube, or well of a microtiter plate:

single-stranded template DNA (0.1 µg/µl)	5 µl
oligonucleotide primer (1 µg/ml, ~160 pmoles/ml)	4 µl
TM buffer	1 µl

2. Close the top of the tube or seal the microtiter plate and anneal the oligonucleotide primer to the template DNA by incubating the reaction mixture for 5–10 minutes at 55°C.

   If necessary, the annealed template and primer may be stored for several months at –20°C.

3. Meanwhile, label four microfuge tubes or four contiguous wells of a 96-well disposable microtiter plate with the letters C, T, A, and G; then add 4 µl of the appropriate ddNTP extension/termination mixture to each tube (i.e., 4 µl of ddCTP mixture to tube/well labeled C, 4 µl of ddTTP mixture to tube/well labeled T, etc.).

4. Place the annealed primer-template solution from Step 2 on ice and add:

[α-^{32}P]dATP *or* [α-^{33}P]dATP *or* [α-^{35}S]dATP	1 µl
Klenow enzyme (~2.5 units)	1 µl
0.1 mM dATP (if [α-^{32}P] or [α-^{33}P] is used)	1 µl
or	
H_2O (if [α-^{35}S]dATP is used)	1 µl

Store the stock of Klenow enzyme at –20°C; do not allow it to warm to ambient room temperature. The enzyme may lose activity if stored in an ice bucket for hours.

5. Transfer 3 µl of the mixture from Step 4 to the walls of each of the C, T, A, and G tubes or to the sides of microtiter wells. Do not allow the radiolabeled mixture to come into contact with the ddNTP extension/termination mixture.

The fluid should be deposited as a droplet on the wall of the tubes or wells, near the rim.

6. Place the microfuge tubes in a microfuge (use appropriate rotor or adaptors for 0.5-ml tubes or place inside decapitated 1.5-ml tubes), or place the microtiter plates in a centrifuge equipped with an appropriate adaptor. Centrifuge the C, T, A, and G tubes or plates for a few seconds at 2000 rpm to mix the components and initiate the extension/termination reactions. Incubate the reactions for 10–12 minutes at 37°C.

Extension/termination and chase reactions catalyzed by the Klenow enzyme work equally well at temperatures ranging from room temperature to 37°C.

7. After 9–11 minutes of incubation, transfer 1 µl of the chase mixture to the side of each C, T, A, and G tube or well. Do not allow the solution to slide into the polymerization reactions. When a total of 10–12 minutes has elapsed, centrifuge the tubes/plates for 2 seconds to introduce the chase mix into the extension/termination reactions. Incubate the reactions for an additional 10–12 minutes at room temperature.

8. After 9–11 minutes of the second incubation, transfer 6 µl of formamide-loading buffer to the sides of each C, T, A, G tube or well. Again, take care that the solution does not slide down into the reaction. At the end of the incubation period, centrifuge the tubes or plates to stop the sequencing reactions.

9. The DNA sequencing reactions may be stored for up to 5 days at –20°C or analyzed directly by denaturing gel electrophoresis (Protocols 8, 9, or 10, 11, and 12). After heat denaturation (2 minutes at 100°C) and quick cooling on ice, load 3 µl of each of the C, T, A, and G reactions into the individual wells of a sequencing gel.

TROUBLESHOOTING

Although dideoxy-mediated sequencing with the Klenow fragment usually goes smoothly, it is hardly ever perfect. For example, it is sometimes necessary to adjust the ratio of ddNTPs to dNTPs in the chain extension/chain termination reactions to maximize the amount of information that can be obtained. More serious problems that compromise the quality of the DNA sequence can be solved by adjustments to the techniques used to prepare templates or by small alterations in the conditions used for chain extension/chain termination reactions or polyacrylamide gel electrophoresis. An important first step is to determine whether the problem is systematic (i.e., affects all sequencing reactions) or whether it is template-specific. If this difference is not immediately obvious from a comparison of the results obtained from different templates sequenced on the same day, it can be rapidly ascertained by carrying out sequencing reactions with a reliable template (i.e., one that has given good results previously or one that is supplied as part of a commercially produced sequencing kit). The most common types of systematic sequencing problems are listed in Table 12-6 in Protocol 3, together with suggestions for solving them. When problems of this type arise, it is often useful to use the reagents provided in commercial sequencing kits to identify the defective component of the chain extension/chain termination reaction.

Template Problems

The vast majority of template-specific problems have one of the four causes listed below. The diagnostic symptoms of each of these problems and suggestions for possible solutions are listed in Table 12-6.

- ***Presence of contaminating DNA*** (usually bacterial chromosomal DNA) in the preparation.
- ***Presence of residual PEG*** or high concentrations of EDTA in the preparation.
- ***Low concentrations of template DNA*** in the chain extension/chain termination reactions.
- ***Absence of a primer-binding site.*** This problem arises chiefly when sequencing deletion mutants generated by digestion with exonuclease III (see Chapter 13, Protocol 9). Occasionally, these deletions extend back into the primer-binding region, thereby eliminating the ability to obtain DNA sequence. This problem can sometimes be corrected by using a primer complementary to sequences that lie further upstream of the target DNA.

Secondary Structure Problems

Regions of high secondary structure (e.g., homopolymeric tracts and palindromic sequences) in a DNA template can give rise to strong stop sequences that appear as bands in all four channels of the sequencing gel autoradiograph. These regions severely impede the progress of the DNA polymerase and are often encountered when using the Klenow fragment. The first solution is to try sequencing the other strand of the DNA. Another solution is to carry out the sequencing reactions at 50–55°C (Gomer et al. 1985). Alternatively, add a boost of Klenow (0.5 unit in a volume of 1.0 µl) at Step 7 to replenish the enzyme that was inactivated during the termination reactions and so enhance extension beyond the block. It is possible to use dITP in place of dGTP to reduce secondary structure problems. If this modification is necessary, then substitute manganese for magnesium in the reaction buffer to enhance the ability of the Klenow enzyme to utilize the analog (Tabor and Richardson 1989b). As a final solution to secondary structure problems, sequence a template using another DNA polymerase such as Sequenase (Protocol 3) or a thermostable DNA polymerase (Protocol 5).

If problems related to secondary structure in the template persist, the addition to the chain extension/chain termination reactions (at Step 4 in the protocol above) of 0.5 µg of single-stranded DNA-binding protein from *E. coli* (e.g., USB) usually eliminates the difficulty. If single-stranded DNA-binding protein is used, the sequencing reactions must be incubated with proteinase K (0.1 µg/reaction) for 20 minutes at 65°C after adding the formamide-loading buffer (Step 8 above). This treatment allows the DNA to enter the sequencing gel and prevents smearing of bands.

Protocol 5

Dideoxy-mediated Sequencing of DNA Using *Taq* DNA Polymerase

IN ADDITION TO THEIR MORE FAMILIAR ROLE IN PCRS, thermostable DNA polymerases can be used in place of Sequenase or the Klenow fragment to catalyze conventional dideoxynucleotide-mediated, chain-terminating sequencing reactions (Innis et al. 1988). The ability to carry out isothermal chain-termination reactions at elevated temperature (70°C) reduces problems associated with mismatched annealing of primers at spurious binding sites in the template DNA and facilitates sequencing of templates rich in secondary structure. However, there are some disadvantages. Thermostable polymerases of the DNA polymerase I family (e.g., *Taq*) and thermostable enzymes encoded by *Archaea* (e.g., *Pfu*) catalyze the incorporation of ddNTPs at a rate that is at least two orders of magnitude slower than the rate of incorporation of dNTPs (please see Table 12-8). In addition, the efficiency of incorporation of a ddNTP at a particular site is affected by the local sequence of the template DNA. Investigators who have used *Taq* DNA polymerase for standard sequencing know the consequences: band-to-band variation in intensity on autoradiographs of sequencing gels, fading of bands from the bottom to the top of the autoradiograph, and shadow bands in locations where none should be.

These problems can be alleviated by using genetically engineered versions of thermostable DNA polymerases that lack 5′→3′ exonuclease activity and catalyze the incorporation of ddNTPs with high efficiency (please see the discussion on Choosing a Sequencing System in the chapter introduction and Table 12-9 and Figure 12-6). However, these modified enzymes are relatively expensive and are best reserved for use in cycle sequencing where equality of band intensity is required to obtain long reads. Wild-type *Taq* DNA polymerase remains a useful alternative to Sequenase when problems caused by mismatching of primers or knotty secondary structures lead to ambiguous results in reading specific segments of sequence.

TABLE 12-8 Relative Efficiency of Incorporation of dNTPs and ddNTPs by Δ*Taq* DNA Polymerase

Ratio of Incorporation of dNTPs:ddNTPs			
G	A	T	C
200:1	2500:1	30,600:1	2400:1

Data from Vander Horn et al. (1997). Δ*Taq* DNA polymerase, which lacks the first 235 amino acids of the wild-type enzyme and is devoid of 5′-3′ exonuclease activity, is sold by Amersham.

TABLE 12-9 Modified Thermostable DNA Polymerases Widely Used to Catalyze Cycle-sequencing Reactions

NAME AND SUPPLIER	STRUCTURE	PROPERTIES
Taq DNA polymerase (numerous sources)	832-amino-acid protein with a deduced molecular mass of 93.9 kD (Lawyer et al. 1989).	*Taq* DNA carries a potent 5′-3′ exonuclease activity (Longley et al. 1990) and can catalyze the incorporation of dNTPs, dUTP, dITP in PCR (Knittel and Picard 1993; Slupphaug et al. 1993) and ddNTP in sequencing reactions; prefers dNTPs to ddNTPs or fluorescent analogs as substrates by a factor of ~10^3 (Tabor and Richardson 1995) and generates ugly ladders in cycle sequencing with highly variable intensity between adjacent bands (Voss et al 1997). The structure of the crytallized enzyme has been defined (please see the information panel on ***TAQ* DNA POLYMERASE** in Chapter 8).
AmpliTaq CS (cycle sequencing) (Perkin-Elmer)	AmpliTaq CS is not a deletion mutant like most other modified DNA polymerases. Instead, it contains a single point mutation (G46D) that eliminates exonuclease activity while retaining the processivity and extension rate of the wild-type enzyme.	Lacks the 5′-3′ exonuclease activity and shows a strong preference for dNTPs over ddNTPs as substrates. AmpliTaq CS is used for cycle sequencing with end-labeled primers or with radiolabeled dNTPs.
AmpliTaq FS (fluorescent sequencing) (Perkin-Elmer)	AmpliTaq FS like AmpliTaq CS contains a point mutation (G46D) that eliminates exonuclease activity. AmpliTaq FS also carries a point mutation (F667Y) that reduces the preference of wild-type *Taq* polymerase for dNTPs over ddNTPs or fluorescent analogs.	Used for fluorescence-based sequencing.
Klentaq1 (AB Peptides, St. Louis, Missouri)	A Klenow-like variant of *Taq* DNA polymerase that lacks the first 278 residues of the wild-type enzyme (Barnes 1992).	Lacks the 5′-3′ exonuclease activity of the wild-type enzyme. Together with Taquenase (and possibly Thermosequenase), it is the most heat stable of the DNA polymerases but is acknowledged to be inferior to Taquenase for cycle sequencing. The structure of the crystallized enzyme has been defined (Korolev et al. 1995).
Taquenase (ScienTech Corp, St. Louis, Missouri)	A Klenow-like variant of *Taq* that lacks the first 278 residues of the wild-type enzyme and carries a point mutation (F667Y) that reduces the preference of wild-type *Taq* polymerase for dNTPs over ddNTPs or fluorescent analogs.	Lacks the 5′-3′ exonuclease activity of the wild-type enzyme. Efficiently catalyzes the incorporation of dNTPs, ddNTPs, and fluorescent derivatives in cycle-sequencing reactions (Voss et al. 1997). Better suited to internal labeling than many other thermostable DNA polymerases.
ThermoSequenase (Amersham)	A Klenow-like variant of *Taq* that lacks the first 272 residues of the wild-type enzyme and carries a point mutation (F667Y) that reduces the preference of wild-type *Taq* polymerase for dNTPs over ddNTPs.	Lacks the 5′-3′ exonuclease activity of the wild-type enzyme. Does not readily accept fluorescent analogs of dNTPs as substrates. When used in combination with a thermostable pyrophosphatase, it produces gels as beautiful as those of Sequenase in dye-primer sequencing.

Several other modified thermostable polymerases are marketed commercially, e.g., TaqEXPRESS (GenPak Co., UK) and SequiTherm (Epicenter Biotechnologies). Many of these modified enzymes resemble Klentaq1 in structure and properties.

Mutated thermostable enzymes are quickly replacing wild-type enzymes as the DNA polymerases of choice in dideoxy-terminator sequencing. Because mutated thermostable enzymes exhibit reduced discrimination between dNTPs and ddNTPs, the ratios of these two deoxynucleotides in the DNA-sequencing reaction must be changed from those recommended in Table 12-10. The manufacturers of thermostable DNA polymerases usually provide recipes for labeling mixes that are optimal for their particular enzyme. In the absence of information from the man-

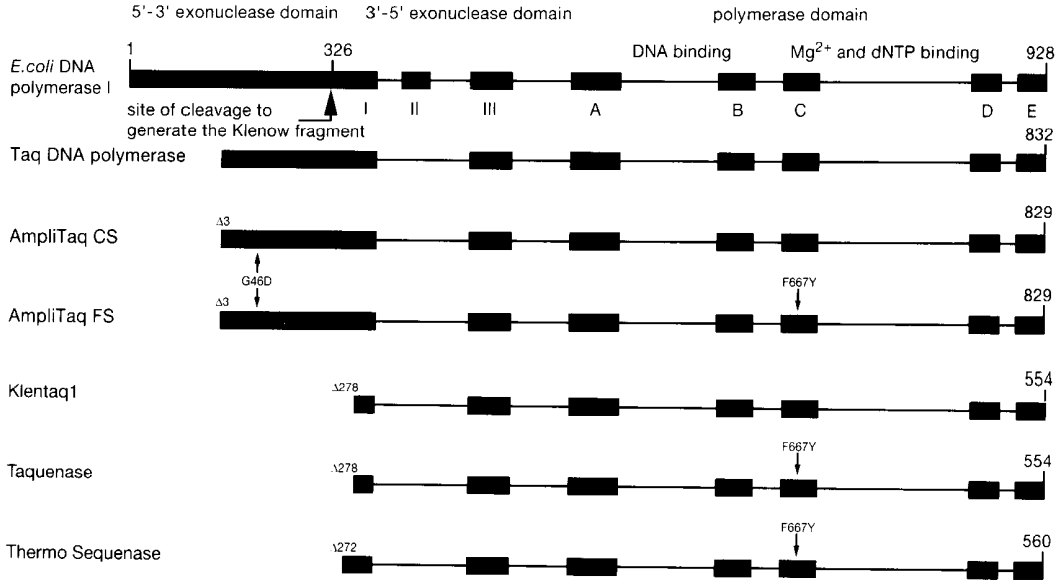

FIGURE 12-6 Structure of Thermostable DNA Polymerases Commonly Used in DNA Sequencing

All of the thermostable polymerases listed in the diagram are modified versions of *Taq* DNA polymerase, which shares the domain structure and many of the motifs conserved among all DNA polymerases of the polymerase I type. In the diagram, the conserved motifs in the 3′→5′ exonuclease domain are marked in Roman numerals. Those in the polymerase domain are marked in uppercase Arabic characters. The numbers above the diagrams designate particular amino acid residues. The sites and nature of point mutations are marked with an arrow. For a description of the properties of these thermostable DNA polymerases, please see Table 12-9. (Diagrams drawn from data in Barnes [1992], Vander Horn et al. [1997], Wayne Barnes Internet Site [http://barnes1.wustl.edu/~wayne/], and literature provided by commercial companies.)

ufacturers, use the following labeling mixture recipes: Mix new ddNTP solutions that contain 150 μM dNTP and 1.5 μM ddNTP. For example, in the ddATP mixture , include 150 μM each of dATP, dTTP, dCTP, and dGTP (or 7-deaza-dGTP) and 1.5 μM of ddATP. Substitute this mixture and the other three ddNTP mixtures for those of Table 12-10 and carry out the protocol as described. The steps involved in sequencing with *Taq* DNA polymerase are similar to those used for Sequenase (Protocol 3):

- ***Denaturation of double-stranded DNA templates*** (if necessary) and annealing of primer to its complementary sequence.
- ***A brief polymerization reaction,*** carried out at low temperature (42°C) in which the primer is elongated by 20–100 nucleotides. This step is performed under conditions where the polymerase is present in excess and the concentrations of the four dNTPs are limiting. A radiolabeled dNTP is included in the reaction so that the short elongation products become radiolabeled at multiple sites. During this preliminary polymerization reaction, most of the available dNTPs, including the radiolabeled dNTP, are incorporated into DNA.
- ***Extension and termination*** of the elongated radiolabeled primers in four reactions that contain high concentrations of unlabeled dNTPs and a single unlabeled ddNTP (ddA, ddG, ddC, or ddT). The extension-termination reactions are carried out at 70°C.

The following protocol was supplied by D. Davis (University of Texas Southwestern Medical Center, Dallas) and is a modification of that described by Innis et al. (1988) and Brow (1990).

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Deionized distilled H_2O (ice cold)

ddNTPs, stock solutions of each of the four ddNTPs (5 mM)

dNTPs, stock solutions of each of the four dNTPs (1 mM)

Formamide-loading buffer **<!>**

10x Labeling mixture and ddNTP chain extension/termination mixtures

When sequencing templates that are rich in secondary structure, replace dGTP in the 10x labeling mixture and the ddNTP extension/termination mixtures with an equimolar amount of 7-deaza-2′-dGTP.

Enzymes and Buffers

5x Reaction buffer

200 mM Tris-Cl (pH 8.8)

25 mM $MgCl_2$

Taq *(5 units/µl) or a similar thermostable DNA polymerase*

Taq *dilution buffer*

25 mM Tris (pH 8.8)

0.01 mM EDTA (pH 8.0)

0.15% Tween-20

0.15% Nonidet P-40

Thermostable enzymes purified from other organisms may require slightly different reaction and dilution buffers. For optimal buffers of individual enzymes, please see the specifications provided by the manufacturer. 1 unit of thermostable DNA polymerase activity is usually defined as that amount which will incorporate 10 nmoles of nucleotide into an acid-precipitable form in 30 minutes at 70–80°C.

Nucleic Acids and Oligonucleotides

Oligonucleotide primer

Use at a concentration of 1.0 pmole/µl (~6.6 ng/µl) in TE (pH 7.6).

For a list of universal primers that bind to vector sequences upstream of the target region, please see the information panel on **UNIVERSAL PRIMERS** in Chapter 8 and the information panel on the **PREPARATION OF STOCK SOLUTIONS OF OLIGONUCLEOTIDE PRIMERS FOR DNA SEQUENCING** at the end of this chapter.

TABLE 12-10 10x Labeling Mixture and ddNTP Chain Extension/Termination Mixtures for Use in Conventional DNA-sequencing Reactions Catalyzed by *Taq* Polymerase

	Stock Solution of dNTP and ddNTPs (All Volumes in µl)								Other Reagents		
Reaction Mixture	dCTP 1 mM	dTTP 1 mM	dATP 1 mM	dGTP 1 mM	ddCTP 5 mM	ddTTP 5 mM	ddATP 5 mM	ddGTP 5 mM	Tris-Cl (1 M, pH 8.0)	EDTA (10 mM, pH 8.0)	H_2O
Labeling	1.5	1.5	–	1.5	–	–	–	–	10	10	975
ddCTP	15	15	15	15	90	–	–	–	10	10	830
ddTTP	15	15	15	15	–	240	–	–	10	10	680
ddATP	15	15	7.5	15	–	–	120	–	10	10	800
ddGTP	15	15	15	15	–	–	–	9	10	10	911

The 10x labeling mixture contains dGTP, dCTP, and dTTP, each at a concentration of 1.5 µM.

The ratios of ddNTP:dNTP in the four ddNTP extension/termination mixtures are 30:1, 80:1, 80:1, and 3:1 for C, T, A, and G, respectively.

The 10x labeling mixture and ddNTP extension/termination mixtures should be dispensed in 50-µl aliquots and stored frozen at –20°C.

Template DNAs (100 ng/µl) in TE (pH 7.6)

Single-stranded DNA (500 ng) or 1.0 µg of denatured double-stranded plasmid DNA is required for each set of four sequencing reactions. Denature and anneal the linear double-stranded DNA to primer by mixing the native template DNA with an excess of primer, heating the mixture in a boiling water bath for ~2 minutes, and then plunging the tube into an ice-water bath. Do not allow the mixture to warm up; use immediately.

The concentration of single-stranded DNA in small-scale preparations of bacteriophage M13 recombinants varies from 0.05 to 0.5 µg/ml, depending on the growth rate of the particular bacteriophage. Under the conditions normally used for sequencing reactions catalyzed by *Taq* polymerase, the template DNA is present in excess. Therefore, small variations in the amounts of template added to different sets of sequencing reactions do not generally affect the quality of the results; however, please see the panel on **TROUBLESHOOTING** in Protocol 4.

Radioactive Compounds

[α-^{32}P]dATP (3000 Ci/mmole, 10 mCi/ml) **<!>**

or

[α-^{35}S]dATP (1000 Ci/mmole, 10 mCi/ml) **<!>**

or

[α-^{33}P]dATP (2000–4000 Ci/mmole, ~10 mCi/ml) **<!>**

or

5′ ^{32}P-labeled oligonucleotide primer **<!>**

Instead of internal labeling with radiolabeled dATP, carry out sequencing with an oligonucleotide primer labeled at the 5′ end with ^{32}P or ^{33}P. In this case, 1.0–1.5 pmoles of the radiolabeled primer and 2 µl of H_2O are included in the reaction mixture in place of the unlabeled primer (Step 1) and radiolabeled dATP (Step 6). All other steps remain the same. The 5′ termini of oligonucleotides are generally labeled by transfer of [γ-^{32}P] from [γ-^{32}P]ATP in a reaction catalyzed by polynucleotide kinase. For details, please see Chapter 10, Protocol 2.

Special Equipment

Microfuge tubes (0.5 ml) or Microtiter plates (flexible, heat-stable, with 96 U-shaped wells of ~300 µl capacity)

Please see the information panel on **MICROTITER PLATES**.

Programmable thermal cycler fitted with multiwell heat blocks (e.g., Dri-Block cyclers, Techne)

Less satisfactory alternatives are water baths preheated to 45°C and 72°C; please see note to Step 8.

Water bath preheated to 65°C

METHOD

1. To a 0.5-ml microfuge tube or well of a microtiter plate, add:

single-stranded template DNA (250 fmoles) (100 ng/µl)	5.0 µl
oligonucleotide primer (0.5 pmole) (~3.3 ng/µl)	3.0 µl
5x reaction buffer	2.0 µl

2. Incubate the tightly closed tube for 2 minutes at 65°C. Remove the tube from the water bath and allow it to cool to room temperature over the course of 3–5 minutes.

   Some investigators prefer to cool the annealing reactions more slowly over the course of 30 minutes in a small heating block or beaker of water. In our hands, both slow- and fast-cooling regimens yield sequence of the same quality.

3. While the primer and template are cooling, thaw the 10x labeling and ddNTP extension/termination mixtures and radiolabeled dATP. Store the thawed solutions on ice.

Preparing ddNTP Extension/Termination Mixtures

4. For each annealing reaction, transfer 4 µl of each ddNTP termination/extension mixture into color-coded 0.5-ml microfuge tubes or into individual wells of a microtiter plate prelabeled C, T, A, and G (i.e., 4 µl of ddCTP mixture to tube/well labeled C, 4 µl of ddTTP mixture into tube/well labeled T, etc.). Store the tubes/microtiter plates on ice.

5. Dilute enough thermostable DNA polymerase enzyme 1:8 for all templates to be sequenced, for example,

Taq DNA polymerase (5–10 units/µl)	1 µl
Taq dilution buffer	7 µl

   2 µl (2 units) of diluted enzyme is needed for each set of four sequencing reactions. The final concentration of the enzyme should be ~1 unit/µl. Store the diluted enzyme on ice at all times.

6. Add the following to each annealing reaction (Step 2 above):

10x labeling mixture	2 µl
radiolabeled dATP	0.5 µl
diluted DNA polymerase enzyme (~1 unit/µl)	8 µl

   Mix the contents of the tube by vortexing and then incubate the reactions for 5 minutes at 45°C.

7. Transfer 4 µl of the labeling reaction to the sides of each of the C, T, A, and G tubes or to the sides of microtiter wells containing the appropriate dideoxy terminator mixtures (Step 4 above).

8. Place the microfuge tubes in a microfuge (use appropriate rotor or adaptors for 0.5-ml tubes or place them inside decapitated 1.5-ml tubes), or place the microtiter plates in a centrifuge equipped with an appropriate adaptor. Centrifuge the C, T, A, and G tubes or plates for a few seconds at 2000 rpm to mix the components of the reactions. Incubate the reactions for 5 minutes at 72°C.

   Incubate the tubes/plates in an efficient heating block or place them in contact with H_2O, oil, or other efficient conductor of heat. Tubes/plates placed in an air incubator set at 72°C will not reach optimum temperature for *Taq* DNA polymerase during the course of the brief incubation.

9. Stop the reactions by adding 4 µl of formamide-loading buffer .

10. The reactions may be stored at –20°C for up to 5 days or analyzed directly by denaturing gel electrophoresis (Protocols 8, 9, or 10, 11, and 12). After heat denaturation (2 minutes at 100°C) and quick cooling on ice, load 3 µl of each of the C, T, A, and G reactions into individual wells of a sequencing gel.

For guidance with any difficulties, please see the panel on **TROUBLESHOOTING** at the end of Protocol 4 and Table 12-13 in Protocol 6.

Protocol 6

Cycle Sequencing: Dideoxy-mediated Sequencing Reactions Using PCR and End-labeled Primers

CYCLE DNA SEQUENCING (MORE PROPERLY CALLED THERMAL CYCLE DNA sequencing or linear amplification DNA sequencing) is a technique in which asymmetric PCR is used to generate a single-stranded template for sequencing by the Sanger dideoxy-chain termination method (Carothers et al. 1989; Murray 1989; Craxton 1991; Lee 1991; E. Lee et al. 1992). Four separate amplification reactions are set up, each containing the same oligonucleotide primer and a different chain-terminating ddNTP. Two cycling programs are typically used in a cycle-sequencing protocol. In the first program, reaction mixtures are subjected to 15–40 rounds of conventional thermal cycling (e.g., please see Halloran et al. 1992; Fulton and Wilson 1994). Each amplification cycle consists of the usual three steps: denaturation of the double-stranded DNA template, annealing of a ^{32}P-labeled sequencing primer to its target sequence, and then extension of the annealed primer by a thermostable DNA polymerase and termination of the extended strand by incorporation of a ddNTP. The resulting partially double-stranded hybrid, which consists of the full-length template strand and its complementary chain-terminated product, is denatured during the first step of the next cycle, thereby liberating the template strand for another round of priming, extension, and termination. Therefore, the radiolabeled, chain-terminated products accumulate in a linear fashion during the entire first phase of the cycle-sequencing reaction. In the second program, the annealing step is omitted so that no further extension of primers is possible. Instead, the "chase" segment provides an opportunity for further extension of reaction products that were not terminated by incorporation of a ddNTP during the initial rounds of conventional thermal cycling. The radiolabeled products of cycle-sequencing reactions are finally displayed on a denaturing polyacrylamide gel and detected by autoradiography. The following are some of the advantages of cycle sequencing:

- ***Works as well with double-stranded as with single-stranded templates*** (Carothers et al. 1989; Murray 1989), thereby eliminating the need to subclone the DNA of interest into bacteriophage M13 or phagemid vectors.
- ***Requires only femtomole amounts of template.*** Sufficient DNA can be obtained from a single plaque or colony or from a PCR product purified from a gel (Smith et al. 1990; Krishnan et al. 1991; Kretz et al. 1994).

- ***Can be set up in either microtiter plates or microfuge tubes.***
- ***Can be adapted for use with internal labeling*** by α-^{32}P-, α-^{33}P-, or α-^{35}S-labeled nucleotides (Carothers et al. 1989; Murray 1989) or with 5′-labeled primers (Lee 1991; Ruano and Kidd 1991; Sears et al. 1992). Cycle sequencing can also accommodate biotinylated and fluorescently labeled nucleotides (e.g., please see Wilson et al. 1990; Civitello et al. 1992; Du et al. 1993; Voss et al. 1997). The fluorescent labels can be attached to either the 5′ end of the primer or to the chain-terminating nucleotides (Rosenthal and Charnock-Jones 1992).
- ***Can be used with commercially available robotic workstations*** (Civitello et al. 1992) and automatic DNA sequencers (Craxton 1991; Rosenthal and Charnock-Jones 1992; Sears et al. 1992).
- ***Accepts nucleotide analogs such as 7-deaza-dGTP*** (Mizusawa et al. 1986) and dITP, which reduce band compressions during electrophoresis (Sears et al. 1992) (please also see the information panels on **COMPRESSIONS IN DNA SEQUENCING GELS** and on **7-DEAZA-dGTP**).
- ***Can be modified to obtain the sequence of each strand of a double-stranded DNA template*** (Ruano and Kidd 1991).
- ***Can be adapted for rapid screening of point mutants*** (Carothers et al. 1989; Hattori et al. 1992).

The key to consistent success in cycle sequencing is the cleanliness of the template DNA. Impurities such as agarose, salts, and proteins all cause premature termination and pausing of DNA polymerases, whereas oligonucleotides produced by degradation of DNA and RNA cause false priming. These impurities lead to an unacceptably high level of false bands and "empty" bands (also known as dropouts). Because the only significant source of impurities in the sequencing reactions is the template DNA, problems can usually be prevented by purifying template DNAs by chromatography through spun columns of Sepharose CL-6B or Sephacryl S-400. When preparing templates from single bacteriophage M13 or λ plaques, use agar or agarose that is warranted to be free of inhibitors of DNA polymerases. When PCR is used to generate the DNA template, residual primers should be removed by spun column chromatography, by electrophoresis through agarose or neutral polyacrylamide gels, or by centrifugal ultrafiltration through devices such as Centricon-100 or Microcon-100 units (Krowczynska and Henderson 1992; Leonard et al 1998; please see Chapter 8, Protocol 3). The requirement for complete removal of residual PCR primers may be eliminated by substituting a 5′ ^{32}P-radiolabeled oligonucleotide primer for α-^{32}P- or α-^{35}S-labeled nucleotides (Protocol 6) in cycle-sequencing reactions.

This protocol is a modification of an unpublished method of N. Sasavage (Life Technologies) which is an elaboration of a method previously published by Lee (1991). The procedure uses 5′ ^{32}P-labeled oligonucleotide primers and can be readily adapted to sequence a variety of DNA templates, including purified DNAs, PCR amplification products (Carothers et al. 1989; Murray 1989), plasmids in *E. coli* hosts (Krishnan et al. 1991), genomic DNA (Ruano and Kidd 1991), and bacteriophage DNAs in plaques (Krishnan et al. 1991).

An additional protocol for cycle sequencing with internal labeling of chain-terminated products by α-^{32}P-, α-^{33}P-, or α-^{35}S-labeled nucleotides is described at the end of this protocol.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

ddNTP extension/termination mixtures

ddNTP solutions of the four ddNTPs, each at 5.0 mM

dNTP solutions of the four dNTPs, each at 1.0 mM

EDTA (0.05 M, pH 8.0)

Formamide-loading buffer **<!>**

Tris-Cl (1 M, pH 8.0)

Enzymes and Buffers

AmpliTaq CS or other exonuclease-deficient versions of Taq *DNA polymerase (5 units/μl)*

5x Cycle-sequencing buffer

200 mM Tris-Cl (pH 8.8)

25 mM $MgCl_2$

Thermostable DNA polymerase

For advice on which enzyme to use, please see Choosing a Sequencing System in the chapter introduction and Table 12-19 in Protocol 5. This protocol has been written with AmpliTaq CS in mind, but it will work well for thermostable enzymes with similar properties.

Nucleic Acids and Oligonucleotides

Oligonucleotide Primers, radiolabeled at the 5′ terminus with ^{33}P or ^{32}P **<!>**

To prepare end-labeled primers, please see Chapter 10, Protocol 2.

Template DNAs

Plasmids, cosmids, bacteriophage λ, and bacteriophage M13 DNAs, purified from large- or small-scale cultures by any of the methods described in Chapters 1–4, can be used as templates. Table 12-12 shows the amounts of each type of template required (please also see Table 12-4).

Special Equipment

Microfuge tubes (0.5 ml) or Microtiter plates (flexible, heat-stable, with 96 U-shaped wells of ~300 μl capacity)

These plates are available color-coded and/or prelabeled C, T, A, and G (please see the information panel on **MICROTITER PLATES**).

Thermal cycler programmed with desired amplification protocol

Please see Step 5.

TABLE 12-11 ddNTP Extension/Termination Mixtures for Use in Cycle-sequencing Reactions

ddNTP Reaction Mixture	Stock Solution of dNTP (1 mM) and ddNTPs (5 mM) (All Volumes in μl)								Other Reagents		
	dCTP	dTTP	dATP	dGTP	ddCTP	ddTTP	ddATP	ddGTP	Tris-Cl (1 M, pH 8.0)	EDTA (10 mM, pH 8.0)	H_2O
ddCTP	20	20	20	20	80	–	–	–	10	10	820
ddTTP	20	20	20	20	–	160	–	–	10	10	740
ddATP	20	20	20	20	–	–	120	–	10	10	780
ddGTP	20	20	20	20	–	–	–	40	10	10	860

Dispense as 50-μl aliquots; store frozen at –20°C.

The ratios of ddNTP:dNTP in the four extension/temination mixtures are 20:1, 40:1, 30:1, and 10:1 for C, T, A, and G, respectively. These ratios were optimized for reactions catalyzed by AmpliTaq CS DNA polymerase. When using other thermostable DNA polymerases, the ratios may need to be re-optimized.

TABLE 12-12 Amounts of Various Types of Templates Required in Cycle-sequencing Reactions

TYPE OF TEMPLATE	AMOUNT OF PURIFIED DNA REQUIRED FOR EACH SET OF FOUR DIDEOXYSEQUENCING REACTIONS (FMOLES)
Double-stranded plasmid DNA	20–200
Single-stranded bacteriophage M13 DNA	1–50
Double-stranded bacteriophage λ DNA	20–200
Double-stranded cosmid DNA	50–200

Cycle sequencing tolerates great variation in the amount of template in the extension/termination reaction. From 1 femtomole to several hundred femtomoles of various types of double-stranded DNA vectors have been reported to work well (Kretz et al. 1994). However, there is little point in using more than 50 fmoles of template since the cycle-sequencing reaction contains only ~1 pmole of radiolabeled oligonucleotide whose concentration will become limiting during the PCR phase.

Although purified DNA templates yield the best results, crude preparations of DNA from bacteriophage M13 plaques, bacteriophage λ plaques, and high-copy-number plasmid DNAs in bacterial colonies may also be sequenced, albeit with reduced efficiency (Krishnan et al. 1991; Kretz et al. 1994). Our experience has shown that freshly grown colonies and plaques produce the best DNA sequence. For unknown reasons, storage of bacterial colonies or lawns of cells containing plaques overnight at 4°C drastically reduces the amount and quality of DNA sequence. This problem can be overcome by streaking the colonies or plaques on fresh agar plates (please see Chapters 1 and 2), followed by sequencing of the new colonies/plaques.

METHOD

1. Transfer 4 µl of appropriate ddNTP extension/termination mixture (please see Table 12-11) into 0.5-ml color-coded microfuge tubes or into individual wells of a heat-stable microtiter plate prelabeled C, T, A, and G (i.e., 4 µl of ddCTP mixture into tube/well labeled C, 4 µl of ddTTP mixture into tube/well labeled T, etc.). Store the tubes/microtiter plates on ice.

2. To the side of each tube or well add:

double-stranded template DNA	10–100 fmoles
1.5 pmoles of 5′ ^{32}P-end labeled primer*	1.0 µl
5x cycle-sequencing buffer	2.0 µl
H_2O	to 5.0 µl

*If using a ^{33}P end-labeled primer: 1.5 µl of a standard preparation of ^{33}P-labeled oligonucleotide contains ~5.0 pmoles of primer (please see the panel on **ADDITIONAL PROTOCOL: CYCLE SEQUENCING REACTIONS USING PCR AND INTERNAL LABELING WITH [α-^{32}]dNTPs** at the end of this protocol). To maintain the stoichiometry of the components of the sequencing reaction, increase the amount of template DNA ~3-fold (30–300 fmoles) *without increasing the total volume of the reaction.*

3. Dilute an aliquot of the preparation of AmpliTaq CS DNA polymerase with 1x cycle-sequencing buffer to a final concentration of 0.5–1.0 unit/µl. Add 1 µl of the diluted enzyme to the side of each tube or well.

4. Mix the reagents by flicking the tubes with a finger or shaking the microtiter plate. If necessary, overlay each reaction with a drop of light mineral oil, cap the tubes, and centrifuge them at 2000 rpm for 2 seconds in a microfuge or briefly in a centrifuge with microtiter plate adaptors.

   Make sure that the mineral oil has not been exposed to UV irradiation. Such exposure can cause the formation of potent inhibitors of PCR.

5. Load the tubes or plate into a thermocycler, preheated to 95°C. Then begin thermal cycling according to the program outlined below.

▲ **IMPORTANT** Do not delay in starting the program. Make sure that the samples are not exposed for >3 minutes to 95°C during the loading/preheating step. Otherwise, the DNA polymerase may be inactivated.

Cycle Number	Denaturation	Annealing	Polymerization
Preheating	60 sec at 95°C		
20–25 cycles	30 sec at 95°C	30 sec at 55°C	60 sec at 72°C
10 cycles	30 sec at 95°C	60 sec at 72°C	60 sec at 72°C

These times are suitable for cycle-sequencing reactions assembled in thin-walled 0.5-ml tubes and incubated in thermal cyclers such as the Perkin-Elmer 9600 or 9700, Master Cycler (Eppendorf), PTC 100 (MJ Research), and Dri-Block MW-1 and PTC- (Techne). Times and temperatures may need to be adapted to suit other types of equipment and reaction volumes.

6. Remove the tubes or plates from the thermocycler and add 5 µl of formamide-loading buffer to each cycle-sequencing reaction.

7. The reactions may be stored for up to 5 days at –20°C or analyzed directly by denaturing gel electrophoresis (Protocols 8, 9, or 10, 11, and 12). After heat denaturation (2 minutes at 100°C) and quick cooling on ice, load 3 µl of each of the C, T, A, and G reactions into individual wells of a sequencing gel.

TROUBLESHOOTING: BACKGROUND IN CYCLE-SEQUENCING GELS

For general guidance on dealing with problems, please see Table 12-13. Background bands are not usually a problem in cycle-sequencing reactions primed by an end-labeled oligonucleotide. However, if the sequencing autoradiograph has bands in the same position in more than one lane, it may be helpful to substitute 7-deaza-dGTP for dGTP in the cycle-sequencing reaction. Make up a new set of ddNTP extension/termination mixtures that contain 7-deaza-dGTP at a concentration of 45 µM, instead of dGTP at a concentration of 20 µM. The concentrations of all other components are unaltered.

Aberrant bands can also be caused by mispriming events. This problem can be alleviated by ensuring that the concentrations of primers and template DNA in the cycle-sequencing reactions are correct.

With some DNA templates, the use of 0.25% (v/v) Nonidet P-40 detergent or 0.1% Tween-20 in the 5x cycle-sequencing buffer may result in a more intense signal with fewer background bands.

TABLE 12-13 Troubleshooting: Problems That Commonly Arise during Dideoxy-DNA Sequencing

SYMPTOM	POSSIBLE CAUSE	QUESTIONS TO ASK	POSSIBLE REMEDIES
1. Faint bands or no bands at all are visible on the autoradiograph.	An essential component (enzyme, dNTPs, primer radioactive precursor) was omitted from reaction. Poor annealing of primer. Saran Wrap was not removed from gel labeled with ^{33}P or ^{35}S. Film processor is broken.	Was the correct labeled dNTP used? Was the specific activity of the labeled dNTP correct? Was the dNTP used within two half-lives? Was a control template included in the experiment? Was the correct primer used? Does the primer have the correct sequence and orientation?	If the lanes containing the control template were faint or blank and if the correct radiolabel was used, the most likely cause of this type of catastrophic failure is the labeling mixture, the DNA polymerase, or the chain extension/termination mixture. Repeat the experiment using new reaction mixtures, a new batch of enzyme, and a positive control template. Check that the film processor is fully functional, that the correct primer is used, and that the gel is correctly processed.
2. Bands are faint at top of gel.	Template DNA is impure. Too much template was used. Ratio of ddNTP to dNTP in the extension/termination mixture was too high.	Was a control template included in the experiment? Was the chain termination/extension mixture appropriate for the DNA polymerase used to catalyze the sequencing reaction?	The key to diagnosis is the control template. If lanes containing the control template show the same symptoms, the most likely cause of the problem is the ratio of ddNTP to dNTP in the extension/termination mixture. Check that the mixture used was appropriate for the sequencing enzyme. Repeat the experiment with a new batch of extension/termination mixture. If lanes containing the control template do not show the symptom, the templates in the remaining lanes must be contaminated with inhibitors. The remedy is to purify the templates further (proteinase K digestion, phenol extraction, and ethanol precipitation) and to redissolve them in H_2O rather than TE.
3. Bands become fainter toward bottom of the gel.	Ratio of ddNTP to dNTP was too low.	Were radiolabeled dNTPs used as precursors in cycle-sequencing reactions or in isothermal reactions catalyzed by *Taq* DNA polymerase or the Klenow fragment? Was the chain termination/extension mixture appropriate for the DNA polymerase used to catalyze the sequencing reaction?	Repeat the experiment using a new batch of chain termination/extension mixture. The best remedy is to change to an end-labeling protocol. Otherwise, repeat the reactions using twice as much labeled dNTP and be prepared to expose the dried gel to film for a long time.
4. One set of sequencing reactions yields four blank tracks.	Template DNA was omitted accidentally, or was degraded, or contains a powerful inhibitor of the sequencing reaction (e.g., EDTA), or does not contain an appropriate primer-binding site.	Were the concentration and integrity of the template verified on an agarose gel?	Purify the template further (proteinase K digestion, phenol extraction, and ethanol precipitation) and redissolve it in H_2O rather than TE. Use another primer that binds to a different site in the template DNA.

5. Three of the four sequencing reactions work well with all templates (including the control) but one lane is always faint or blank.	One of the four chain extension/termination mixtures is defective.	Was the frozen stock of extension/termination mixture maltreated, e.g., by thawing in a water bath? Or was it left at room temperature after thawing?	Make a fresh batch of chain extension/termination mixture. Compare the results obtained from both batches in reactions containing a control template. If the A-track is causing the problem with all templates (including the control), the stock of dATP may be degraded. If the problem is confined to the test templates, the DNAs may be rich in A residues.
6. Amount of radiolabel incorporated during the sequencing reaction varies from template to template.	Templates are present at different concentrations. Template DNAs are partially degraded, or they contain an inhibitor of the sequencing reaction (e.g., EDTA).		Check the concentrations of the template DNAs on agarose gels; make sure that all sequencing reactions contain approximately equal amounts of template. If necessary, purify a new batch of template DNAs, dissolving them in H_2O rather than TE.
7. High background of radiolabeled bands in all four lanes makes the sequences difficult to read.	Template DNAs are impure. Samples were heated too long before loading or, if labeled with ^{32}P, may have undergone radiolysis during storage. Gel plates contain a residue of silanizing agent. DNA polymerase has deteriorated or its concentration is limiting. Samples evaporated during incubation.	Was a control template included in the experiment? Is a smear of chromosomal DNA visible when the template DNAs are analyzed by agarose gel electrophoresis? How long were the samples boiled/stored before loading the gel?	If the control template is exempt from the problem, the homemade DNA templates are most likely contaminated by fragments of chromosomal DNA, which cannot be easily removed by further purification of the template DNAs. The best solution may be to isolate and more carefully purify a new set of template DNAs from freshly picked plaques or colonies. If the background is high in lanes containing the control DNA, the samples may have been heated too vigorously or stored too long and/or the DNA polymerase may be anemic. Repeat the sequencing reactions using a new preparation of DNA polymerase. Make sure the reactions are covered with mineral oil before incubation in a thermal cycler. Transfer the samples to microfuge tubes and denature them by heating to 95°C for 5 minutes; chill the samples to 0°C and load them onto the gel within 20 minutes. Make sure the gel plates are clean.
8. Shadow bands or double bands are present in one set of sequencing reactions.	More than one template is present. Primer is binding to more than one site.		Repurify the template DNA from a freshly picked plaque or colony. If the problem persists, use another primer that binds to a different site in the template DNA.
9. Shadow bands are present in all sequencing reactions.	Concentration of primer is too high. DNA polymerase has deteriorated or its concentration is limiting.	Was the annealing step carried out at the correct temperature?	Titrate the primer, using a new preparation of DNA polymerase. If this does not solve the problem, purify the primer by polyacrylamide gel electrophoresis. If using cycle sequencing, reduce the number of cycles to ~30. Repeat the reactions using DNA polymerase that lacks 5′-3′ exonuclease activity. Please also see Symptom 7, above.

(Continued on following pages.)

TABLE 12-13 *(Continued)*

SYMPTOM	POSSIBLE CAUSE	QUESTIONS TO ASK	POSSIBLE REMEDIES
	Primer is heterogeneous in length and/or the annealing step was carried out at suboptimal temperature.		
	Samples were boiled too long or, if labeled with ^{32}P, may have undergone radiolysis during storage.		
	DNA polymerase carrying 5′-3′ exonuclease activity was used to catalyze the sequencing.		
10. Bands are present in all four tracks in particular regions of sequence *or* bands are missing from particular regions of sequence.	Template contains homopolymeric tracts or regions of stable secondary structure.	Was the template generated by PCR? If so, a primer-dimer or other PCR artifact may have been carried over to the sequencing reaction and has become labeled.	Sequence the complementary strand. Use a different DNA polymerase. Carry out chain extension/termination reactions at higher temperature. Substitute 7-deaza-dGTP for dGTP in ddNTP mixtures and substitute $MnCl_2$ for $MgCl_2$ in sequencing buffer (please see the information panel on **COMPRESSIONS IN DNA SEQUENCING GELS**). Increase the temperature of electrophoresis to 60°C. Alternatively, use a polyacrylamide gel containing 40% formamide.
11. Bands are diffuse through the length of the gel.	Polyacrylamide gel and/or electrophoresis buffer is defective. Samples contain high concentrations of salt. Urea is present in the loading area of the gel. Temperature of the gel is too high during electrophoresis and/or during drying. Poor contact between gel and film.	Does the control template show the same problem?	If the bands in the control template are sharp, the test templates probably contain too much salt. Repurify the template DNA from a freshly picked plaque or colony. If the bands in the template DNA are diffuse, make up new gel mixtures/electrophoresis buffer and new ammonium sulfate solution. The sequencing gel should polymerize rapidly (within 15 minutes). Make sure that the gel mixture is at room temperature when the gel is cast; otherwise, urea may precipitate. Make sure that the loading area of the gel is thoroughly washed before the samples are loaded. Make sure that the temperature of the gel during electrophoresis is ~60°C and that the temperature control on the gel dryer is set correctly.

	Ammonium persulfate solution used to catalyze the polymerization of acrylamide was not fresh.	Make sure that the gel is in close contact with the film during exposure of the autoradiograph. If using single-sided film, make sure that the emulsion side faces the dried gel.
12. Diffuse bands extending across all lanes of the gel (including the control) ~75 bases from the 3′ end of the primer.	Radiolabeled dNTP has deteriorated during storage.	Repeat the sequencing reactions using a fresh batch of radiolabel.
13. Wavy bands.	Sample wells were not thoroughly washed before loading.	Pour a new gel and wash wells thoroughly to remove urea, unpolymerized acrylamide, and loose fragments of polyacrylamide.
14. Black dots on the autoradiograph.	Precipitation of borate or urea from the gel mixtures.	Make up new gel mixtures using freshly purified components. Make sure that the gel mixture is at room temperature when gel is cast; otherwise, urea may precipitate.
15. Radioactivity remained in the sample well.	Samples were not properly denatured.	Transfer the samples to microfuge tubes and denature them by heating to 95°C for 5 minutes; chill the samples to 0°C and load them onto the gel within 20 minutes.
16. Bands are distorted at the top of the gel.	Excess glycerol is present in samples loaded onto the gel.	Use a glycerol-tolerant gel or reduce the amount of glycerol in the samples. Please see the information panel on **GLYCEROL IN DNA SEQUENCING REACTIONS**.
17. Bubbles in gel.	Gel plates were not cleaned properly or gel was poured too quickly.	Pour a new sequencing gel, using clean gel plates.
18. Samples from adjacent lanes become mixed after loading.	Top of the gel was not tightly clamped and/or the comb was not inserted deeply enough into the slot.	Pour a new sequencing gel, taking care to clamp the gel properly and to insert the comb to the correct depth.

ADDITIONAL PROTOCOL: CYCLE SEQUENCING REACTIONS USING PCR AND INTERNAL LABELING WITH [α-^{32}P]dNTPs

Most radiolabeled cycle-sequencing reactions use 5′ ^{32}P-labeled oligonucleotide primers to generate labeled chain-terminated products that can be detected on sequencing gels by autoradiography. Another way to achieve the same goal is to include [α-^{32}P]dNTPs in cycle-sequencing reactions. This method, however, in our hands, produces messier gels with higher backgrounds and cannot be recommended with enthusiasm. The following protocol is an amalgam of methods harvested from individual investigators and from the manufacturers of thermostable DNA polymerases. The protocol has been optimized for use with AmpliTaq CS, but similar thermostable enzymes from other manufacturers should be equally effective (please see Choosing a Sequencing System in the chapter introduction and Table 12-9).

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Additional Materials

[α-^{32}P]dATP (3000 Ci/mmole, 10 mCi/ml) **<!>**
or
[α-^{35}S]dATP (1000 Ci/mmole, 10 mCi/ml) **<!>**
or
[α-^{33}P]dATP (2000–4000 Ci/mmole, ~10 mCi/ml) **<!>**
Cycle-sequencing extension/termination mixtures
Prepared as outlined in Table 12-14.
Oligonucleotide primer (unlabeled and dissolved in H_2O at a concentration of 20 μM)

Method

1. Transfer 2 μl of the appropriate ddNTP mixture (see Table 12-14) into 0.5-ml color-coded microfuge tubes or into individual wells of a heat-stable microtiter plate prelabeled C, T, A, and G (i.e., 2 μl of ddCTP mixture into tube/well labeled C, 2 μl of ddTTP mixture into tube/well labeled T, etc.). Store the tubes/microtiter plates on ice.
2. For each template to be sequenced, prepare 30 μl of the following mixture and add the reagents in the order shown.

template DNA in H_2O	1–100 fmoles
oligonucleotide primer (10 μM)	1.0 μl
α-labeled dATP	1.5 μl
5x cycle-sequencing buffer	8.0 μl
H_2O	to 30 μl

   Mix the reagents by gently flicking the outside of the closed tube. If necessary, centrifuge the tube briefly to deposit all the reagents in the bottom.
3. Transfer 6 μl of the mixture prepared in Step 2 into each of the four tubes/wells prepared in Step 1.
4. Dilute an aliquot of the preparation of AmpliTaq CS DNA polymerase with 1x cycle-sequencing buffer to a final concentration of 0.5–1.0 unit/μl. Add 1 μl of the diluted enzyme to the side of each tube or well.
5. Follow Steps 4–7 of the main protocol.

TABLE 12-14 ddNTP Extension/Termination Mixtures for Use in Cycle-sequencing Reactions with Radiolabeled dATP

ddNTP Reaction Mixture	Stock Solution of dNTP (1 mM) and ddNTPs (5 mM) (All Volumes in μl)								Other Reagents		
	dCTP	dTTP	dATP	dGTP	ddCTP	ddTTP	ddATP	ddGTP	Tris-Cl (1 M, pH 8.0)	EDTA (10 mM, pH 8.0)	H_2O
ddCTP	20	20	20	20	80	–	–	–	10	10	820
ddTTP	20	20	20	20	–	160	–	–	10	10	740
ddATP	20	20	20	20	–	–	120	–	10	10	780
ddGTP	20	20	20	20	–	–	–	40	10	10	860

Protocol 7

Chemical Sequencing

UNLIKE THE CHAIN-TERMINATION TECHNIQUE, WHICH INVOLVES ENZYMATIC SYNTHESIS, the Maxam-Gilbert method entails chemical degradation of a segment of DNA. A fragment of DNA radiolabeled at one end is partially cleaved in five separate chemical reactions, each of which is specific for a particular base or type of base (Maxam and Gilbert 1977, 1980). For further discussion on end-labeling, please see the panel **ADDITIONAL PROTOCOL: PREPARATION OF END-LABELED DNA FOR CHEMICAL SEQUENCING** at the end of this protocol and Figure 12-7. The cleavage reactions generate five populations of radiolabeled molecules that extend from a common point (the radiolabeled terminus) to the site of chemical cleavage. Each population consists of a mixture of molecules whose lengths are determined by the locations of a particular base along the length of the original DNA. These populations are then resolved by electrophoresis through polyacrylamide gels, and the end-labeled molecules are detected by autoradiography (please see Figure 12-7). For further details, please see the introduction (p. 12.3).

The Maxam-Gilbert method has not changed significantly since its initial development. Although additional chemical cleavage reactions have been devised (e.g., please see Ambrose and Pless 1987) and other reactions have been simplified (Muro et al. 1993; Pichersky 1996), most investigators rely on the quintet of reactions originally described by Maxam and Gilbert (1977, 1980). These cleavage reactions are carried out in two stages: (1) Specific bases (or types of bases) undergo chemical modification and (2) the modified base is removed from its sugar, and the phosphodiester bonds 5′ and 3′ to the modified base are cleaved (please see Table 12-15).

TABLE 12-15 Chemical Modifications Used in the Maxam-Gilbert Method

BASE	SPECIFIC MODIFICATION
G	Methylation of N_7 with dimethylsulfate at pH 8.0 renders the C_8–C_9 bond specifically susceptible to cleavage by base.
A+G	Piperidine formate at pH 2.0 weakens the glycosidic bonds of adenine and guanine residues by protonating nitrogen atoms in the purine rings, resulting in depurination.
C+T	Hydrazine opens pyrimidine rings, which recyclize in a five-membered form that is susceptible to removal.
C	In the presence of 1.5 M NaCl, only cytosine reacts appreciably with hydrazine.
A>C	1.2 N NaOH at 90°C results in strong cleavage at A residues and weaker cleavage at C residues.

The volatile secondary amine piperidine is used to cleave the sugar-phosphate chain of DNA at the sites of base modifications. For discussions of mechanism of cleavage, please see Maxam and Gilbert (1980) and Mattes et al. (1986).

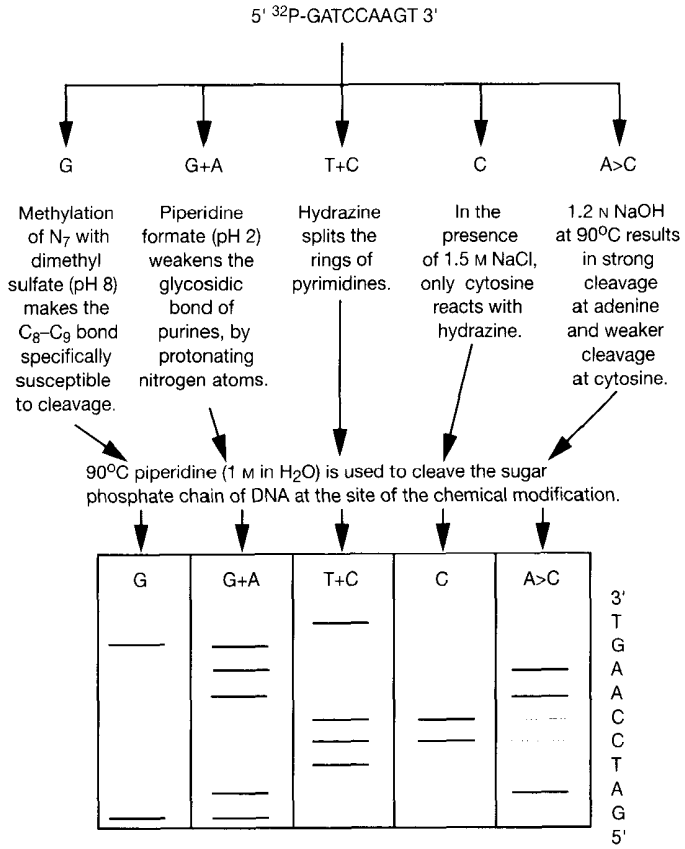

FIGURE 12-7 Sequencing by the Maxam-Gilbert Method of Chemical Degradation

The oligonucleotide in this example (5′ GATCCAAGT 3′) is subjected to five chemical cleavage reactions (G, G+A, T+C, C, A>C). The resulting products of each of the reactions are separated by electrophoresis through a denaturing acrylamide gel and visualized by autoradiography, and the the original sequence is determined from the "ladders" of oligonucleotide products. For details of the chemistry of these reactions, please see the accompanying text and Table 12-15.

In every case, the reactions are carried out under carefully controlled conditions to ensure that on average only one of the target bases in each DNA molecule is modified. Subsequent cleavage of a phosphodiester bond adjacent to the damaged base by hot piperidine yields a set of end-labeled molecules whose lengths range from one to several hundred nucleotides. The piperidine is removed by either ethanol precipitation or vacuum drying or a combination of both. The end-labeled molecules are resuspended, denatured by heating to 90°C in a buffer containing 90% formamide, and then separated by electrophoresis through a polyacrylamide gel. The DNA sequence can then be read from an autoradiograph of the sequencing gel. For a number of reasons (e.g., the use of ^{32}P as a radiolabel, the low specific activity of end-labeled DNA, the statistical distribution of cleavage sites, and the limitations of gel technology), the range of the Maxam-Gilbert method is less than that of the Sanger method. The most that can be expected from a set of Maxam-Gilbert reactions is ~250 bases of sequence, beginning 10–15 bases from the radiolabeled end.

Chemical sequencing of large tracts of DNA fell out of favor in the late 1980s. This was due to two improvements in enzymatic sequencing of DNA: the introduction of DNA polymerases tailor-made for sequencing reactions, and the application of automation through robotics and

fluorescence-based sequencing machines. By contrast, DNA sequencing by the chemical method remained labor-intensive. Nevertheless, chemical sequencing retains one clear advantage: It enables sequencing to begin anywhere in the target DNA where a restriction site can be labeled or an end-labeled fragment can be produced via PCR. In addition, the target DNA can be of any length and can be radiolabeled in a number of ways, depending on the nature of the termini of the DNA (please see Figure 12-8 and the panel on **ADDITIONAL PROTOCOL: PREPARATION OF END-LABELED DNA FOR CHEMICAL SEQUENCING** at the end of this protocol). The sequence obtained in this way can be used as an entry point to generate oligonucleotides that can be used to prime enzymatic sequencing reactions.

In addition, the chemical method continues to have a crucial role in establishing the sequence of oligonucleotides, in the functional dissection of transcriptional control signals (e.g., methylation inerference assays; Carey and Smale 2000), and in the identification and characterization of these regions in intact cells (genomic footprinting; Church and Gilbert 1984).

This protocol is based on the classic Maxam and Gilbert procedure. Investigators are encouraged to read the lucid and comprehensive treatise by Allan Maxam and Walter Gilbert (published in 1980), before carrying out this protocol.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Acetic acid (1 M), freshly diluted from glacial acetic acid (17.4 M) **<!>**

Ethanol (absolute) chilled to –20°C.

Dimethylsulfate (DMS) (99%) (Gold label 99% from Aldrich) **<!>**

DMS (10% v/v) in ethanol **<!>**

DMS buffer

50 mM sodium cacodylate (pH 7.0) **<!>**

1 mM EDTA (pH 8.0)

▲ **WARNING** Wear gloves and a mask when weighing solid sodium cacodylate and gloves when handling DMS buffer.

DMS stop solution

1.5 M sodium acetate (pH 7.0)

1 M β-mercaptoethanol **<!>**

250 μg/ml yeast tRNA

EDTA (0.5 M, pH 8.0)

Formamide **<!>**

Formamide-loading buffer **<!>**

Hydrazine (95%) **<!>**

Store hydrazine (Eastman Kodak) in small aliquots in tightly capped microfuge tubes at –20°C.

Hydrazine stop solution

0.3 M sodium acetate (pH 7.0)

0.1 mM EDTA (pH 8.0)

100 μg/ml yeast tRNA

NaCl (5 M)

NaOH (1.2 N) containing 1 mM EDTA **<!>**

Piperidine (1 M) in H_2O **<!>**

This solution should be freshly made by mixing 1 volume of piperidine (10 M; Fisher) with 9 volumes of H_2O in a graduated glass cylinder.

Piperidine formate (1 M)

Prepared by adjusting a 4% solution of formic acid in H_2O to pH 2.0 with 10 M piperidine.

Sodium acetate (3 M, pH 5.2)

Gels

Polyacrylamide sequencing gel <!>

The products of Maxam-Gilbert sequencing reactions are usually analyzed on 6% or 8% denaturing polyacrylamide gels (please see Protocol 8).

Nucleic Acids and Oligonucleotides

Salmon sperm DNA (1 mg/ml) in H_2O

Sheared salmon sperm DNA is the material traditionally used as carrier in the chemical sequencing method. In fact, almost any DNA will serve the purpose equally well. Sheared salmon sperm DNA can be purchased from commercial suppliers (e.g., Sigma), or it can be generated in the laboratory as described in Chapter 6, Protocol 10.

Target DNA, radiolabeled <!>

Prepare at least 5×10^5 cpm of DNA, asymmetrically end-labeled with ^{32}P and dissolved at a concentration of ~5000 cpm/µl in H_2O (please see the panel on **ADDITIONAL PROTOCOL: PREPARATION OF END-LABELED DNA FOR CHEMICAL SEQUENCING**). The DNA solution *must* be free of salt.

When the quantity of radiolabeled DNA is limiting, it is possible to determine an unambiguous DNA sequence by carrying out only four (C, C+T, A+G, and G) of the five reactions detailed in the flowchart.

Yeast tRNA (1 mg/ml) in H_2O

Special Equipment

Dry ice–ethanol bath <!>

Equipment for Cerenkov counting (see Appendix 8)

Ice-water bath

Microfuge tubes

Cleavage reactions are generally carried out in standard 1.5-ml microfuge tubes. When sequencing a number of DNAs at the same time, use different colored microfuge tubes to facilitate the identification of each base-specific cleavage reaction. Some investigators prefer to use siliconized tubes. However, this precaution is unnecessary if care is taken to ensure that all of the radioactive DNA is dissolved after each precipitation step, for example, by using a pipette tip to roll a bead of buffer over the entire inner surface of the tube, or by vigorous and extensive vortexing.

Rotary vacuum evaporator

For example, a Savant SpeedVac.

Round bath rack with screw-down pressure plate

For example, Research Products International.

Optional, please see Step 4.

Sequencing gel apparatus and power pack

Please see Protocol 11.

Water bath or heating block preset to 37°C and 90°C

METHOD

1. Subject the radiolabeled DNA to the base modification procedures outlined in the flowchart in Table 12-16.

   It is usually possible to determine an umabiguous DNA sequence by carrying out only four (C, C+T, A+G, and G) of the five reactions detailed in the flowchart.

2. Resuspend each of the four or five lyophilized DNA samples containing the base-modified DNA by vortexing with 100 µl of 1 M piperidine.

   Piperidine is used to cleave the sugar-phosphate chain of DNA at the sites of chemical modification.

TABLE 12-16 Flowchart of Traditional Method of Maxam-Gilbert Sequencing

G	A+G	C+T	C	A>C
Mix 190 µl DMS buffer 4 µl sonicated DNA 5 µl ^{32}P-labeled DNA	Mix 10 µl H_2O 4 µl sonicated DNA 10 µl ^{32}P-labeled DNA	Mix 10 µl H_2O 4 µl sonicated DNA 10 µl ^{32}P-labeled DNA	Mix 15 µl 5 M NaCl 4 µl sonicated DNA 5 µl ^{32}P-labeled DNA	Mix 100 µl 1.2 N NaOH,1 mM EDTA 4 µl sonicated DNA 5 µl ^{32}P-labeled DNA
Chill to 0°C.	Chill to 0°C.	Chill to 0°C.	Chill to 0°C.	Close top of tube tightly and secure with plastic tape.
Add 5 µl 10% DMS and mix.	Add 4 µl piperidine formate (pH 2.0) and mix.	Add 30 µl hydrazine and mix gently.	Add 30 µl hydrazine and mix gently.	
Incubate 5 minutes at 20°C.	Incubate 15 minutes at 37°C.	Incubate 7 minutes at 20°C.	Incubate 5 minutes at 20°C.	Incubate 7 minutes at 90°C. Chill to 0°C.
Add 50 µl DMS stop solution (at 0°C) and mix.	Add 240 µl hydrazine stop solution (at 0°C) and mix.	Add 200 µl hydrazine stop solution (at 0°C) and mix.	Add 200 µl hydrazine stop solution (at 0°C) and mix.	Add 150 µl 1 M acetic acid, 5 µl tRNA (1 mg/ml) and mix.
Add 750 µl of ethanol (–20°C) and mix.	Add 750 µl of ethanol (–20°C) and mix.	Add 750 µl of ethanol (–20°C) and mix.	Add 750 µl of ethanol (–20°C) and mix.	Add 750 µl of ethanol (–20°C) and mix.
Store for 5 minutes at –70°C.	Store for 5 minutes at –70°C.	Store for 5 minutes at –70°C.	Store for 5 minutes at –70°C.	Store for 5 minutes at –70°C.
Centrifuge 5 minutes at 12,000*g* at 4°C.	Centrifuge 5 minutes at 12,000*g* at 4°C.	Centrifuge 5 minutes at 12,000*g* at 4°C.	Centrifuge 5 minutes at 12,000*g* at 4°C.	Centrifuge 5 minutes at 12,000*g* at 4°C.
Remove the supernatant carefully and dispose of it in the appropriate waste bottle.	Remove the supernatant.	Remove the supernatant carefully and dispose of it in the appropriate waste bottle.	Remove the supernatant carefully and dispose of it in the appropriate waste bottle.	Remove the supernatant.

Add 300 µl 0.3 M sodium acetate (pH 5.2) at 0°C and mix by vortexing.
Add 900 µl ethanol (–20°C) and mix.
Store 5 minutes at –70°C.
Centrifuge 5 minutes at 12,000*g* at 4°C.
Remove supernatant carefully.
Add 1 ml ethanol (–20°C) and mix.
Centrifuge 2 minutes at 12,000*g* at 4°C.
Remove supernatant carefully.
Lyophilize pellet of DNA.
Add 100 µl 1 M piperidine. Secure the tops of the tubes with plastic tape and mix the contents of the tubes.
Incubate 30 minutes at 90°C.
Lyophilize.
Add 20 µl of H_2O. Vortex for 30 seconds.
Centrifuge 10 seconds at room temperature.
Lyophilize.
Add 20 µl of H_2O. Vortex for 30 seconds.
Centrifuge 10 seconds at room temperature.
Lyophilize.
Add 10 µl sequencing gel-loading buffer. Vortex for 20 seconds.
Centrifuge 10 seconds at room temperature.
Close the tops of the tubes tightly. Heat to 90°C for 1 minute.
Load 3 µl of each sample on a lane of a sequencing gel.

3. Close the tops of the tubes securely. Mix the contents of the tubes by vortexing. If necessary, centrifuge the tubes briefly (2000 rpm) to deposit all of the fluid at the bottom.

4. Incubate the tubes for 30 minutes at 90°C. To prevent the tops of the tubes from popping open during heating, either place a heavy weight on the tubes or seal the tops with plastic tape. Alternatively, use a round bath rack with a screw-down pressure plate (e.g., Research Products International).

5. Allow the tubes to cool to room temperature. Open the lids of the tubes, and seal the open tubes with Parafilm. Pierce several holes in the Parafilm with a 21-gauge needle and evaporate the contents of the tubes to dryness in a rotary vacuum evaporator (e.g., Savant SpeedVac).

   To avoid smeary bands in the final sequencing gel, it is essential to remove the last traces of piperidine from the base-specific cleavage reactions. This is best achieved by lyophilizing using an efficient rotary vacuum evaporator. This step usually takes 1–4 hours depending on the efficiency of the evaporator. Some investigators prefer to freeze the samples in a dry ice–ethanol bath just before placing the tubes in the evaporator.

6. Remove the tubes from the evaporator. Discard the Parafilm and add 20 µl of H_2O to each tube. Close the caps of the tubes, and vortex the tubes for 30 seconds to dissolve the DNA. Centrifuge the tubes briefly to deposit all of the fluid at the bottom. Use a hand-held minimonitor to check that all of the radiolabeled DNA has been washed from the walls of the tubes by the H_2O and is dissolved in the fluid.

7. Once again, evaporate all of the samples to dryness in a rotary vacuum evaporator (see Step 5 above). This step usually takes 15–30 minutes, depending on the efficiency of the evaporator.

8. Repeat Steps 6 and 7.

   To ensure that all of the piperidine has been removed, some investigators prefer to dissolve the DNA once more in 10 µl of H_2O and to carry out an additional cycle of evaporation. However, this step is necessary only if the samples have an "oily" look or if abnormally long periods of evaporation have been required to reduce them to dryness.

9. Estimate the amount of radioactivity remaining in each of the tubes by Cerenkov counting, and dissolve the individual modification and cleavage reactions in sequencing gel-loading buffer. An overnight exposure on Kodak XAR-5 film requires ~25,000 cpm of reactions that cleave the DNA after only one base (i.e., the C and G reactions), and ~50,000 cpm of reactions that cleave after two bases (C+T, A+G, and A>C). Therefore, the modified and cleaved DNAs should be dissolved in sequencing gel-loading buffer so that the C and G reactions contain ~25,000 cpm/3 µl and the C+T, A+G, and A>C reactions contain ~50,000 cpm/3 µl. Vortex the tubes to dissolve the DNA fully. Centrifuge the tubes briefly to deposit all of the fluid at the bottom. If necessary, the samples may be stored at –20°C for a few hours while the sequencing gel is prepared.

10. Heat the tubes for 1 minute at 90°C to denature the DNA before quick-cooling on ice. Analyze the reactions by electrophoresis through denaturing polyacrylamide gels as described in Protocols 8, 9, or 10, 11, and 12.

    If difficulties arise with chemical sequencing, the best course of action is to read the article by Maxam and Gilbert (1980), which explains in detail how to diagnose and correct problems. Table 12-17 is reproduced, with permission, from this article.

TABLE 12-17 Diagnosis and Correction of Aberrations in Sequencing Band Patterns

PROBLEM	PROBABLE CAUSES	SUGGESTED SOLUTIONS
1. Any of all of the following: **a.** Smearing of pyrimidine cleavage products. **b.** Loss of electrophoresis dye color in C and/or C+T samples. **c.** Bands in C and/or C+T ladders at positions where purines follow pyrimidines in the sequence. **d.** Large, water-insoluble pellets after the first ethanol precipitation. **e.** Poor suppression of Ts in the C ladder.	Fragments of DNA broken at pyrimidines contain one or more internal thymines and/or cytosines that reacted with hydrazine but did not then cleave with piperdine. Each of these legitimate cleavage products blurs because its charge and/or mass is heterogeneous, due to the varying number and nature of internal hydrazine reaction products. Causes include an inadequate piperidine reaction and secondary reactions with residual hydrazine during the 90°C strand-scission and heat denaturation steps. Hydrazine can be carried through the procedure when ethanol precipitation and/or lyophilization fails to remove it. An insoluble complex of hydrazine, magnesium, and possibly other ions, which appears as a larger pellet, and poor vacuum during the lyophilization steps are common causes of this problem.	If magnesium acetate is still used in the hydrazine stop solution as originally suggested, delete it. If piperidine reactions are done in microfuge tubes, be sure to use at least 100 µl and to seal the cap tightly (otherwise, use flame-sealed capillaries). After the piperidine reaction, use a strong vacuum with rewetting of the residue to ensure removal of any residual hydrazine during lyophilization.
	Hydrazine has undergone oxidation.	Replace the hydrazine with a fresh aliquot or new stock bottle.
2. Ts are weak in the C+T ladder.	Residual salt from ethanol precipitation of end-labeled DNA is carried over into the sequencing reactions and partially suppresses the reaction of hydrazine with thymine in the C+T sample.	As a final purification step, dissolve end-labeled DNA in 25 µl of H_2O and 1 ml of ethanol, mix, chill, centrifuge, and dry the pellet. Then dissolve it in H_2O and distribute into sequencing reactions.
3. Bands are present in C and/or C+T ladders at *all* guanine positions, not just those where guanine follows a pyrimidine in the sequence as in **1c** above or **4** below.	A reaction between hydrazine and guanine at lower pH (perhaps due to residual sodium acetate), after which piperidine breaks the DNA at guanines.	Keep the samples at 4°C or below during the ethanol precipitations steps. Use chilled (0–4°C) hydrazine stop solution, sodium acetate, and ethanol. See solution to problem **2**.
4. Bands in C and/or C+T ladders at positions where purines follow pyrimidines in the sequence, but not at every purine in a run as in **3** above. See also problem **1c** above.	Residual sodium acetate from the second ethanol precipitation buffers piperidine, leading to incomplete phosphate elimination reactions, which require a high pH. The 3′ termini of 5′-labeled fragments then retain deoxyribosyl residues, have one less negative charge, and move one position slower in the gel.	Rinse the last pellet well with 95% ethanol or dissolve it in 25 µl of H_2O; add 1 ml of 95% ethanol, mix, chill, and collect the reprecipitated DNA by centrifugation.
	Some labeled DNA is not dissolved in the piperidine and therefore does not react with it at 90°C.	After adding piperidine to a tube containing dry DNA, close the cap and bat the tube with fingers to splash the liquid up the walls; then collect it at the bottom with a quick spin.
5. All DNA bands and both electrophoresis dyes are retarded in some ladders.	Effect of residual piperidine on gel electrophoresis.	Wet the DNA residue, freeze, and lyophilize under a strong vacuum.
6. Bands in A>G ladders produced by the older R2 reaction[a] are not sharp.	Overmethylation. Fragments cleaved at adenines carry too many ring-opened 7-methylguanines and are heterogeneous in charge.	Use the same dimethylsulfate reaction conditions used for reaction R5[a] guanine cleavage. (Weak A>G bands can be strengthened by mixing more often during the acid release, slightly increasing the acid concentration, or introducing extra labeled DNA into samples destined for A>G cleavage.)

(*Continued on following page.*)

TABLE 12-17 (*Continued*)

PROBLEM	PROBABLE CAUSES	SUGGESTED SOLUTIONS
7. All ladders exhibit uniform chemical cleavage of desired base specificity, but the bands are not sharp enough to permit reading very far into the sequence.	Sample not evenly distributed in sample well. Diffusion or secondary structural effects during electrophoresis. Parallax or scatter during autoradiography.	Layer samples with a pointed glass capillary, using a slow, side-to-side, sweeping motion. Turn the power up until the gel runs at 50°C. Use a slab gel no more than 1.5 mm thick, preferably 0.5 mm, and compress the X-ray film against it with lead bricks during autoradiography. Dry the gel on a commercial gel dryer before autoradiography.
8. Sudden loss of expected bands, bad spacing, or band order in all four ladders in the middle of a sequencing patterns.	Nested end-labeled cleavage products become long enough to fold into stable hairpins and move anomalously in the gel (the so-called compression effect).	Be sure that the DNA is thoroughtly denatured when loaded on the sequencing gel. Prerun and run the gel at a voltage that generates as much heat as the glass plates will tolerate (>50°C).
9. Loss of just one band in both pyrimidine ladders in the middle of a sequencing pattern.	Presence of 5-methylcytosine, which reacts so slowly with hydrazine (relative to unmodified cytosine) that the DNA is not cleaved at that position.	Look for guanine at the corresponding position in the sequence of the complementary strand.
10. Extraneous bands in all ladders throughout a sequencing pattern.	Contaminating end-labeled fragment. Terminal heterogeneity generated before or during end-labeling by a contaminating nuclease. Unavoidable terminal heterogeneity originating in vivo or as a consequence of DNase I or nuclease S1 treatment in vitro.	Strive for better DNA resolution on the fragment-division or strand-separation gel, or use a different restriction enzyme for secondary cleavage. Purify restriction enzyme, phosphatase, kinase, or terminal transferase. After labeling ragged ends, cleave with restriction enzymes that will give end segments <100 bp long, denature, and fractionate on a 1.5-mm 8% sequencing gel. Strands differing in length by one or more nucleotides will resolve and can be extracted for sequence analysis.
11. An extraneous band across all four ladders at one position in a sequencing pattern	Some double-stranded DNA molecules are nicked by a restriction enzyme at a sequence that closely resembles the enzyme's true recognition site or by a sequence-specific contaminating enzyme. After end-labeling, a double-stranded fragment isolated on a nondenaturing gel retains the hidden break, which is then revealed on the denaturing sequencing gel. This can be confirmed by electrophoresis of some unreacted end-labeled DNA in parallel with the sequencing samples. Unique endogenous nicks and alkali-labile nucleotides are unlikely causes, but they are possible in rare cases and subject to similar tests.	Attempt to derive the sequence surrounding the break on both strands, and compare it with the recognition sequences of all restriction enzymes used to generate that DNA fragment. In making this comparison, remember that bands in the sequencing pattern arise from fragments that lack the nucleotide with which they are identified, whereas enzymatic cleavage products retain all nucleotides. If 3/4, 4/5, or 5/6 of the bases are homologous, tentatively assume nicking at the variant site. Then avoid excesses of that restriction enzyme in subsequent DNA digestions, ideally using just enough pure enzyme to cleave every legitimate site. If the problem persists, avoid that enzyme altogether and use another cleavage route or strand separation.

12. One or a few bands in two ladders produced by cleavage reactions that do not normally share base specificity. Cleavage is consistent with base specificity everywhere else in the sequencing pattern.	Sequence heterogeneity in the DNA at that position.	Confirm by getting the complementary effect on the other strand.
	Compression.	See **8** above.
13. Difficulty in identifying the band corresponding to chemical cleavage of the ultimate 5′ nucleotide (^{32}P-labeled with polynucleotide kinase and [γ-^{32}P]ATP).	[^{32}P]Orthophosphate is the product of base-specific chemical cleavage of the ^{32}P-labeled 5′-terminal nucleotide, and this migrates so rapidly that it is usually run off the gel and missed altogether. A diffuse hydrazinolysis artifact product that sometimes appears between the first and third bands further confuses the interpretation.	Put some [^{32}P]phosphate in formamide–buffer–dyes solution, and run as a marker adjacent to products of the four base-specific reactions on a 20% sequencing gel. Prerun the gel, load the five samples, run the gel until the bromophenol blue marker has proceeded one third of the way down the gel, and autoradiograph. A band in one or two of the four usual lanes running even with the phosphate in the fifth indicates which base-specific reaction(s) cleaved the 5′-terminal nucleotide.
14. Difficulty in identifying the band corresponding to chemical cleavage of ultimate 3′ nucleotide (^{32}P-labeled and incorporated by terminal transferase or DNA polymerase).	With DNA 3′ end-labeled by addition of more than one ^{32}P-labeled nucleotide, chemical attack at the *ultimate*, added 3′ ribonucleotide releases [^{32}P]phosphate, which is usually run off the sequencing gel and missed altogether. Furthermore, be aware that none of the four recommended reactions (G, A+G, T+C, C) will cleave riboadenylic acid, since ribonucleotides do not depurinate readily. The three other ribonucleotides should cleave like deoxynucleotides in these reactions.	Put some [^{32}P]phosphate in formamide–buffer–dyes solution, and run adjacent to products of the four base-specific reactions on a 20% sequencing gel as described under the solution to **13** above. This marker will indicate the product of a reaction with the *ultimate* 3′ base.
	With DNA 3′ end-labeled with DNA polymerase, chemical attack at the *penultimate* deoxynucleotide releases the ^{32}P-labeled ultimate 3′ nucleotide intact.	Digest some of the end-labeled DNA with DNase and snake venom phosphodiesterase, lyophilize, dissolve in formamide–buffer–dyes, and run adjacent to products of the four base-specific reactions on a 20% sequencing gel as described under the solution to **13.** This marker will indicate the product of a reaction with the *penultimate* 3′ base.
15. More than one strong band appears at the position of uncleaved DNA at the top of all sequence ladders.	One is a single-stranded DNA and the other double-stranded DNA.	Increase dimethylsulfate or hydrazine reaction times, use stronger denaturation before loading samples on the gel, or both.
	Variant or incomplete restriction enzyme cleavage.	See **11** above.
	Contaminating end-labeled fragment.	See **10** above.
	Fragment length heterogeneity.	See **10** above.

Reproduced, with permission, from Maxam and Gilbert (1980).

[a]For descriptions of R2 and R5 reactions, please see Maxam and Gilbert (1980).

ALTERNATIVE PROTOCOL: RAPID MAXAM-GILBERT SEQUENCING

During the past years, the five chemical cleavage reactions routinely used in the Maxam-Gilbert method of DNA sequencing have been supplemented by a number of additional base-specific cleavage reactions (e.g., please see Rubin and Schmid 1980; Ambrose and Pless 1987; McCarthy 1989; Jelen et al. 1991; Iverson and Dervan 1993; Muro et al. 1993). The additional reactions are usually easier and faster, but the results are generally not as clean as those obtained from the traditional set of Maxam-Gilbert reactions. Rapid methods of chemical sequencing are particularly useful for resolving regions of doubtful sequence, for confirming a known DNA sequence, or for generating DNA sequence ladders for use as size standards in DNase I footprinting (see Chapter 17). A flowchart for rapid Maxam-Gilbert sequencing is given in Table 12-18.

Additional Materials

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Allyl alcohol (2-propen-1-ol; Fisher)

n-Butanol (HPLC grade or better) **<!>**

Formic acid (8.8%) **<!>**

Prepared by diluting 1 volume of concentrated formic acid (88%) with 9 volumes of H_2O.

NaOH (30% w/v) **<!>**

Prepared by dissolving 30 g of NaOH in 50 ml of H_2O.
After the pellets have completely dissolved and the solution has cooled, adjust the volume to 100 ml with H_2O.
▲ **WARNING** NaOH is dissolved exothermically, and it is therefore essential to add the pellets slowly to prevent the solution from boiling.

Potassium permanganate (2 mg/ml) in H_2O **<!>**

Prepare in the dark at room temperature. This stock solution may be stored in the dark for up to 1 week.
The working solution of $KMnO_4$ is made on the day of use by diluting the stock solution 1:100 in H_2O.

Method

1. Prepare ^{32}P-end-labeled DNA as described in the panel on **ADDITIONAL PROTOCOL: PREPARATION OF END-LABELED DNA FOR CHEMICAL SEQUENCING** at the end of this protocol.
2. Subject the DNA to the chemical modifications outlined in the flowchart in Table 12-18.
3. After the ethanol precipitation step at the end of the flowchart, resuspend the modified DNA in 100 µl of 1 M piperidine and follow Steps 2–10 of the main protocol.

TABLE 12-18 Flowchart of Rapid Method of Maxam-Gilbert Sequencing (Alternative Protocol)

A+G	A>C	C+T (C>T)	T
Mix 4 µl sonicated DNA 10 µl ^{32}P-labeled DNA	Mix 4 µl sonicated DNA 5 µl ^{32}P-labeled DNA	Mix 4 µl sonicated DNA 10 µl ^{32}P-labeled DNA	Mix 4 µl sonicated DNA 5 µl ^{32}P-labeled DNA
Add 3 µl 8.8% formic acid.	Add 1 µl 30% NaOH.	Add 15 µl hydrazine.	
Incubate 7 minutes at 37°C.	Incubate 6 minutes at 90°C.	Incubate 4 minutes at 20°C.	Incubate 2 minutes at 90°C.
Chill to 0°C.	Chill to 0°C.	Chill to 0°C.	Chill to 0°C.
Add 150 µl 1 M piperidine (at 0°C).	Add 150 µl 1 M piperidine (at 0°C).	Add 1 ml *n*-butanol. Vortex for 30 seconds.	Add 20 µl $KMnO_4$ (20 µg/ml).
Store on ice until all reactions are ready for incubation.	Store on ice until all reactions are ready for incubation.	Centrifuge at 12,000*g* for 2 minutes at 4°C.	Incubate 8 minutes at 20°C.
		Remove *all* supernatant.	Add 10 µl allyl alcohol. Vortex for 30 seconds.
		Add 150 µl H_2O. Add 1.2 ml *n*-butanol. Vortex for 30 seconds.	Lyophilize.
		Centrifuge at 12,000*g* for 2 minutes at 4°C.	Add 150 µl 1 M piperidine.
		Remove all supernatant.	Store on ice until all reactions are ready for incubation.
		Lyophilize.	
		Add 150 µl 1 M piperdine.	
		Store on ice until all reactions are ready for incubation.	
Incubate 30 minutes at 90°C.	Incubate 30 minutes at 90°C.	Incubate 30 minutes at 90°C.	Incubate 30 minutes at 90°C.
	Add 150 µl ethanol (70%)		
Add 1.2 ml *n*-butanol. Vortex for 30 seconds.	Add 1.2 ml *n*-butanol. Vortex for 30 seconds.	Add 1.2 ml *n*-butanol. Vortex for 30 seconds.	Add 1.2 ml *n*-butanol. Vortex for 30 seconds.

↓

Centrifuge 2 minutes at 12,000*g* at 4°C.
Remove supernatant *completely*.
Add 150 µl 1% SDS, 1–2 ml *n*-butanol. Vortex for 30 seconds.
Centrifuge 2 minutes at 12,000*g* at room temperature.
Remove supernatant *completely*.
Lyophilize for 20 minutes.
Add 10 µl sequencing gel-loading buffer. Vortex for 20 seconds.
Centrifuge 10 seconds at 12,000*g* at room temperature.
Close the tops of the tubes tightly. Heat to 90°C for 1 minute.
Load 3 µl of each sample on a lane of a sequencing gel.

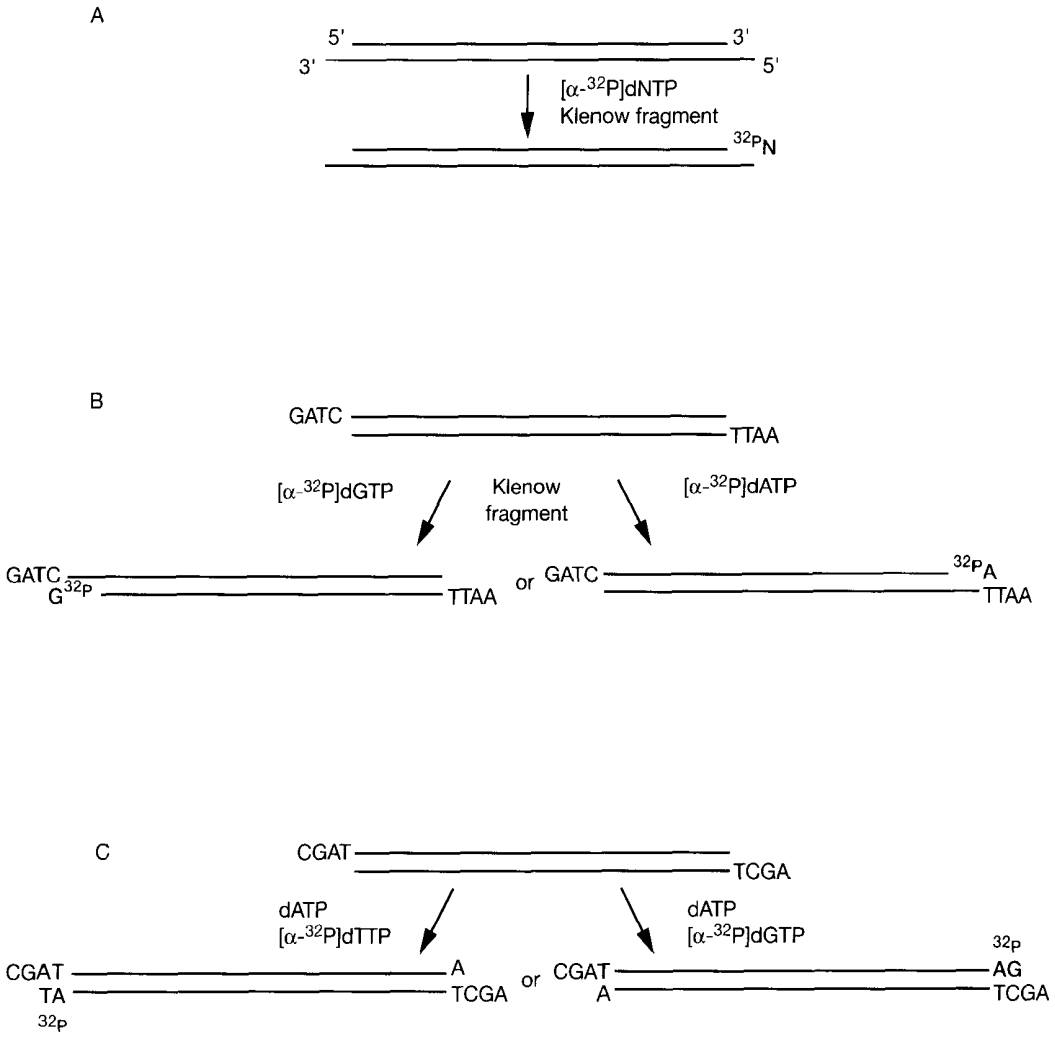

FIGURE 12-8 Examples of Methods Commonly Used to Label Double-stranded DNA Asymmetrically

(*A*) Isolate target DNA by cleavage with two restriction enzymes, only one of which generates a recessed 3′ terminus. Radiolabel recessed terminus with the appropriate [α-^{32}P]dNTP and the Klenow fragment. (*B*) Isolate target DNA by cleavage with two restriction enzymes that generate different recessed 3′ termini. Radiolabel one of the recessed terminals with the appropriate [α-^{32}P]dNTP and the Klenow fragment. (*C*) A variation of method B can be used to label asymmetrically target DNA that carries recessed 3′ termini with similar, but not identical, sequences.

ADDITIONAL PROTOCOL: PREPARATION OF END-LABELED DNA FOR CHEMICAL SEQUENCING

The ends of double-stranded DNA can be labeled as follows:

- Transfer the γ-P from [γ-^{32}P]ATP or, less commonly, [γ-^{33}P]ATP to the free hydroxyl group at the 5′ termini of double-stranded DNA. This in vitro reaction is catalyzed by bacteriophage T4 polynucleotide kinase (please see Chapter 9, Protocols 14 and 15). (Note that [γ-^{35}S]ATP is not a good substrate for polynucleotide kinase and is transferred inefficiently to 5′-hydroxyl groups.)
- Transfer the chain-terminating base analog [α-^{32}P]cordycepin triphosphate (3′-desoxyribonucleoside triphosphate) to the free hydroxyl group at the 3′ termini of double-stranded DNA (Chapter 9, Protocol 12). This reaction is catalyzed by calf thymus deoxynucleoside terminal transferase (Tu and Cohen 1980).
- Fill recessed 3′ termini with [α-^{32}P]dNTPs in a synthetic reaction catalyzed by the Klenow fragment (Chapter 9, Protocol 10) (Cobianchi and Wilson 1987). Whether this reaction generates DNAs that are labeled at one or both termini depends on whether one or both termini are recessed, and if so, on the sequence of the protruding tails. Often, the filling reaction can be set up so that the radiolabeled dNTP is incorporated into only one terminus of the DNA. In this case, there is no need to cleave the radiolabeled DNA with a restriction enzyme or to purify a fragment by gel electrophoresis before proceeding to chemical sequencing. Examples of this type of asymmetric labeling are shown in Figure 12-8.
- Carry out a PCR with one radiolabeled primer and one unlabeled primer (Hooft van Huijsduijnen 1992; Konat et al. 1994) (Chapter 8). Because only one of the two strands of the PCR products is labeled, there is no need to cleave the radiolabeled DNA with a restriction enzyme or to purify a fragment by gel electrophoresis before proceeding to chemical sequencing.

Because the first two methods almost always result in the introduction of radiolabel at both termini of the DNA, additional steps are usually required to obtain asymmetrically labeled molecules. In most cases, the radiolabeled DNA is digested with one or more restriction enzymes, and the resulting end-labeled double-stranded fragments are then purified by conventional nondenaturing agarose or polyacrylamide gel electrophoresis. The sole disadvantage of this digestion step is that it requires some prior knowledge of the pattern of cleavage of the DNA by the particular restriction enzyme(s) used.

For the reasons listed below, labeling by PCR is now the method of choice for preparing end-labeled DNAs for Maxam-Gilbert sequencing.

- Radiolabeling can be carried out using small-scale preparations of plasmid DNA.
- Target DNA can often be sequenced from both ends.
- Because labeling by PCR is rapid and simple, many different templates can be prepared for sequencing or manipulation simultaneously.
- There is no need to map the positions of restriction sites within the target DNA before sequencing.

Whatever the method used for radiolabeling, the end-labeled target fragment must contain at least 5×10^5 cpm of ^{32}P (by Cerenkov counting, please see Appendix 8) in order to obtain an autoradiograph of a sequencing gel that can be read after 24–48 hours of exposure. To achieve this goal, it is usually necessary to radiolabel at least 0.3 pmole of the target DNA (e.g., 1 μg of a 5-kb fragment) and to use ^{32}P-labeled precursors of high specific activity (>3000 Ci/mmole). ^{33}P or ^{35}S labeling is not used to prepare DNAs for Maxam-Gilbert sequencing, largely because the lower energy of decay and longer half-lives of these isotopes greatly extend the times required to establish satisfactory autoradiographs.

Whether or not the radiolabeled target DNA is recovered from a gel or directly from an enzymatic reaction, it should be purified by extraction with phenol:chlorofrom and ethanol precipitation in the presence of 0.3 M sodium acetate (pH 5.2). The pellet of DNA and the sides of the tube should then be washed several times with ice-cold 70% ethanol to remove residual salt. The nearly dry pellet of DNA should then be dissolved in H_2O at a concentration that equals 5000 cpm/μl. If the quantity of radiolabeled DNA is limiting, it is usually possible to determine an unambiguous DNA sequence by carrying out only four (C, C+T, A+G, and G) of the five reactions detailed in the flow chart.

▲ **IMPORTANT** Do not dissolve the DNA in TE or any solvent containing salt. Salt interferes with the reaction between hydrazine and thymine and so reduces the intensity of the bands in the T+C reaction. Buffers such as Tris that are rich in amine groups can suppress the depurination of A and G.

Protocol 8

Preparation of Denaturing Polyacrylamide Gels

IN SEQUENCING, FOUR SETS OF DNA FRAGMENTS ARE RESOLVED BY ELECTROPHORESIS under denaturing conditions through a thin polyacrylamide gel. This protocol describes how to pour a DNA sequencing gel that contains one concentration of buffer and a single concentration of acrylamide throughout the gel. Urea is included in the gel as a denaturant to ensure that the separated DNA strands remain apart and migrate through the gel as linear molecules. The gel is cast between two glass plates that are separated by two thin Teflon or nylon spacers. A so-called shark's tooth comb or, less frequently, a standard slotted comb forms the sample wells into which the DNA sequencing reactions are loaded before electrophoresis.

Polyacrylamide gels used in the early days of DNA sequencing were grossly thick by today's standards. Autoradiographic exposure times were long, and the bands of DNA were diffuse as a result of quenching and dispersion of the radioactive signal. To alleviate these problems, Fred Sanger and Alan Coulson (1978) devised a method whereby "thin gels" were poured using ultrathin spacers ranging in thickness from 0.2 mm to 0.5 mm. Thin gels are now used ubiquitously to resolve the products of DNA sequencing reactions.

The following protocol is a third-generation product (Fred Sanger of the MRC, Cambridge, UK; Michael Smith of the University of British Columbia; and David W. Russell of the University of Texas Southwestern Medical Center, Dallas) of the original Sanger and Coulson method for pouring thin gels.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Acrylamide solution (45% w/v) **<!>**

acrylamide (DNA-sequencing grade)	434 g
N,N'-methylenebisacrylamide	16 g
H_2O	to 600 ml

Heat the solution to 37°C to dissolve the chemicals. Adjust the volume to 1 liter with distilled H_2O. Filter the solution through a nitrocellulose filter (e.g., Nalge, 0.45-μm pore size), and store the filtered solution in dark bottles at room temperature.

An alternative, but more expensive method of preparing the acrylamide stock solution is to purchase a premixed powder of acrylamide:bis from a commercial manufacturer (e.g., Bio-Rad) and to reconstitute the mixture with H_2O. Stabilized, premixed solutions of acrylamide:bis are available from National Diagnostics, Atlanta, Georgia.

Cheaper grades of acrylamide and bisacrylamide are often contaminated with metal ions. Stock solutions of acrylamide made with these grades can easily be purified by stirring overnight with ~0.2 volume of monobed resin (MB-1, Mallinckrodt), followed by filtration through Whatman No. 1 paper.

During storage, acrylamide and bisacrylamide are slowly converted to acrylic acid and bisacrylic acid. This deamination reaction is catalyzed by light and alkali. Check that the pH of the acrylamide solution is 7.0 or less, and store the solution in dark bottles at room temperature. Fresh solutions should be prepared every few weeks.

Ammonium persulfate (1.6% w/v) in H_2O **<!>**

Ammonium persulfate is used as a catalyst for the polymerization of polyacrylamide gels. The polymerization reaction is driven by free radicals that are generated by an oxido-reduction reaction in which a diamine (e.g., TEMED) is used as the adjunct catalyst (Chrambach and Rodbard 1972). Old ammonium persulfate solutions may not have the catalytic power to drive the polymerization reaction to completion. Fuzzy bands of DNA and various other forms of matrix distortion are the inevitable consequence.

Deionized H_2O

Detergent, household dishwashing

Ethanol

KOH/Methanol solution **<!>**

The solution, which is used to clean glass plates used to cast sequencing gels, is prepared by dissolving 5 g of KOH pellets in 100 ml of methanol. Store the solution at room temperature in a tightly capped glass bottle.

Silanizing fluid **<!>**

The traditional silanizing fluids (e.g., Sigmacote from Sigma and Repelcote from BDH Inc.) contain dichlorodimethylsilane, which is toxic, volatile, and highly flammable (for information about dichlorodimethylsilane, please see the information panel on **DICHLORODIMETHYLSILANE**). In recent years, nontoxic alternatives have become available, including Gel Slick (FMC Bioproducts), RainX (Unelko, Scottsdale Arizona), and Acrylease (Stratagene).

10x TBE electrophoresis buffer

TBE is used at a working strength of 1x (89 mM Tris-borate, 2 mM EDTA) for polyacrylamide gel electrophoresis. This 1x concentration is twice the strength usually used for agarose gel electrophoresis (please see Chapter 5). The buffer reservoirs of the vertical tanks used for polyacrylamide gel electrophoresis are fairly small, and the amount of electric current passed through them can be considerable. Use of the 1x TBE concentration provides the necessary buffering power. The pH of the buffer should be 8.3. It is generally not necessary to adjust the pH; however, the pH of each new batch of 10x TBE stock must be carefully checked.

Use the same stock of 10x TBE to prepare both the gel and the running buffers. Small differences in ionic strength or pH produce buffer fronts that can greatly distort the migration of the DNAs.

A modification of the standard TBE buffer using taurine (36 g/liter of 10x TTE buffer) in place of boric acid will eliminate distortions at the top of the gel caused by glycerol-borate anionic ester compounds (Pisa-Williamson and Fuller 1992). For further information, please see the information panel on **GLYCEROL IN DNA SEQUENCING REACTIONS**.

TEMED (N,N,N′,N′-tetramethylethylenediamine) **<!>**

Electrophoresis-grade TEMED is sold by many manufacturers including Sigma and Bio-Rad. TEMED is hygroscopic and should be stored in a tightly sealed bottle at 4°C. TEMED is used as an adjunct catalyst for the polymerization of acrylamide.

Urea, solid

Special Equipment

Bulldog binder clips (5-cm length; five to seven per gel)

Gel-drying racks

Although not essential, gel-drying racks are certainly extremely convenient for drying and storing glass plates used for sequencing. These racks are available from several manufacturers including BioWhittaker.

Gel-sealing tape

For example, 3M Scotch Stretchable Tape (Lab Safety Supply, Janesville, Wisconsin), 3M Scotch yellow electrical tape #56 (Life Technologies), or 3M Scotch polytetrafluorethylene (PFTE) extruded film tape. For a discussion of the usefulness of various types of tape and other methods of sealing gel plates, please see Hengen (1996).

Glass plates (matched pair) and Spacers

The rectangular plates are made from nontempered glass, with one plate 3.5–4.0 cm longer than the other, or with one plate notched. Glass is a liquid and thus plates become deformed during use. To reduce the possibility of leaks and cracking, it is best to keep sequencing plates in matched pairs and to use the plates specified by the manufacturer of the sequencing gel tanks.

Gloves (talc-free, disposable rubber or PVC)

Petroleum jelly

Optional, please see Step 4.

Protective bench paper

Plastic-backed paper (Kaydry Lab Cover from Fisher) or Benchkote.

Sharkstooth comb (0.4-mm thick, with 32, 64, or 96 teeth, depending on the capacity of the gel apparatus)

Side-arm flask (250 ml)

Spacers (two per gel, either constant thickness or wedge shaped)

Spacers are made of thin (usually 0.4 mm) flexible plastic or Teflon (Sanger and Coulson 1978) and are used to keep the glass plates apart. A watertight seal is formed between the plates and spacers, so that the unpolymerized gel solution does not leak out when the gel is cast.

Wedge-shaped spacers are used to produce gels that are thicker at the bottom than the top. During electrophoresis, the increased cross-sectional area generates field-strength gradients, resulting in sharpening of bands and a more uniform spacing of bands over the length of the gel (Ansorge and Labeit 1984; Olsson et al. 1984). Wedge-shaped gels are recommended when the goal is to increase the read-length of the gel but are not necessarily beneficial when the aim is to resolve compressions or to maximize resolution of a particular region of sequence. Although wedge-shaped gels may overcome band spacing problems, they are difficult to pour and often crack upon drying.

Syringe (60 cc)

Optional, please see Step 15.

Test-tube rack

Water bath preset at 55°C

Pour the sequencing gels no less than 30 minutes before use. After polymerization, the gels can be stored for up to 24 hours.

METHOD

▲ **IMPORTANT** To prevent contamination of the glass surfaces by skin oils, wear talc-free gloves at all times and handle the plates by their edges.

Preparation of Glass Plates

1. If necessary, remove old silanizing reagent from plates by swabbing them with KOH/methanol solution.
2. Wash the plates and spacers in a warm, dilute solution of dishwashing liquid and then rinse them thoroughly in tap water, followed by deionized H_2O. Rinse the plates with absolute ethanol to prevent water spots, and allow them time to dry.

   The plates must be cleaned meticulously to ensure that air bubbles do not form when the gel is poured.

3. Treat the inner surface of the smaller or notched plate with silanizing solution. Lay the plate, inner surface uppermost, on a pad of paper towels in a chemical fume hood, and pour or spray a small quantity of silanizing fluid onto the surface of the plate. Wipe the fluid over the entire surface with a pad of Kimwipes and then allow the fluid to dry in the air (1–2 minutes). Rinse the plate first with deionized H_2O and then with ethanol, and allow the plate time to dry.
4. Lay the larger (or unnotched) glass plate (clean side up) on an empty test tube rack on the bench and arrange the spacers in place along each side of the glass plate (please see Figure 12-9) so they are flush with the bottom of the plate.

   If using wedge-shaped spacers, place the thicker end of the spacers at the bottom of the plate.

   Small dabs of petroleum jelly between the spacers and the larger (unnotched) plate will help keep the spacers in position during the next steps.
5. Center the shorter (notched) plate, siliconized side down, on top of larger (unnotched) plate. Make sure that the spacers remain in position at the very edges of the two plates.

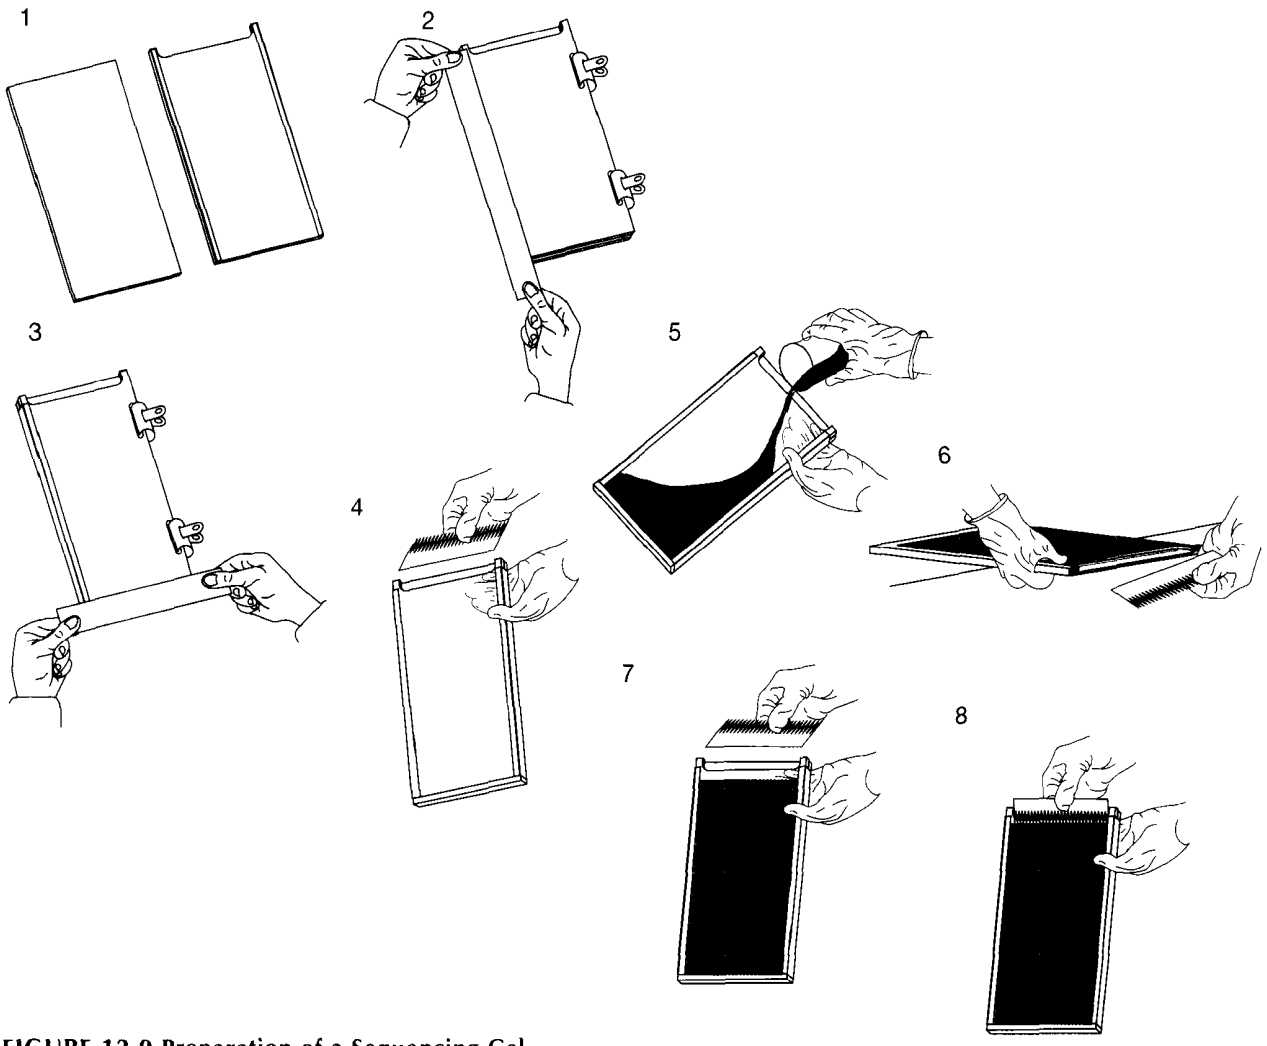

FIGURE 12-9 Preparation of a Sequencing Gel

6. Clamp the plates together on one side with two or three large (5-cm length) bulldog binder clips. Bind the entire length of the other side and the bottom of the plates with gel-sealing tape to make a watertight seal.

   The aim is to create a watertight seal between the plates and spacers so that unpolymerized acrylamide solution does not leak out. Most leaks occur at the bottom corners of the plates, so it is important to take particular care to leave no gaps when folding the tape around the corners. If possible, the corner sections of tape should be folded as "hospital corners."

7. Remove the bulldog clips and seal this side of the gel plates with gel-sealing tape.

8. Place the flat side of the sharkstooth comb into the open end of the gel mold so that it fits snugly. Remove the comb and lay the empty gel mold on the test-tube rack.

Pouring the Gel

9. Cover the working area of the bench with plastic-backed protective paper.

   It is almost impossible to pour sequencing gels without dripping acrylamide solutions onto the bench. Some investigators place a large developing tray on the bench to contain catastrophic spills.

10. In a 250-ml side-arm flask, prepare a sequencing gel solution containing the desired concentration of acrylamide as specified in Table 12-19. The volumes given in the table are sufficient for a single 40 x 40-cm sequencing gel and can be proportionally adjusted to accommodate smaller or larger gels.

    ▲ **IMPORTANT** The preparation of the gel must be completed without interruption from this point onward.

11. Combine all of the reagents and then heat the solution in a 55°C water bath for 3 minutes to help dissolution of the urea.

    Solubilization of urea is an endothermic reaction that proceeds slowly unless an external source of heat is used. The volume of the solution will be ~66 ml. Add H_2O to the solution bringing the final volume to 100 ml.

12. Remove the solution from the water bath and allow it to cool at room temperature for 15 minutes. Swirl the mixture from time to time.

13. Attach the side-arm flask to a vacuum line and de-gas the solution.

    This step prevents the formation of air bubbles in the gel mixture during polymerization of acrylamide, which is an exothermic reaction.

14. Transfer the solution to a 250-ml glass beaker. Add 3.3 ml of freshly prepared 1.6% ammonium persulfate and swirl the gel solution gently to mix the reagents.

    Old ammonium persulfate solutions may not have the catalytic power to drive the polymerization reaction to completion. Fuzzy bands of DNA and various other forms of matrix distortion are the inevitable consequence.

TABLE 12-19 Acrylamide Solutions for Denaturing Gels

	4% Gel	6% Gel	8% Gel	10% Gel
Acrylamide:bis solution (45%)	8.9 ml	13.3 ml	17.8 ml	22.2 ml
10x TBE buffer	10 ml	10 ml	10 ml	10 ml
H_2O	45.8 ml	41.4 ml	36.9 ml	32.5 ml
Urea	42 g	42 g	42 g	42 g

15. Add 50 µl of TEMED to the gel solution and swirl the solution gently to mix the reagents. Pour the gel solution into the mold directly from the beaker in which it has been prepared (as shown in Figure 12-9). Alternatively, draw ~40 ml of the solution into a 60-cc hypodermic syringe. Do not suck air bubbles into the syringe!

    Compared with polyacrylamide gels used to resolve proteins, a massive amount of TEMED is used to cast sequencing gels. The large amount of TEMED ensures that polymerization will occur rapidly and uniformly throughout the large surface area of the gel. Because the rate of polymerization is temperature-dependent, cooling the gel solution allows more time for casting the gel. Experienced gel pourers can often cast two or more 40 x 40-cm gels from a single gel solution by judicious precooling.

    Work as quickly as possible from here onward because the gel solution will polymerize rapidly. Polymerization can be appreciably slowed by putting the gel solution on ice, a boon for inexperienced gel pourers!

16. Allow a thin stream of gel solution to flow from the beaker or syringe into the top corner of the gel mold while holding the mold at an ~45° angle to the horizontal (please see Figure 12-9).

TROUBLESHOOTING: AIR BUBBLES

To avoid producing air bubbles, the solution must flow in a continuous stream.

- When using a syringe, gradually lower the mold to a horizontal position as it is filled. When the syringe is nearly empty, refill it with gel solution and quickly resume pouring the gel. Take care that no air bubbles form and that the solution migrates evenly toward the top of the gel mold. This movement can be facilitated by tilting the gel as described and filling the mold at a constant rate.
- If air bubbles form while pouring the gel, tilt the mold so that the level of the acrylamide solution reaches the level of the bubble. With luck, the air bubble will fuse with the meniscus of the acrylamide solution. If this does not happen spontaneously, try tapping the glass.

Bubbles in the upper portion of the gel can sometimes be moved by tapping the glass plates or by inserting a thin spacer (bubble hook) and herding the bubbles to a position where they will not interfere with the migration of the DNA samples. The latter solution is possible only when the full width of the gel is not to be used for loading samples.

Unless the air bubbles can be moved out of the way, the preparation must be done over again. The presence of bubbles is a sign that the gel plates were not cleaned thoroughly before the mold was assembled.

17. Lay the mold down on the test-tube rack (see Figure 12-9).

    This positioning reduces the hydrostatic pressure at the base of the mold and prevents leaks and bowing of the gel plates.

18. Immediately insert the *flat side* of a shark's tooth ~0.5 cm into the gel solution. Insert both ends of the comb into the fluid to an equal depth so that the flat surface is level when the gel is standing in a vertical position.

    If any air bubbles are visible near the comb, slowly remove the comb from the gel. Wipe the acrylamide solution from the surface of the comb and then slowly reinsert the comb into the gel.

19. Clamp the comb into position using bulldog binder clips. Use the remaining acrylamide/urea solution in the hypodermic syringe/pipette to form a bead of acrylamide across the top of the gel. Allow the gel to polymerize for at least 15 minutes at room temperature.

20. Wash out the 60-cc syringe so that it does not become clogged with polymerized acrylamide.

    ▲ **WARNING** A small amount of unpolymerized acrylamide is released during washing. Wear gloves.

21. After 15 minutes of polymerization, examine the gel for the presence of a Schlieren line just underneath the flat surface of the comb. This is a sign that polymerization is occurring satis-

factorily. When polymerization is complete (~1 hour after the gel was poured), remove the bulldog clips.

▲ **WARNING** A small amount of unpolymerized acrylamide may be released. Wear gloves.

22. The gel can be used immediately (please see Protocol 11) or stored for up to 24 hours at room temperature or 48 hours at 4°C. To prevent dehydration during storage, leave the tape in place and surround the top of the gel with paper towels dampened with 1x TBE. Cover the paper towels with Saran Wrap. Do not remove the comb at this stage.

TROUBLESHOOTING: LEAKING GELS

Leakage of the gel solution from the bottom of the mold seems to be an inevitable part of a sequencer's life. Several methods are available to prevent leakage.

- Add an extra band of stretchable tape around the bottom of the glass plates. This remedy is also usually effective when older plates with chipped corners are used in the mold.
- Seal the edges of the plates with molten 3% (w/v) agarose. This approach is messy and requires some artistic talent.
- Insert a plastic spacer into the open space at the bottom of the mold, seal with tape, and then clamp the plates together with bulldog clips. (Note: A bulldog clip should be used on the bottom of the gel mold only when this third spacer is in place; otherwise, the gel will vary slightly in thickness, which in turn can cause electrophoretic abnormalities and crack the glass plates.)
- Seal the bottom of the plate with a strip of filter paper and impregnate with catalyzed acrylamide (Wahls and Kingzette 1988). This is a messy and laborious procedure.

We recommend that investigators use whichever of these methods they find to be most reliable with the particular type of gel mold that is available. Do not get discouraged if the first gel leaks. Most first-time gel pourers have a batting average of ~300. With practice, a majority of taped gel molds will not leak, batting averages will improve, and it will not generally be necessary to go to great lengths to seal the bottom of the gel.

Protocol 9

Preparation of Denaturing Polyacrylamide Gels Containing Formamide

A RECURRING PROBLEM IN DNA SEQUENCING IS THE PRESENCE OF COMPRESSIONS in the sequence caused by secondary structure in the DNA. A simple and straightforward method to eliminate secondary structure during electrophoresis is to include formamide in the sequencing gel (Deininger 1983). Formamide gels are particularly useful and almost a necessity when sequencing DNA templates with a G/C content >55%.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

This protocol requires all of the reagents listed in Protocol 8, plus:

Formamide (100%) **<!>**

METHOD

1. Clean and assemble glass plates to form a gel mold as described in Steps 1–8 of Protocol 8.
2. Cover the working area of the bench with plastic-backed protective paper.

   It is almost impossible to pour sequencing gels without dripping acrylamide solutions onto the bench. Some investigators place a large developing tray on the bench to contain catastrophic spills.
3. In a 250-ml side-arm flask, prepare a sequencing gel solution containing the desired concentration of acrylamide as specified in Table 12-20. The volumes given in this table are sufficient for a single 40 x 40-cm sequencing gel and can be proportionally adjusted to accommodate smaller or larger gels.

   ▲ **IMPORTANT** The preparation of the gel must be completed without interruption from this point onward.
4. Combine all of the reagents and then heat the solution in a 55°C water bath for 3 minutes to help dissolution of the urea.

   Solubilization of urea is an endothermic reaction that proceeds slowly unless an external source of heat is used.

TABLE 12-20 Acrylamide Solutions for Denaturing Polyacrylamide Gels Containing Formamide

	4% GEL	6% GEL	8% GEL	10% GEL
Acrylamide:bis solution (45%)	8.9 ml	13.3 ml	17.8 ml	22.2 ml
10x TBE	10 ml	10 ml	10 ml	10 ml
H_2O	20.8 ml	16.4 ml	11.9 ml	7.5 ml
Formamide	25 ml	25 ml	25 ml	25 ml
Urea	42 g	42 g	42 g	42 g

5. Remove the solution from the water bath and allow it to cool for 15 minutes at room temperature. Swirl the mixture from time to time. Add H_2O to the solution bringing the final volume to 100 ml.
6. Attach the side-arm flask to a vacuum line and de-gas the solution.

   This step prevents the formation of air bubbles in the gel mixture during polymerization of acrylamide, which is an exothermic reaction.
7. Transfer the solution to a 250-ml glass beaker. Add 3.3 ml of freshly prepared 1.6% ammonium persulfate and swirl the gel solution gently to mix the reagents.
8. Add 50 µl of TEMED to the gel solution, and swirl the solution gently to mix the reagents. Draw approximately 40 ml of the solution into a 60-ml hypodermic syringe.
9. Pour the gel solution into the mold, as described in Steps 16–22 of Protocol 8.

▲ **IMPORTANT** Because formamide slows the polymerization reaction substantially, allow the gel to polymerize for 2–3 hours before clamping it in an electrophoresis apparatus.

COMPRESSIONS

Listed below are several variations on the above protocol that can be used to melt particularly stubborn compressions.

- Replace all of the H_2O in the gel solution with formamide.
- Double the TBE concentration in the gel solution and electrophoresis buffer. This modification causes the gel to run at a higher temperature by increasing the electrical resistance and therefore lowers the stability of secondary structure.
- Carry out electrophoresis at very high wattage (see Protocol 11) or in a 37°C warm room, both of which increase the temperature of the gel and reduce formation of secondary structure.

▲ **WARNING** Be on the lookout for cracked plates when running gels at temperatures higher than normal. Stop the electrophoresis run immediately if a plate should crack.

Protocol 10

Preparation of Electrolyte Gradient Gels

A CHARACTERISTIC FEATURE OF STANDARD, DENATURING POLYACRYLAMIDE GELS used to resolve the products of DNA-sequencing reactions is that the space between the bands of the DNA is greater at the bottom of the gel than at the top of the gel. Progressively greater separation of bands along the length of the gel reflects the logarithmic relationship between the length of a fragment of DNA and its mobility in the gel. The result is that fewer bases can be read from the autoradiograph. The bands at the top are crowded while those at the bottom are sparse.

Several methods have been developed to overcome this drawback observed in sequencing gels of constant thickness, including the pouring of "wedge gels," in which tapered spacers are used to cast polyacrylamide gels that are thicker at the bottom than at the top (Ansorge and Labeit 1984; Olsson et al. 1984). The progressive increase in thickness per unit length of the gel results in a voltage gradient along the length of the gel. Because the electrophoretic mobility of DNA through polyacrylamide gels is, to a first approximation, a linear function of the electric field or voltage gradient (Cantor and Schimmel 1980; Sheen and Seed 1988; Slater et al. 1996; Yager et al. 1997), the migration of the DNA through wedge gels is slower in the thicker (anodic) part of the gel and faster in the thinner (cathodic) part. The net effect is a compression of the spacing between bands of DNA in the lower part of the gel. Although wedge gels elegantly overcome the band-spacing problem, they are difficult to pour, require specialized gel spacers, and often crack upon drying.

Another method of reducing the spacing between smaller DNA fragments and increasing the spacing between larger DNA fragments is to increase progressively the ionic concentration in the lower (anodic) portion of the gel. The voltage carried through the gel decreases with increasing ionic strength, which causes the DNA to migrate more slowly as it travels anodically through the gel. These so-called ionic gradient gels were initially used by Biggin et al. (1983) and were formed by drawing a polyacrylamide gel solution of low ionic strength into a pipette followed by a second solution of higher ionic strength. One or more bubbles were then pulled into the pipette to mix the two solutions at the interface and thereby create a "gradient" between the extremes of ionic strength. The formation of the ionic gradient by this procedure was difficult to control, which in turn led to autoradiographs that often resembled the quills of a porcupine rather than an ordered ladder of DNA bands.

A clever and simple solution to the band-spacing problem was devised by Sheen and Seed (1988), who created an electrolyte gradient within the gel by using buffers of different concentrations in the upper (low electrolyte concentration) and lower (high electrolyte concentration) chambers of the electrophoresis device. The polyacrylamide gel itself is poured with a single concentration of electrolyte throughout, using standard thin (0.4 mm) spacers. The use of these electrolyte gradient gels leads to an increase of ~30% in the number of bases that can be read on an autoradiograph.

This protocol derived from Sheen and Seed (1988) describes how to pour electrolyte gradient gels.

MATERIALS

CAUTION:Please see Appendix 12 for appropriate handling of materials marked with <!>.

This protocol requires all of the reagents listed in Protocol 8, plus:

Formamide (optional) **<!>**

Electrolyte gradient gels are poured in 1x TBE buffer and can be run in the presence or absence of formamide. For information on denaturing polyacrylamide gels containing formamide, please see Protocol 9.

Sodium acetate (3 M, pH 7.0)

METHOD

1. Clean and assemble a set of glass plates to form a gel mold as described in Steps 1–8 of Protocol 8.
2. Cover the working area of the bench with plastic-backed protective paper.
3. Prepare a denaturing polyacrylamide gel as described in Protocol 8 or Protocol 9.
4. Clamp the gel into the electrophoresis device. Fill the upper chamber with 0.5x TBE buffer and the lower chamber with a buffer composed of 2 parts 1x TBE and 1 part 3 M sodium acetate. Load the sequencing reactions and perform electrophoresis as described in Protocol 11.

   As electrophoresis progresses, migration of the tracking dyes becomes progressively slower and essentially stops when the bromophenol blue reaches the bottom of the gel. Typically, electrophoresis is continued until the xylene cyanol dye is within 5–10 cm of the bottom of the gel and the bromophenol blue dye is at the bottom.

   Bands of DNA can be compressed at different times during the experiment by delaying the addition of the 3 M sodium acetate solution to the lower buffer reservoir. The electrophoretic run is begun with 1x TBE in both the lower and upper reservoirs. At an appropriate stage during the run, one part (0.5 volume) of a solution of 3 M sodium acetate (pH 7.0) is added to the lower buffer reservoir. With experience, it is possible to compress different regions of the sequencing ladder as required to maximize read lengths.

Protocol 11

Loading and Running DNA-sequencing Gels

THE SETS OF NESTED DNA FRAGMENTS GENERATED BY THE ENZYMATIC or chemical methods of DNA sequencing are resolved by electrophoresis through thin denaturing polyacrylamide gels. The four reactions (G, A, T, and C) in a sequencing set are loaded into adjacent lanes of a polyacrylamide gel, to which a large current is then applied. The negatively charged DNAs migrate anodically at rates that are determined by their sizes. A typical denaturing polyacrylamide gel will resolve DNA fragments in the 15–400-nucleotide size range. For a discussion on the physical basis of DNA movement through gels, please see the information panel on **ELECTRICAL MOBILITY OF DNA.**

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

0.5x TBE and/or 1x TBE

Gels

Denaturing polyacrylamide gel <!>
Prepared as described in Protocol 8, 9, or 10.

Nucleic Acids and Oligonucleotides

DNA sequencing reactions <!>
Carry out the reactions as described in Protocols 3–7.

Special Equipment

Automatic micropipettor (20 µl)
The micropipettor should be equipped with flat capillary pipette tips (e.g., Multi-Flex tip, Research Products International) or other loading device (please see the panel on **LOADING SEQUENCING GELS** following Step 8).

Bulldog binder clips (5-cm length; five to seven per gel)

Gel temperature-monitoring strips

These strips are thermochromic liquid crystal (TLC) indicators that change color as the temperature of the gel rises during electrophoresis. Temperature-monitoring strips are sold by several commercial companies, including BioWhittaker. If using an electrophoresis apparatus that has a built-in thermal sensor, the gel temperature-monitoring strips are not needed.

Pasteur pipette

Plastic-covered metal plate

Optional, please see Step 2.

Power pack capable of delivering >75 W at constant power

Most power packs can be set to deliver constant voltage, constant power, or constant current, with automatic crossover. A power pack equipped with multiple sets of outlet sockets and capable of delivering ~300 W of constant power at up to 7000 V can easily handle two or three sequencing gels simultaneously.

Scalpel fitted with disposable blade

The scalpel is used to remove the tape from the sequencing gel mold and sometimes to scrape residual polyacrylamide from the walls of the loading well.

Sequencing gel tanks

Many types of electrophoresis apparatuses are commercially available. All follow the same general design, but the arrangement of the glass plates and spacers differs slightly from manufacturer to manufacturer. Most commercial devices work well and the choice of manufacturers is largely a personal one. However, we recommend the purchase of devices with built-in metal plates. These plates, which are usually aluminum, distribute heat arising from electrical resistance evenly across the surface of the gel, thereby preventing "smiling" artifacts at the edges of the gel.

Sharks tooth comb (0.4-mm thick, with 32, 64, or 96 teeth, depending on the capacity of the gel apparatus)

It is essential to use the same shark's tooth comb that was used during the casting of the gel.

Syringe (10 cc) and 22-gauge hypodermic needles

Water bath set at 85°C or heating block set at 100°C

The water bath is required only if the sequencing reactions were carried out in microtiter dishes. The heating block is required if the reactions were carried out in microfuge tubes.

METHOD

▲ **WARNING** Large voltages are passed through DNA-sequencing gels at substantial amperages. More than enough current is used in these gels to cause severe burns, ventricular fibrillation, central respiratory arrest, and asphyxia due to paralysis of the respiratory muscles. Make sure that the gel boxes used for electrophoresis are well insulated, that all buffer chambers are covered, and that the box is used on a stable bench top that is dry. Always turn off the power to the box before sample loading or dismantling the gel.

1. Use damp paper towels or a wet sponge to wipe away any dried polyacrylamide/urea from the outside of the gel mold. Pipette several ml of 1x TBE buffer along the top of the smaller or notched glass plate and slowly remove the comb from gel. Cut the electrical tape with a scalpel and strip it from the bottom of the gel mold. *Do not remove the tape from the sides of the gel!*

2. Attach the gel mold to the electrophoresis apparatus with bulldog binder clips, plastic-coated laboratory clamps, or, in the case of electrophoretic devices with built-in screw clamps, according to manufacturer's instructions. The smaller or notched plate should be in direct

contact with the electrophoresis device. The larger, unnotched plate should face the investigator.

If the device does not contain a metal plate to distribute heat produced during electrophoresis, clamp a metal plate to the gel. A plastic-covered aluminum plate, cut to the same size as the unnotched glass plate works well and weighs very little.

3. Fill the upper and lower reservoirs of the apparatus with the appropriate buffer.

FOR STANDARD OR FORMAMIDE-CONTAINING GELS

a. Fill the upper and lower buffer reservoirs with 1x TBE. Make sure that the level of the buffer in the lower chamber is well above the bottom of the plates. The level of the buffer in the upper chamber should be well above the level of the upper edge of the shorter or notched plate and be in direct contact with the gel.

b. Use a 10-ml syringe filled with 1x TBE to rinse the top of the gel. Make sure that excess polyacrylamide and urea are removed from the gel. If necessary, use a syringe needle to scrape off any polyacrylamide sticking to the glass plates. Remove air bubbles under the bottom of the glass plates in the lower reservoir using a Pasteur pipette.

c. Attach the electrodes to the electrophoresis apparatus and the power supply. The cathode (black lead) should be attached to the upper reservoir and anode (red lead) to the bottom. Attach the built-in thermal sensor (if available) or temperature-monitoring strip. Run the gel at constant wattage (50–70 W) for ~45 minutes or until the temperature of the gel reaches 45–50°C. Turn off the power supply and disconnect the electrodes.

FOR ELECTROLYTE GRADIENT GELS

a. Fill the upper reservoir with 0.5x TBE, and the lower reservoir with a solution consisting of 2 volumes of 1x TBE plus 1 volume of 3 M sodium acetate (please see Protocol 10).

b. Wash the well with 0.5x TBE and remove urea/polyacrylamide as described above. Do not pre-run electrolyte gradient gels.

4. Incubate the microfuge tubes containing the sequencing reactions for 2 minutes in a heating apparatus set at 100°C. If the reactions have been carried out in a microtiter plate, remove the cover from the plate and float the open plate in a water bath for 5 minutes at 85°C.

5. While the tubes or plates are incubating, fill a 10-cc syringe fitted with a 22-gauge hypodermic needle with 0.5x or 1x TBE, as appropriate. Squirt the TBE forcibly across the submerged loading surface of the gel to remove any remaining urea and fragments of polyacrylamide from the loading area. Continue squirting until no more urea can be seen in the loading area.

Urea quickly diffuses from the gel and will remain as a cushion at the bottom of the well or slot. The urea cushion, being of higher density than the sequencing reactions, will displace the reactions from the base of the well. Displacement results in an uneven migration of the DNA fragments into the gel and distortion in the sequence ladder.

6. Gently insert the shark's tooth comb (teeth downward) into the loading slot. Push the comb down until the points of the teeth just penetrate the surface of the gel.

7. Transfer the microfuge tubes or microtiter plate from the water bath or heating block to ice. Keep the samples at 0°C until they are loaded onto the gel. Quick-cooling to low temperature retards renaturation of the template and radiolabeled strands.

8. Load 1–5 µl (please see Protocols 3–7 for recommended volumes) of each sequencing reaction into adjacent slots of the gel.

   Please see the panel on **LOADING SEQUENCING GELS.**

   The sample will flow into the well and form a tight band on the surface of the polyacrylamide gel. Keep a record of the order of the templates and load the samples in every reaction set in the same order.

   An aliquot of an old sequencing reaction can be loaded into an extra slot at the end of the gel to serve as a landmark. This control unambiguously distinguishes right from left on the final autoradiograph.

LOADING SEQUENCING GELS

Order of Bases

The four or five base-specific reactions generated in an enzymatic or chemical DNA-sequencing experiment are loaded onto denaturing polyacrylamide gels in a specific order from left to right. Many investigators prefer to load the reactions into adjacent lanes in the order TCGA. The two tracks (G and C) that suffer most from abnormal patterns of migration (e.g., compression) are then located next to each other, which facilitates base-calling. Other investigators prefer the order CTAG, because that is the way it has always been done in Cambridge, England. Fred Sanger preferred an alphabetical order with his pyrimidines first followed by his purines. If the gel is loaded in either of these two orders, then the sequence of the complementary strand (3′-5′) can be read by flipping the autoradiograph over and reading the gel from the bottom. The tracks on the flipped autoradiograph are read from left to right and their order is then recorded as TCGA or CTAG.

Some types of DNA sequencings call for a specialized loading order. For example, when sequencing a G/C-rich template, there are advantages to loading the reactions in duplicate in the order GATCGTAC. Each of the four sequencing reactions is then adjacent to the other three, which allows closely spaced bands to be ordered more easily. A similar tactic is followed when using base analogs such as 7-deaza-dGTP and dITP. The quality of sequence produced with these analogs is not as high as that produced with dGTP, and the migration of DNAs containing them is slightly different. To alleviate gel reading problems, it is helpful to load adjacent lanes of a polyacrylamide gel in the order IATCITAC, where I is the sequencing reaction in which dITP or 7-deaza-dGTP was substituted for dGTP in the chain-terminating reaction.

In some enzymatic sequencing reactions, only a single dideoxynucleotide reaction is carried out. These so-called T tracks or G tracks, etc., were initially used by Sanger et al. (1980) to distinguish between large numbers of bacteriophage M13 templates in a shotgun DNA-sequencing strategy. A variation on this strategy can be put to good use when using DNA sequencing to screen for naturally occurring or induced mutations in a gene or exon. In a typical experiment, DNA templates corresponding to a normal or wild-type gene and one or more putative mutation-bearing alleles are sequenced separately by the enzymatic method using all four ddNTPs. On the resulting sequencing gel, all of the ddC reactions derived from the normal and mutant allele templates are loaded next to each other, followed by all of the ddTTP reactions, the ddATP reactions, and the ddGTP reactions. If one wild-type and three mutant templates were sequenced, then the order on the gel would be CCCC, TTTT, AAAA, GGGG, where the first lane in each group of four corresponds to the normal allele. This type of loading simplifies the identification of templates whose DNA sequence differs from that of the normal allele. Bases that are identical between the normal and mutant alleles will generate bands at the same position, whereas a mutant will not. In the case of a point mutation, for example, a novel band corresponding to the substituted base will appear at the position of the normal base. Insertion or deletion mutations can be easily located by identifying the position on the gel at which the correspondence between bands obtained from mutant and wild-type alleles first becomes disrupted.

Loading Devices

Several different methods can be used to load the samples into the wells of the gel. The best by far is a automatic micropipettor (20 µl) equipped with a flat capillary pipette tip that fits comfortably into the well formed by the teeth of a shark's tooth comb (Multi-Flex Tip, Research Products International). The sample can thus be layered directly on the surface of the gel. The tip should be washed out with 0.5x or 1x TBE between loadings.

Alternatively, a syringe equipped with a 30-gauge needle can be used. This needle is narrow enough to enter the space between the two glass plates, and the sample can be layered directly on the surface of the gel. Take care not to touch the gel with the needle. The syringe and needle must be washed well with 0.5x or 1x TBE between samples. Excess TBE should be ejected before the next sample is drawn into the syringe and needle.

TABLE 12-21 Migration Rates of Marker Dyes through Denaturing Polyacrylamide Gels

POLYACRYLAMIDE GEL	BROMOPHENOL BLUE[a]	XYLENE CYANOL FF[a]
5%	35	130
6%	29	106
8%	26	76
10%	12	55
20%	8	28

In electrolyte gradient gels, bromophenol blue migrates progressively more slowly as it travels anodically through the gel. Migration essentially ceases when the dye nears the bottom of the gel. The xylene cyanol tracking dye behaves in a similar fashion. Typically, electrophoresis is continued until the xylene cyanol dye is within 5–10 cm of the bottom of the gel and the bromophenol blue dye is at the bottom.

[a]The numbers are the approximate sizes of DNA (in nucleotides) with which the indicated marker dye will comigrate in a standard DNA sequencing gel.

9. When all of the samples have been loaded, connect the electrodes to the power pack and the electrophoresis apparatus: cathode (black) to the upper reservoir and anode (red) to the bottom reservoir. Run the gel at sufficient constant power to maintain a temperature of 45–50°C.

Gel Size (cm)	Power (W)	Voltage (V)
20 x 40	35–40	~1700
40 x 40	55–75	~2–3000
40 x 40 (electrolyte gradient gel)	75	~2100

The time required to achieve optimal resolution of the sequence of interest must be determined empirically. Monitor the progress of the electrophoretic run by following the migration of the marker dyes in the formamide gel-loading buffer (please see Table 12-21).

10. Depending on the distance between the sequence of interest and the oligonucleotide primer, apply a second loading of the sequencing samples to a standard or formamide-containing denaturing polyacrylamide gel ~15 minutes after the bromophenol blue in the first set of samples has migrated to the bottom of the gel (1.5–2.0 hours). The sequence obtained from the first loading will be more distal to the primer, whereas that obtained from the second loading will be more proximal. The length of readable sequence can be extended by ~35% by reloading the samples into a fresh set of lanes 2 hours after the samples were first loaded.
    a. Turn off the power supply and disconnect the sequencing apparatus.
    b. Replace the buffer in the top and bottom reservoirs.
    c. Denature the samples by heating as described in Step 4 above.
    d. Load the samples.
    e. Reconnect the sequencing apparatus to the power supply.
    f. Run the gel, as before, at sufficient constant power to maintain a temperature of 45–50°C.
    Alternatively, extend the length of readable sequence by replacing the buffer in the lower chamber with a buffer composed of 2 parts 1X TBE and 1 part 3 M sodium acetate at an appropriate stage in the electrophoretic run (please see Protocol 10).
11. At the end of the run, follow the procedures described in Protocol 12 to dismantle the gel and perform autoradiography.

Protocol 12

Autoradiography and Reading of Sequencing Gels

FOR FURTHER INFORMATION ABOUT AUTORADIOGRAPHY, PLEASE REFER to the discussion in Appendix 9.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Gel-fixing solution (mix in the order shown) **<!>**

300 ml of methanol
2.4 liters of H_2O
300 ml of glacial acetic acid

Radioactive Compounds

Radioactive ink or Chemiluminescent markers **<!>**

Please see Appendix 9.

Reusable alternatives to radioactive ink are chemiluminescent markers available from Stratagene (Glogos). The markers can be used multiple times and should be exposed to fluorescent light just prior to a new round of autoradiography.

Gels

DNA sequencing gels

Prepared and run as described in Protocols 8–11.

Special Equipment

Autoradiography cassettes (metal, spring-loaded 35.6 x 43.2 cm)

Enhancing screens (as appropriate).

Two large enhanced calcium tungstate screens (e.g., Lightening Plus, Dupont) are needed per film.

Gel dryer set at 80°C.

The gel dryer should be connected via a trap to a vacuum system.

Mylar sheet (~5 cm larger than the gel in length and breadth)

The Mylar sheet is used to keep the gel flat during drying under vacuum.

Saran Wrap
Stainless steel metal spatula or scalpel
Tray for fixing the gel
The tray should be ~5 cm larger than the gel in length and breadth.
Whatman 3MM CHR paper (or equivalent)
Whatman 3MM paper (or equivalent)
X-ray film (blue sensitive 35 x 43 cm)
For ^{32}P-labeled DNA, use a double-sided film such as X-Omat-AR (Kodak) or BioMax MS (Kodak). For ^{33}P- and ^{35}S-labeled DNAs, use a single-sided film such as BioMax MR (Kodak).
X-ray film processor

METHODS

1. At the end of the electrophoretic run (Protocol 11), turn off the power and disconnect the sequencing apparatus from the power pack. Dispose of the electrophoresis buffer and then remove the gel mold from the apparatus.
2. Lay the gel mold flat on plastic-backed protective bench paper with the smaller (notched) plate uppermost. Allow the gel to cool to <37°C before proceeding.
3. Remove any remaining pieces of gel-sealing tape. Use the end of a metal spatula to pry apart the plates of the mold slowly and gently. The gel should remain attached to the longer (non-siliconized) glass plate.

   ▲ **WARNING** Wear safety glasses. Glass plates will occasionally chip during this procedure. Note that the surfaces of the glass plates that were in contact with the gel may be contaminated with radioactivity and should be treated appropriately.

   If the gel adheres to both plates, replace the partially dislodged, smaller or notched plate back on the gel, invert the plates, and try again. If the gel remains stuck, follow the gel-fixing procedure described in Step 12 of this protocol to float the gel off one of the plates.

   Steps 4–13 of this protocol may be omitted if the products of the sequencing reactions are labeled with ^{32}P, for example, if the enzymatic sequencing was primed with ^{32}P-labeled oligonucleotide primer or if [α-^{32}P]dNTP was incorporated during extension of an unlabeled primer. A reading of 20–100 cps when a minimonitor is used to scan the surface of the gel indicates that sufficient radioactivity is present to forego drying. In this case, cover the gel with Saran Wrap, make sure that there are no wrinkles, mark the orientation, and directly expose the gel (still attached to its glass plate) to X-ray film. This procedure has the disadvantages of tying up gel electrophoresis plates during autoradiography and does not yield bands that are as sharp or as intense as those of a dried gel. In addition, radioactive fluid tends to ooze from the gel during exposure to X-ray film. Having come this far, do not take such a risk for the sake of saving a couple of hours work.

   The radiolabeled products of Maxam-Gilbert sequencing reactions are generally not labeled sufficiently to forego fixing and drying.
4. When the glass plates have been separated, cut off a bottom or top corner on the side of the gel that was loaded first. This landmark serves to orient the gel during subsequent manipulations.
5. Fix the gel in gel-fixing solution (methanol/acetic acid; please see Materials).

   Sequencing gels with ^{33}P or ^{35}S should be fixed before drying. This step is optional for gels labeled with ^{32}P. However, fixation improves resolution, sometimes enhances the signal derived from low amounts of radioactivity, and eliminates high concentrations of urea or formamide from the gel. Fixation is also a last resort for removing a gel that is impossibly stuck to both plates of the mold.

6. Transfer the gel (together with its supporting glass plate), to a shallow tray containing methanol:acetic acid solution. Fix the gel for 30 minutes at room temperature. Do not agitate the fluid while the gel is being fixed.

   Thinner gels are fixed more rapidly, thicker more slowly. A gel 0.2 mm in thickness is fixed in 10 minutes; a gel 0.6 mm in thickness requires ~1 hour.

   The same batch of fixation fluid can be used to fix several gels. If the gel shows signs of detaching from the supporting glass plate, cover it with a piece of stiff plastic netting (available from many hardware stores) to prevent the gel from escaping and forming a crumpled mass.

7. After 30 minutes, lift the glass plate very, very slowly from the fixation solution. Try to keep the plate horizontal until most of the fixation solution has drained away. Lay the plate, gel side uppermost, on a stack of paper towels. Blot excess fixation solution from the glass plate with Kimwipes. Try not to touch the surface of the gel with the Kimwipes. Remove wrinkles and blemishes from the gel by gently caressing its surface with gloved fingers.

8. Prepare a piece of Whatman 3MM CHR paper (or equivalent) that is slightly larger (2–3 cm) than the gel in both length and width. Hold the paper in a bow shape and touch the center of the bow to the center of the gel. Let the paper fall gently onto the surface of the gel and then apply gentle pressure so that the gel becomes firmly attached to the rough surface of the paper.

9. Hold the paper in place with one hand and pick up the supporting glass plate with the other hand. Quickly flip the sandwich over and lay it down on the bench top with the glass plate facing upward. Gently separate the 3MM CHR paper from the glass plate by lifting the plate upward. The gel will stick to the 3MM CHR paper as the glass plate is pulled away.

10. Lay the 3MM CHR paper (gel uppermost) on two pieces of Whatman 3MM paper of the same size. Cut a piece of Saran Wrap slightly longer and wider than the gel and lay it on top of the gel. Try to avoid creases and bubbles. This step is more easily accomplished with the help of another person. Hold the corners of the Saran Wrap and pull outward so that it is tightly stretched. Lower the stretched Saran Wrap onto the surface of the gel. Once the Saran Wrap has touched the gel, do not attempt to remove it, since this can cause the gel to tear. The flat end of an agarose gel comb, a Kimwipe, or a plastic card can be used to remove any bubbles of air trapped between the gel and wrap.

    Alternatively, stretch and tape an appropriately sized piece of Saran Wrap to the bench, ensuring that there are no wrinkles. Then invert the gel and place face down on the Saran Wrap.

11. Use a paper cutter or sharp pair of scissors to trim all three pieces of Whatman paper and the Saran Wrap to approximately the same size as the gel.

12. Place the sandwich of paper, gel, and Saran Wrap on the gel dryer, with the plastic wrap uppermost. Use a sheet of Mylar to keep the sandwich flat during drying.

13. Following the instructions of the manufacturer of the gel dryer, dry the gel for 30–60 minutes under vacuum at 80°C.

    Drying the gel reduces the distance that radioactive particles must travel before hitting the X-ray film, thereby increasing the sensitivity of detection.

14. Remove the gel from the dryer and peel off the Saran Wrap. The dried gel should feel smooth to the touch and not sticky. A quick remedy to stickiness is to turn a powdered latex glove inside out and use the talcum powder on the inside of the glove to dust the gel. To orient the gel, attach a small adhesive label marked with radioactive or chemiluminescent ink to the 3MM CHR paper in the space created by cutting the bottom corner of the gel (Step 4).

15. In a darkroom, place the dried gel (gel side up) in a spring-loaded metal cassette. Cover the gel with a sheet of unexposed X-ray film. Close the cassette. Establish an autoradiograph by exposing the gel to the film for 16–24 hours at room temperature or –80°C.

    The time required for a perfect exposure of a sequencing gel cannot be predicted with accuracy. If everything has gone very well during the sequencing reactions, 16–24 hours may turn out to be too long by a factor of 5 or more. In less fortunate circumstances, considerably longer exposure may be required. The major aim at this point is to take a first look at the gel, to see if the sequencing reactions have gone well, and to use the intensity of the bands as a guide to set up one or more additional exposures.

16. Develop the autoradiograph according to the recommendations of the manufacturer of the film and read the sequence of the DNA as described in the information panel on **READING AN AUTORADIOGRAPH**.

From a book full of mysterious pictures, they learned about the uses of hair and eggshells and feces and worms, herbs and the blood of a red-haired man. They painted black the walls of their room and then hung pictures they snipped from their books; alchemists' labs juxtaposed with models of DNA and the three-dimensional structure of hemoglobin. Their father turned dirt and sunlight into wine; was that alchemy or chemistry? Either one might turn their isolation into freedom.

And so of course they studied biochemistry in college... .

Andrea Barrett, *The Marburg Sisters* In *Ship Fever.*

AUTOMATED DNA SEQUENCING

From its inception, the dideoxy chain-termination method of DNA sequencing (Sanger et al. 1977a), with enzymatic reactions carried out in aqueous solvents at moderate temperatures, was an obvious candidate for automation. By the early 1980s, the development of automated sequencing was well under way, using DNA molecules labeled with fluorescent dyes rather than the traditional radioisotopes (Smith et al. 1986). By the middle of the decade, automated fluorescent sequencers had been developed in which the products of dideoxy-sequencing reactions were separated by gel electrophoresis, dye molecules were excited by a laser beam, and the fluorescent signals were amplified and detected by photomultiplier tubes (or a CCD camera in later models) (for reviews, please see Chen et al. 1991; Hunkapiller et al. 1991; Chen 1994). Because fluorescent signals could be detected and processed continuously, gels could be run for longer times and more data could be collected. Computer software identified each nucleotide based on the distinctive color (emission wavelength) of each different dye, to identify (call) each base according to the shape of the fluorescent peak and the distance between successive peaks.

Evolution of the Technology

The events leading to current automated sequencing technology are summarized in Figure 12-10. The powerful impact of technical advances on sequencing efficiency is evident from the improvement in the number of samples (and average read-length per sample) that can be achieved in 1 week by a skilled, dedicated investigator. Judged from today's standards, the capacity of automated sequencers available up to 1990 was low, and data were often variable and poor in quality (Martin and Davies 1986; Chen et al. 1991; Hunkapiller et al. 1991). However, there was a great leap forward when PCR was harnessed to the dideoxy method in "cycle sequencing" (Carothers et al. 1989), a process that linearly amplifies signals and thereby greatly augments the sensitivity of sequencing. Additional improvements in dye chemistry and modifications of DNA polymerases have been a further source of enormous progress throughout the 1990s. As a consequence, the rate of sequencing had increased ~30-fold by 1998, so that a single investigator in a well-equipped laboratory could handle 500 samples a week with an average read-length of 650 bases per sample. By the year 2000, that rate had increased by another order of magnitude in high-throughput facilities equipped with capillary-based sequencers and robotic tools.

Initially, there were two major types of commercial instruments, both of which used gel electrophoretic separation of DNA fragments, one using single-dye four-lane separation (Ansorge et al. 1987), and the other using four-dye single-lane separation (Smith et al. 1986). Because of their higher throughput, greater consistency, and lower sensitivity to electrophoretic artifacts, the single-lane instruments have gradually become the approach of choice. The current slab gel model ABI 377 automated sequencer, which dominated the commercial market during the late 1990s, has a capacity of 96 samples per run, with two to four runs a day (depending on the read-lengths desired).

Capillary-based equipment delivers six to eight runs a day while eliminating the tedious gel preparation and sample loading steps. Capillary electrophoresis (Swerdlow and Gesteland 1990; Smith 1991; Yan et al. 1996; Dovichi 1999) also offers other advantages over traditional slab gel systems.

- Because each capillary is very small in diameter (50–100 μm), heat generated during electrophoresis can be rapidly dissipated. Very high voltages can therefore be applied to achieve separation of the products of sequencing reactions in a shorter period of time.
- Because each sample is loaded into a discrete capillary, there is no need for time-consuming tracking of lanes on gel images.

As of early 2000, three 96-channel, one 8-channel, and one 1-channel capillary-based sequencers were available (Boguslavsky 2000): MegaBACE (96-channel, Molecular Dynamics, California), ABI 3700 and ABI 310 (96-channel and 1-channel, respectively; PE Biosystems), SCE9610 (96-channel, Spectru-Medix, Pennsylvania), and CEQ 2000 (8-channel, Beckman Coulter, California). The ABI 3700 model is also equipped with an automated loader, permitting >6 runs a day unattended by an operator, or a capability of >4000 samples a week. Including the resultant savings in person power, this machine can increase sequencing efficiency by tenfold from the operations using previous models and has the potential to reduce the cost per finished base by a comparable factor.

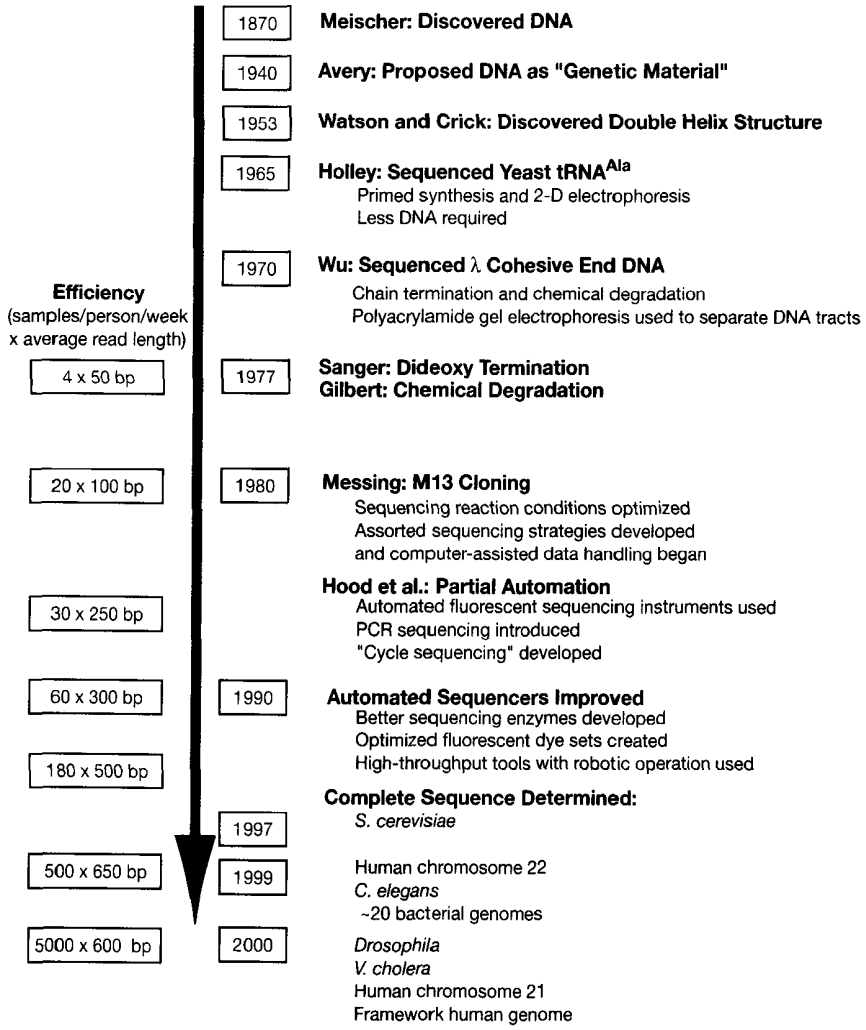

FIGURE 12-10 DNA Sequencing History

Courtesy of E.Y. Chen.

Of course, sequencing efficiency is also directly related to the nature of the DNA substrate. In general practice, DNA molecules that contain more repetitive sequence tracks or homopolymer sequence elements, or higher GC content, require more work (E.Y. Chen et al. 1996). Within a single project, some regions also tend to be more troublesome. To solve specific problems, several modifications of the dideoxy method have been developed in the past decade. For example, the use of nucleotide analogs such as inosine or deaza compounds can help eliminate "gel-compression" problems (Jensen et al. 1991), in which a sequence tract is concealed in a single unresolved band; the inclusion of pyrophosphatase to decompose the pyrophosphate accumulated during chain elongation prevents the loss of peaks ("missing peaks") resulting from reverse polymerase reactions (Tabor and Richardson 1990); the addition of single-strand-binding proteins to sequencing reactions improves the quality of the data produced from DNA templates enriched in looping structures (Chen et al. 1991); and, finally, the use of different cloning vectors provides an alternative when a particular M13 clone is unstable (Chen and Seeburg 1985; Chissoe et al. 1997). Many of these variations have been incorporated into current automated sequencing protocols, particularly as part of extensive projects.

Methods in Automated Sequencing

The following discussion is based on the specifications of the ABI model Automated Sequencer, the equipment currently used by most sequencing facilities.

Dye-Primer Sequencing

In sequencing with dye primers, four separate reactions are carried out for each DNA sample, each reaction containing a different dye-labeled primer. This set of four reactions is then mixed and loaded into a single channel for gel electrophoresis (Smith et al. 1986; Lee et al. 1997). The sequencing reagent "kit" has a set of four primers, each containing a different dye incorporated into an oligonucleotide, typically 17–20 bases in length. Sensitivity can be improved and signal intensity enhanced by using "energy transfer" (ET) primers that carry two separate dyes (Ju et al. 1995; Lee et al. 1997). These ET primers typically contain a single donor dye, which can be easily excited by the argon ion laser. The donor dye transfers the energy to one of four secondary (acceptor) dyes, each with a distinctive emission spectrum. Compared to the earlier single-dye primer sets, the ET primers typically provide three- to fourfold stronger signals (Ju et al. 1995). Amersham and PE Biosystems are two vendors of dye-primer reagents. Amersham (ET primer kit) provides the two dyes attached at two different bases, about five nucleotides apart; PE Biosystems (BigDye-primer kit) provides the two dyes connected by an aminobenzoic acid linker (the so-called BigDye), both attached to the 5′ end of the primers.

Either *Taq* polymerase, T7 DNA polymerase (Sequenase; Tabor and Richardson 1987a, 1995), or Thermo Sequenase (Reeve and Fuller 1995) can be used, but the *Taq* polymerase mutant (e.g., AmpliTaq FS from PE Biosystems) is frequently used under cycle sequencing conditions. With thermostable enzymes, the signal is linearly amplified, and hence only 0.1 μg or less of template is needed. This feature is especially important when a robotic operation is used to prepare hundreds of templates in smaller quantities. The standard sequencing kit replaces dGTP with deaza-dGTP to reduce gel compression (see above). For unknown reasons, the use of the deaza compound sometimes results in peak broadening, which reduces the readable length of sequencing tracts. Nevertheless, the average read-length with dye-primer sequencing has now reached 650–700 bp at >99% accuracy in 11–12-hour runs (2400 V with 48-cm slab gel) on the ABI 377 Sequencer (C. Chen et al. 1996). Detailed experimental protocols are provided with convenient manufacturer's kits that contain all of the reagents necessary for dye-primer sequencing reactions.

Dye-Terminator Systems

Although the dye-primer method is suitable for sequencing projects that use universal primers, projects that require custom-designed primers become cumbersome and expensive because each primer must be modified in four separate dye-labeling reactions. One way around this problem is to attach the fluorescent dyes to dideoxynucleotides that become incorporated at the 3′ end of the products of sequencing reactions (L. Lee et al. 1992; Rosenblum et al. 1997). Each of the four ddNTPs is labeled with a different dye linked to the nitrogenous base via a linker. Four chain-extension reactions can then be carried out with the same primer in a single tube, sparing considerable labor and cost. By contrast to dye-primers, dye-terminator chemistry has the additional advantage that it eliminates noise arising from premature chain termination without attendant incorporation of dideoxynucleotides.

In its earlier phase of development, dye-terminator chemistry had major problems resulting from the attachment of bulky dye moieties to the dideoxy terminator molecules. Because substrate affinity was altered, it became necessary to tailor a specific set of dye-labeled terminators for use with each DNA polymerase (L. Lee et al. 1992). Unfortunately, the intensity of the signals generated by these polymerase-substrate pairs was frustratingly uneven, which reduced the accuracy of base calling and limited the range of readable sequence (please see Figure 12-11A). During the late 1990s, this problem was largely solved by the use of modified enzymes (please see Figure 12-11B and discussion below) as well as by the introduction of optimized sets of new dyes and linker arms (Figure 12-11C,D). These improvements provided clearer peak patterns, minimal mobility shifts, and cleaner signals. As a consequence, the quality of the data from current dye-terminator sequencing became comparable to results obtained using dye-primers (Rosenblum et al. 1997; Heiner et al. 1998).

At present, two sets of second-generation dye terminators are available. One incorporates dichlororhodamine dyes (dRhodamine Terminator, PE Biosystems); the other incorporates the BigDyes (BigDye Terminator, PE Biosystems). The BigDyes are used in dye-primer sequencing (see above). They contain a fluorescein isomer as the donor dye and four dichlororhodamine dyes as the acceptors. Both terminators work well with AmpliTaq polymerase FS (please see Figure 12-11, bottom panels). Convenient cycle-sequencing conditions are normally used, and the sequencing reactions can be carried out with any primer and with a wide variety of templates (single-stranded DNA, double-stranded DNA, or PCR-generated

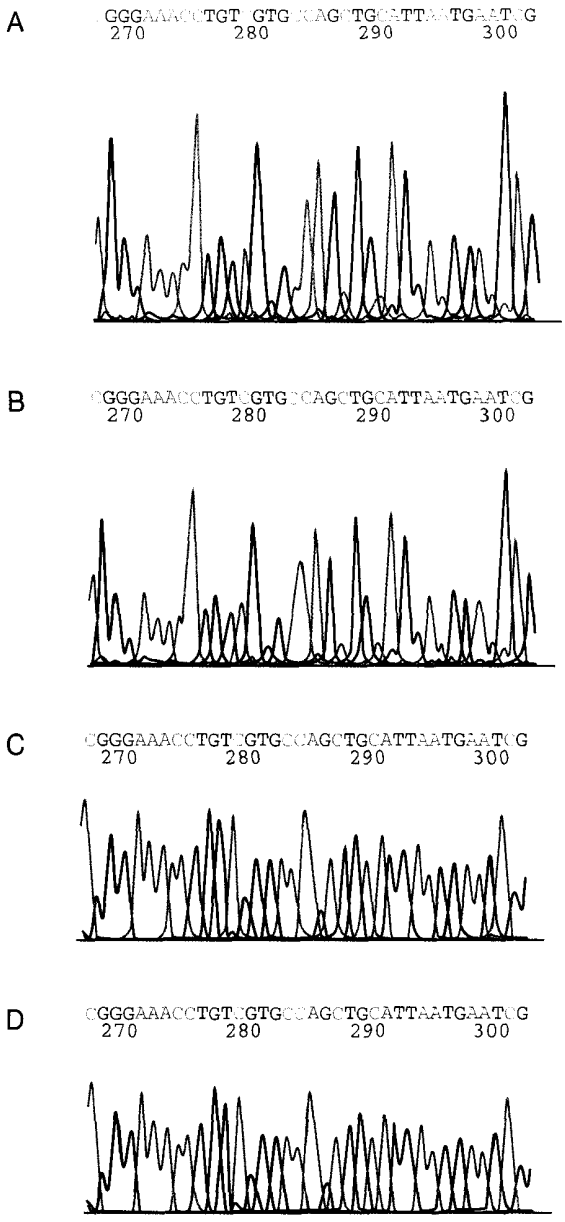

FIGURE 12-11 Comparison of Profiles of Dye-Terminator Sequencing Chemistries

(*A*) Rhodamine dye terminators sequenced with AmpliTaq polymerase results in very uneven peak pattern. The most noticeable ones are the small C peaks after G, small T peaks after T and G, and large C peaks after C (Parker et al. 1995). (*B*) Rhodamine dye terminators sequenced with AmpliTaq polymerase FS results in a much improved pattern when compared to the original AmpliTaq sequencing data. However, small G peaks after A and C, and large A peaks after G can sometimes cause errors in base calling (Parker et al. 1996). (*C*) Dichlororhodamine dye terminators and AmpliTaq polymerase FS result in very even peak patterns. The overall signal is slightly weaker than the rhodamine terminator chemistry, but the weak G peaks after A and large A peaks after G are moderated. (*D*) BigDye terminators sequenced with AmpliTaq polymerase FS result in very even peak heights and stronger signals. The overall signal and evenness of peak height are much improved compared to dichlororhodamine terminator chemistry. (Courtesy of E.Y. Chen.)

DNA). In addition, because reactions with AmpiTaq FS use far fewer dye terminators, tedious gel-filtration (spun column) steps to remove unincorporated dyes before gel loading can often be replaced by simple ethanol precipitation. Again, dGTP is replaced with dITP (deoxyinosine triphosphate) to reduce gel compressions.

Sequencing Enzymes

Naturally occurring polymerases have features that are often not optimal for DNA sequencing. The relevant and desirable properties of sequencing polymerases include (Tabor and Richardson 1987a, 1989a,b, 1995):

- ***High processivity.*** Processivity is the degree to which chain extension continues before the enzyme dissociates from a primer-template annealing complex. T7 Sequenase is the most processive of the current catalog of sequencing enzymes, whereas the Klenow fragment is the least.
- ***Thermostability.*** Resistance to inactivation or dissociation at high temperatures is a most important factor in the cycle-sequencing reactions that are the basis for modern high-throughput sequencing. *Taq* polymerase or variants are the only feasible options.
- ***Incorporation of nucleotide analogs such as dye terminators.*** The ability to incorporate analogs is a critical factor for the dideoxy chain-termination method. The efficiency of chain termination with each of the dye-labeled terminators must be similar to avoid low-quality data with uneven peaks (see Figure 12-11). Enzymes such as AmpliTaq FS with a high affinity for their dye terminators have an advantage because a much lower concentration of the dye terminators can be used, with savings in both cost and effort otherwise needed to remove the unincorporated dyes.
- ***Exonuclease activities.*** Polymerases often have 3′-exonuclease "proofreading" and/or 5′-exonuclease activities that remove RNA primers after DNA replication. Because neither activity is desirable for sequencing, variants of the polymerases should be used that lack these activities (e.g., Thermal Sequenase [Amersham] and AmpliTaq polymerase FS [PE Biosystems]).

For more information on modified thermostable DNA polymerases. Please see Table 12-9 in Protocol 5.

Sequencing Templates

Until recently, the primary data in large-scale sequencing operations have been traditionally collected using dye-primer sequencing; dye-terminator sequencing has been used only to fill gaps or to deal with troublesome regions (E.Y. Chen et al. 1996). However, obtaining "finished" data of the highest quality requires that all sequences be acquired either in both orientations or using both chemistries. Comparison of the results obtained using both chemistries provides a check of sequence quality, because the pattern of errors for each chemistry is usually different (Chissoe et al. 1997). With recent improvements, however, the less laborious dye-terminator method is gradually replacing dye-primers in most large-scale sequencing projects. Sequencing with two sets of dye terminators, dRhodamine and BigDye, could become a new standard for the achievement of the desired "double coverage."

BigDye terminator sequencing reactions work well with a wide variety of templates, including single-stranded, double-stranded, and PCR-generated DNAs, as well as with bacterial artificial chromosome (BAC) clones or genomic DNA fragments as large as 5 Mb (C. Chen et al. 1996; Heiner et al. 1998). The optimal sequencing conditions for various templates are given in Table 12-22. Although the intensity of signals tends to be lower with larger templates, base-calling quality remains high, because the baseline noise is sharply reduced by the increased brightness and improved spectral resolution of the dyes (Rosenblum et al. 1997). To compensate for the lower molarity of larger templates in sequencing reactions, increased primer concentrations (2–5x) may be used, and the reaction can be maintained for an increased number of cycles. These alterations enhance signal intensities and produce more accurate, longer read-lengths.

Optimizing the Reaction

Several other factors remain important for achieving optimal results with automated sequencing.

- Although this is a "low-tech" consideration, it is critical to use template DNA clean and free of any contaminants that might interfere with primer annealing. For PCR products in particular, contaminating oligonucleotides and dNTPs can be conveniently digested by *Exo*I/SAP treatment (Hanke and Wink 1994; Werle et al. 1994; C. Chen et al. 1996).
- For loading on capillary-based automated DNA sequencers, samples must be free of ions as they interfere with the electrokinetic injection process. Take special care to eliminate excess dye-terminators before loading samples on gels in both conventional and automated sequencers. This is particularly important when template DNAs are large, since residual dyes can make obscure low-intensity signals (Heiner et al. 1998).

TABLE 12-22 BigDye-Terminator Sequencing Conditions for Various Types of Templates

Template types	M13/ PCR Products	Plasmid	BAC	Microbial DNA
Typical sizes	2–9 kb	<10 kb	200 kb	up to 5 Mb
Reaction mix				
Template DNA (approximately)	30 ng	400 ng	500 ng	2–3 μg
BigDye Terminator Mix	3 μl	4 μl	16 μl	16 μl
Primer	3 pmoles	3 pmoles	6 pmoles	12 pmoles
Total volume	10 μl	10 μl	40 μl	40 μl
Cycling conditions				
Initial denaturation	96°C/1 minute	96°C/1 minute	95°C/5 minutes	95°C/5 minutes
Denaturation	96°C/10 seconds	96°C/10 seconds	95°C/30 seconds	95°C/30 seconds
Annealing	52°C/10 seconds	52°C/10 seconds	55°C/20 seconds	55°C/20 seconds
Extension	60°C/4 minutes	60°C/4 minutes	60°C/4 minutes	60°C/4 minutes
Number of cycles	25	25–50	30–75	45–99
Reaction clean-Up				
Ethanol or isopropanol precipitation	yes	yes	yes	yes?
G-50 Spun column	no	no	yes	yes
Loading on 377 Sequencing Gel				
Resuspension volume	3+ μl	3+ μl	2 μl	2 μl
Loading volume	1 μl	1 μl	1–2 μl	2 μl
Read-length (bases)	750+	750+	550–750	500–600

- As might be expected, the design of the primer is critical. In general, the same rules are used to design primers for automated sequencers and for sequencing by hand. In brief, successful primers consist of a unique sequence of 16–25 nucleotides (the larger the template DNAs, the longer the oligonucleotides), with an appropriate GC content and a low predisposition to fold into secondary structure (Buck et al. 1999).
- For laboratories analyzing large numbers of samples, an effective quality-controlling system, together with operational tools such as liquid-handling robots, is essential to maintain consistently high-throughput and accuracy.

Genome Sequencing Strategy

The expansive increase in data throughput resulting from technological advances has been accompanied by innovations in sequencing strategies. Until 1998, the general approach taken for sequencing larger genomes (those >5 Mb, including yeast, nematode, *Arabidopsis*, and humans) consisted of mapping followed by sequencing. Specifically, the construction of overlapping arrays of large-insert *E. coli* subclones (e.g., BACs) averaging 150–200 kb was followed by the complete sequencing of each of these clones one by one. The BAC clones are sequenced by a well-established shotgun method that uses random cloning of 1–2-kb fragments, followed by the sequencing of enough samples to cover the target region randomly.

With increased sequencing throughput, the mapping process tends to become a bottleneck. However, recent sequencing approaches based on a whole-genome shotgun approach (Weber and Myers 1997; Venter et al. 1998) have successfully challenged the traditional clone-by-clone strategy (Green 1997). This strategy has been used as an alternative to finish the Human Genome Project and to move ahead with mouse and other complex genomes (for news report, see Pennisi 2000). The technical difference lies in the fact that the whole-genome shotgun approach for a large genome like that of the human requires the "simultaneous" assembly of some 60 million sequence reads (~500 bases each), whereas the former strategy (mapping followed by sequencing) relies on the assembly of a few thousand reads at a time. Thus, intense arguments

among the proponents of the two approaches have focused on issues such as computing capability, gap-filling problems, and cost efficiency. Nevertheless, it is generally agreed that a whole-genome shotgun approach can rapidly generate new data, albeit in an often fragmentary form, to facilitate faster discovery of novel genes. The successful application of this strategy is dependent on high-powered computers and sophisticated software that can digitize data quality while comparing and matching the reads from both ends of each of the millions of sequencing samples. In the real world, shotgun approaches also make use of a variety of mapping information from clones, genes, and genetic markers, all of which help to assist assembly. Furthermore, using DNA samples from multiple individuals will likely result in the discovery and cataloging of millions of polymorphic sites. By early 2000, a growing number of scientists believed that a combination of the map/sequence and shotgun strategies was the optimal approach (see Pennisi 2000).

Prospects

The last 15 years have brought sequencing instrumentation and chemistry to a point that truly approaches fully automatic sequencing (please see Figure 12-10). Accompanying improvements in base-calling software, assembly software, and template preparations have progressively simplified both the sequencing operation and the later editing processes. As a result, the limiting factors for most large-scale projects are the purchase and upkeep of machines and the cost of reagents rather than the involvement of a large number of highly skilled personnel. Investigators should thus be free to carry out the tasks for which automated sequencing was invented in the first place — to identify genes, rivet them to physical maps, chase them to their evolutionary roots, and chart their organization, patterns of expression, and biological function.

MICROTITER PLATES

The components of dideoxy-mediated DNA sequencing reactions can be assembled in the wells of heat-resistant microtiter plates with 96 U-shaped wells of ~300-µl capacity. All steps of the subsequent reactions — from initial annealing of primers and template to addition of formamide-dye stop mixture — can then be carried out without transferring the reaction mixtures to fresh tubes or plates. Microtiter plates are especially valuable when several sets of sequencing reactions are performed simultaneously. The various components of the reaction can be transferred to the wells with 8- or 12-channel multichannel pipettors so efficiently that 96 sequencing reactions can be completed with ease within 1 hour. Because the individual components of the reactions are delivered as droplets to the walls of the wells, all 96 reactions can be started simultaneously simply by centrifuging the plates in a swing out rotor equipped with plate holders. Both fluorescent and radioactive labels can be accommodated (Smith et al. 1993). The following are the chief problems.

- ***Heating the microtiter plate*** during the annealing step, so that the fluid in all of the wells of the plate is the same. It is important to use microtiter plates that are designed for use in thermal cyclers and are thin enough to facilitate rapid transfer of heat into and out of the plate. Incubation at 55°C (the annealing step), 37°C (the extension-termination step), or 85°C (the denaturation step) can then be carried out in a thermal cycler or by purchasing or constructing a heating block that can be accommodated in a standard modular heating unit (Koop et al. 1990). Sequencing reactions were heated in earlier days by floating open microtiter plates, like armadas, on the surface of water baths. This was fun but led to contamination of many water baths by radioactivity and the ruination of many sequencing reactions by flooding or evaporation.
- ***Condensation and evaporation.*** Nowadays most heating devices and thermal cyclers are usually equipped with heated covers, which greatly reduce evaporation and condensation. Evaporation can be further reduced by covering the plate with Saran Wrap or with a well-fitting plastic lid (e.g., Falcon 3913; Becton Dickinson).
- ***Cross-contamination of wells.*** Careful handling is required to prevent accidental transfer of fluid between different wells. It is best to seal the plates for the mixing and storage steps with plastic plate sealers and pressure-sensitive film (Falcon 3073; Becton Dickinson).
- ***Centrifugation.*** A centrifuge fitted with a rotor capable of supporting microtiter plates and capable of speeds up to 4000 rpm is required. The rotor trays should be well-padded with rubber or polystyrene foam.

THE KLENOW FRAGMENT OF *E. COLI* DNA POLYMERASE I

E. coli DNA polymerase I (Pol I), an enzyme central to DNA replication and repair (Kornberg and Baker 1992), is cleaved by mild treatment with subtilisin into two fragments, the larger of which, comprising residues 326–928, is known as the Klenow fragment. The DNA polymerase and 3′→5′ exonuclease activities of Pol I are carried on the Klenow fragment (Brutlag et al. 1969; Klenow and Henningsen 1970; Klenow and Overgaard-Hansen 1970), whereas the 5′→3′ exonuclease activity of the holoenzyme is carried on the smaller amino-terminal fragment (residues 1–325), which is nameless (for review, please see Joyce and Steitz 1987; please also see Table 12.23).

The nucleotide sequence of the Pol I gene is known (Joyce et al. 1982), and the segment of DNA encoding the Klenow fragment has been cloned into various expression vectors. Large amounts of the protein have been prepared both for commercial purposes and for biophysical and biochemical studies, including X-ray crystallography (e.g., please see Joyce and Grindley 1983; Pandey et al. 1993).

Uses of Klenow Enzyme in Molecular Cloning

- ***Filling the recessed 3′ termini created by digestion of DNA with restriction enzymes.*** In many cases, a single buffer can be used for both cleavage of DNA with a restriction enzyme and subsequent filling of recessed 3′ termini. The end-filling reaction can be controlled by omitting one, two, or three of the four dNTPs from the reaction and thereby generating partially filled termini that contain novel cohesive ends.

- ***Labeling the 3′ termini of DNA fragments by incorporation of radiolabeled dNTPs.*** In general, these labeling reactions contain three unlabeled dNTPs each at a concentration in excess of the K_m and one radiolabeled dNTP at a far lower concentration, which is usually below the K_m. Under these conditions, the proportion of label that is incorporated into DNA can be very high, even though the rate of the reaction may be far from maximal. The presence of high concentrations of three unlabeled dNTPs lessens the possibility of exonucleolytic removal of nucleotides from the 3′ terminus of the template. Which of the four α-labeled dNTPs is added to the reaction depends on the sequence and nature of the DNA termini.

  Recessed 3′ termini can be labeled with any dNTP whose base is complementary to an unpaired base in the protruding 5′ terminus. Therefore, radioactivity can be incorporated at any position within the rebuilt terminus depending on the choice of radiolabeled dNTP. To ensure that all the radiolabeled molecules are the same length, it may be necessary to complete the end-filling reaction by carrying out a "chase" reaction containing high concentrations of all four unlabeled dNTPs.

  Blunt-ended and protruding 3′ termini may be labeled in an enzymatic reaction that uses both domains of the Klenow fragment. First, the 3′→5′ exonuclease activity removes any protruding tails from the DNA and creates a recessed 3′ terminus. Then, in the presence of high concentrations of one radiolabeled precursor, exonucleolytic degradation is balanced by incorporation of radiolabeled dNTP at the 3′ terminus. This reaction, which consists of cycles of removal and replacement of the 3′ terminus from recessed or blunt-ended DNA, is sometimes called an exchange or replacement reaction. The specific activities that can be achieved with this reaction are modest because the 3′→5′ exonuclease of the Klenow enzyme is rather sluggish, especially on double-stranded substrates. T4 DNA polymerase carries a more potent 3′→5′ exonuclease that is ~200-fold more active than the Klenow fragment and is the enzyme of choice for this type of reaction.

TABLE 12-23 Division of *E. coli* Pol I into Functional Domains

ENZYMATIC FUNCTION	DOMAIN
Polymerization of dNTPs	Carboxy-terminal domain (46 kD) (residues 543–928)
Exonucleolytic digestion of DNA in a 3′→5′ direction	Central domain (22 kD) (residues 326–542)
Exonucleolytic digestion of DNA in a 5′→3′ direction	Amino-terminal domain (residues 1–325)

The first two domains constitute the Klenow fragment of polymerase I.

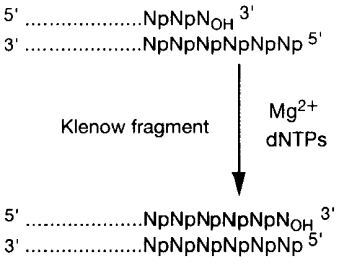

FIGURE 12-12 Filling-in Recessed 3′ Termini of DNA Fragments Using Klenow DNA Polymerase

The 3′ termini generated by digestion with restriction endonucleases may be labeled using the Klenow fragment of DNA polymerase I in the presence of dNTPs and Mg^{2+}.

If a [^{35}S]dNTP is used instead of the conventional [α-^{32}P]dNTP, the reaction is limited to one cycle of removal and replacement since the 3′→5′ exonuclease of *E. coli* DNA Pol I, unlike the exonuclease of T4 DNA polymerase, cannot attack thioester bonds (Kunkel et al. 1981; Gupta et al. 1984).

- ***Labeling single-stranded DNA by random priming*** (Feinberg and Vogelstein 1983, 1984) (please see Chapter 9, Protocol 1).
- ***Production of single-stranded probes by primer extension*** (Meinkoth and Wahl 1984; Studencki and Wallace 1984) (please see Chapter 7, Protocol 12).

For many years, the Klenow enzyme was the highest-quality DNA polymerase that was commercially available and, in consequence, was the enzyme of first and last resort for in vitro synthesis of DNA. However, as polymerases that are better suited to various synthetic tasks have been discovered or engineered, Klenow has been gradually replaced and is no longer the enzyme of first choice for a wide variety of procedures in molecular cloning. Listed below are some of these procedures.

- ***DNA sequencing by the Sanger method.*** Klenow has been replaced by T7 DNA polymerase (Sequenase) and thermostable polymerases that give longer read-lengths.
- ***Synthesis of double-stranded DNA from single-stranded templates*** during in vitro mutagenesis. Although the Klenow fragment is still widely used for in vitro synthesis of circular DNAs using mutagenic primers, it is not always the best enzyme for this purpose. Unless large quantities of ligase are present in the polymerization/extension reaction mixture, the Klenow enzyme can displace the mutagenic oligonucleotide primer from the template strand, thereby reducing the number of mutants obtained. This problem can be solved by using DNA polymerases that are unable to carry out strand displacement, including bacteriophage T4 DNA polymerase (Nossal 1974; Lechner et al. 1983; Geisselsoder et al. 1987), bacteriophage T7 DNA polymerase (Bebenek and Kunkel 1989), and Sequenase (Schena 1989). Bacteriophage T4 gene *32* protein can be used in primer-extension reactions catalyzed by DNA polymerases (including the Klenow enzyme) to alleviate stalling problems caused by templates rich in secondary structure (Craik et al. 1985; Kunkel et al. 1987).
- ***Polymerase chain reactions.*** The Klenow fragment was the enzyme used in the first PCRs (Saiki et al. 1985). However, it has now been completely replaced by thermostable DNA polymerases that need not be replenished after each round of synthesis and denaturation.

Facts and Figures

The standard assay used to measure the polymerase activity of the Klenow fragment is that of Setlow (1974) with poly(d[A-T]) as template. One unit of polymerizing activity is the amount of enzyme that catalyzes the incorporation of 3.3 nmoles of dNTP into acid-soluble material in 10 minutes at 37°C. A sample of pure Klenow fragment has a specific activity of ~10,000 units/mg protein (Derbyshire et al. 1993). The reaction is usually carried in the presence of Mg^{2+}. Substitution of Mn^{2+} for Mg^{2+} increases the rate of misincorporation and decreases the accuracy of proofreading (Carroll and Benkovic 1990). The K_m of the enzyme for the four dNTPS varies between 4 and 20 μM. For methods to assay the exonuclease activity of the Klenow fragment, please see Freemont et al. (1988) and Derbyshire et al. (1988).

PREPARATION OF STOCK SOLUTIONS OF OLIGONUCLEOTIDE PRIMERS FOR DNA SEQUENCING

Dideoxy-mediated DNA-sequencing reactions generally contain five to ten times more molecules of oligonucleotide primers than single-stranded DNA template. However, this is not a hard and fast rule, and investigators should not feel constrained to maintain the ratio of primer:template if the results of sequencing reactions are unsatisfactory. Among the problems that can often be solved by increasing or decreasing the ratio of primer:template are sequencing artifacts caused by multiple priming events; inefficient priming of double-stranded DNA templates; and low yields of products in cycle-sequencing reactions. With custom-synthesized oligonucleotide primers, it is sometimes necessary to determine empirically the optimum ratio of primer to template in the sequencing reaction.

Stock solutions of oligonucleotide primers can be used for both DNA sequencing and 5′-end labeling. Wear gloves when dissolving or diluting oligonucleotide primers. If the oligonucleotide primers are to be used solely for DNA sequencing, lyophilized powder stocks should be dissolved at a concentration of 1–2 μg/ml (0.03–0.05 A_{260}/ml) in H_2O. Stock solutions are stored at –20°C.

It is often convenient to have on hand two solutions of an oligonucleotide primer, one of 185 μg/ml (5.0 A_{260}/ml), which can be phosphorylated in reactions catalyzed by polynucleotide kinase (see Chapter 10, Protocol 2) and used in sequencing reactions, and the other at a concentration of 1–2 μg/ml (0.03–0.05 A_{260}/ml) for sequencing reactions with a radiolabeled dNTP.

A universal primer (1 μg) that is 19 nucleotides in length is ≈160 pmoles. For conversion values of oligonucleotides of other lengths, please see Table 12-24.

Primers synthesized in the laboratory and destined for DNA sequencing in the presence of a radiolabeled dNTP generally need not be purified by gel electrophoresis before use. The amount of contamination by "off size" oligonucleotides is usually too small (<10%) to affect the quality of the DNA sequence. This observation is not true when 5′-radiolabeled oligonucleotides are used as primers in sequencing reactions. Primers that have been purified by gel electrophoresis (see Chapter 10, Protocol 1) are preferred for this purpose. Primers purified in this way also yield the best sequence data in cycle-sequencing protocols (Protocol 6).

Universal primers of several different lengths (from 15 to 26 nucleotides) are available from a number of different commercial suppliers (please see the information panel on **UNIVERSAL PRIMERS** in Chapter 8). There is no detectable difference in the quality of the sequence obtained from recombinant bacteriophage M13 templates with primers of different lengths. However, when denatured double-stranded DNA templates such as bacteriophage or plasmids are used, longer primers (>20 nucleotides) give rise to fewer artifactual bands.

TABLE 12-24 Converting Molarities of Oligonucleotides to Units of Weight

Size of Oligonucleotide (Nucleotides)	pmoles of DNA in 1 μg	Molecules of DNA in 1 μg
8	385	2.32×10^{14}
10	308	1.85×10^{14}
12	257	1.55×10^{14}
14	220	1.34×10^{14}
16	193	1.16×10^{14}
18	171	1.03×10^{14}
20	154	9.27×10^{13}

Numbers given in the table are calculated, based on the assumed molecular mass of the nucleotide of 324.5 daltons and the value of Avogadro's number to be 6.0220×10^{23}.

SEQUENASE

Wild-type T7 DNA Polymerase

This polymerase consists of two subunits, one encoded by the bacteriophage, the other by the *trxA* gene of *E. coli*. Gene 5 of bacteriophage T7 encodes a DNA polymerase (M_r ~80,000) that consists of three separate domains, one of which bears a high degree of homology with the DNA-binding and polymerization domains of other members of the B(Polα) family of DNA polymerases, including *Taq* polymerase and *E. coli* DNA polymerase I (for reviews, please see Joyce and Steitz 1994, 1995; Pelletier 1994; Perler et al. 1996; Steitz 1998). The binding/polymerization domain occupies most of the carboxy-terminal sequences of the wild-type T7 DNA polymerase. The amino-terminal domain of the molecule carries a powerful 3′-5′ exonuclease activity that is active on both single- and double-stranded DNAs. A third domain of the polymerase (the 76-residue "thumb" domain) forms a 1:1 complex with the host-encoded protein, thioredoxin (Doublié et al. 1998; Kiefer et al. 1998).

Because of its rapid rate of polymerization and high processivity, the polymerase:thioredoxin complex is able to replicate the entire genome of T7 without dissociating from the template DNA (Huber et al. 1987; Tabor et al. 1987; Bedford et al. 1997).

Sequenase Versions 1.0 and 2.0

The potent 3′-5′ exonuclease activity of wild-type T7 DNA polymerase, which would butcher any attempt to use the enzyme for DNA sequencing, can be greatly reduced by incubating the enzyme for several days with a reducing agent, molecular oxygen, and stoichiometric concentrations of ferrous ions (Tabor and Richardson 1987b). Inactivation is thought to be the result of site-specific modifications of the exonuclease domain by locally produced free radicals. Bacteriophage T7 DNA polymerase that had been chemically modified in this fashion was at one time marketed by United States Biochemical (USB), under the trade-name Sequenase. This first version of the sequencing enzyme was later superseded by Sequenase version 2.0 in which the 3′-5′ exonuclease domain has been completely inactivated by deletion of 28 amino acids (Tabor and Richardson 1989a). The exonuclease-deficient forms of Sequenase display a powerful strand-displacement ability, which enables them to negotiate regions of template that are folded into secondary structures.

One unit of Sequenase catalyzes the incorporation of 1 nmole of nucleotide into an acid-insoluble form is 30 seconds at 37°C, using 5 μg of primer and M13mp18 DNA as the template under standard assay conditions. Because the specific activities of Sequenase and Sequenase version 2.0 are different from each other, the manufacturer (USB) used different definitions for the units of activity of the two enzymes. Approximately 2.5 units of Sequenase is equivalent to 1 unit of Sequenase version 2.0. Both enzymes are supplied by the manufacturer at a concentration that generally is optimal for sequencing after dilution by 8–20-fold. Dilution is required to reduce the concentration of glycerol, which reacts with borate ions in the electrophoresis buffer and causes distortions in the region of the sequencing gel that contains fragments of DNA in the 400–600-nucleotide range (please see the information panel on **GLYCEROL IN DNA SEQUENCING REACTIONS**).

Sequenase Efficiently Incorporates ddNTPs and Other Analogs of dNTPs

Sequenase is such a good enzyme for DNA sequencing because it generates long sequencing ladders with little variation in labeling intensity from one band to the next (Fuller 1992). Remarkably, this property turns out to be in large part due to a single hydroxyl group attached to the tyrosine residue at position 526 of the enzyme (Tabor and Richardson 1995). Sequencing polymerases other than Sequenase catalyze the incorporation of ddNTPs at only 0.02–1% of the rate of dNTPs. Sequenase is far more efficient. Under conditions routinely used for DNA sequencing, Sequenase catalyzes the incorporation of ddNTPs at ~100 nucleotides/second, which is ~33% of the rate of dNTPs. However, replacing the tyrosine residue at position 526 with phenylalanine decreases the efficiency of usage of ddNTPs by >2000-fold. Conversely, replacing the analogous amino acid of *E. coli* DNA polymerase I or *Taq* polymerase with a tyrosine residue increases the efficiency of usage of ddNTPs up to 8000-fold (Tabor and Richardson 1995). Enzymes that have been modified in this way (please see Table 12-9) can generate sequencing gels that match those of Sequenase in length, beauty, and sharpness. Like several other sequencing enzymes, Sequenase readily uses as substrates

dye-labeled terminators (L. Lee et al. 1992; Fuller et al. 1996), α-thio dNTPs, and dGTP analogs such as 7-deaza dGTP and dITP, which are used to eliminate compression artifacts from sequencing gels (Tabor and Richardson 1987a).

The development of Sequenase has been predominantly the work of just one laboratory — that of Charles Richardson at Harvard Medical School — with the bulk of the work being carried by Stanley Tabor, then an M.D./Ph.D. student. Tabor is the son of Herbert Tabor, for many years the Editor-in-Chief of the *Journal of Biological Chemistry*, and Cecilia Tabor, a leader in the field of polyamines. In a logical and elegant series of papers, Tabor and Richardson reported the use of the chemically modified version of bacteriophage T7 DNA polymerase as a replacement in dideoxy-sequencing reactions for the Klenow enzyme of *E. coli* DNA polymerase I (Tabor and Richardson 1987b); the use of Mn^{2+} instead of Mg^{2+} (Tabor and Richardson 1989b) to generate bands that are highly uniform in intensity (Tabor and Richardson 1989b); the engineering of Sequenase version 2.0 (Tabor and Richardson 1989a); the use of pyrophosphatase to prevent pyrophosphorylytic removal of ddNTP residues from the 3′ terminus of terminated chains that can occur during prolonged sequencing reactions (Tabor and Richardson 1990); and finally, the identification of the residue critical for efficient use of ddNTPs as substrates (Tabor and Richardson 1995). This entire body of wonderful work is an example of the power of enzymology in intelligent hands. The most detailed descriptions of the work are published in a series of patents issued to Tabor and Richardson in the late 1980s and early 1990s (U.S. Patents 4,946,786; 4,795,699; and 4,910,130).

CONVENTIONAL CHAIN-TERMINATION SEQUENCING OF PCR-AMPLIFIED DNA

Methods to sequence the amplified double-stranded products of PCRs are attractive in theory but unreliable in practice. The methods appeal to the investigator who wants to sequence either or both strands of template DNA, and they offer the ability to generate templates for sequencing without the labor of cloning into bacterial or bacteriophage vectors. However, direct sequencing of double-stranded PCR products remains a technical challenge, as the diversity and number of papers on the topic make manifest.

The keys to success are rigorous optimization of the amplification step to suppress mispriming and meticulous purification to rid the PCR product of residual primers, thermostable DNA polymerase, unused dNTPs, and nonspecific reproductions of the original template. Purification generally involves chromatography through spun columns or commercial resins, followed by elution of the desired fragment from an agarose or polyacrylamide gel. With this amount of work, it is perhaps not surprising that many investigators turn to cycle sequencing (please see Protocol 6) or opt for the well-trodden traditional route of cloning PCR products into plasmids or bacteriophage M13 vectors.

Because of differences in the size, yield, and specificity of the amplification product, none of the available purification methods can be used to purify each and every PCR product. However, with some effort, it is almost always possible to devise a successful purification scheme for the products of a specific PCR. The following guide lists the main options that are available. Detailed protocols for many of these options are presented in other sections of this manual.

- ***Removal of Residual Primers and Unused dNTPs***

  Spun column chromatography through Sepharose CL-6B or Sephacryl S-400 (please see Appendix 8). Sepharose CL-6B equilibrated in TE (pH 7.6) excludes double-stranded DNAs >190 bp in size. Sephacryl S-400 excludes double-stranded DNAs >260 bp in size. Both matrices will retard the passage of dNTPs, primers, and primer-dimers.

  Centrifugal ultrafiltration through Centricon-100 or Microcon-100 units (Krowczynska and Henderson 1992; Leonard et al. 1998; please see Chapter 8, Protocol 3).

- ***Elimination of Residual Thermostable DNA Polymerase***

  Taq polymerase, and presumably other thermostable DNA polymerases, survive extraction with phenol:chloroform, ethanol precipitation, and other regimens commonly used to purify the products of PCR (Crowe et al. 1991; Barnes 1992). The continuing presence of the DNA polymerase together with residual dNTPs may befoul chain-termination sequencing reactions catalyzed by other thermostable enzymes such as Thermo Sequenase and AmpliTaq. A method to remove residual thermostable DNA polymerase is described in Chapter 8, Protocol 3.

- ***Elimination of Nonspecific Amplification Products***

  Target DNA can be separated from amplified DNAs that differ in size by electrophoresis through low melting/gelling temperature agarose (please see Chapter 5). The desired PCR product can then be recovered from the gel by one of the methods described in Chapter 5.

When the PCR yields a heterogeneous set of products of similar size, it may be necessary to carry out a second round of PCR using nested primers, or to use a restriction enzyme to cleave unwanted products, or to use a more sophisticated electrophoretic system, for example, denaturing gradient gel electrophoresis (Fischer and Lerman 1983; for review, please see Myers et al. 1998).

Finally, some of the difficulties encountered in sequencing amplified DNAs are not unique. Like any other double-stranded DNA, amplified DNAs will inevitably reassociate after denaturation, whereupon the sequencing primer may be unable to anneal or the DNA polymerase may be unable to proceed along the full length of the template (Gyllensten and Erlich 1988). These problems can be minimized by rapidly transferring the amplified DNA, after denaturation by heat (Kusukawa et al. 1990) or alkali (Wrischnik et al. 1987), to conditions that do not favor reassociation of DNA strands, namely, low temperature and low ionic strength. The quicker the denatured DNA is used in the annealing and extension/termination reactions, the better (please see Protocol 2).

PREPARATION OF STOCK SOLUTIONS OF dNTPS AND ddNTPS FOR DNA SEQUENCING

At each step during the primer-extension phase of dideoxy-sequencing reactions, there are two possible outcomes: chain elongation and chain termination. Chain elongation occurs when the DNA polymerase catalyzes the incorporation of a conventional dNTP into the growing chain of DNA; chain termination results from the incorporation of a ddNTP molecule. Therefore, the balance between chain elongation and chain termination is determined by the ratio of dNTP to ddNTP in each sequencing reaction.

Each of the DNA polymerases used for dideoxy-mediated sequencing has a different affinity for conventional dNTPs and chain-terminating ddNTPs. Thus, reaction mixtures that give good results with one enzyme are unlikely to work well with another. It is almost always necessary to "fine-tune" the concentration of ddNTPs to obtain optimal results for the particular task at hand. When sequencing for the first time with a particular DNA polymerase, we recommend purchasing a kit from a commercial manufacturer that contains the relevant DNA polymerase, pretested chain extension/termination mixtures, single-stranded templates, and oligonucleotide primers (for suppliers, please see Appendix 13). As components of the kit are used up, they may be replaced with homemade materials, which are less expensive and can be made in a wide range of concentrations. Each new batch of reagents should be checked by setting up a series of test reactions with a standard template and primer and a range of concentrations of dNTPs and ddNTPs. Initially, it is best to use fixed concentrations of dNTPs and variable concentrations of ddNTPs. Often, several series of test reactions are necessary to define optimal conditions. The following stock solutions are used to prepare the working solutions of dNTPs and ddNTPs for sequencing reactions using either the Klenow fragment of *E. coli* DNA polymerase I, Sequenase, or thermostable (e.g., *Taq*) DNA polymerases.

Stock solutions usually contain a single dNTP or ddNTP at a concentration of 10 mM or 20 mM, according to the needs of the investigator. These stocks are stored at –20°C in small aliquots, and they may be diluted to generate, for example, solutions that contain all four dNTPs at a concentration of 5 mM.

A microbalance is used to weigh out the required amounts of dNTP or ddNTP into sterile microfuge tubes. Either use a disposable spatula or clean the spatula well with ethanol between each weighing when making up solutions of different dNTPs or ddNTPs. The table shows the amount of solid, anhydrous deoxynucleotide or dideoxynucleotide required to make 1 ml of a 20 mM stock solution.

Deoxynucleotide	FW	Amount (in mg) required to make 1 ml of a 20 mM solution
dATP	491.2	9.82
dCTP	467.2	9.34
dTTP	482.2	9.64
dGTP	507.2	10.14
dITP	508.2	10.16
ddATP	475.2	9.50
ddCTP	451.2	9.02
ddTTP	466.2	9.32
ddGTP	491.2	9.82
7-deaza-dGTP	506.2	10.12
7-deaza-dITP	507.2	10.14

Dissolve the deoxynucleotides or dideoxynucleotides in a small volume of H_2O, and then use pH paper and an automatic pipeting device to adjust the pH to ~8.0 by adding small amounts of 2 N NaOH until the pH reaches 8.0.

Alternatively, the stock solutions may be generated from monosodium salts of the deoxynucleotide triphosphates or dideoxynucleotide triphosphates by dissolving an appropriate amount of the solid in 1.0 ml of H_2O. Mix the contents of the tube well and store the stock solution in small aliquots at –20°C.

pH-adjusted solutions of dNTPs and ddNTPs are available from many commercial manufacturers.

The base analogs dITP and 7-deaza-dGTP are substituted for dGTP in chain extension/termination reactions to reduce secondary structure problems. These analogs form base pairs with dC that contain only two hydrogen bonds instead of the three normally formed by G-C base pairs. Therefore, the analog-C base pairs are more readily denatured before separation by gel electrophoresis and have less of a tendency to form secondary structure during the actual electrophoretic run. However, because the use of dITP and 7-deaza-dGTP accentuates pauses in the chain extension/termination reaction, sequencing reactions containing a base analog should always be run in parallel with reactions containing dGTP.

GLYCEROL IN DNA SEQUENCING REACTIONS

Most DNA polymerases used in DNA sequencing are supplied by commercial manufacturers in buffers containing 50% glycerol, which allows the enzyme preparations to be stored at –20°C without freezing. Because glycerol and other vicinal diols also stabilize protein-protein interactions (including interdomain interactions in single-subunit proteins) and therefore protect enzymes against denaturation, DNA-sequencing reactions may be carried out at higher temperatures and for longer times, without significant loss of enzyme activity. However, high concentrations of glycerol (>5%) in samples applied to DNA-sequencing gels generate bends in the sequencing tracks and blurring of bands >300 bases in size (Tabor and Richardson 1987a). These effects are almost certainly due to the reaction of glycerol with boric acid in the gel-running buffer to form negatively charged esters that migrate anodically through the gel during electrophoresis. This problem can be solved in several ways (Pisa-Williamson and Fuller 1992):

- ***Dilute the DNA polymerase*** into ice-cold buffers that do not contain glycerol. As a general rule, use enzymes immediately after dilution and discard any unused remnants.
- ***Remove the glycerol*** from the manufacturer's buffer by centrifugation through a spun column of P2 gel filtration medium (Bio-Rad), equilibrated in the manufacturer's recommended storage buffer without glycerol (Trevino et al. 1993).
- ***Precipitate the products*** of the sequencing reaction with ethanol before loading onto the gel.
- ***Replace boric acid in the gel*** and in the electrophoresis buffer with taurine, a weak aminosulfonic acid with a pK_a similar to that of boric acid (Pisa-Williamson and Fuller 1992). Taurine/EDTA/Tris electrophoresis buffer consists of 89 mM Tris, 29 mM taurine, and 0.1 mM EDTA. A 20X solution therefore contains 216 g of Tris, 72 g of taurine, and 2 g of EDTA per liter.

COMPRESSIONS IN DNA SEQUENCING GELS

Compressions occur when two or more single-stranded DNAs of different lengths migrate through a polyacrylamide gel with the same mobility. This results in coincidence of bands in different lanes and anomalous spacing of bands above and below the region of compression. Because of the difficulty in calling the correct sequence from these bands, compression artifacts often appear as regions of different sequence on the two DNA strands. Compressions arise when single-stranded DNAs are not fully denatured during electrophoresis. DNAs containing secondary structures are less subject to viscous drag than are single-stranded DNAs of equivalent length and sequence and so migrate more rapidly through the gel.

Compressions, which occur in both the Maxam-Gilbert and Sanger sequencing methods, mostly affect reading of the G and C tracks, although the A and T tracks are by no means immune. Compressions arise when sequences displaying dyad symmetry are located at or near the 3′ termini of single-stranded DNAs, particularly those DNAs ending in regions with three or more G/C base pairs in succession. Such sequences may form intrastrand secondary structures (hairpins and cruciforms) that are not fully denatured during electrophoresis through standard sequencing gels (50°C and 7 M urea).

Several methods can be used to resolve compressions in sequencing gels. The easiest, which cures about half of the problems, is simply to use a different DNA polymerase to catalyze the chain-terminating sequencing reaction. GC-rich regions that bar the passage of one type of DNA polymerase will frequently yield to another. Many compressions can be bypassed by sequencing the other strand of DNA. In some cases, the compression turns out to be specific to one strand; in others, the compression occurs in both strands but is offset by a few nucleotides. Either way, a composite sequence can be constructed through the region of compression. If all else fails, try adding cosolvents such as dimethylsulfoxide or formamide to a final concentration of 10% in the chain-terminating sequencing reaction. Glycerol can also be used, again at a concentration of 10%. However, it is then necessary to use a glycerol-tolerant electrophoresis buffer to prevent artifacts caused by the interaction of glycerol with borate ions in conventional TBE buffer (please see the information panel on **GLYCEROL IN DNA SEQUENCING REACTIONS**).

Another way to alleviate compressions is to reduce the opportunity for base pairing during electrophoresis. None of these methods is foolproof and all of them have drawbacks. Furthermore, the choice between them is not straightforward since few head-to-head comparisons have been published of their ability to relieve compressions of various severities. In the most thorough study to date, F. Blattner (pers. comm.) has analyzed the ability of nucleotide analogs and gel additives to resolve a battery of bacteriophage M13 clones that produce sequencing compressions of various types. The gel additives were generally ineffective when standard dNTPs were used in the reaction mixtures. However, the combination of nucleotide analogs and gel additives was able to resolve even the most stubborn compressions. One nucleotide analog — dITP — was effective against all compressions, as was a combination of 7-deaza-dGTP and 7-deaza-dATP. 7-deaza-dGTP alone resolved ~50% of the compressions. Please note that dITP should not be used in sequencing reactions catalyzed by *Taq* DNA polymerase and its numerous derivatives (please see Table 12-25).

TABLE 12-25 Methods to Resolve Compressions

METHOD	COMMENTS
dITP dITP and ddITP are substituted for dGTP and ddGTP in the chain extension/termination reactions. Usually, the dITP:dGTPratio in the reaction mixtures is 4 and the concentration of ddITP:ddGTP in the G termination mixture is 8.	Inosine forms base pairs containing only two hydrogen bonds instead of the three normally formed by G-C base pairs. The consequent weakening of Watson-Crick base pairing results in a substantial reduction in the formation of intramolecular "hairpin" structures. Sequenase is the choice polymerase for reactions containing inosine nucleotides. Avoid *Taq* DNA polymerase and its various derivatives (please see Table 12-9) when using dITP as a substrate. Because the use of dITP accentuates pauses in the chain-termination reaction, always run sequencing reactions containing the base analog in parallel with standard reactions containing dGTP. Substitution of dITP for dGTP causes nucleic acids to migrate slightly faster through polyacrylamide gels. The USB ThermoSequenase-radiolabeled terminator sequencing kit recommends dITP be used for all new sequences and any that give rise to compressions. With dITP, USB suggests using an "extension" temperature of 60°C with a duration of at least 4 minutes. The quality of sequence is never as good when base analogs are used in place of conventional dNTPs. It is therefore helpful to load each set of reactions into eight adjacent lanes of a polyacrylamide gel in the order IATCITAC. This ensures that each of the four sequencing reactions is adjacent to the other three and allows the order of closely spaced bands to be determined more easily. References: Mills and Kramer (1979); Bankier and Barrell (1983); Barr et al. (1986); Tabor and Richardson (1987a); Innis et al. (1988).
7-deaza dGTP 7-deaza-2′-deoxy-guanosine-5′-triphosphate is substituted for dGTP in the chain extension/termination reactions. Usually, equimolar amounts of 7-deaza-GTP and dGTP are used in the reaction mixtures.	The methine group at the N-7 position of 7-deaza-dGTP is thought to preclude formation of Hoogstein bonds and thereby to suppress formation of secondary structures (Barr et al. 1986). However, this mechanism has since been called into question (Jensen et al. 1991). It now seems likely that 7-deaza analogs cure compressions by reducing vertical stacking interactions between purines (Seela et al. 1982, 1989; Jensen et al. 1991). 7-deaza-dGTP is effective at resolving many compressions preceded by a G residue. Compressions preceded by A are best resolved by 7-deaza-dATP or by a combination of both analogs (Jensen et al. 1991). Because the use of 7-deaza-dGTP accentuates pauses in the chain-termination reaction, sequencing reactions containing the base analog should always be run in parallel with standard reactions containing dGTP. Substitution of 7-deaza-dGTP for dGTP causes nucleic acids to migrate slightly faster through polyacrylamide gels. The quality of sequence is never as good when base analogs are used in place of conventional dNTPs. It is often helpful to load each set of reactions into eight adjacent lanes of a polyacrylamide gel in the order aZATCaZTAC. This ensures that each of the four sequencing reactions is adjacent to the other three and allows the order of closely spaced bands to be determined more easily. Reference: Mizusawa et al. (1986).
7-deaza-dATP 7-deaza-2′-deoxyadenosine-5′-triphosphate is used to replace dATP in the chain extension/termination reactions.	The methine group at the N-7 position of 7-deaza-dATP may preclude formation of Hoogstein bonds and thereby suppress formation of secondary structures. However, 7-deaza-dATP may also cure compressions by reducing vertical stacking interactions between purines (Jensen et al. 1991). 7-deaza-dATP helps to resolve compressions preceded by an A residue. This type of compression usually cannot be resolved by 7-deaza-dGTP alone. Reference: Jensen et al. (1991).
Formamide Including 20–50% formamide in the sequencing gel resolves some compressions.	Inclusion of formamide in sequencing gels run at 50°C has been reported to resolve compressions. However, gels containing formamide run slower and cooler than conventional polyacrylamide gels run at the same voltage. It is usually necessary to increase the voltage by ~10% to maintain temperature. Because gels containing formamide are extremely sticky and difficult to dry, it is best wherever possible to freeze the wet gel for exposure to X-ray film. References: Martin (1987); Rocheleau et al. (1992).
Voltage	Increasing the voltage raises the temperature of the gel which, in turn, destabilizes secondary structures. Unfortunately, it also generates steep temperature gradients across the glass plates, which then crack.
Chemical modification of cytosine residues	Deamination of cytosine with bisulfite or bisulfite plus methoxyamine converts the base to uracil and reduces the potential for G-C base pairing. Reference: Ambartsumyan and Mazo (1980).

7-DEAZA-dGTP

7-deaza-dGTP (also called 7-aza-dGTP) is a base analog of dGTP that destabilizes intramolecular interactions in single-stranded nucleic acids (see Figure 12-13). The substitution of 7-deaza-dGTP for dGTP most likely reduces vertical stacking interactions between adjacent purine residues because of alterations of the p electron system and a decrease in the dipole moment (Seela et al. 1982, 1989; Jensen et al. 1991). 7-deaza-dGTP is used under the following circumstances in molecular cloning:

- ***To relieve compressions*** in chain-termination DNA sequencing (Barr et al. 1986; Mizusawa et al. 1986). 7-deaza-dGTP is used as a substrate in chain extension/termination reactions that contain either no dGTP or equimolar amounts of dGTP and the base analog. Under these conditions, many compressions that are preceded by G are resolved. Compressions preceded by A are more efficiently relieved by 7-deaza-dATP, whereas compound compressions may require a combination of 7-deaza-dGTP and 7-deaza-dATP (Jensen et al. 1991; please also see the information panel on **COMPRESSIONS IN DNA SEQUENCING GELS**).
- ***Because 7-deaza-dGTP (aZ) accentuates pauses*** in the chain-termination reaction, sequencing reactions containing the base analog should be run in parallel with standard reactions containing dGTP. In addition, because the quality of sequence is never as good when base analogs are used in place of conventional dNTPs, each set of reactions should be loaded into eight adjacent lanes of a polyacrylamide gel in the order aZATCaZTAC. This ensures that each of the four sequencing reactions is adjacent to the other three and allows the order of closely spaced bands to be determined more easily. The substitution of 7-deaza-dGTP for dGTP causes nucleic acids to migrate slightly faster through polyacrylamide gels.
- ***To facilitate PCR amplification*** of DNA templates containing G+C-rich regions or stable secondary structures (McConlogue et al. 1988). However, there is a price to pay for this increased efficiency. When 7-deaza-dGTP is substituted for dGTP in PCR, the resulting amplified fragment is resistant to cleavage with many restriction enzymes whose recognition sites contain one or more G residues, for example, *Eco*RI, *Sma*I, *Sal*I, *Pst*I, *Bam*HI, *Sau*3A, *Alu*I, and *Acc*I (Grime et al. 1991).

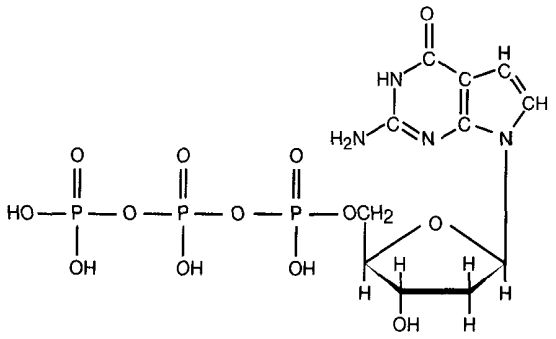

FIGURE 12-13 Structure of the Nucleotide Analog 7-deaza-dGTP

DICHLORODIMETHYLSILANE

Dichlorodimethylsilane is one of a large family of organosilicon oxide polymers that display remarkably high chemical stability and an unusual lack of adhesive properties. The best known of these compounds are (1) Silly Putty, whose deformative, elastic, and recoiling properties are sure to be well known to those who grew up in the 1960s, and (2) GAK, a revolting green goo that was a source of delight for 4-year olds in the 1990s.

In molecular cloning, organosilicon oxide polymers are used to prevent loss of material by adsorption onto surfaces. Dichlorodimethylsilane, for example, is the active ingredient in silanizing solutions that are commonly used to prevent thin polyacrylamide gels used for DNA sequencing from sticking to their supporting glass plates. Most commercial silanizing solutions contain 2% dichlorodimethylsilane dissolved in 1,1,1-trichloroethane. This mixture is smeared over the surface of one of the two glass plates and allowed to dry in air. A more even and durable coating can be achieved by standing the plates in a bath of 5% dichlorodimethylsilane dissolved in chloroform or heptane. The glass plates are allowed to dry at room temperature and then rinsed many times with H_2O before use.

Small items (e.g., microfuge tubes and disposable pipette tips) used in the Maxam-Gilbert method of DNA sequencing are best siliconized by evaporative deposition of a small amount of undiluted dichlorodimethylsilane inside a glass desiccator. Glassware is then baked for 2 hours at 180°C and plasticware is rinsed extensively with H_2O before use.

READING AN AUTORADIOGRAPH

Reading DNA sequences from gels is an acquired skill — it is not as easy as it looks. The following list of tips may help to simplify the process and minimize problems.

- As soon as the autoradiograph is developed, label the film with the date, exposure time, and names of the templates. Mark each set of sequencing reactions clearly. Indicate the order of the sequencing reactions loaded in each lane (e.g., CTAG).
- Be sure to distinguish the left and the right sides of the gel. The image of the radioactive ink or chemiluminous marker should appear next to the sequencing reaction that was loaded on the first track of the gel.
- When searching for correspondence between a new DNA sequence and one that is already known, or for overlap between complementary sequences or sequential gel loads, look for obvious "signatures" such as homopolymeric runs (e.g., consecutive T residues) or alternating purine and pyrimidines (e.g., GTGTGT). Once found, use these signatures to locate the sequence of interest quickly.
- Read and record an unknown sequence at least twice, preferably by different people. Alternatively, enter the sequence twice if a computer-assisted gel reader is used. Compare the two readings and resolve the discrepancies by careful reinspection and, if necessary, by further sequencing. When reading DNA sequences generated on a machine, compare separate sequencing reactions on a computer and resolve discrepancies by reinspection of the original color-coded printout. Pay careful attention to peak heights and overlaps, and ask the person in charge of the machine to help resolve discrepancies.
- If the gel has been loaded in the order TCGA or CTAG, read the sequence of the complementary strand (3′ to 5′) by flipping the autoradiograph over and reading the gel from the bottom. (The tracks on the flipped autoradiograph are read from left to right and their order is assumed to be TCGA or CTAG.)
- The following guidelines are useful when reading gels:

  Pay special attention to gaps or uneven spacing in the autoradiograms. These are usually signatures of compression or DNA polymerase pausing problems. In sequences generated by the Maxam-Gilbert procedure, watch for gaps associated with the sequence 5′-CA/TGG-3′. Hydrazine will not modify 5-methylated cytosine residues in the sequence C<u>C</u>A/TGG, the recognition sequence for a restriction/modification system in *E. coli*, thus leading to a gap between the first C residue and the A/T residue (see Comment below).

  In enzymatic reactions, single C bands are generally weaker than single bands of the three other nucleotides.

  The first A in a homopolymeric run of As is generally stronger than the rest.

  The first C in a homopolymeric run of Cs is usually much weaker than the second.

  G bands are weak when they are preceded by a T.

These latter observations are variably true depending on the DNA polymerase used in the sequencing reactions.

- It is initially somewhat more difficult to determine the sequence of DNA from a chemical-degradation sequencing gel than from a Sanger dideoxy-mediated chain-termination sequencing gel. Because the chemical cleavage reactions are not all absolutely base-specific, it is necessary to deduce the position of T residues by subtracting bands appearing in the C track from those in the C+T track. Similarly, the position of A residues is deduced by subtracting bands in the G track from those in the A+G track. The presence of an A residue is confirmed if a strong band is present in the A>C track. Beware of the sequence 5′-CA/TGG-3′, as this sequence may indicate the presence of a methylated C<u>C</u>A/TGG sequence in the DNA. This is an *Eco*RII restriction endonuclease site and the second C is methylated at the 5-position in almost all standard laboratory *E. coli* strains (with the exception of those carrying a *dcm* allele). The 5-methylated C is not susceptible to hydrazine modification and therefore appears as a blank (i.e., C_A/TGG) sequence in the ladder.
- Because Maxam-Gilbert sequencing is carried out with ^{32}P-labeled DNA, the bands are fuzzier and broader than those obtained from DNA sequenced by the Sanger method in which [^{35}S]dNTPs or [^{33}P]dNTPs have been used. This lack of resolution limits the amount of reliable sequence that can be obtained from a single gel to ~200–250 nucleotides.

ELECTRICAL MOBILITY OF DNA

A lively debate has been ongoing for several years about the mechanism by which DNA molecules move through gels. One theory treats DNA as a chain passing through a tube. At any one point, the shape and dimensions of the tube are defined by the neighboring fibers of the gel. In the absence of an electric current, long-chain polymers diffuse through these snake-like tubes by a form of random motion known as reptation (de Gennes 1971). Under the influence of a constant electric field, the diffusion process becomes biased so that the flexible DNA molecules tend to move through the tube toward the anode (Lerman and Frisch 1982; Bean and Hervet 1983; Lumpkin et al. 1985; Slater and Noolandi 1989). Reptation theory assumes that the DNA is always encased in a tube and that the overall length of the tube varies little when the electric field strength remains low. Higher electric fields cause straightening of the DNA molecules with an effective increase in the length of the tube. DNA molecules can then take a more direct path toward the anode and hence travel faster through the gel (Lumpkin et al. 1985).

In recent years, reptation theory has come under increasingly severe scrutiny with the understanding of the physical nature of gels and the better documentation of the behavior of DNA in different types of electrical fields. In several cases, experimental data conflict with predictions made from reptation theory. For example, reptation theory anticipates that DNAs will show the same dependence of mobility on chain length in both constant- and variable-field gel electrophoresis. However, this prediction is clearly at odds with the observed separation of large fragments of DNA by pulsed-field gel electrophoresis. Second, tube models predict that the mobility of shorter segments of DNA should depend on electric field strength raised to an exponent greater than one. In fact, however, DNA mobility through a variety of gels is directly proportional to the electrical field strength over a wide range of DNA sizes (Johnson and Grossman 1977; McDonell et al. 1977; Calladine et al. 1991). Finally, reptation theory fails to account adequately for the observation that a segment of curved DNA or a curved protein-DNA complex reduces mobility when it is located in the middle, but not the ends, of a long DNA fragment (Wu and Crothers 1984).

A number of alternative theories of DNA mobility have been proposed that deal comfortably with these and other issues by suggesting that the microstructure of the gel presents an entropic barrier to DNA movement (Smisek and Hoagland 1990; Zimm and Lumpkin 1993; Völkel and Noolandi 1995; for review, please see Yager et al. 1997). The mobility of the DNA therefore becomes a statistical variable that depends chiefly on the size of the DNA relative to the spacing and strength of barriers. Whenever a DNA molecule encounters a barrier, it piles up against it, eventually applying sufficient force to dislodge the obstacle from the direct pathway to the anode. The model therefore accounts for the extra band broadening that occurs during diffusion or electrophoresis and predicts that the electrophoretic mobility of DNA should scale inversely with the third power of DNA length. This dependence, which has been confirmed under certain electrophoretic conditions (Calladine et al. 1991), is much stronger than that predicted by reptation models.

Chapter 13

Mutagenesis

IN VITRO MUTAGENESIS IS USED TO CHANGE THE BASE SEQUENCE of a segment of DNA. The changes may be localized or general, random or targeted. More catholic and less specific methods of mutagenesis are better suited to analysis of regulatory regions of genes, whereas more precise types of mutagenesis are used to understand the contribution of individual amino acids, or groups of amino acids, to the structure and function of a target protein. Both methods share the virtue of generating mutants in vitro, without phenotypic selection.

MUTAGENESIS OF REGULATORY REGIONS

Most of the *cis*-acting elements that control expression of mammalian genes were originally identified and localized by analyzing nested sets of deletions, generated by in vitro mutagenesis, that penetrate the region of interest for different distances. To make these deletions, the target DNA was digested from a fixed point upstream or downstream from the region of interest with an enzyme such as BAL 31, which progressively shortens a double-stranded DNA fragment, or with exonuclease III, which digests double-stranded DNA from 3′ termini. For further details on these enzymes, please see the information panels on **BAL 31** and **EXONUCLEASE III** at the end of this chapter. Nested deletions allowed definition of the outer borders of the regulatory domains and opened the way to more precise mapping and analysis of internal subdomains by linker scanning (please see the information panel on **LINKER-SCANNING MUTAGENESIS**) and site-directed mutagenesis.

Work of this type was central to our current understanding of mammalian gene control and led to the description of binding sites for many transcription factors and to the identification of other types of *cis*-acting elements. Productive as this work may have been, it was certainly formulaic and dreary! To our great relief, nested deletions and linker-scanning mutagenesis passed their zenith sometime in the late 1980s and are now used only rarely (please see Protocols 9 and 10). Regulatory elements are nowadays more easily identified by computer searches for consensus sequences in regulatory regions, whereas mutations in *cis*-acting elements are more efficiently constructed by polymerase chain reaction (PCR)-mediated methods (please see Protocols 5 and 6).

MUTAGENESIS OF CODING SEQUENCES

Several different types of mutagenesis are used to understand the contribution of specific amino acids and groups of amino acids to the structure and function of proteins.

Saturation Mutagenesis

Saturation mutagenesis is used to generate mutations at many sites in a particular coding sequence. Every effort is made to introduce mutations in an unbiased fashion; preconceptions and knowledge about the functions of individual amino acids in the wild-type sequence are disregarded. The aim is to gather information about the entire "sequence space," i.e., about the relationship between the amino acid sequence and the three-dimensional structure of the protein.

Saturation mutagenesis is usually carried out on small segments of DNA that encode an individual structural domain. At its best, the method can provide catalogs of amino acids or combinations of amino acids that are tolerated within a domain without deleterious effect on structure and function. Studies of the bacteriophage λ repressor, for example, have shown that a large number of combinations of amino acids can satisfy the structural and functional requirements

of the hydrophobic core and α helices of the molecule (Reidhaar-Olson and Sauer 1988; Lim and Sauer 1989). For further details about saturation mutagenesis, please see the information panel on **RANDOM MUTAGENESIS.**

Scanning Mutagenesis

Alanine-scanning mutagenesis is used to analyze the function(s) of particular amino acid residues on the surface of a protein. The charged residues that normally dapple the surface of proteins are not usually required for structural integrity, but they are generally involved in ligand binding, oligomerization, or catalysis. Systematic replacement of charged amino acids with alanine residues eliminates side chains beyond the β-carbon and disrupts the functional interactions of the amino acids without changing the conformation of the main chain of the protein. Alanine scanning is therefore a powerful method for assigning functions to particular regions of the protein surface (Cunningham and Wells 1989) (please see the information panel on **ALANINE-SCANNING MUTAGENESIS**).

In an extension of this approach — cysteine-scanning mutagenesis — unpaired cysteine residues are used to replace individual amino acid residues at particular sites in the protein. Unpaired cysteine residues are of average size, uncharged, and hydrophobic. Because they react efficiently with modifying reagents such as *N*-ethylmaleimide, cysteine residues introduced by scanning mutagenesis can be used as biochemical tags to verify the topology of transmembrane proteins and to measure the accessibility of residues to modifying reagents in the aqueous or lipid phases (e.g., please see Akabas et al. 1992; Dunten et al. 1993; Kürz et al. 1995; Frillingos and Kaback 1996, 1997; He et al. 1996; Frillingos et al. 1997a,b, 1998).

Oligonucleotide-directed Mutagenesis

Oligonucleotide-directed mutagenesis is used to test the role of particular residues in the structure, catalytic activity, and ligand-binding capacity of a protein. In the absence of a three-dimensional structure, this type of protein engineering relies on informed guesses concerning the structure of the protein and the contribution of individual residues to protein stability and function. A major problem is distinguishing mutations that affect local structures from those that have profound and deleterious effects on the folding or stability of the entire protein. Consider a typical experiment in which a number of point mutations have been generated at various sites in a gene coding for an enzyme. When the activities of these mutants are assayed, some of them show a reduction in catalytic function and others do not. In the absence of any other data, it is not possible to draw firm conclusions about the structure of the enzyme from this result. There is no way to know whether the substitution of one amino acid for another has affected only the function of the active site or whether it has had more global effects. The problem would remain even if the three-dimensional structure of the wild-type enzyme were known. No algorithms have yet been devised that accurately predict the perturbations in protein structure caused by the substitution, addition, or deletion of amino acid residues. However, these difficulties can be alleviated by developing independent assays for the folding of the protein of interest. Such assays commonly include the ability of the protein to react with mono- or polyclonal antibodies that are specific for native or unfolded epitopes, the proper movement and posttranslational modification of the protein within a cell, the retention of catalytic or ligand-binding functions, and the sensitivity or resistance of the mutant protein to digestion with proteases.

If reliable assays are available to confirm that the mutagenized protein is correctly folded, oligonucleotide-directed mutagenesis becomes an analytical technique with both exquisite specificity and extraordinary breadth. Mutations that could never be found in nature can now be

placed precisely in the target gene; functions of proteins can be mapped to specific structural domains; undesirable activities of enzymes can be eliminated and their desirable catalytic and physical properties can be enhanced. In short, oligonucleotide-directed mutagenesis has become the genetic engineer's alchemy.

METHODS OF OLIGONUCLEOTIDE-DIRECTED MUTAGENESIS

The scientific literature on oligonucleotide-directed mutagenesis is both highly redundant and unnecessarily complex. In fact, the hundreds of methods that have been described during the last two decades are all based on a simple concept (Zoller and Smith 1982, 1983, 1984; for review, please see Smith 1985).

- A synthetic oligonucleotide encoding the desired mutation is annealed to the target region of the wild-type template DNA where it serves as a primer for initiation of DNA synthesis in vitro.
- Extension of the oligonucleotide by a DNA polymerase generates a double-stranded DNA that carries the desired mutation.
- The mutated DNA is then inserted at the appropriate location of the target gene, and the mutant protein is expressed.

Figure 13-1 shows one way in which this general scheme has been adapted for use with a plasmid vector and a DNA polymerase such as bacteriophage T4 DNA polymerase. Many elaborations and improvements have been made to this scheme over the years, particularly since the advent of PCR, but the basic principles have not changed.

DESIGN OF MUTAGENIC OLIGONUCLEOTIDES

A crucial step in site-directed mutagenesis is the design of the mutagenic oligonucleotide. By definition, mutagenic oligonucleotides must contain at least one base change, but they may incorporate far more complicated mutations including insertions, deletions, and compound substitutions. The minimum length of the mutagenic oligonucleotide is defined by the complexity of the mutation. Simple single-base substitutions can be accomplished with oligonucleotides ~25 bases in length. More complicated mutations may require oligonucleotides 80 bases or more in length, which is close to the practical limit of most automated synthesizers. Once the length of the oligonucleotide is defined, other properties such as base sequence, base composition, melting temperature, propensity to form secondary structures, and specificity of annealing must be brought into balance in order to maximize the efficiency of mutagenesis. For the principles that guide these design features, please see the information panel on **MUTAGENIC OLIGONUCLEOTIDES**.

CLASSICAL SITE-DIRECTED MUTAGENESIS

The feasibility of introducing specific changes at defined locations in DNA was first recognized in the early 1970s from work aimed at mapping the locations of mutations on the single-stranded genome of the small bacteriophage ϕX174. When fragments of denatured wild-type bacteriophage DNA were transfected into susceptible bacteria together with intact single-stranded bacte-

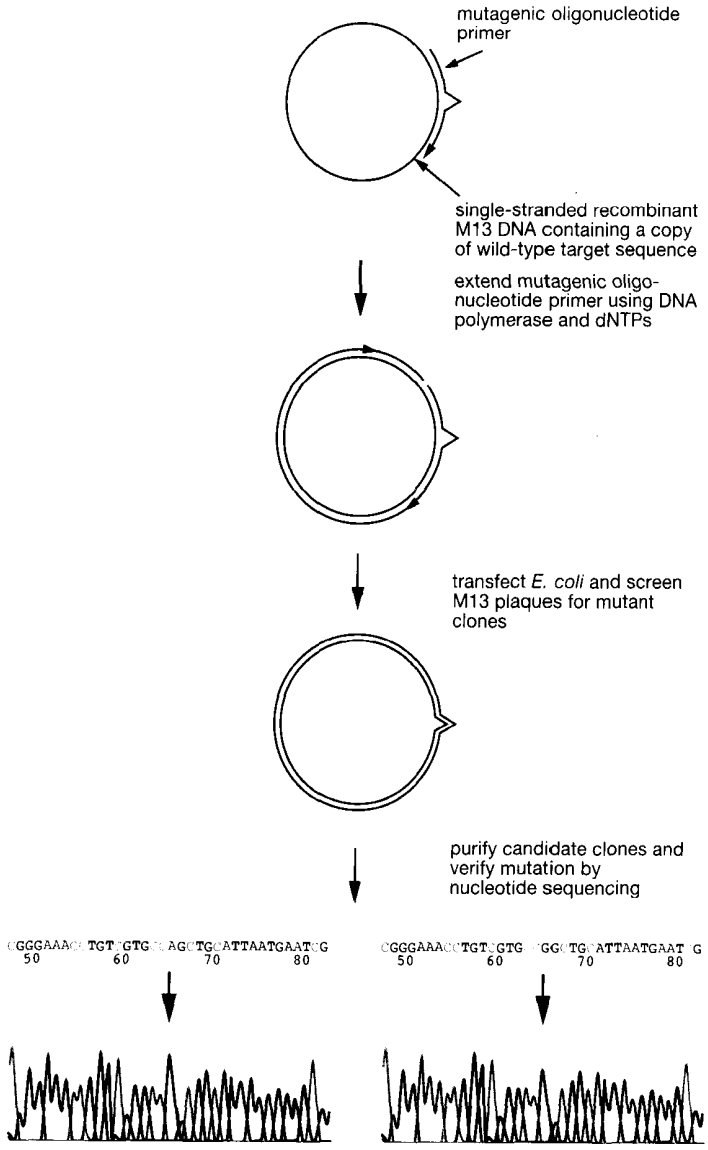

FIGURE 13-1 General Scheme for Oligonucleotide-directed Mutagenesis

riophage DNA carrying an amber mutation, "marker rescue" was observed, i.e., bacteriophages carrying wild-type genomes were generated. Marker rescue occurred in the transfected bacteria because the fragment of wild-type DNA annealed to the corresponding sequence of the amber mutant, forming a mismatched heteroduplex that was converted by host-specified mismatch-repair systems into a full-length wild-type genome. It was quickly realized that this process could also be used in reverse, i.e., that specific mutations could be introduced into wild-type DNA using mutated double-stranded fragments of viral DNA (Weisbeek and van de Pol 1970; Hutchison and Edgell 1971). Later, when pioneering work in DNA chemistry led to the routine synthesis of oligonucleotides (Letsinger and Lunsford 1976; Khorana 1979; Caruthers et al. 1983), and when the availability and quality of DNA polymerases and DNA ligases had improved, Smith and colleagues developed in vitro techniques for oligonucleotide-directed DNA mutagenesis. The first methods used synthetic oligonucleotides that were completely homologous to single-stranded

bacteriophage ϕX174 DNA except for a single base change that, if incorporated into the bacteriophage genome, would generate a selectable phenotype. The oligonucleotides were annealed to single-stranded bacteriophage ϕX174 DNA and used as primers for DNA synthesis catalyzed in vitro by the Klenow fragment of *Escherichia coli* DNA polymerase I. When the resulting heteroduplexes were transfected into bacteria, a dramatic increase was observed in the frequency of bacteriophages displaying the desired phenotype (Hutchison et al. 1978; Razin et al. 1978).

Many of the methods used for oligonucleotide-mediated mutagenesis differ little in principle from the marker rescue techniques used originally by Clyde Hutchison and his colleagues at Chapel Hill, North Carolina. Throughout the 1980s, protocols for oligonucleotide-mediated mutagenesis typically involved the following steps:

- Design and synthesis of mutagenic oligonucleotides.
- Hybridization of mutagenic oligonucleotides to single-stranded target DNA cloned in a bacteriophage or phagemid vector. Use of such single-stranded templates eliminates competition between the mutagenic oligonucleotide and a complementary strand of DNA.
- Extension of the hybridized oligonucleotide by DNA polymerase in the presence of all four deoxynucleoside triphosphates (dNTPs).
- Formation of closed circular DNA by ligation with DNA ligase.
- Transfection of susceptible bacteria.
- Screening of clones by hybridization (e.g., to the mutagenic oligonucleotide primer) for those carrying the desired mutation.
- Preparation of single-stranded DNA from the mutagenized clones.
- Confirmation by DNA sequencing that the target DNA in the mutagenized clones carries the desired mutation and no other.
- Recovery of the mutated fragment of DNA.
- Substitution of the mutagenized fragment for the corresponding segment of wild-type DNA.

Throughout the 1980s, a succession of improvements to virtually all of the technical aspects of the procedure included:

- Development of a versatile set of bacteriophage M13 and phagemid vectors, equipped with polycloning sites.
- Use of two oligonucleotide primers, one of which is a standard universal primer and the other a mutagenic primer (Norris et al. 1983; Zoller and Smith 1984, 1987). The use of two primers in the extension reaction eliminated the need to isolate covalently closed circular DNA.
- Use of two primers and a double-stranded plasmid or phagemid DNA as template (Schold et al. 1984). This procedure, although less efficient in terms of yield of mutants, eliminated the need to subclone target DNA into a bacteriophage M13 vector.
- Improvement of techniques to screen bacteriophage M13 plaques for the desired mutation by oligonucleotide hybridization (Wallace et al. 1979, 1981; Suggs et al. 1981).
- Use of highly accurate DNA polymerases encoded by bacteriophage T4 or T7, which shorten the time required to synthesize the heteroduplex from 12 hours to 1 or 2 hours (Nossal 1974; McClary et al. 1989; Schena 1989). These polymerases have the additional advantage of not causing displacement of the 5′ end of the mutagenic oligonucleotide primer.

In classical methods of site-directed mutagenesis, the proportion of clones containing the desired mutation varies from 0.1% to >50% depending on the efficiency of the mutagenic oligonucleotide. Several methods have been developed to select against clones that contain nonmutant DNAs, including (1) selective digestion of template DNAs by removal of modified bases (Kunkel 1985; Kunkel et al. 1991), restriction enzymes (Hofer and Kühlein 1993), or exonucleases (Taylor et al. 1985); (2) restoration of an antibiotic resistance gene or an origin of replication (Hashimoto-Gotoh et al. 1995); and (3) elimination of a restriction site from mutant DNAs (Deng and Nickoloff 1992). For a more detailed discussion of these methods, please see the information panel on **SELECTING AGAINST WILD-TYPE DNA IN SITE-DIRECTED MUTAGENESIS.**

Because of these improvements, the classic method of oligonucleotide-mediated site-directed mutagenesis over the years became extremely efficient and reliable. However, like many other elegant and inventive techniques, it was quickly rendered obsolete by PCR and is no longer the first choice to create mutations in a target segment of DNA. Most site-directed mutations these days are more easily generated by one of the many variants of PCR than by the classic methods.

PCR-MEDIATED SITE-DIRECTED MUTAGENESIS

Most of the PCR-based methods of mutagenesis in current use are direct descendants of techniques originally described in the late 1980s, soon after the introduction of thermostable DNA polymerases to PCR (Higuchi et al. 1988; Ho et al. 1989; Kadowaki et al. 1989; Vallette et al. 1989). At that time, it was already known that centrally located single-base mismatches in hybrids between oligonucleotide primers and the target DNA did not affect the efficiency of amplification. Early investigators showed that these mismatches could be converted into mutations located in the primer regions of PCR products, which, in turn, could be substituted for the homologous wild-type segment in, for example, a recombinant plasmid. The following are important advantages of PCR-based methods for site-directed mutagenesis:

- ***High rates of recovery of mutants.*** In many cases, the yield of mutants is so high that selection against nonmutant templates is not required.
- ***Ability to use double-stranded DNA templates*** and to introduce mutations at almost any site.
- ***Use of high temperatures*** to reduce the ability of the template DNA to form secondary structures that lower the efficiency of the extension reaction on single-stranded DNA templates.
- ***Development of methods*** in which all of the reactions are carried out in one tube (e.g., please see Marini et al. 1993; Picard et al. 1994; Ke and Madison 1997).
- ***Availability of commercial kits.***
- ***Speed and ease.*** No more cloning in bacteriophage M13 vectors!

The following are potential disadvantages of PCR-based methods:

- ***Relatively high rate of errors in PCR products*** that often contain unwanted mutations in addition to desired alterations. This problem can be minimized by (1) limiting the number of amplification cycles and (2) using, in preference to *Taq*, thermostable DNA polymerases, such as *Pfu* and *Vent*, which carry a 3′-5′ exonuclease activity and have an editing ability.
- ***Introduction of unwanted nucleotides at the 3′ termini of amplified DNAs.*** This problem can also be solved by using *Pfu* DNA polymerase rather than *Taq*.

- ***Large number of primers and amplification reactions required for each mutagenesis experiment by some PCR-based methods.*** For example, some of the "megaprimer" methods discussed below require three or four primers and/or three sequential PCRs.
- ***Requirement to optimize the conditions for PCR for each new set of primers and/or template.*** Without optimization, the DNA products of the PCR-based methods may be heterogeneous in size and may migrate through agarose gels as a smear, rather than as a discrete band.
- ***High frequency of unmutagenized clones resulting from contamination of the PCR-amplified*** DNA with the parental, wild-type DNA used as template in the PCR. This problem is best solved by using a restriction enzyme such as *Dpn*I to digest the plasmid selectively (e.g., please see Weiner et al. 1994; Ansaldi et al. 1996; Li and Wilkinson 1997) (please see the information panel on **SELECTING AGAINST WILD-TYPE DNA IN SITE-DIRECTED MUTAGENESIS**).
- ***Inefficiency in amplifying DNA fragments longer than 2–3 kb by standard PCR.*** Potential solutions to this problem are discussed in Chapter 8, Protocol 13.

This list of disadvantages may seem long, but it should not be seen as formidable. Most of the problems can be avoided entirely with a little forethought and planning; solutions to others are available either in Chapter 8 of this manual, in the literature that accompanies commercially available mutagenesis kits, on manufacturers' Internet sites, or in the scientific literature.

METHODS OF PCR-BASED MUTAGENESIS

Of the many published variants of PCR-based mutagenesis, two stand out for their durability and robustness: overlap extension mutagenesis and megaprimer mutagenesis.

In overlap extension mutagenesis (Higuchi et al. 1988; Ho et al. 1989), two overlapping DNA fragments are amplified in separate PCRs (please see Protocol 6). The mutation of interest is constructed in the region of overlap and is present in both amplified fragments. The overlapping fragments are mixed and, in a third PCR, are amplified into a full-length DNA using two primers that bind to the extremes of the two initial fragments. The method is surprisingly effective, but it requires two mutagenic primers, two flanking oligonucleotides, and three PCRs to construct a mutation. In some cases, a simpler version of the method can be used (one mutagenic primer and two sequential PCRs) if strategically placed restriction sites are available to clone the segment of amplified DNA containing the mutation (Aiyar et al. 1996). This is not always the case.

The megaprimer method introduced by Kammann et al. (1989) and subsequently modified by Sarkar and Sommer (1990, 1992), Giebel and Spritz (1990), and Landt et al. (1990) is the simplest and most cost-effective method of PCR-based mutagenesis currently available. The method involves two rounds of PCR that employ two flanking primers and one internal mutagenic primer containing the desired base substitutions. The flanking primers can be complementary to sequences in the cloned gene or to adjacent vector sequences. The mutagenic primer can, in theory, be oriented toward either of the flanking primers. In practice, however, the mutagenic primer is always oriented toward the nearer of the two flanking primers so that the length of the megaprimer is kept to a minimum.

In the original protocols (please see Figure 13-2), the first round of PCR is performed with the mutagenic primer, the nearer of the flanking primers, and a wild-type DNA template. The product of this first reaction, a double-stranded megaprimer, is purified and used in a second PCR, together with the reverse flanking primer. The product is a double-stranded DNA that contains the mutation and whose size is equal to the distance between the two outside flanking

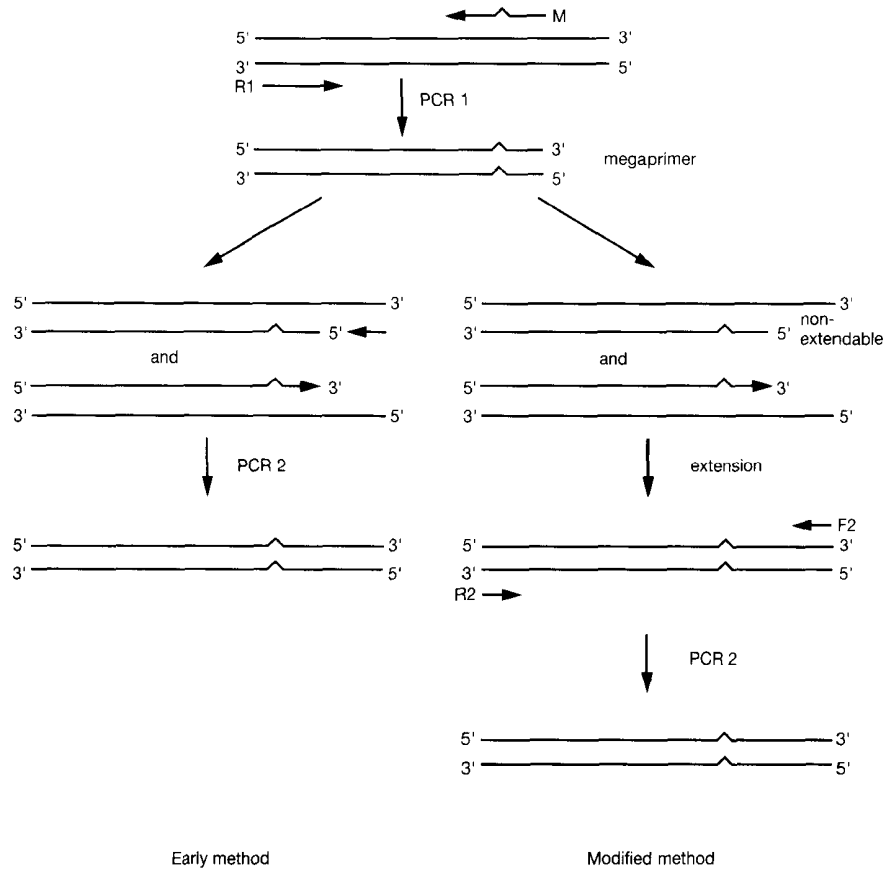

FIGURE 13-2 The Basic Megaprimer Method

PCR 1 is performed with a mutagenic forward primer (M) and a reverse primer (R1) to generate and amplify a double-stranded megaprimer (shown in color). (*Left*) In the early method, the megaprimer is purified and used with an additional forward primer (F2) in PCR 2 to obtain the desired full-length mutant. (*Right*) In the modified method, the megaprimer is extended on the original template to form mutant:wild-type heteroduplexes, which are used as templates in a second PCR (PCR 2), primed by oligonucleotides R2 and F2. (Modified, with permission, from Ling and Robinson 1997 [©Academic Press].)

primers. If the flanking primers contain restriction sites for ease of cloning, the product of the second-round PCR can be used to reconstruct a mutagenized version of the target gene.

In the second and more recent method, a purified or unpurified megaprimer is extended on a wild-type DNA template (Marini et al. 1993). Because only one strand of the megaprimer can be extended, the product of the reaction is a full-length single-stranded DNA that carries the desired mutation(s). This DNA is then amplified using the two flanking primers (Picard et al. 1994; Ling and Robinson 1997). In our hands, however, this protocol is tricky and works well only when the extended megaprimer is purified and used in high concentration in a second PCR whose parameters have been carefully optimized.

The chief problem with both variants of the megaprimer method is the time-consuming and laborious purification step, which is usually accomplished by agarose gel electrophoresis and elution. Purification is required to remove residual primers from the amplified megaprimer synthesized in the first PCR. An ingenious and simple solution to this difficulty is to use flanking primers with significantly different melting temperatures (T_m) to prime the two PCRs (Ke and Madison 1997). The first flanking primer is just 15 or 16 bases long and has a calculated T_m of

~45°C. The first PCR is therefore programmed with a low annealing temperature. At the end of the first PCR, the second flanking primer, 25–30 bases in length and with a calculated T_m of 72–80°C, is added directly to the reaction tube. The second PCR is then carried out using a high-temperature annealing step (usually 72–80°C). The final, full-length DNA product is therefore generated by priming with the megaprimer and the second flanking primer. Because annealing of the first flanking primer is suppressed at high temperature, the wild-type template DNA is not amplified efficiently in the second PCR. The product of the second PCR therefore consists almost entirely of mutated DNA.

METHODS USED IN THIS CHAPTER

TABLE 13-1 Site-directed Mutagenesis

PROTOCOL	TEMPLATE	METHOD USED TO ENRICH FOR MUTANTS
1 and 2	single-stranded DNA	selection against uracil-substituted DNA
3	double-stranded DNA	selection of mutants with *DpnI*
4	double-stranded DNA	elimination of a restriction site (USE mutagenesis)
5	double-stranded DNA	megaprimer
6	double-stranded DNA	splice overlap extension

The methods of site-directed mutagenesis described in the first six protocols of this chapter are summarized in Table 13-1. Protocol 7 describes screening of bacteriophage plaques for mutants by radiolabeled oligonucleotides, whereas Protocol 8 describes two methods to detect mutations: SSCP and heteroduplex analysis. For further details of screening, scanning, and identification of mutations, please see the information panel on **MUTATION DETECTION** and its accompanying table that summarizes methods commonly used to detect mutations. In addition, we describe methods to generate nested unidirectional (Protocol 9) and bidirectional deletions (Protocol 10) using exonuclease III and BAL 31 nuclease, respectively.

Finally, as is increasingly the trend for many methods in molecular biology, a wide variety of kits are available from various manufacturers (please see the information panel on **COMMERCIAL KITS FOR SITE-DIRECTED MUTAGENESIS**).

Any sufficiently advanced technology is indistinguishable from magic.

Arthur C. Clarke

Protocol 1

Preparation of Uracil-containing Single-stranded Bacteriophage M13 DNA

THE CLASSIC KUNKEL METHOD OF OLIGONUCLEOTIDE-DIRECTED MUTAGENESIS takes advantage of the strong selection against uracil-substituted DNA exhibited by strains of *E. coli* that express uracil-DNA glycosylase (please see the information panel on **MUTAGENIC OLIGONUCLEOTIDES**). Template DNA is first prepared by growth of an appropriate recombinant bacteriophage M13 in a strain of *E. coli* that is *dut*$^-$ *ung*$^-$ F′ (described in this protocol). The resulting uracil-containing single-stranded DNA is used as the template in a standard oligonucleotide-directed mutagenesis procedure to generate a heteroduplex molecule with uracil in the template strand and thymine in the strand synthesized in the in vitro reaction (Protocol 2). Transformation of this DNA into an *ung*$^+$ strain results in destruction of the template strand, with consequent suppression of the production of wild-type bacteriophages. A large proportion (up to 80%) of the progeny bacteriophages are therefore derived from replication of the transfected uracil-free (–) strand. Because the synthesis of this strand is primed by the mutagenic oligonucleotide, a high proportion of the progeny bacteriophages carry the desired mutation.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Ethanol
NaCl (2.5 M) containing 15% polyethylene glycol (w/v, PEG 8000) **<!>**
Phenol (pH 8.0) **<!>**
Phenol:chloroform (1:1, v/v) **<!>**
Sodium acetate (3 M, pH 5.2)
TE (pH 7.6)

Gels

Agarose gel
Please see Step 16.

Nucleic Acids and Oligonucleotides

Marker DNA, single-stranded DNA from the original bacteriophage M13 recombinant

Media

2x YT medium
2x YT medium containing 0.25 μg/ml uridine

Centrifuges and Rotors

Sorvall GSA rotor or equivalent
Sorvall SS-34 rotor or equivalent

Special Equipment

Corex centrifuge tubes (15 ml and 30 ml)
Pasteur pipettes
Spun-column chromatography resin
Use a prepacked resin such as Sephacryl S-400 (Pharmacia) or Miniprep Spun Columns (Promega).
Water bath preset to 60°C

Additional Reagents

Step 1 of this protocol requires the reagents listed in Chapter 3, Protocols 3, 4, and 6.
Step 6 of this protocol requires the reagents listed in Chapter 3, Protocol 1.

Vectors and Bacterial Strains

Please see Appendix 3.
E. coli *strain CJ236 (dut⁻ ung⁻ F′)*
For details, please see Kunkel (1985) and Kunkel et al. (1987).
E. coli *strain TG1, JM109, or equivalent*
Please see Step 6.

METHOD

1. Prepare for mutagenesis.

   a. Clone a small fragment of DNA (<500 bp) carrying the target sequence into an appropriate bacteriophage M13 vector such as M13mp18 or mp19.

   b. Isolate single-stranded template DNA and double-stranded replicative form DNA from a freshly grown plaque generated by the recombinant bacteriophage.

      Methods for cloning into bacteriophage M13 vectors and for preparation of single-stranded and replicative form bacteriophage DNA are given in Chapter 3, Protocols 3, 4, and 6.

   c. Check the fidelity of the recombinant clone by restriction mapping of the replicative form DNA and by DNA sequencing of the single-stranded DNA.

      The Kunkel procedure can also be applied to produce uracil-substituted single-stranded DNAs generated from phagemid vectors (McClary et al. 1989; Wang et al. 1989; Liu et al. 1990; for review, please see Hagemeier 1996). Here, the double-stranded phagemid DNA containing the target sequence is first used to transform *E. coli* CJ236 (or another strain of genotype *dut⁻ ung⁻* F′) to ampicillin resistance. The resulting bacteria are superinfected with a helper bacteriophage to shift the replication mode of the phagemid DNA from the production of double-stranded DNA to single-stranded DNAs (please see Chapter 3, Protocol 8). Following growth in medium containing uridine, the single-stranded DNAs, which contain uracil residues in place of some of the thymine bases, are packaged into viral particles and

secreted into the growth medium. This DNA is then isolated (as described from Step 5 onward) and used as a template in site-directed mutagenesis (Protocol 2). The use of phagemid vectors circumvents the need to clone the starting target DNA into a bacteriophage M13 vector before site-directed mutagenesis.

2. Use a sterile Pasteur pipette to transfer a single plaque produced by the bacteriophage M13 recombinant to a microfuge tube containing 1 ml of 2x YT medium.

3. Incubate the tube for 5 minutes at 60°C to kill bacterial cells. (It is important to kill the bacterial cells to prevent them from continuing to produce thymidine-containing viral DNA during the next round of bacteriophage growth.) Vortex the tube vigorously for 30 seconds to release the bacteriophages trapped in the top agar. Remove dead bacterial cells and fragments of agar by centrifuging the tube at maximum speed for 2 minutes at 4°C in a microfuge.

4. Transfer 50 µl of the supernatant to a 500-ml flask containing 50 ml of 2x YT medium supplemented with 0.25 µg/ml uridine. There is no need to supplement the medium with thymidine or adenosine as originally described by Kunkel (1985). Add 5 ml of a mid-log-phase culture of *E. coli* strain CJ236 (*dut*$^-$ *ung*$^-$ F′). Incubate the culture with vigorous shaking (300 cycles/minute on a rotary shaker) for 6 hours at 37°C. Efficient aeration is crucial for efficient growth of bacteriophages.

   The bacteriophage suspension used as an inoculum typically contains between 10^9 and 10^{10} pfu/ml. A mid-log-phase culture of *E. coli* contains ~5 x 10^8 bacteria/ml. The low multiplicity of viral infection (0.02–0.2 pfu/cell) ensures that the vast majority of the bacteriophages recovered from the culture will have been generated in the *dut*$^-$ *ung*$^-$ F′ strain of *E. coli*.

5. Pellet the cells by centrifugation at 5000*g* (6470 rpm in a Sorvall SS-34 rotor) for 30 minutes at 4°C. Transfer the supernatant to a fresh 250-ml centrifuge bottle that will fit into a Sorvall GSA rotor or equivalent.

6. Determine the relative titer of the bacteriophage suspension on *E. coli* strain CJ236 (*dut*$^-$ *ung*$^-$ F′) and a strain such as JM109 or TG1 (please see Chapter 3, Protocol 1). The titer on strain CJ236 should be four to five orders of magnitude greater than that on the *dut*$^+$ *ung*$^+$ strain of *E. coli*.

   To save time, most investigators purify the bacteriophage particles before the results of the titration are available. However, if the purification is postponed, store the crude bacteriophage suspension in ice.

   The yield of bacteriophages varies from recombinant to recombinant. Typically, the titer of virus particles in the supernatant, measured on a *dut*$^-$ *ung*$^-$ F′ *E. coli* strain (CJ236), is 5 x 10^{10} to 1 x 10^{11} pfu/ml. However, poorly growing recombinants may attain titers of only 1 x 10^{10} to 2 x 10^{10} pfu/ml. If the yield of single-stranded DNA is inadequate, the following are two possible remedies:

   - Measure the titer of the bacteriophage stock used to infect the *dut*$^-$ *ung*$^-$ F′ strain of *E. coli*. Adjust the volume of the inoculum to achieve a multiplicity of infection of 0.1 pfu/bacterial cell. Grow the infected culture for 6 hours as described.
   - Incubate the infected cultures for 12 hours rather than 6 hours. As discussed in Chapter 3, deleted variants may outgrow the original recombinant during extended periods of incubation, and thus it is advisable to verify that the majority of the single-stranded DNA used as template is of the correct size. Methods to analyze the size of bacteriophage M13 DNA by gel electrophoresis are described in Chapter 3, Protocol 7.

7. Measure the volume of the bacteriophage suspension, and then add 0.25 volume of 2.5 M of NaCl containing 15% (w/v) PEG 8000. Mix the contents of the centrifuge bottle by swirling, and store the bottle on ice for 1 hour.

8. Recover the precipitated bacteriophage particles by centrifugation at 5000*g* (5500 rpm in a Sorvall GSA rotor) for 20 minutes at 4°C. Remove the supernatant by aspiration, and then

invert the bottle to allow the last traces of supernatant to drain away. Use a pipette attached to a vacuum line to remove any drops of solution adhering to the walls of the bottle.

9. Resuspend the bacteriophage pellet in 4 ml of TE (pH 7.6). Transfer the suspension to a 15-ml Corex centrifuge tube, and wash the walls of the centrifuge bottle with another 2 ml of TE (pH 7.6). Transfer the washing to the Corex tube. Vortex the suspension vigorously for 30 seconds, and then store the tube on ice for 1 hour.

10. Vortex the suspension vigorously for 30 seconds, and then pellet the bacterial debris by centrifugation at 5000*g* (6470 rpm in a Sorvall SS-34 rotor) for 20 minutes at 4°C.

11. Taking care not to disturb the pellet of bacterial debris, transfer the supernatant to a 15-ml polypropylene tube. Extract the suspension twice with phenol (pH 8.0) and once with phenol:chloroform. Separate the phases by centrifugation at 4000*g* (5800 rpm in a Sorvall SS-34 rotor) for 5 minutes at room temperature. Avoid transferring material from the interface.

12. Transfer the aqueous phase from the final extraction to a glass centrifuge tube (e.g., a 30-ml Corex tube). Measure the volume of the solution, and add 0.1 volume of 3 M of sodium acetate (pH 5.2), followed by 2 volumes of ethanol at 0°C. Mix the contents of the tube thoroughly, and then store the tube on ice for 30 minutes.

13. Recover the DNA by centrifugation at 5000*g* (6470 rpm in a Sorvall SS-34 rotor) for 20 minutes at 4°C. Carefully remove the supernatant. Add 10 ml of 70% ethanol at room temperature, vortex the solution briefly, and recentrifuge.

14. Carefully remove the supernatant by aspiration and store the tube in an inverted position at room temperature until the last traces of ethanol have evaporated. Dissolve the DNA in 200 µl of TE (pH 7.6).

15. Purify the resuspended single-stranded uracil-containing bacteriophage M13 DNA by spun-column chromatography using columns that exclude large DNAs (>100 nucleotides) as described in Appendix 8.

    The single-stranded bacteriophage M13 DNA that has been propagated in the *dut*$^-$ *ung*$^-$ F′ strain of *E. coli* is purified by spun-column chromatography to remove contaminating small DNA and RNA oligonucleotides. These nonspecific oligonucleotides can act as primers in subsequent mutagenesis reactions, causing a high background of false positive plaques.

16. Measure the DNA spectrophotometrically at 260 nm (1 OD_{260} = 40 µg/ml) (for details on quantitating DNA, please see Appendix 8). Analyze the size of an aliquot of the DNA (0.5 µg) by gel electrophoresis, using single-stranded DNA of the original bacteriophage M13 recombinant (Step 1) as a size marker.

17. Carry out oligonucleotide-directed mutagenesis as described in Protocol 2.

Protocol 2

Oligonucleotide-directed Mutagenesis of Single-stranded DNA

THIS CLASSIC PROTOCOL COMBINES THE DOUBLE-PRIMER TECHNIQUE of Zoller and Smith (1984, 1987) and the Kunkel (1985) method of enriching the yield of mutants (please see the information panel on **SELECTING AGAINST WILD-TYPE DNA IN SITE-DIRECTED MUTAGENESIS**). The single-stranded DNA templates used in the protocol contain a higher than normal number of uracil residues because they are prepared from M13 bacteriophages grown in a strain of *E. coli* that carries mutations in the *ung* and *dut* genes (please see Protocol 1).

MATERIALS

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

ATP (10 mM)

10x PE1 buffer

200 mM Tris-Cl (pH 7.5)
100 mM $MgCl_2$
500 mM NaCl
10 mM dithiothreitol

10x PE2 buffer

200 mM Tris-Cl (pH 7.5)
100 mM $MgCl_2$
100 mM dithiothreitol

Enzymes and Buffers

Bacteriophage T4 DNA ligase

Bacteriophage T4 polynucleotide kinase

Klenow fragment of E. coli *DNA polymerase I*

Any of several different DNA polymerases may be used in the extension reaction (Steps 4 and 5). The Klenow fragment lacks 5′ exonucleolytic activity and is therefore incapable of degrading the template. However, other enzymes, such as bacteriophage T4 DNA polymerase (Nossal 1974; Geisselsoder et al. 1987), native T7 DNA polymerase (Bebenek and Kunkel 1989), and Sequenase (Schena 1989; Venkitaraman 1989) require shorter incubation times. These enzymes are obligatory when a phospho-

rylated mutagenic oligonucleotide is used as the single primer in the polymerization/extension reaction. Unlike the Klenow fragment, neither Sequenase nor the native DNA polymerases encoded by bacteriophages T4 and T7 are able to displace the mutagenic oligonucleotide from its template (Nossal 1974; Kunkel 1985; Bebenek and Kunkel 1989; Schena 1989).

Nucleic Acids and Oligonucleotides

Bacteriophage M13 universal sequencing primer

Any commercially available universal primer used to prime dideoxy sequencing reactions from (+) strand bacteriophage M13 templates will work well in this protocol.

dNTP solution containing all four dNTPs, each at 2 mM

Use dNTPs of the highest quality to minimize the possibility that contaminating dUTP will be incorporated into the newly synthesized strand of DNA. The concentrated dNTP solutions sold by Pharmacia have worked well in our hands.

Mutagenic bacteriophage M13 single-stranded DNA template

Mutagenic oligonucleotide primer

The mutagenic oligonucleotide should be designed as outlined in the information panel on **MUTAGENIC OLIGONUCLEOTIDES**. Before use in site-directed mutagenesis, purify the mutagenic oligonucleotide by Sep-Pak C_{18} column chromatography to remove salts and other impurities (please see Chapter 10, Protocol 6). It is not necessary to purify the oligonucleotide by polyacrylamide gel electrophoresis unless the oligonucleotide is more than 30 nucleotides in length or is to be used for "loop-in" or "loop-out" mutagenesis.

Media

2x YT top agar and YT agar plates

Special Equipment

Falcon 2059 tubes (chilled) or Electroporation cuvettes

Heat block or water bath preset to 47°C

Water baths preset to 16°C, 42°C, and 68°C

Water bath preset to the appropriate denaturation temperature

Please see Step 3. Alternatively, a thermal cycler can be used for this step.

Additional Reagents

Step 1 of this protocol requires the reagents listed in Protocol 1 of this chapter.

Step 7 of this protocol requires the reagents listed in Chapter 12, Protocol 3 or 4.

Step 7 of this protocol may require the reagents listed in Protocol 7 of this chapter.

Vectors and Bacterial Strains

Please see Appendix 3.

E. coli *strain suitable for transformation (e.g., TG1)*

E. coli *strain TG1, competent for transformation*

Prepare competent cells as described in Chapter 1, Protocol 25 or 26.

E. coli *strain TG1, overnight culture*

METHOD

1. Prepare the single-stranded bacteriophage M13 template as described in Protocol 1. Purify the uracil-containing template by spun-column chromatography.
2. Phosphorylate the mutagenic oligonucleotide and the universal sequencing primer with bacteriophage T4 polynucleotide kinase. In separate microfuge tubes mix:

synthetic oligonucleotide	100–200 pmoles
10x bacteriophage T4 polynucleotide kinase buffer	2 µl
10 mM ATP	1 µl
bacteriophage T4 polynucleotide kinase	4 units
H_2O	to 20 µl

Incubate the reactions for 1 hour at 37°C and then heat them for 10 minutes at 68°C to inactivate the polynucleotide kinase.

3. Anneal the phosphorylated mutagenic oligonucleotide and universal sequencing primer to the single-stranded bacteriophage M13 DNA containing the target sequence. Mix:

single-stranded template DNA (~1 µg)	0.5 pmole
phosphorylated mutagenic oligonucleotide	10 pmoles
phosphorylated universal primer	10 pmoles
10x PE1 buffer	1 µl
H_2O	to 10 µl

Heat the mixture for 5 minutes to 20°C above the theoretical T_m of a perfect hybrid formed by the mutagenic oligonucleotide, calculated from the formula $T_m = 4(G+C) + 2(A+T)$, where (G+C) = the sum of G and C residues in the oligonucleotide and where (A+T) = the sum of the A and T residues in the oligonucleotide. Transfer the tube containing the reaction mixture to a beaker containing H_2O at 20°C above the T_m. Stand the beaker on the bench, and allow the reaction to cool slowly to room temperature (~20 minutes). Centrifuge the tube briefly (5 seconds) in a microfuge to collect any fluid that has condensed on the walls of the tube.

Alternatively, heat and cool the nucleic acids and oligonucleotides in a thermal cycler.

The molar ratio of primer to template should be between 10:1 and 50:1. Using more primer will increase the frequency of mutation at ectopic sites in the target DNA.

4. While the annealing reaction cools to room temperature, mix the following reagents in a fresh 0.5-ml microfuge tube:

10x PE2 buffer	1.0 µl
2 mM dNTP solution	1.0 µl
10 mM ATP	1.0 µl
bacteriophage T4 DNA ligase	5 Weiss units
Klenow fragment	2.5 units
H_2O	to 10 µl

Store the mixture on ice until needed.

When using bacteriophage T4 DNA polymerase or Sequenase, incubate the polymerization/extension reaction (Step 5) for 5 minutes at 0°C, 5 minutes at room temperature, and then 2 hours at 37°C. Incubation at low temperature optimizes initiation of DNA synthesis from the 3′ terminus, and the subsequent incubation at 37°C improves the efficiency of the extension reaction. In addition, the concentration of each of the four dNTPs in the reaction should be increased to 500 µM. This increase enhances the efficiency of the extension reaction and suppresses the strong 3′ exonuclease activity of bacteriophage T4 DNA polymerase.

5. Add 10 µl of the ice-cold reaction mixture from Step 4 to the reaction mixture containing single-stranded DNA and annealed oligonucleotides (Step 3). Incubate the final reaction mixture for 6–15 hours at 16°C.

6. Transfect competent *E. coli* of an appropriate host strain (e.g., TG1) as follows:

   a. Prepare a series of dilutions of the reaction mixture (1:10, 1:100, and 1:500) in 10 mM Tris-Cl (pH 7.6).

   b. To a series of chilled (0°C) Falcon 2059 tubes, transfer 1 µl and 5 µl of (i) the original reaction mixture and (ii) each dilution. Add 200 µl of a preparation of competent TG1 cells to each tube.

   c. Store the mixtures on ice for 30 minutes, and then transfer them for exactly 2 minutes to a water bath equilibrated at 42°C.

   d. Remove the transfected cultures from the water bath, and add 100 µl of a standard overnight culture of TG1 cells. The addition of cells makes it easier to see bacteriophage M13 plaques in the lawn of bacterial cells.

      There is no need to add TG1 cells if freshly prepared, rather than frozen, competent bacterial cells are used in Step b.

   e. Add 2.5 ml of 2x YT top agar (melted and cooled to 47°C) to each tube, and plate the resulting mixtures on separate YT agar plates. Incubate the plates for 12–16 hours at 37°C to allow plaques to form.

      The mutated DNA can also be introduced into *E. coli* by electroporation. Because the frequency of transfection is in general much higher with electroporation, an aliquot of the mutagenesis reaction should first be diluted 1/100, 1/500, 1/1000, and 1/10,000 in H_2O before electroporation of 1–10 µl of the diluted mixtures.

   If single-stranded DNA derived from a phagemid such as pUC118 or pUC119 is used as the template for mutagenesis, use 1-µl and 5-µl aliquots of the undiluted reaction mixture to transform competent cultures of an *E. coli* strain suitable for phagemid propagation (for a description of this strain, please see Chapter 3, Protocol 8; for a description of the transformation method, please see Chapter 1). Plate 50-µl and 100-µl aliquots of each transformation mixture onto LB agar plates containing 50 µg/ml ampicillin. Ampicillin-resistant colonies should appear after 18–24 hours of incubation at 37°C. Screen the transformed colonies as described in Protocol 7.

7. Screen plaques by sequencing preparations of single-stranded bacteriophage DNA (please see Chapter 12, Protocol 3 or 4). If necessary, the plaques can be screened by hybridization with a radiolabeled oligonucleotide probe to detect mutants that arise at a low frequency (Protocol 7).

TROUBLESHOOTING

If plaques obtained after transfection do not contain the desired DNA sequence:

- Purify the mutagenic oligonucleotide by polyacrylamide gel electrophoresis before carrying out the mutagenesis protocol.
- Repurify the bacteriophage M13 template by spun-column chromatography as described in Appendix 8. Use a resin (e.g., Sephacryl S-400) that excludes high-molecular-weight DNAs.
- Test the mutagenic oligonucleotide for its ability to prime DNA synthesis at the appropriate location on the single-stranded template DNA (Zoller and Smith 1987). Use a universal sequencing primer as a positive control. If priming occurs from more than one site, synthesize a longer mutagenic oligonucleotide that binds specifically to the template DNA. Use a shorter oligonucleotide as a hybridization probe to screen for the desired mutant as described in Protocol 7. If priming by the mutagenic oligonucleotide is inefficient, resynthesize the oligonucleotide and purify it by polyacrylamide gel electrophoresis.

Protocol 3

In Vitro Mutagenesis Using Double-stranded DNA Templates: Selection of Mutants with *Dpn*I

IN BOTH THIS PROTOCOL AND PROTOCOL 4, TWO OLIGONUCLEOTIDES are used to prime DNA synthesis by a high-fidelity polymerase on a denatured plasmid template. The two oligonucleotides both contain the desired mutation and have the same starting and ending positions on opposite strands of the plasmid DNA. In this protocol, the entire lengths of both strands of the plasmid DNA are amplified in a linear fashion during several rounds of thermal cycling, generating a mutated plasmid containing staggered nicks on opposite strands (Hemsley et al. 1989).

Because of the amount of template DNA used in the amplification reaction, the background of transformed colonies containing wild-type plasmid DNA can be quite high unless steps are taken to enrich for mutant molecules. In this protocol, the products of the linear amplification reaction are treated with the restriction enzyme *Dpn*I, which specifically cleaves fully methylated $G^{Me6}ATC$ sequences (Vovis and Lacks 1977). *Dpn*I will therefore digest the bacterially generated DNA used as template for amplification, but it will not digest DNA synthesized during the course of the reaction in vitro (please see the information panel on **N^6-METHYLADENINE, DAM METHYLASE AND METHYLATION-SENSITIVE RESTRICTION ENZYMES**). *Dpn*I-resistant molecules, which are rich in the desired mutants, are recovered by transforming *E. coli* to antibiotic resistance. Depending on the complexity of the mutation, and the length of the template DNA, between 15% and 80% of the transformed colonies will contain plasmids with the desired mutation (Weiner et al. 1994). Because the method works well with virtually any plasmid of moderate size (<7 kb), it can be used to introduce mutations directly into full-length cDNAs and eliminates the need for subcloning into specialized vectors.

The key to success with this method, which is often called circular mutagenesis, lies in the design of the primers and the choice of the appropriate thermostable DNA polymerase.

DESIGN OF PRIMERS

The two oligonucleotide primers:

- ***Must anneal to the complementary strands*** of the same target sequence.
- ***Must be of equal length*** (between 25 and 45 bp), with a calculated melting temperature of 78°C or greater. The T_m should be high enough to suppress false priming and low enough to allow complete dissociation of primer-primer hybrids during the denaturation step of the amplification reaction.

- ***Should terminate in a G or C residue.***
- ***Need not be phosphorylated.*** This is because *Pfu*, the thermostable DNA polymerase most commonly used to catalyze the amplification reaction, is unable to displace oligonucleotides hybridized to their target sequence, whether or not the oligonucleotides are phosphorylated.
- ***Can generally be used without purification.*** However, higher efficiencies of mutation, especially with insertions and deletions, are obtained if the primers are purified by either fast-performance liquid chromatography (FPLC) or polyacrylamide gel electrophoresis (PAGE).

When a point mutation is to be introduced, one primer carries a wild-type sequence, whereas the other primer carries the desired mutation and has a minimum of 12 bases of correct sequence on each side of the centrally placed mutation. If a deletion is to be introduced, the two primers may both have a wild-type sequence, but they are spaced a distance apart on the template that corresponds to the length of the deletion. Insertion mutations require one primer of wild-type sequence and one with the sequence to be inserted located at its 5′ terminus.

THERMOSTABLE DNA POLYMERASE

Three properties are required of thermostable DNA polymerases used for mutagenesis of denatured plasmid templates:

- an efficient proofreading activity
- a low rate of incorporation of mismatched bases
- a lack of untemplated terminal transferase activity

Taq does not fulfill these criteria and is therefore entirely unsuitable for site-directed mutagenesis (Stemmer and Morris 1992; Watkins et al. 1993). However, a 160:1 mixture of Klentaq (AB Peptides) and *Pfu* polymerase (Stratagene) has the appropriate set of properties. A typical mixture contains 0.187 unit of *Pfu* and 33.7 units of Klentaq1 in a total volume of 1.2 µl. Examples of commercially available mixtures include TaqPlus from Stratagene and the Expand High Fidelity PCR System from Boehringer Mannheim.

Single thermostable DNA polymerases that have been used successfully in circular PCR include *Pwo* DNA polymerase (Hidajat and McNicol 1997), r*Tth* DNA polymerase XL (Du et al. 1995; Gatlin et al. 1995), *VentR* DNA polymerase (Hughes and Andrews 1996), and *Pfu* DNA polymerase (please see below). These polymerases have one major disadvantage: Relatively high concentrations of oligonucleotide primers are required (1) to counteract the effects of degradation by 3′-5′ exonuclease activity and (2) to ensure that the primers are in vast molar excess (50–100-fold) over the template DNA (please see Chapter 8, Table 8-1). Unfortunately, such high concentrations favor the formation of hybrids between the two complementary oligonucleotide primers, thereby reducing the efficiency of the amplification reaction. Because of the consequent uncertainty about the effective concentration of primers, some investigators carry out preliminary experiments to optimize the components of the amplification reaction. Typically, these experiments use agarose gel electrophoresis to measure the yield of linear full-length DNA synthesized in amplification reactions containing a constant amount of template DNA (usually 50 ng) and a range of primer concentrations (e.g., please see Parikh and Guengerich 1998). However, in our hands, optimization of primers is unnecessary unless the mutations are complex (more than three single-base changes; deletion or insertion of more than two nucleotides).

When using single thermostable DNA polymerases, additional steps may be taken to further minimize the chance of unwanted mutants accumulating during amplification:

- The initial concentrations of dNTPs and Mg^{2+} in the reaction mixture must not exceed 250 µM and 1.5 mM, respectively.
- Because thermostable DNA polymerases such as *Pfu* and *Pwo* require a more alkaline buffer than *Taq*, the pH of the Tris-buffered reaction mixture should be 8.9 (measured at 25°C).
- The number of cycles of linear amplification must be kept to a bare minimum (please see Step 6 of this protocol), even if this constraint means using relatively large amounts of template DNA in the reaction mixture.

Commercially available kits for circular mutagenesis include QuikChange (Stratagene), which has a plasmid DNA template and mutagenic primers that can be used as a positive control. The kit is therefore especially useful for investigators who are using circular mutagenesis for the first time.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

ATP (10 mM)

dNTP solution containing all four dNTPs, each at 5 mM

10x Long PCR buffer (when using mixtures of DNA polymerases)

500 mM Tris-Cl (pH 9.0 at room temperature)
160 mM ammonium sulfate
25 mM $MgCl_2$
1.5 mg/ml bovine serum albumin

Buffers supplied by the manufacturer and suitable for use with thermostable DNA polymerases may be used in place of the above buffers.

or

10x Mutagenesis buffer (when using DNA polymerases such as Pfu*)*

100 mM KCl
100 mM ammonium sulfate
200 mM Tris (pH 8.9 at room temperature)
20 mM $MgSO_4$
1% Triton X-100
1 mg/ml nuclease-free bovine serum albumin

NaOH (1 M)/EDTA (1 mM) (optional) **<!>**

Sodium acetate (3 M, pH 4.8) (optional)

This solution is used as a neutralizing agent and therefore has a slightly lower pH than most sodium acetate solutions used in molecular cloning.

TE (pH 8.0)

Enzymes and Buffers

Bacteriophage T4 DNA ligase (optional)

Bacteriophage T4 polynucleotide kinase (optional)

DpnI *restriction endonuclease*

Themostable DNA polymerase (e.g., Pfu *DNA polymerase)*

The conditions described in this protocol are optimized for *Pfu*Turbo DNA polymerase. However, they are easly adapted for use with other thermostable polymerases or mixtures of polymerases. *Pfu* is avail-

able from Stratagene in three forms: the native enzyme, a recombinant enzyme expressed from a cloned version of the *Pfu* gene, and a preparation *Pfu*Turbo which is a formulation of recombinant *Pfu* DNA polymerase and a novel thermostability factor whose nature is undisclosed but which is said to enhance the yield of amplified product without altering the fidelity of DNA replication. The manufacturer claims that *Pfu*Turbo DNA polymerase is able to amplify DNAs 15 kb in length. In our hands, however, the efficiency of amplification decreases when the length of double-stranded plasmid DNA exceeds 7–8 kb.

Gels

Agarose gel (1%) containing 0.5 μg/ml ethidium bromide **<!>**

Please see Step 8.

Nucleic Acids and Oligonucleotides

Oligonucleotide primers

For advice on the design of oligonucleotide primers, please see the introduction to this protocol and the information panel on **MUTAGENIC OLIGONUCLEOTIDES**. The best results are achieved if the oligonucleotide primers are purified by FPLC or PAGE to reduce the level of contamination with salts (please see Chapter 10, Protocol 1 or 5). The purified primers are dissolved in H_2O at a concentration of 20 mM.

Plasmid DNA

The template DNA used for mutagenesis is a circular plasmid containing the gene or cDNA of interest. In general, the shorter the plasmid, the more efficient the amplification of the target DNA. Plasmids with a total length of <7 kb work well; however, success has been achieved with plasmid templates up to 11.5 kb in length (Gatlin et al. 1995). The plasmid DNA should be dissolved at 1 μg/ml in 1 mM Tris-Cl (pH 7.6) containing a low concentration of EDTA (<0.1 mM).

Special Equipment

Barrier tips for automatic micropipettes

Microfuge tubes (0.5 ml, thin-walled for amplification) or Microtiter plates

Positive-displacement pipette

Thermal cycler programmed with desired amplification protocol

If the thermal cycler is not equipped with a heated lid, use either mineral oil or paraffin wax to prevent evaporation of liquid from the reaction mixture during PCR.

Additional Reagents

Step 14 of this protocol requires the reagents listed in Chapter 1, Protocol 23.

Step 15 of this protocol requires the reagents listed in Chapter 1, Protocol 1.

Step 16 of this protocol requires the reagents listed in Chapter 12, Protocol 3, 4, or 5.

Vectors and Bacterial Strains

Please see Appendix 3.

Competent E. coli *strain with an* hsdR17 *genotype (e.g., XL1-Blue, XL2-Blue MRF′, or DH5α)*

METHOD

Amplification of the Target DNA with Mutagenic Primers

Steps 1 and 2 are optional (please see note after Step 3).

1. Denature the plasmid DNA template in a reaction containing 1–10 μg of plasmid DNA dissolved in 40 μl of H_2O plus 10 μl of 1 M NaOH/1 mM EDTA. Incubate the DNA in the denaturing solution for 15 minutes at 37°C.

2. Add 5 μl of 3 M sodium acetate (pH 4.8) to neutralize the solution. Precipitate the DNA with 150 μl of ice-cold ethanol.

3. Collect the denatured plasmid DNA by centrifugation for 10 minutes at 4°C in a microfuge. Carefully decant the ethanolic supernatant and rinse the pellet with 150 µl of 70% ethanol. Recentrifuge for 2 minutes, decant the supernatant, and allow the last traces of ethanol to evaporate at room temperature. Resuspend the DNA in 20 µl of H_2O.

   In theory, there is no need to denature the plasmid DNA before it is used as a template in PCR. If the alkaline denaturation step is omitted, superhelical, native double-stranded DNA will be denatured by heating to 94°C in the first cycle of PCR. So why bother with Steps 1 and 2? The answer probably lies in the state of the plasmid DNA after prolonged denaturation in alkali. During exposure to 0.2 N NaOH, the plasmid DNA collapses into a dense, irreversibly denatured coil that can serve as a template in PCR but has little ability to transform bacteria. The background of colonies containing unmutated wild-type DNA is therefore markedly reduced (Du et al. 1995; Dorrell et al. 1996). By contrast, brief exposure to 95°C in the first cycle of PCR disrupts Watson-Crick base pairs but does not necessarily destroy the transforming capacity of the plasmid molecules. A higher proportion of the transformed colonies will therefore contain unmutated, parental, plasmid molecules. The value of alkaline denaturation does not become apparent until the end of the experiment when the investigator is faced with the task of sifting through colonies to identify those that contain mutated DNA. If the efficiency of mutagenesis is low and the selection by *DpnI* inefficient, the proportion of colonies containing wild-type molecules may be unacceptably high.

4. In sterile 0.5-ml microfuge tubes, set up a series of reaction mixtures containing different amounts (e.g., 5, 10, 25, and 50 ng) of plasmid DNA and a constant amount of each of the two oligonucleotide primers.

10x mutagenesis buffer	5 µl
template plasmid DNA	5–50 ng
oligonucleotide primer 1 (20 mM)	2.5 µl
oligonucleotide primer 2 (20 mM)	2.5 µl
dNTP mix	2.5 µl
H_2O	to 50 µl

   Add 2.5 units of *Pfu*Turbo DNA polymerase.

   It is important to add the reagents in the order shown to reduce the opportunity for the 3′-5′ exonuclease activity of *Pfu*Turbo to degrade the primers.

5. If the thermal cycler is not fitted with a heated lid, overlay the reaction mixtures with 1 drop (~50 µl) of light mineral oil or a bead of paraffin wax to prevent evaporation of the samples during repeated cycles of heating and cooling. Place the tubes in the thermal cycler.

6. Amplify the nucleic acids using the denaturation, annealing, and polymerization times and temperatures listed in the table.

Cycle Number	Denaturation	Annealing	Polymerization
1 cycle	1 min at 95°C		
2–18 cycles[a]	30 sec at 95°C	1 min at 55°C	2 min/kb of plasmid DNA at 68°C
Last cycle	1 min at 94°C	1 min at 55°C	10 min at 72°C

These times are suitable for 50-µl reactions assembled in thin-walled 0.5-ml tubes and incubated in thermal cyclers such as the Perkin-Elmer 9600 or 9700, Master Cycler (Eppendorf), and PTC 100 (MJ Research). Times and temperatures may need to be adapted to suit other types of equipment and reaction volumes.

[a]For single-base substitutions, use 12 cycles of linear amplification; for substitution of one amino acid with another (usually two or three contiguous base substitutions), use 16 cycles; for insertions and deletions of any size, use 18 cycles.
The rate of DNA synthesis is 1.5–2.0 times slower in amplification reactions catalyzed by *Pfu* than in reactions catalyzed by *Taq*.
A small number of cycles is used together with a large amount of starting template to reduce the introduction of spurious mutations during amplification of the plasmid DNA and gene/cDNA.

7. After amplification of the DNA, place the reactions on ice.

8. Verify that the target DNA was amplified by analyzing 10 µl of each reaction by electrophoresis through a 1% agarose gel containing 0.5 µg/ml ethidium bromide. As standards, load 50 ng of unamplified linearized plasmid DNA and a 1-kb DNA ladder into the outer lanes of the gel.

   If the efficiency of amplification is low, set up a series of reactions to optimize the components of the amplification reaction and the cycling parameters.

Ligation and Transformation of Amplified Product

Steps 9–12 are optional and are generally used only when the efficiency of mutagenesis is expected to be low (e.g., when constructing insertions and deletions).

9. Extract the amplified DNAs twice with phenol:chloroform and precipitate with ethanol.

10. Resuspend the DNA pellets in the following:

10x bacteriophage T4 polynucleotide kinase buffer	5 µl
10 mM ATP	5 µl
bacteriophage T4 polynucleotide kinase	5 units
H_2O	to 50 µl

Incubate the reactions for 1 hour at 37°C. Inactivate the kinase enzyme by heating at 68°C for 10 minutes. Extract the phosphorylated DNAs twice with phenol:chloroform and collect the DNAs by ethanol precipitation.

11. Resuspend the pellets of phosphorylated DNA (~0.9 µg each) in 90 µl of TE. Set up a series of ligation reactions containing the phosphorylated DNAs at concentrations ranging from 0.1 to 1 µg/ml.

phosphorylated DNA	(10 ng to 100 ng)
10x bacteriophage T4 DNA ligase buffer	10 µl
10 mM ATP	10 µl
bacteriophage T4 DNA ligase	4 units
H_2O	to 100 µl

Incubate the reactions for 12–16 hours at 16°C.

If the 10x bacteriophage T4 ligase buffer supplied by the manufacturer contains ATP, omit the ATP in the above ligation reactions.

Conditions that favor the formation of monomeric circles during ligation are well understood in theory (Collins and Weissman 1984) but are difficult to achieve in practice. The molar concentration of DNA ends must be low in order to favor the formation of intramolecular circles over concatenates. However, it is difficult to calculate an appropriate concentration when working with amplified DNAs generated by inverse PCR because the proportion of full-length products with undamaged termini is unknown.

12. Extract the ligated DNAs twice with phenol:chloroform and collect the DNA by ethanol precipitation. Resuspend each pellet in 45 µl of H_2O. Add 5 µl of 10x *Dpn*I buffer to each tube.

13. Digest the amplified DNAs by adding 10 units of *Dpn*I directly to the remainder of the amplification reactions (Step 7) or to the phosphorylated and ligated DNAs (Step 12). Mix the reagents by pipetting the solution up and down several times, centrifuge the tubes for 5 seconds in a microfuge, and then incubate them for 1 hour at 37°C.

    If temperature cycling was carried out in the presence of mineral oil or wax, it is important to ensure that the *Dpn*I is added to the aqueous portion of the reaction mixture. Use barrier micropipette tips and be sure to insert the end of the tip below the mineral oil or wax overlay.

14. Transform competent *E. coli* with 1, 2, and 5 µl of digested DNA according to the procedure described in Chapter 1, Protocol 23.

    Make sure that no mineral oil is transferred from the digestion mixture to the competent cells.

    The use of ultracompetent XL2-Blue MRF′ *E. coli* (Stratagene) and a modified transformation procedure have been reported to facilitate the recovery of mutants (Dorrell et al. 1996). However, in our hands, homemade preparations of highly competent *E. coli* are adequate for most forms of circular mutagenesis.

15. Prepare plasmid DNA from at least 12 independent transformants. Screen the DNA preparations for mutations by DNA sequencing, by oligonucleotide hybridization (see Protocol 7), or by restriction digestion of small preparations of plasmid DNA if a site was created or destroyed by the introduced mutation, or if an insertion or deletion was introduced into the template.

16. Sequence the entire segment of target DNA to verify that the desired mutation has been generated and that no spurious mutations occurred during amplification (please see Chapter 12, Protocol 3, 4, or 5).

TROUBLESHOOTING

- If none of the plasmids prepared in Step 15 carry the desired mutation, the entire population of transformants can be screened by oligonucleotide hybridization to identify rare colonies that carry the desired mutation.
- If the amplification reactions have worked well but the yield of mutants is poor, *Dpn*I is the likely culprit. Set up a series of reactions to check that the enzyme is capable of digesting 50 ng of parental plasmid to completion in 1x *Pfu* reaction buffer. If necessary, adjust the amount of *Dpn*I used and the time of the digestion.
- If digestion with *Dpn*I is working efficiently, consider using two-stage amplification reactions (Wang and Malcolm 1999). In the first stage, two separate asymmetric amplification reactions are set up, each containing just one of the two oligonucleotide primers. The products of these reactions are single-stranded DNAs that can serve as templates for the second-stage linear amplification, which is carried out with both oligonucleotides, essentially as described above. The goal of the first-stage reaction is to generate templates to which the mutagenic primers can bind perfectly, without competition from a wild-type duplex.

Protocol 4

Oligonucleotide-directed Mutagenesis by Elimination of a Unique Restriction Site (USE Mutagenesis)

IN THIS METHOD, TWO OLIGONUCLEOTIDE PRIMERS ARE HYBRIDIZED to the same strand of a denatured double-stranded recombinant plasmid. One primer (the mutagenic primer) introduces the desired mutation into the target sequences, whereas the second primer carries a mutation that destroys a unique restriction site in the plasmid. Both primers are elongated in a reaction catalyzed by bacteriophage T4 or T7 DNA polymerase. Nicks in the strand of newly synthesized DNA are sealed with bacteriophage T4 DNA ligase. The product of the first part of the method is a heteroduplex plasmid consisting of a wild-type parental strand and a new full-length strand that carries the desired mutation but no longer contains the unique restriction site. The population of plasmids therefore consists (1) of wild-type molecules that, for one reason or another, were never used as templates for DNA synthesis primed by the two oligonucleotide primers and (2) of heteroduplex molecules that have lost the unique restriction site and gained the desired mutation.

In the second phase of the method, the mixed population is incubated with the restriction enzyme that cleaves the unique site. The wild-type molecules are linearized and the mutated plasmids are resistant to digestion. The mixture of circular heteroduplex DNA and linear wild-type DNA is then used to transform a strain of *E. coli* that is deficient in repair of mismatched bases. Because linear DNA transforms 10–1000-fold less efficiently than circular DNA (Conley and Saunders 1984), many of the wild-type molecules are unable to reestablish themselves in *E. coli*. The circular heteroduplex molecules, however, begin to replicate. Because the mismatched bases are not repaired, the first round of replication generates a wild-type plasmid that carries the original restriction site and a mutated plasmid that does not. DNA from the first set of transformants is recovered, digested once more with the same restriction enzyme to linearize the wild-type molecules, and then used to transform a standard laboratory strain of *E. coli*. This biochemical selection can be sufficiently powerful to ensure that a high proportion of the resulting transformants carry the desired mutation (Deng and Nickoloff 1992; Zhu 1996). The theoretical maximum yield of mutants in the standard form of USE (unique site elimination) described in this protocol is 50%. However, in most laboratories, the frequency with which mutant plasmids are recovered varies between 5% and 30%, depending on the complexity of the mutation and the efficiency of cleavage with the restriction enzyme. If necessary, the rate of mutant recovery can be improved significantly by combining USE with the Kunkel method of selection against uracil-containing template DNAs (Markvardsen et al. 1995) or by increasing the concentration of the mutagenic primer to 10:1 in favor of the mutagenic primer.

With the USE method, a gene may, in principle, be mutated in any double-stranded circular vector provided the vector contains a unique restriction site and a selectable marker (e.g., a gene conferring antibiotic resistance). Several companies sell selection primers and kits containing a range of the components required for USE mutagenesis (Chameleon Double-stranded Site-directed Mutagenesis kit marketed by Stratagene; Transformer sold by CLONTECH, and the USE mutagenesis kit sold by Pharmacia). These kits can be used successfully with many of the commonly used vectors; however, please see the panel on **TROUBLESHOOTING** at the end of this protocol.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

10x Annealing buffer

200 mM Tris-Cl (pH 7.5)
100 mM $MgCl_2$
500 mM NaCl

10x Synthesis buffer

100 mM Tris-Cl (pH 7.5)
dTTP, dATP, dCTP, and dGTP, each at a concentration of 5 mM
10 mM ATP
20 mM dithiothreitol

Enzymes and Buffers

Bacteriophage T4 DNA ligase

Bacteriophage T4 DNA polymerase or Sequenase

The native DNA polymerase encoded by bacteriophage T4 is unable to displace the oligonucleotide primers from the template DNA (Nossal 1974; Kunkel 1985; Bebenek and Kunkel 1989; Schena 1989).

Unique site restriction endonuclease

Gels

Agarose gel (1%) containing 0.5 μg/ml ethidium bromide <!>

Nucleic Acids and Oligonucleotides

Mutagenic primer

Selection primer

Both mutagenic and selection primers must anneal to the same strand of the target DNA, and the 5′ end of each primer must be phosphorylated. The mutagenic primer should be designed as described in the information panel on **MUTAGENIC OLIGONUCLEOTIDES**, with the engineered mutations in the middle flanked on each side by 10–15 bases that pair perfectly with the template DNA. The oligonucleotide primers should be purified by FPLC or PAGE before use (please see Chapter 10, Protocol 1 or 5).

Several companies (CLONTECH, Pharmacia) sell selection primers and some companies (e.g., Pharmacia) also market pairs of "toggle" primers that are used for forward and reverse conversion of restriction sites and allow sequential rounds of mutagenesis without subcloning of the template.

Plasmid DNA

Closed circular plasmid DNA, purified either by chromatography through a commercial resin or by the alkaline lysis method (please see Chapter 1, Protocol 2 or 9).

Media

LB agar plates and LB medium containing the appropriate antibiotic

Special Equipment

Water baths preset to 70°C and to the appropriate temperature for restriction endonuclease digestion

Additional Reagents

Steps 7 and 14 of this protocol require the reagents listed in Chapter 1, Protocol 23, 24, or 26 for the transformation of E. coli.

Steps 10 and 16 of this protocol require the reagents listed in Chapter 1, Protocol 1 for the minipreparation of plasmid DNA.

Step 17 of this protocol requires the reagents listed in Chapter 12, Protocol 3, 4, or 5.

Vectors and Bacterial Strains

Please see Appendix 3.

E. coli *strain with a* mutS *genotype (e.g., BMH 71-18) competent for transformation*

E. coli *strain with a* mut^+ *phenotype competent for transformation*

Please see Step 14.

METHOD

Synthesis of the Mutant DNA Strand

1. Mix the following components in a microfuge tube:

10x annealing buffer	2 µl
plasmid DNA	0.025 to 0.25 pmole
selection primer	25 pmoles
mutagenic primer	25 pmoles
H_2O	to 20 µl

Incubate the tube in a boiling water bath for 5 minutes.

The optimal amount of plasmid DNA is dependent on both the primer and the plasmid to be used.

2. Immediately chill the tube in ice for 5 minutes. Centrifuge the tube for 5 seconds in a microfuge to deposit the fluid at the base.

3. To the tube of annealed primers and plasmid, add:

10x synthesis buffer	3 µl
bacteriophage T4 DNA polymerase (2–4 units/µl)	1 µl
bacteriophage T4 DNA ligase (4–6 units/µl)	1 µl
H_2O	5 µl

Mix the reagents well by gentle up and down pipetting. Centrifuge the tube for 5 seconds in a microfuge to deposit the fluid at the base. Incubate the reaction for 1–2 hours at 37°C.

4. Stop the reaction by heating the tube for at least 5 minutes at 70°C to inactivate the enzymes. Store the tube on the bench to allow it cool to room temperature.

Primary Selection by Restriction Endonuclease Digestion

5. Adjust the NaCl concentration of the reaction to a level that is optimal for the selected unique site restriction endonuclease. Use the 10x annealing buffer, a stock of NaCl, or the 10x buffer supplied with the restriction enzyme.

   The concentration of NaCl in the synthesis/ligation mixture is 37.5 mM in a total volume of 30 µl.

   If the restriction digestion needs less or no NaCl, the DNA mixture in the synthesis/ligation buffer can be precipitated with ethanol or passed through a spun column and resuspended in the appropriate restriction enzyme buffer.

6. Add 20 units of the selective restriction endonuclease to the reaction mixture. Incubate the reaction for at least 1 hour at the appropriate digestion temperature.

   ▲ **IMPORTANT** The volume of enzymes added to the reactions (including polymerase and ligase) should not exceed 10% of the total reaction volume. Adjust the reaction volume accordingly.

First Transformation and Enrichment for Mutant Plasmids

7. Transform a *mutS E. coli* strain such as BMH 71-18 with the plasmid DNAs contained in the digestion mixture, using one of the transformation procedures described in Chapter 1, Protocols 23–26.

8. Spread 10, 50, and 250 µl of the transformation mixture onto LB agar plates containing the appropriate antibiotic. Incubate the plates overnight at 37°C. Carry out Step 9 while the plates are incubating.

   These plates are used to determine the number of primary transformants, which should be between 100 and 300 colonies per 50 µl of transformation mixture plated.

9. Amplify the plasmids by adding the remaining transformation mixture to 3 ml of LB medium containing the appropriate antibiotic. Incubate the culture overnight at 37°C with shaking.

10. The next day, prepare plasmid DNA from ~2.5 ml of the overnight culture (please see Chapter 1, Protocol 1).

11. Digest the plasmid DNA prepared in Step 10 with the selective restriction enzyme:

plasmid DNA	500 ng
10x restriction enzyme buffer	2 µl
unique site restriction endonuclease	20 units
H_2O	to 20 µl

    Incubate the reaction for 2 hours at the appropriate temperature.

12. Add an additional 10 units of the restriction enzyme, and incubate for at least 1 further hour.

13. Assess the extent of digestion by running 5–10 µl of the plasmid DNA on a 1% agarose gel containing 0.5 µg/ml ethidium bromide.

    Linearized plasmid DNA will run as a discrete band; undigested (circular) DNA will run as two bands, corresponding to the relaxed circular form and the supercoiled form. However, since the parental plasmid makes up a greater part of the total plasmid pool, the bands corresponding to the undigested mutant plasmids may be quite faint compared to the digested parental plasmid band.

Final Transformation

14. Transform competent *mutS*$^+$ *E. coli* cells with either 2–4 µl of the digested plasmid DNA (~50–100 ng) for transformation of chemically treated competent cells or 1 µl of plasmid DNA diluted fivefold with sterile H_2O (~5 ng) for transformation by electroporation (please see Chapter 1, Protocols 23–26).

15. Spread 10, 50, and 250 µl of the transformation mixture onto LB agar plates containing the appropriate antibiotic. Incubate the plates overnight at 37°C.

16. The next day, prepare minipreparations of plasmid DNA from at least 12 independent transformants. Screen the preparations by restriction endonuclease digestion and agarose gel electrophoresis to identify plasmids that are resistant to cleavage by the selective restriction enzyme.

17. Use DNA sequencing to confirm that the plasmids contain the desired mutation (please see Chapter 12, Protocol 3, 4, or 5).

TROUBLESHOOTING

If the rate of mutant recovery is low, try

- combining USE with the Kunkel method of selection against uracil-containing template DNAs (Markvardsen et al. 1995)

  and/or

- increasing the concentration of the mutagenic primer so that the molar ratio of the two primers is 10:1 in favor of the mutagenic primer (Hutchinson and Allen 1997).

- incubating the extension reaction catalyzed by T4 DNA polymerase at 42°C rather than 37°C (Pharmacia Instruction Booklet)

Vectors of the pBluescript family have been reported to yield mutants with very low efficiency, perhaps because they contain a knotty region of secondary structure that impedes the progress of the DNA polymerase during the extension of primers in vitro. This problem can be avoided completely by using a plasmid vector that is not a member of the pBluescript family or by using a thermostable DNA polymerase and DNA ligase and incubating the extension reaction at high temperatures (Wong and Komaromy 1995).

Protocol 5

Rapid and Efficient Site-directed Mutagenesis by the Single-tube Megaprimer PCR Method

THE MEGAPRIMER METHOD INTRODUCED BY KAMMANN et al. (1989) and subsequently modified by many investigators, including Sarkar and Sommer (1990, 1992), Giebel and Spritz (1990), Landt et al. (1990), Marini et al. (1993), Picard et al. (1994), and Ling and Robinson (1997), is the simplest and most cost-effective method of PCR-based mutagenesis currently available. The megaprimer method of site-directed mutagenesis uses three oligonucleotide primers and two rounds of PCR. One of the oligonucleotides is mutagenic, and the other two are forward and reverse primers that lie upstream and downstream from the binding site for the mutagenic oligonucleotide (please see Figure 13-3). The flanking primers can be complementary to sequences in the cloned gene or to adjacent vector sequences. The mutagenic primer can, in theory, be oriented toward either one of the flanking primers. In practice, however, the mutagenic primer is oriented toward the nearer of the two flanking primers so that the length of the megaprimer is kept to a minimum.

The mutagenic primer and the nearer of the external primers are used in the first PCR to generate and amplify a mutated fragment of DNA. This amplified fragment — the megaprimer — is used in the second PCR in conjunction with the remaining external primer to amplify a longer region of the template DNA (Kammann et al. 1989; Giebel and Spritz 1990; Landt et al. 1990; Sarkar and Sommer 1990, 1992).

The original megaprimer methods were efficient only when the megaprimer was purified by polyacrylamide gel electrophoresis from the residual oligonucleotides used to prime the first PCR (Kammann et al. 1989; Giebel and Spritz 1990). Purification was a time-consuming and wearisome step in an otherwise elegant protocol. Recently, Ke and Madison (1997) have developed a megaprimer method that has the important advantage of not requiring purification of DNA between the two rounds of PCR. The method uses forward and reverse external primers with significantly different melting temperatures. A megaprimer is synthesized in the first amplification reaction using a mutagenic primer, an external primer with a low T_m, and a low annealing temperature. The second PCR is performed in the same tube as the first and utilizes the megaprimer produced in the first reaction, an external primer with a high T_m, and an annealing temperature (usually 72°C) high enough to prevent priming by the residual low T_m primer. The average mutagenesis efficiency of this method is >80% (Ke and Madison 1997).

Careful design of DNA primers is essential for achieving rapid and highly efficient mutagenesis using this PCR-based protocol. Optimal, short external primers are usually 15–16 bases long

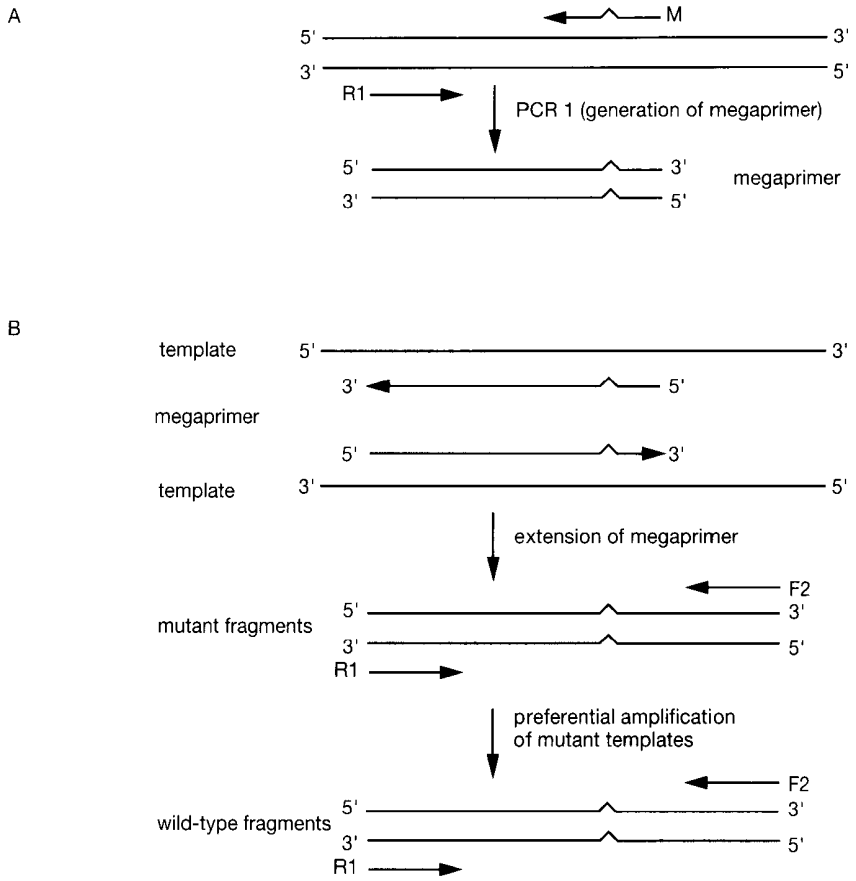

FIGURE 13-3 The Megaprimer Method

(*A*) PCR 1 is performed with a mutagenic forward primer (M) and a reverse primer (R1) to generate and amplify a double-stranded megaprimer (shown in color). (*B*) In the first cycle(s) of PCR 2, the megaprimer formed in PCR 1 is extended on the original template. In the subsequent cycles, which use forward and reverse primers F2 and R2, the desired mutants are further amplified. (Modified, with permission, from Colosimo et al. 1999.)

and typically possess a calculated T_m between 42°C and 46°C. The T_m (in °C) of oligonucleotide primers can be estimated using the standard formulas:

$$T_m = 4(G+C) + 2(A+T)$$

where $(G+C)$ is the sum of G and C residues in the oligonucleotide and $(A+T)$ is the sum of the A and T residues in the oligonucleotide.

or

$$T_m = 81.5 + 16.6 \log_{10} [Na^+] + 0.41 (\%[G+C]) - (675/n) - (\% \text{ mismatch})$$

where n is the length of the primer in bases. The first formula is appropriate for short oligonucleotides, whereas the second formula is used with longer DNA.

The mutagenic oligonucleotide should also be designed to have a low estimated T_m and a length of 16–25 bases. The desired mutation, and therefore the mismatched region of the primer/template duplex, should be located in the middle of the primer with 8–10 bases of correctly

matched sequences on each side of the mismatched region. When using *Taq* DNA polymerase, which possesses a terminal transferase-like activity that sometimes incorporates an untemplated dA residue at the 3′ end of the amplified megaprimer, the mutagenic primer is designed so that its first 5′ nucleotide follows a T residue in the same strand of the template sequence. The longer of the two flanking primers should be designed to contain 25–30 bases and possess a calculated T_m between 72°C and 85°C.

This protocol was kindly provided by Ed Madison and Song Ke of Corvas Inc., San Diego, California.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

10x Amplification buffer

dNTP solution containing all four dNTPs, each at a 2.5 mM

Enzymes and Buffers

Thermostable DNA polymerase (Hot-Tub DNA Polymerase [Amersham] or equivalent)

Most thermostable DNA polymerases are supplied in a storage buffer containing 50% glycerol. This solution is very viscous and is difficult to pipette accurately. The best sampling method is to centrifuge the tube containing the enzyme at maximum speed for 10 seconds at 4°C in a microfuge and then to withdraw the required amount of enzyme using a positive-displacement pipette. Use automatic pipetting devices equipped with barrier tips to assemble the components of PCRs.

Gels

Agarose gel (1%) or polyacrylamide gel containing 0.5 μg/ml ethidium bromide **<!>**

Please see Step 6.

Nucleic Acids and Oligonucleotides

Primers

Dissolve the forward and reverse external primers in H_2O at a concentration of 100 μM (100 pmoles/μl). Dissolve the mutagenic primer in H_2O at a concentration of 10 μM (10 pmoles/μl).

Template DNA

Superhelical, double-stranded plasmid DNA, purified by ethidium bromide–CsCl density gradient centrifugation (Chapter 1, Protocol 10 or 11) or chromatography on a Qiagen resin (Chapter 1, Protocol 9). Dissolve the template DNA in TE (pH 8.0) at a concentration of 0.1 μg/ml.

Special Equipment

Barrier tips for automatic micropipettes

Microfuge tubes (5 ml, thin-walled for amplification)

Positive-displacement pipette

Thermal cycler programmed with desired amplification protocol

If the thermal cycler is not equipped with a heated lid, use either mineral oil or paraffin wax to prevent evaporation of liquid from the reaction mixture during PCR.

Additional Reagents

Step 6 of this protocol requires the reagents listed in Chapter 1, Protocol 17 or 19.

METHOD

1. In a sterile 0.5-ml microfuge tube or amplification tube (on ice), mix the following reagents for the first amplification reaction:

10x amplification buffer	10 µl
plasmid template DNA	200–400 pg
2.5 mM dNTP solution	8 µl
mutagenic primer	10 pmoles
low T_m flanking primer	100 pmoles
thermostable DNA polymerase	0.5 µl (2.5 units)
H_2O	to 100 µl

If the 10x amplification buffer supplied by the manufacturer of the thermostable DNA polymerase does not contain $MgCl_2$, add an appropriate volume of 0.1 M $MgCl_2$ so that the reaction mixture contains the optimum concentration of divalent ion for the particular DNA polymerase being used.

2. If the thermocycler does not have a heated lid, overlay the PCRs with 1 drop (~50 µl) of light mineral oil. Place the tubes in a thermocycler.

3. Amplify the nucleic acids using the denaturation, annealing, and polymerization times and temperatures listed in the table.

Cycle Number	Denaturation	Annealing	Polymerization
1st cycle	4 min at 94°C	1 min at 42–46°C	1 min at 72°C
24 cycles	40 sec at 94°C	1 min at 42–46°C	1 min at 72°C
Last cycle	40 sec at 94°C	1 min at 42–46°C	5 min at 72°C

These times are suitable for 100-µl reactions assembled in thin-walled 0.5-ml tubes and incubated in thermal cyclers such as the Perkin-Elmer 9600 or 9700, Master Cycler (Eppendorf), and PTC 100 (MJ Research). Times and temperatures may need to be adapted to suit other types of equipment and reaction volumes.

Polymerization should be carried out for 1 minute for every 1000 bp of length of the target DNA.

4. After completion of the first PCR, add to the reaction tube:

high T_m flanking primer	100 pmoles
thermostable DNA polymerase	0.5 µl (2.5 units)
2.5 mM dNTP solution	3 µl

Mix the reagents gently by pipetting the reaction mixture up and down several times. If necessary, centrifuge the tube briefly to deposit the reagents in the bottom.

If desired, successful synthesis of the megaprimer PCR product can be verified at this point by using 3–5 µl of reaction mixture to perform rapid, analytical agarose gel electrophoresis.

5. Carry out the second amplification reaction, which consists of 25 cycles with the following two-step temperature profile:

94°C for 40 seconds
72°C for 90 seconds with a final extension step for 5 minutes at 72°C

6. Analyze 5% of the second amplification reaction on an agarose or polyacrylamide gel and estimate the concentration of amplified target DNA.

   If restriction sites were placed in the sequences of the external primers, digest the amplified DNA with the appropriate enzymes and then subclone it into an appropriate vector. Alternatively, phosphorylate the amplified DNA fragment from Step 5 and then ligate it into a vector that has been cleaved with a restriction enzyme that yields blunt ends. Because this method yields mutants with an efficiency of ~80%, it is generally necessary to select only six colonies for DNA sequencing to verify the presence of the desired mutation(s) and to confirm the absence of any additional mutations in the entire product DNA sequence.

Protocol 6

Site-specific Mutagenesis by Overlap Extension

FOUR PRIMERS ARE NEEDED TO INTRODUCE A SITE-SPECIFIC MUTATION by overlap extension (please see Figure 13-4) (Higuchi et al. 1988; Ho et al. 1989). One pair of primers is used to amplify the DNA that contains the mutation site together with upstream sequences. The forward primer (FM) contains the mutation(s) to be introduced into the wild-type template DNA, whereas the reverse primer R2 contains a wild-type sequence. Many investigators include a restriction site in the 5′ region of primer 1 to facilitate subcloning of the mutated segment of DNA.

The second pair of primers is used to amplify the DNA that contains the mutation site together with downstream sequences. The reverse primer (RM) of this pair contains the mutation(s) to be introduced into the template DNA. At least 15 bases of primer RM should be exactly complementary to primer FM. The forward primer (F2) has a wild-type sequence and may, if desired, have a restriction site in its 5′ region.

The two sets of primers are used in two separate amplification reactions to amplify overlapping DNA fragments (reactions 1 and 2 of Figure 13-4). The mutation(s) of interest is located in the region of overlap and therefore in both sets of resulting amplified fragments. The overlapping fragments (resulting from the first and second rounds of amplification) are mixed, denatured, and annealed to generate heteroduplexes that can be extended and, in a third PCR (reaction 3), amplified into a full-length DNA using two primers that bind to the extremes of the two initial fragments. The method is surprisingly effective, but it requires two mutagenic primers, two flanking oligonucleotides, and three PCRs to construct a mutation. In some cases, a simpler version of the method can be used (one mutagenic primer and two sequential PCRs) if strategically placed restriction sites are available to clone the segment of amplified DNA containing the mutation (Aiyar et al. 1996).

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

10x Amplification buffer

dNTP solution containing all four dNTPs, each at 20 mM

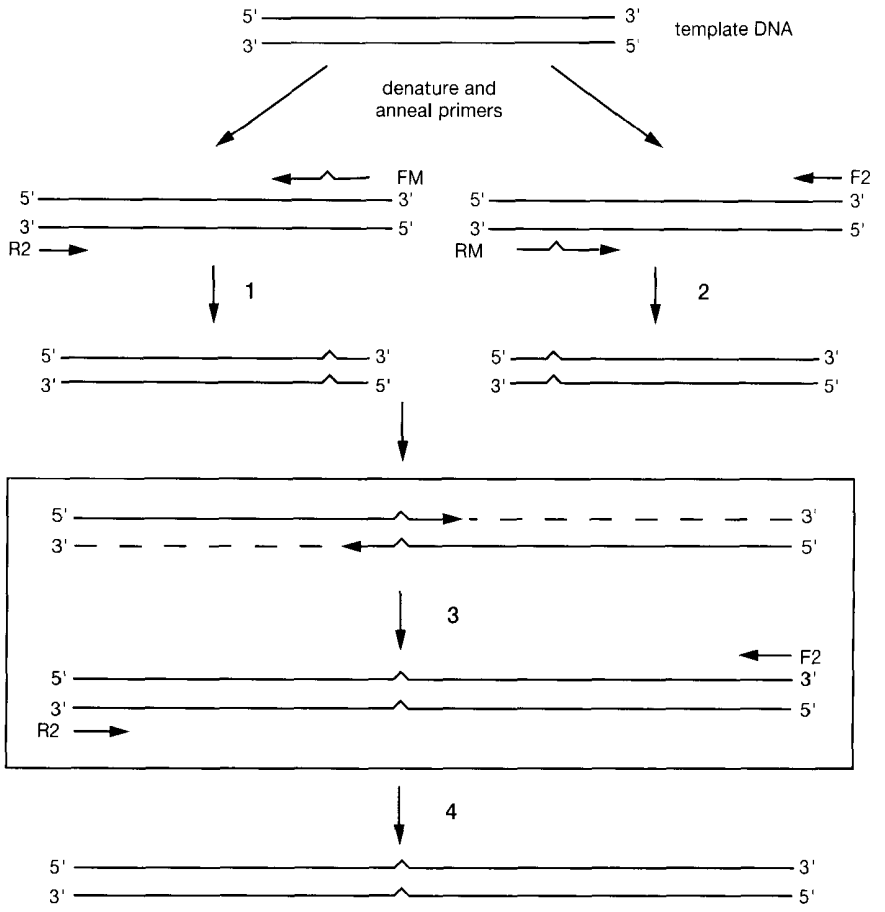

FIGURE 13-4 Site-directed Mutagenesis by Overlap Extension

In separate amplifications, 1 and 2, two fragments of the target gene are amplified. PCR 1 utilizes primers FM and R2, whereas PCR 2 utilizes primers RM and F2. The boxed portion of the figure represents the intermediate steps that are likely to occur during the course of PCR 3, in which denatured FMR 2 and RMF 2 anneal at the region of overlap are extended as shown by the dashed lines to form full-length double-stranded mutant DNA. In PCR 4, the full-length mutant DNA is amplified using primers R2 and F2. (Modified, with permission, from Ho et al. 1989 [©Elsevier Science].)

Enzymes and Buffers

Thermostable DNA polymerase

To avoid the introduction of erroneous bases, use a highly processive thermostable DNA polymerase with 3′-5′ exonuclease "proofreading" capacity in overlap extension mutagenesis. In addition, the DNA polymerase used must not catalyze the nontemplate addition of adenine residues. Thermostable DNA polymerases with the appropriate properties include *Pwo* DNA polymerase (Boehringer Mannheim), r*Tth* DNA polymerase XL (Perkin-Elmer), *VentR* DNA polymerase (New England Biolabs), and *Pfu* DNA polymerase (Stratagene).

Mixes of thermostable DNA polymerases designed for use in long PCR are also well suited for overlap extension mutagenesis.

Gels

Agarose gel (1%) or polyacrylamide gel containing 0.5 µg/ml ethidium bromide <!>

Please see Steps 6 and 11.

Nucleic Acids and Oligonucleotides

Oligonucleotide Primers

Each primer should be 20–30 nucleotides in length and contain approximately equal numbers of the four bases, with a balanced distribution of G and C residues and a low propensity to form stable secondary structure. The sequences of the mutagenic oligonucleotide primers FM and RM should share at least a 15-bp overlap (please see Figure 13-4), and the mismatched base pairs within these primers should be located in the center of the oligonucleotide. The primer sequences at the 5′ and 3′ ends of the DNA fragment to be amplified (i.e., those with wild-type sequences R2, F2) can incorporate unique restriction endonuclease cleavage sites to aid in the subsequent cloning of the mutagenized DNA fragment. For general features of primer design, please see the discussion on Design of Oligonucleotide Primers in the introduction to Chapter 10.

Oligonucleotide primers synthesized on an automated DNA synthesizer can generally be used in overlap extension mutagenesis without further purification.

Template DNA

The template DNA used for mutagenesis is usually a plasmid DNA containing the gene or cDNA of interest. Dissolve the DNA at 1 µg/ml in 10 mM Tris-Cl (pH 7.6) containing a low concentration of EDTA (<0.1 mM).

Special Equipment

Barrier tips for automatic micropipettes

Microfuge tubes (0.5 ml, thin-walled for amplification) or Microtiter plates

Positive-displacement pipette

Thermal cycler programmed with desired amplification protocol

If the thermal cycler is not equipped with a heated lid, use either mineral oil or paraffin wax to prevent evaporation of liquid from the reaction mixture during PCR.

Additional Reagents

Step 11 of this protocol requires the reagents listed in Chapter 1, Protocol 17 or 19.

Step 12 of this protocol requires the reagents listed in Chapter 12, Protocol 3, 4, or 5.

METHOD

1. Design and synthesize oligonucleotide primers FM, RM, R2, and F2 based on the known sequence of the DNA, as outlined in the protocol introduction and Materials section.
2. In a sterile 0.5-ml microfuge tube or amplification tube, set up PCR 1 by mixing the following reagents:

template DNA	~100 ng
10x amplification buffer	10 µl
20 mM mixture of four dNTPs	1.0 µl
5 µM primer FM (30 pmoles)	6.0 µl
5 µM primer R2 (30 pmoles)	6.0 µl
thermostable DNA polymerase	1–2 units
H_2O	to 100 µl

3. In a second sterile 0.5-ml microfuge tube or amplification tube, set up PCR 2 by mixing the following reagents:

template DNA	~100 ng
10x amplification buffer	10 µl
20 mM mixture of four dNTPs	1.0 µl
5 µM primer RM (30 pmoles)	6.0 µl
5 µM primer F2 (30 pmoles)	6.0 µl
thermostable DNA polymerase	1–2 units
H_2O	to 100 µl

4. If the thermocycler does not have a heated lid, overlay the PCRs with 1 drop (~50 µl) of light mineral oil. Place the tubes in a thermocycler.

5. Amplify the nucleic acids using the denaturation, annealing, and polymerization times and temperatures listed in the table below.

Cycle Number	Denaturation	Annealing	Polymerization
20 cycles	1 min at 94°C	1 min at 50°C	1–3 min at 72°C
Last cycle	1 min at 94°C	10 min at 72°C	

These times are suitable for 100-µl reactions assembled in thin-walled 0.5-ml tubes and incubated in thermal cyclers such as the Perkin-Elmer 9600 or 9700, Master Cycler (Eppendorf), and PTC 100 (MJ Research). Times and temperatures may need to be adapted to suit other types of equipment and reaction volumes.

The length of the polymerization step should be calculated from the polymerization rate of the thermostable DNA polymerase employed and the length of the DNA template to be amplified.

The temperature of the annealing reaction may have to be adjusted depending on the sequence of the mutagenic primers.

6. Analyze 5% of each of the two PCRs on an agarose or polyacrylamide gel and estimate the concentration of amplified target DNAs.

7. (*Optional*) Purify the two PCR products using one of the protocols described in Chapter 5. Including this purification step often increases the yield of the desired amplification product in Step 8 of the protocol and reduces the background of spurious amplification products.

8. In a sterile 0.5-ml microfuge tube or amplification tube, mix the following reagents in an amplification reaction to join the 5′ and 3′ ends of the target gene:

amplification product PCR 1 (Step 2)	~50 ng
amplification product PCR 2 (Step 3)	~50 ng
10x amplification buffer	10 µl
5 µM primer F2 (30 pmoles)	6.0 µl
5 µM primer R2 (30 pmoles)	6.0 µl
thermostable DNA polymerase	1–2 units
H_2O	to 100 µl

9. If the thermocycler does not have a heated lid, overlay the PCRs with 1 drop (~50 µl) of light mineral oil. Place the tubes in a thermocycler.

10. Amplify the nucleic acids using the denaturation, annealing, and polymerization times and temperatures listed above in Step 5.

11. Analyze 5% of the PCR on an agarose or polyacrylamide acrylamide gel and estimate the concentration of amplified target DNA.

If restriction enzyme sites were placed in the sequences of primers F2 and R2, digest the amplified DNA with these enzymes and then subclone them into an appropriate vector. Alternatively, phosphorylate the amplified DNA fragment from Step 10 and then ligate it into a vector that has been cleaved with a restriction enzyme that yields blunt ends.

12. Verify the complete sequence of the amplified DNA fragment after cloning to ensure that no mutations other than those in primers FM and RM were introduced during these manipulations.

All DNA polymerases exhibit a measurable error rate when used in in vitro reactions.

Protocol 7

Screening Recombinant Clones for Site-directed Mutagenesis by Hybridization to Radiolabeled Oligonucleotides

WHEN PROTOCOLS FOR SITE-DIRECTED MUTAGENESIS of single-stranded bacteriophage M13 DNA were developed in the early 1980s, genetic techniques to select against the wild-type template strand were not available. Because the efficiency of mutagenesis was often low, methods were required to identify a small minority of mutant plaques in a dense background of wild-type plaques. For many years, the technique of choice was screening of plaques by hybridization, using a radiolabeled mutagenic oligonucleotide as a probe (e.g., please see Zoller and Smith 1982, 1983). Hybridization was carried out under conditions that allowed the radiolabeled oligonucleotide to anneal to both mutant and wild-type DNAs. The resulting hybrid between the radiolabeled mutagenic oligonucleotide and the wild-type sequence would therefore contain one or more mismatched base pairs, whereas the hybrid formed between the newly created mutant and the oligonucleotide probe would be perfectly matched. The thermal stability of these two types of hybrids would be expected to differ, with mismatched hybrids dissociating at a temperature lower than that of the corresponding perfect hybrid. At the time, however, the quantitative effects of mismatches on thermal stability of oligonucleotide duplexes were not well understood. It was obvious that the position of the mismatch, the number of mismatched bases, the length of the oligonucleotide, the content of G and C residues, and sequence context effects would all influence the stability of the mismatched hybrid. But it proved difficult to weave these factors into an equation that would satisfy all circumstances. In the absence of a strong underlying theory, the success of site-directed mutagenesis depended on the ability of the investigator to find an empirical combination of temperature and ionic strength that caused mismatched hybrids to dissociate but had no effect on perfect hybrids.

Although methods to reduce the proportion of wild-type clones have substantially reduced the need for screening by hybridization, the protocol described here remains useful in situations where the desired mutant is obtained with low frequency (e.g., when creating large deletions or complex rearrangements). In addition, this protocol has other applications in molecular biology, including allele-specific oligonucleotide hybridization, colony hybridization, identification of specific mutations among a population of random mutants, and measuring the relatedness among members of a gene family.

The main protocol describes the screening of bacteriophage M13 recombinant clones, whereas an alternative protocol presents a method for screening phagemid-containing bacterial colonies. A final alternative protocol included in this collection describes the detection of defined mutants using PCR.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Ammonium formate (0.2 M) **<!>**

Oligonucleotide hybridization solution

6x SSC
5x Denhardt's reagent
10^6 to 10^7 dpm/ml radiolabeled oligonucleotide

Oligonucleotide prehybridization solution

6x SSC
5x Denhardt's reagent
0.1% (w/v) SDS

6x SSC

6x SSC should be warmed to various temperatures. Please see Steps 11, 12, and 13.

TE (pH 7.6)

Enzymes and Buffers

Bacteriophage T4 polynucleotide kinase

Restriction enzymes

Please see Steps 18 and 19.

Gels

Preparative agarose gel

Please see Step 18.

Nucleic Acids and Oligonucleotides

Mutagenic oligonucleotide (10 pmoles/μl)

Radioactive Compounds

[γ-^{32}P]ATP (>5000 Ci/mmole, 10 mCi/ml) **<!>**

Media

2x YT top agar and YT agar plates

Special Equipment

Forceps, blunt-ended (e.g., Millipore forceps)

Hypodermic needle (18 gauge) and India Ink (optional)

Incubator preset to 65°C, for prehybridization

Incubator preset to appropriate hybridization temperature

Please see note to Step 7.

Nitrocellulose or nylon filters

Vacuum oven

Water bath preset to 68°C
Whatman DEAE paper (DE-81)
Store the paper at room temperature, and wear gloves when handling.

Additional Reagents

Step 4 of this protocol requires the reagents listed in Chapter 10, Protocol 4.
Step 14 of this protocol requires the reagents listed in Chapter 3, Protocol 4.
Steps 15 and 16 of this protocol require the reagents listed in Chapter 12, Protocol 3, 4, or 5.
Step 17 of this protocol requires the reagents listed in Chapter 3, Protocol 3.
Step 20 of this protocol requires the reagents listed in Chapter 6, Protocols 8 and 10.

Vectors and Bacterial Strains

Bacteriophage M13 recombinants, previously mutagenized
Please use plates containing bacteriophage M13 plaques generated in Protocol 2.
Bacteriophage M13 recombinants, nonmutagenized
These serve as a negative control; please see Step 5.
E. coli *strain TG1 or equivalent*

METHOD

Radiolabeling of Oligonucleotides by Phosphorylation

1. In a sterile microfuge tube, mix:

mutagenic oligonucleotide (10 pmoles/µl)	1 µl
10x bacteriophage T4 polynucleotide kinase buffer	1 µl
10 mCi/ml [γ-^{32}P]ATP (10–50 pmoles)	1 µl
H_2O	6 µl
5–10 units/µl bacteriophage T4 polynucleotide kinase	1 µl

Incubate the reaction mixture for 30 minutes at 37°C.

2. Dilute the reaction mixture to 100 µl by the addition of 90 µl of TE (pH 7.6) and inactivate the polynucleotide kinase by heating for 10 minutes at 68°C.

3. Measure the efficiency of transfer of ^{32}P to the oligonucleotide and estimate its specific activity by chromatography on DE-81 paper as follows:

   a. Cut a strip of Whatman DE-81 paper ~1 cm wide and 7–10 cm long. With a soft-lead pencil, draw a fine line across the strip ~1.5 cm from one end. This line marks the origin of the chromatogram.

   b. Spot 1.0 µl of the diluted phosphorylation reaction at the origin. Fill a 250-ml beaker to a depth of ~0.5 cm with ~25–50 ml of 0.2 M ammonium formate. Place the DE-81 strip vertically in a beaker so that the radioactive sample(s) at the origin is just above the buffer solution. Cover the beaker with a glass plate or aluminum foil and allow the chro-

matogram to develop until the solvent front has migrated almost to the top of the beaker.

c. Wrap the strip of DE-81 paper in Saran Wrap and subject it to a very brief period of autoradiography. Use the developed X-ray film as a guide to cut out the radioactive region at the solvent front, the origin, and any other region that contains radioactivity. Measure the amount of radioactivity in each section in a scintillation counter.

Oligonucleotides remain at the origin, whereas ATP and inorganic phosphate migrate in the same direction as the solvent. Inorganic phosphate migrates slightly behind the solvent front, whereas ATP is approximately equidistant from the origin and the inorganic phosphate. Thus, transfer of phosphate from [γ-^{32}P]ATP to the oligonucleotide results in the appearance of radioactivity at the origin. Calculate the specific activity of the radiolabeled probe from the molar quantities of oligonucleotide, the specific activity of the [γ-^{32}P]ATP in the reaction, and the efficiency of transfer of the label to the oligonucleotide. >50% of the radioactivity in the reaction mixture (Step 1) should be transferred to the oligonucleotide.

4. (*Optional*) Remove unincorporated radiolabel from the oligonucleotide by precipitation with cetylpyridinium bromide as described in Chapter 10, Protocol 4.

This step is necessary only when background hybridization is a persistent problem. Under normal circumstances, the unfractionated reaction mixture may be used as a probe.

Screening of Bacteriophage M13 Plaques

5. Prepare replicas of the bacteriophage M13 plaques that are to be screened with the radiolabeled oligonucleotide as follows:

a. Transfer plates containing 100–500 plaques to 4°C for at least 30 minutes.

Include at least one plate that contains plaques of the original wild-type recombinant bacteriophage M13. This plate serves as a negative control in the hybridization and washing steps.

b. When the plates are thoroughly chilled, remove them from the cold room and immediately lay a numbered, dry nitrocellulose or nylon filter on the agar surface of each plate. Use an 18-gauge hypodermic needle to make a series of holes in each filter and the underlying agar. These holes will later serve to key the filters to the plates.

To make an indelible spot, dip the needle in a small amount of India Ink before stabbing the filter.

c. After 30 seconds to 4 minutes, use blunt-ended forceps to peel each filter carefully from its plate. Spread out all of the filters (plaque side up) on a pad of paper towels. Wrap the plates in Saran Wrap, and store them at 4°C until they are needed.

d. When the filters have dried (~30 minutes at room temperature), bake them for 1 hour at 80°C in a vacuum oven.

It is not necessary to denature the DNA by base treatment when screening bacteriophage M13 plaques because the baking step releases the single-stranded DNA from the virus.

6. Transfer all of the filters to a heat-sealable plastic bag (e.g., Sears Seal-A-Meal), or to an evaporating dish of the appropriate diameter, or to a hybridization roller bottle. Add oligonucleotide prehybridization solution (~10 ml/82-mm filter in bags or dishes; 5 ml/82-mm filter in bottles). Seal the bag, cover the evaporating dish with Saran Wrap, or cap the roller bottle, and incubate the filters for 1–2 hours at 65°C.

7. Discard the prehybridization solution, and replace it with oligonucleotide hybridization solution (~5 ml/82-mm filter). Reseal the bag, recover the evaporating dish, or recap the hybridization roller bottle, and incubate the hybridization reaction for 4–6 hours at the appropriate temperature.

   Perform hybridization with the radiolabeled oligonucleotide at a temperature 5–10°C below the T_m estimated from the following formula:

   $$T_m = 4(G+C) + 2(A+T).$$

   where $(G+C)$ is the sum of G and C residues in the oligonucleotide, and where $(A+T)$ is the sum of the A and T residues in the oligonucleotide.

8. At the end of the hybridization period, quickly transfer the filters to a tray containing 200–300 ml of 6x SSC at room temperature. Cover the tray with Saran Wrap, and place it on a rotating shaker for 15 minutes. Replace the washing fluid every 5 minutes. Meanwhile, transfer the remainder of the radioactive hybridization solution from the bag, dish, or roller bottle to a disposable plastic tube. Close the tube tightly, and store the radioactive solution at –20°C until it is needed for rescreening positive plaques (Step 13).

   Label and store the tube appropriately.

9. At the end of the washing period, quickly transfer the filters to a piece of Saran Wrap stretched on the bench. Cover the filters with another piece of Saran Wrap. Fold the edges of the two pieces of Saran Wrap together to form a tight seal. Apply adhesive dot labels marked with radioactive or chemiluminescent ink to the outside of the package, and generate an autoradiograph by exposing the package of filters to X-ray film for 1–2 hours at –70°C, using an intensifying screen (please see Appendix 9).

   ▲ **IMPORTANT** Do not allow the filters to dry on the Saran Wrap.

10. Compare the pattern of hybridization with the distribution of plaques. At this stage, it is normal to find that virtually every plaque hybridizes to the probe. Typically, however, some plaques hybridize more strongly than others, and these often turn out to be the plaques carrying the desired mutation.

11. Transfer the filters to a plastic box containing 100–200 ml of 6x SSC that has been warmed to 10°C below the T_m. Agitate the filters in the solution for 2 minutes (please see note below), and then transfer them to a piece of Saran Wrap as described in Step 9. Establish another autoradiograph. At this stage, it is often possible to identify two types of plaques: those whose radioactive signal has decreased in intensity and those that show no change in intensity.

    If a short oligonucleotide probe (<20 bases) is used, do not wash the filters for more than 2 minutes at 10°C below the T_m. Otherwise, the perfect hybrids formed between the radioactive oligonucleotide and the mutagenized target sequence may dissociate. Longer oligonucleotide probes require more extensive washing times which must be established empirically. This optimization can be done using a hand-held minimonitor and listening for a decrease in the intensity of the radioactive signal as washing proceeds.

12. Repeat the cycles of washing and autoradiography, increasing the temperature of the washing solution by 2–10°C in each cycle. The aim is to find a temperature that does not markedly affect perfect hybrids but causes dissociation of mismatched hybrids (such as those formed between the mutagenic oligonucleotide and the original wild-type sequence).

    With practice, it is possible to eliminate some of the cycles of washing and autoradiography by scanning the filters after each wash with a hand-held minimonitor.

Purification of Positive Plaques

13. Positively hybridizing plaques usually contain a mixture of both mutant and wild-type sequences. It is therefore *essential* to plaque-purify the bacteriophages from positively hybridizing plaques as follows:

    a. Touch the blunt end of a sterile, disposable wooden toothpick to the surface of a positively hybridizing plaque.

    b. Drop the toothpick into a sterile tube containing 1 ml of sterile TE (pH 7.6). Store the tube for 10–15 minutes at room temperature, shaking it from time to time to dislodge bacteriophage particles.

    c. Make a series of tenfold dilutions of the bacteriophage suspension with TE (pH 7.6). Mix 10 µl of the 10^{-3}, 10^{-4}, and 10^{-5} dilutions with 100-µl aliquots of an overnight culture of an appropriate strain of *E. coli* (e.g., TG1).

    d. Add 2.5 ml of 2x YT top agar (melted and cooled to 45°C) to each culture, and plate the entire mixture on a single YT agar plate. Incubate the plate for 16 hours at 37°C to allow plaques to form.

    e. Rescreen the plaques with the radiolabeled oligonucleotide as described in Steps 5–12. In this second round of screening, there is no need to increase the temperature of the washing solution in a stepwise fashion. Instead, the filters can be transferred directly from the washing solution at room temperature (Step 8) to 6x SSC previously warmed to the discriminatory temperature found empirically in Step 12.

14. Pick two plaques from each of three independent putative mutants. Prepare single-stranded DNA from small-scale cultures infected with bacteriophages derived from each of these plaques as described in Chapter 3, Protocol 4.

15. Carry out DNA sequencing by the dideoxy-mediated chain-termination method (please see Chapter 12, Protocol 3 or 4) through the region containing the target sequence. Use either a universal sequencing primer or a custom-synthesized primer that binds 50–100 nucleotides upstream of the mutation site.

16. When the presence of the mutation has been confirmed, verify the sequence of the entire region of the target DNA cloned in the bacteriophage M13 vector to ensure that no adventitious mutations have been generated during propagation of the recombinant in bacteriophage M13. Often, this requires the synthesis of custom-designed sequencing primers that are complementary to segments of the target DNA spaced ~200–400 bp apart.

17. Isolate bacteriophage M13 replicative form DNA from a culture infected with plaque-purified recombinant bacteriophages (Step 14) that carry the desired mutation and show no other changes in sequence in the target region. For methods to isolate and purify bacteriophage M13 replicative form DNA, please see Chapter 3, Protocol 3.

18. Recover the mutated target sequence by digestion of bacteriophage M13 replicative form DNA with the appropriate restriction enzyme(s) and preparative gel electrophoresis. Clone the target DNA into the desired vector.

19. Use several different restriction enzymes to digest aliquots of either a recombinant that carries the original (nonmutagenized) target sequence or the recombinant that carries the mutagenized target sequence.

20. Separate the resulting fragments by gel electrophoresis, and transfer them to a solid support (e.g., nitrocellulose or nylon membrane) as described in Chapter 6, Protocol 8. Carry out Southern hybridization at 10°C below the T_m, using the ^{32}P-labeled mutagenic oligonucleotide as a probe. Wash the filter under the discriminatory conditions and establish an autoradiograph.

    The final autoradiograph should show hybridization only to the relevant fragments of the mutagenized target DNA.

TROUBLESHOOTING

The hybridization and washing conditions described above work well for short oligonucleotides (<20 bases), and it is almost always possible to identify strongly hybridizing plaques or colonies after several cycles of washing and autoradiography. If after repeated washings, all the plaques or colonies continue to hybridize to the oligonucleotide probe, consider the following:

- Check that there is no region of extensive homology between the probe and ectopic regions of the vector or the target DNA.
- Increase the stringency of washing by decreasing the concentration of SSC in the buffer or dramatically increasing the temperature. For longer oligonucleotide probes (e.g., 40-mers), such as those used to delete large segments of a cloned DNA, washing may require 0.1x SSC buffers and a washing temperature of 80°C. Unusual base compositions or secondary structures in oligonucleotide probes may require the use of tetramethylammonium salts to distinguish mutant from wild-type templates (please see Chapter 10, Protocol 8).
- Remove bacterial debris from the filters before hybridization by wiping the filters with Kimwipes soaked in warm 2x SSC, 0.1% SDS.
- Purify the mutagenic oligonucleotide by polyacrylamide gel electrophoresis. If the background problem persists, resynthesize the oligonucleotide, and consider synthesizing a shorter oligonucleotide for use as a probe.

ALTERNATIVE PROTOCOL: SCREENING PHAGEMID-CONTAINING BACTERIAL COLONIES BY HYBRIDIZATION TO RADIOLABELED OLIGONUCLEOTIDES

This protocol is identical in principle and similar in practice to the main protocol (screening bacteriophage M13). However, because colonies of bacteria transformed by the products of site-directed mutagenesis reactions often contain a mixture of wild-type and mutated molecules, a second round of transformation and screening is required to segregate the two types of phagemids. Note that simple restreaking of positive colonies does not generally yield pure populations of bacteria: The copy number of phagemids is so high that complete segregation of mutant from wild-type phagemids occurs only rarely.

An alternative method of obtaining pure mutant phagemids before oligonucleotide hybridization is to scrape the colonies transformed by the products of in vitro DNA synthesis into a small volume of liquid medium. Phagemid DNA is isolated from the pooled colonies by a standard minipreparation method and used to transform another batch of competent *E. coli* cells. The resulting colonies, which will contain pure populations of either mutant or wild-type phagemids, are then screened by hybridization using the mutagenic oligonucleotide as a probe.

Additional Materials

E. coli *strain MV1184, competent for transformation*
Please see Chapter 3, Protocol 8, for phagemid strain information.
LB medium containing the appropriate antibiotic
Please see Step 6.
2x SSC containing 0.1% (w/v) SDS
Water bath preset to 55°C

Method

1. Radiolabel the mutagenic oligonucleotide by phosphorylation, as described in Steps 1–4 of the main protocol.
2. Transfer the transformed colonies to nitrocellulose or nylon filters as described in Chapter 1, Protocol 29.
   Incubate the bacterial master plates for a few hours at 37°C to allow the colonies to regrow, then seal the plates in Saran Wrap, and store them at 4°C until they are needed.
3. Lyse the colonies transferred to the filter with alkali (please see Chapter 1, Protocol 31). Neutralize the filters, and then fix the liberated DNA in situ by baking for 1 hour at 80°C in a vacuum oven.
4. Soak the filters in 6x SSC, 0.1% (w/v) SDS at 37°C. Use Kimwipes soaked in the same solution to gently rub the filters to remove all bacterial debris. Incubate the filters in fresh 6x SSC, 0.1% (w/v) SDS for 3 hours at 55°C.
5. Carry out hybridization with the ^{32}P-labeled mutagenic oligonucleotide as described in Steps 6–12 of the main protocol.
6. Identify colonies that hybridize preferentially to the mutagenic oligonucleotide. Set up a number of small-scale liquid cultures in LB medium using individual colonies as inocula. Grow the cultures to saturation in the presence of the appropriate antibiotic.
7. Isolate superhelical phagemid DNA from each of the cultures by one of the methods described in Chapter 1.
8. Transform competent *E. coli* with each of the phagemid DNA preparations.
9. Prepare single-stranded phagemid DNA by superinfection of individual transformants as described in Chapter 3, Protocol 8.
10. Sequence the target DNA to verify the presence of the desired mutation and to confirm that no adventitious mutations have arisen.
11. Recover the mutated fragment by digestion of the phagemid vector with the appropriate restriction enzyme(s) and preparative gel electrophoresis. Clone the target DNA into an appropriate vector (if needed).
12. Confirm the presence of the mutation by Southern hybridization as described in Steps 19 and 20 of the main protocol.

ALTERNATIVE PROTOCOL: DETECTION OF DEFINED MUTANTS BY PCR

Several techniques have been described to screen DNA samples for the presence or absence of a defined mutation (Glisic and Alavantic 1996; Zhu and Clark 1996; Humbert and Elard 1997; Alavantic et al. 1998). All of these methods are built on the observation that PCRs require the 3′-terminal base of the oligonucleotide primer to be perfectly complementary to the DNA template. If the 3′-terminal base cannot form a conventional Watson-Crick base pair with the base in the corresponding position of the template, the efficiency of priming drops dramatically.

Figure 13-5 outlines the technique described by Glisic and Alavantic (1996), which requires four primers. Oligonucleotides 1 and 4 are forward and reverse primers for amplification of the target region containing the mutation site. Oligonucleotides 2 and 3 are allele-specific primers that anneal to a defined sequence within the target region and differ only in the 3′-terminal base: one of the oligonucleotides corresponds to the wild-type allele, and the other corresponds to the mutant allele. Two amplification reactions are set up, with 35 pmoles of oligonucleotides 1, 2, and 4 in one tube and identical amounts of oligonucleotides 1, 3, and 4 in the other tube. The template DNA can be mammalian genomic DNA (500 ng), yeast genomic DNA (10 ng), bacteriophage M13 DNA (1–5 pg), plasmid DNA (1–5 pg), or in fact any other DNA that may carry the defined mutation.

Amplification is carried out under standard PCR conditions and the products are analyzed by agarose gel electrophoresis. Both reactions should yield a prominent band of amplified DNA corresponding in size to the target region. This DNA, whose synthesis is primed by oligonucleotides 1 and 4, serves as a template for amplification by the allele-specific oligonucleotides. If the template DNA is homozygous, one of the two reactions should contain a second smaller band whose synthesis is primed by oligonucleotide 1 and either oligonucleotide 2 or oligonucleotide 3, depending on whether the template is mutant or wild-type. If the template DNA is heterozygous, both reactions will yield two bands.

The smaller band is usually present in lower molar concentration than the larger band. The reason is that amplification by the allele-specific oligonucleotide depends on prior amplification of the target region by oligonucleotides 1 and 4.

This method is simple, rapid, and robust, and can be used to screen many samples simultaneously. The disadvantage is that it requires four separate oligonucleotides and two amplification reactions.

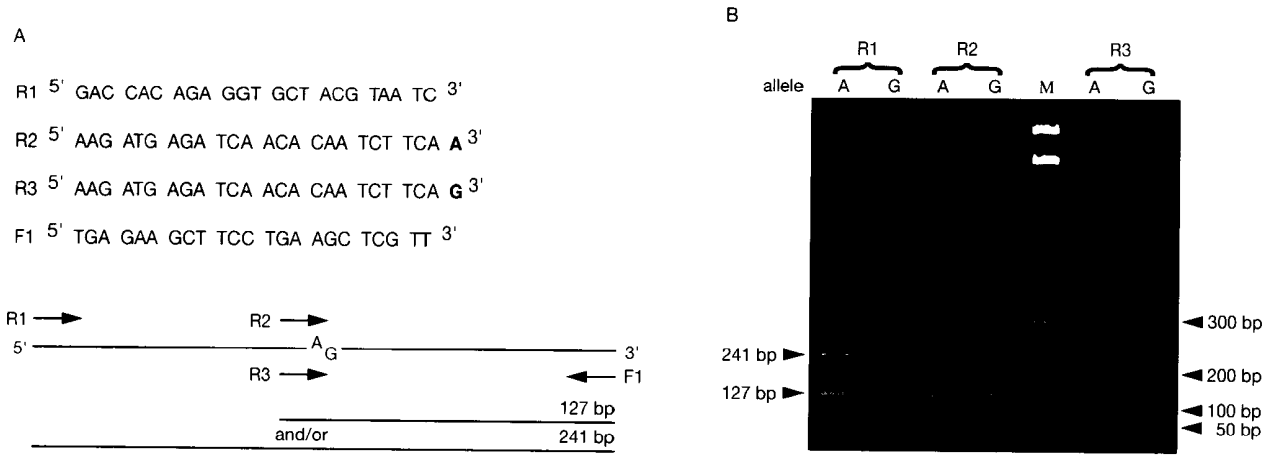

FIGURE 13-5 PCR Amplification of Specific Alleles

(*A*) Primers R1 and F1 generate a 241-bp fragment, which serves as a template for either primer R2 or primer R3 that differ in their 3′-terminal nucleotide. Use of either primer R2 or R3 in combination with F1 generates a 127-bp fragment that matches either allele A or allele G. (*B*) Gel electrophoresis of the products of a PCR to detect a point mutation at nucleotide 12932 (codon 4311) in exon 29 of the *apoB* gene. Each sample is represented by two lanes of the gel. Sample 1 is homozygous for allele A, sample 2 is a heterozygote, and sample 3 is homozygous for allele G. (Lane M) DNA standards (AmpliSize; Bio-Rad). (Modified, with permission, from Glisic and Alavantic 1996 [©Elsevier Science].)

Protocol 8

Detection of Mutations by Single-strand Conformational Polymorphism and Heteroduplex Analysis

DETECTION OF MUTATIONS IS ESSENTIAL FOR MOLECULAR CHARACTERIZATION, diagnosis, prevention, and treatment of inherited diseases of humans and, more generally, to correlate phenotype with genotype in organisms as diverse as mice and slime molds. The goal of mutation detection is to locate and precisely describe changes in DNA sequence that are responsible for particular phenotypes. The range of possible mutations is very great and includes deletions, insertions, inversions, translocations, transitions, and transversions. Some large-scale changes can be detected, for example, by cytochemical analysis of chromosomes or Southern blotting of genomic DNA. However, base-by-base comparison of wild-type and mutant DNAs is at present the only method to pinpoint mutations that affect single bases or groups of bases. Because sequencing of kilobase lengths of DNA is expensive, slow, and dreary, many different techniques have been developed to localize mutations and hence reduce sequencing to a minimum. These scanning methods differ widely in their power, accuracy, speed, and cost, and each can detect only a subset of mutations. At present, therefore, detection and localization of uncharacterized point mutations often require the sequential application of two or more scanning methods, followed by DNA sequencing to specify the mutation. The order in which these scanning methods are applied and their sensitivity vary from gene to gene and from mutation to mutation.

Scanning methods in common use are based on differences in electrophoretic migration and chromatographic behavior between mutant and reference (wild-type) DNAs. These methods, which include single-strand conformational polymorphism (SSCP; this protocol), heteroduplex analysis (HA; this protocol), denaturing gradient gel electrophoresis (DGGE), and, more recently, coupling ion-pair reversed-phase liquid chromatography, can map mutations to an accuracy of ±200 bp. Dideoxyfingerprinting (ddF), a hybrid between dideoxysequencing and SSCP, is more difficult and expensive, but it is capable of mapping mutations with a resolution of ~10 bp.

SINGLE-STRAND CONFORMATIONAL POLYMORPHISM

SSCP involves three steps:

- amplification by PCR of the target region of the gene
- denaturation of the PCR product
- electrophoresis of the single-stranded DNA through a gel at neutral pH

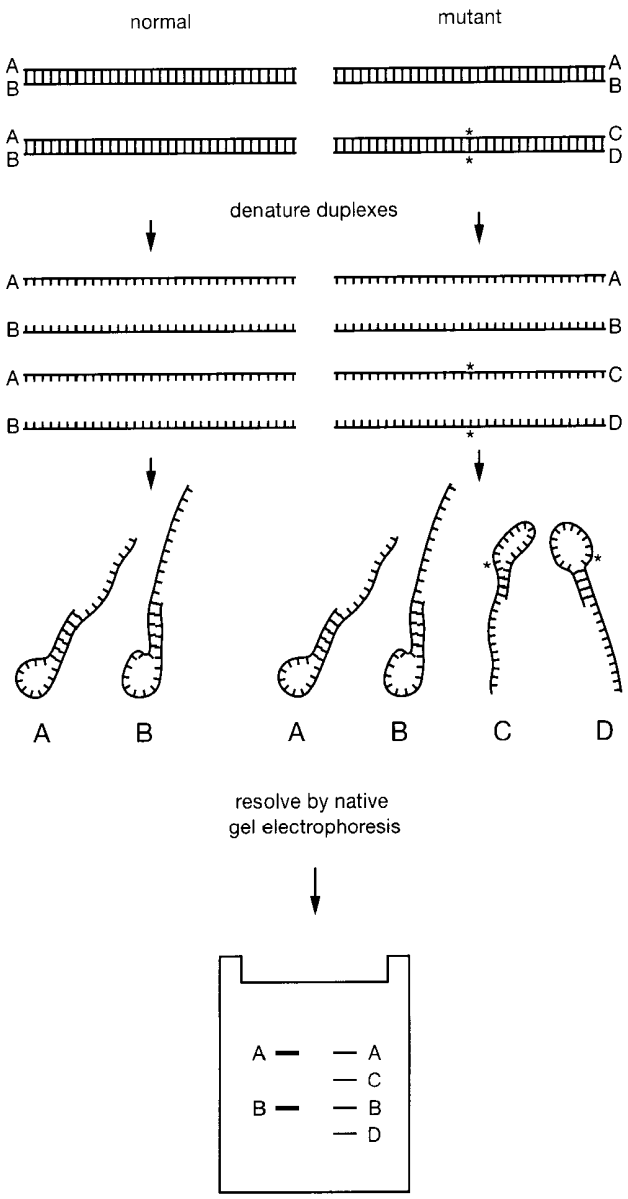

FIGURE 13-6 Schematic for Single-stranded Conformational Polymorphism

A mixed population of DNA duplexes consisting of normal (wild type) as well as mutant sequences is denatured as described in the text, and the resulting single-stranded probes are resolved by electrophoresis under nondenaturing conditions.

Single-stranded DNA molecules fold into complex three-dimensional structures as a result of intrastrand base pairing. Single strands of equal length but different sequence can therefore vary considerably in electrophoretic mobility as a result of the looping and compaction caused by intrastrand pairing. Alteration of the nucleotide sequence of the molecule by as little as a single base can reshape the secondary structure, with consequent changes in electrophoretic mobilities through native gels (please see Figure 13-6). SSCP exploits the differences in mobility between wild-type and mutant strands of DNA (Orita et al. 1989a,b, 1990; Ainsworth et al. 1991; Dean and Gerrard 1991; Condie et al. 1993; Glavac and Dean 1993; for reviews, please see Fan et al. 1993; Axton and Hanson 1998; Jaeckel et al. 1998; Nataraj et al. 1999).

Amplification

Both single- and double-stranded DNAs can be analyzed by SSCP. In each case, the DNA is amplified from genomic DNA templates by either conventional PCR or asymmetric PCR (PCR-SSCP). Using double-stranded DNA allows both strands of the target region to be analyzed simultaneously. This may be an advantage since the sensitivity of mutation detection is often greater for one strand of DNA than the other, and it is not possible to predict which strand will yield the best conformers for SSCP.

Most investigators find that the efficiency of detection of mutations is maximal when the DNA is 150–200 bases in length and decreases rapidly as the size of the DNA increases (Sheffield et al. 1993; Ravnik-Glavac et al. 1994). However, others report that the effects of fragment length are not so dramatic (Fan et al. 1993; Highsmith et al. 1999).

A majority of investigators use *Taq* or *Pfu* to catalyze amplification reactions, which are generally run under standard conditions. There is usually no need to remove unused primers or dNTPs before the sample is analyzed. However, it is important to minimize the production of nonspecific amplification products, whose presence can complicate the interpretation of results of gel electrophoresis.

Denaturation

Before loading on the gel, double-stranded DNA is denatured by alkali or, more commonly, by a combination of formamide and heat. If the DNA has been amplified from a heterozygote, a proportion of the denatured complementary strands may reanneal to one another before the DNA is loaded onto the gel. A proportion of these molecules will be heteroduplexes formed by annealing of complementary wild-type and mutant strands. The presence of both single-stranded and heteroduplex DNAs in the same sample provides an opportunity to use two scanning methods simultaneously (SSCP and HA; see below). If the DNA under test has been amplified from a haploid organism or from a homozygous diploid, the formation of heteroduplexes can be promoted by adding an appropriate amount of the corresponding segment of wild-type (Axton and Hanson 1998). However, we recommend the simultaneous use of two scanning techniques only for those investigators who are fluent in SSCP and HA.

Electrophoresis

Conformers of single-stranded DNA are separated by gel electrophoresis under nondenaturing conditions. Because their mobility varies considerably with temperature and ionic strength, it is usually necessary to analyze samples under two or more sets of conditions to obtain acceptable resolution of different conformers. Close to 100% of mutations can be detected if SSCP is carried out in a range of buffers and temperatures (e.g., 0.5x TBE at 4°C and 15°C or 0.5x TBE with and without compounds such as glycerol that are rich in hydroxyl groups [Glavac and Dean 1993; Hayashi and Yandell 1993; Highsmith et al. 1999; Liu et al. 1999]) (please see the information panel on **GLYCEROL**). Accurate control of temperature during electrophoresis is essential to prevent dissociation of intrastrand base pairs, destabilization of conformers, and, consequently, loss of resolution.

The sensitivity of SSCP varies with the type of gel matrix, with optimum results being obtained from cross-linked polyacrylamide. To achieve reproducibility, many investigators use premade commercial solutions of acrylamide and bisacrylamide (e.g., Acrylogel BDH). However, the best resolution is obtained from the Hydrolink series of gel matrices (Molinari et al. 1993); these are sold under the trade name of MDE (Mutation Detection Enhancement) by FMC BioProducts, Rockland, Maine.

Detection

To suppress the formation of a surfeit of double-stranded molecules, only small amounts of DNA can be loaded onto thin (0.4 mm) gels. The conformers are then detected by autoradiography of PCR products or by staining of unlabeled DNA with SYBR Gold or silver. When thick (1 mm) gels are used, the DNA may be detectable by staining with ethidium bromide.

Advantages and Disadvantages of SSCP

SSCP has dramatically improved the efficiency with which mutations can be identified by molecular analyses of mammalian tissues. The method can also be used to detect different mutant alleles arising from chemical mutagenesis, cassette mutagenesis, or site-directed mutagenesis with families of oligonucleotide mutagens. The technique requires no special equipment, is relatively straightforward to perform, is well suited to nonradioactive methods of detection, and can be adapted to a range of electrophoretic conditions.

A major disadvantage is that the technique is empirical. At present, there are no algorithms capable of accurately predicting the number of conformers of a segment of single-stranded DNA or their electrophoretic properties. Gels containing multiple bands can therefore be difficult to interpret. Finally, SSCP is capable of detecting almost 100% of mutations, but it may require a variety of electrophoretic conditions to do so.

The following protocol obtained from Daphne Davis (University of Texas Southwestern Medical Center, Dallas) describes SSCP analysis of a segment of human genomic DNA.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

10x Amplification buffer

dNTP solution (PCR grade) containing all four dNTPs, each at a concentration of 1 mM (pH 7.0)

Formamide-loading buffer **<!>**

Sucrose gel-loading buffer (buffer type I)

10x TBE electrophoresis buffer

Use TBE at a working strength of 1x (89 mM Tris-borate, 2 mM EDTA) for polyacrylamide gel electrophoresis. Use of the 1x TBE concentration provides the necessary buffering power. The pH of the buffer should be 8.3. It is generally not necessary to adjust the pH; however, check this variable with each new batch of 10x TBE stock prepared in the laboratory.

Use the same stock of 10x TBE to prepare both the gel and the running buffers. Small differences in ionic strength or pH produce buffer fronts that can greatly distort the DNA bands.

Enzymes and Buffers

Restriction enzymes (optional)

Thermostable DNA polymerase

Taq DNA polymerase is recommended.

Nucleic Acids and Oligonucleotides

Human genomic DNA to be screened for point mutations

Dissolve the DNA at 10 µg/ml in TE (pH 7.6).

Oligonucleotide primers, forward and reverse (35 µM each) in TE (pH 7.6)

Radioactive Compounds

[α-^{32}P]dCTP (3000 Ci/mmole, 10 mCi/ml) **<!>**

Gels

Acrylamide:bisacrylamide (29:1%; w/v) **<!>**

Many investigators use premade commercial solutions of acrylamide and bisacrylamide (e.g., Acrylogel, BDH). However, the best resolution of conformers is obtained from the Hydrolink series of gel matrices (Molinari et al. 1993), which are sold under the trade name of MDE (Mutation Detection Enhancement) by FMC BioProducts (Rockland, Maine).

Ammonium persulfate (10% w/v) **<!>**

Glycerol

Use a highly purified grade, such as UltraPure (Life Technologies). Please see the information panel on **GLYCEROL**.

TEMED (N,N,N′,N′-tetramethylethylenediamine) **<!>**

Electrophoresis-grade TEMED is sold by many manufacturers including Sigma and Bio-Rad. TEMED is hygroscopic and should be stored in a tightly sealed bottle at 4°C.

TEMED is used as an adjunct catalyst for the polymerization of acrylamide.

Special Equipment

Barrier tips for automatic micropipettor
Boiling-water bath
Electrophoresis plates, glass (two 40 x 40 cm) with 0.4-mm spacers
Gel-drying apparatus
Glass capillary tube (drawn-out) or Micropipettor with gel-loading tips
Hamilton syringe or Pasteur pipette
Microfuge tubes (0.5 ml, thin-walled for amplification)
Positive-displacement pipette
Thermal cycler programmed with desired amplification protocol

If the thermal cycler is not equipped with a heated lid, use either light mineral oil or paraffin wax to prevent evaporation of liquid from the reaction mixture during PCR.

Water bath(s) preset to the appropriate temperature(s) for restriction endonuclease digestion
Whatman 3MM filter paper

METHOD

Amplification of the DNA to be Screened for Point Mutations

1. In a sterile 0.5-ml microfuge tube, mix in the following order:

1 mM dNTP solution	1 µl
10x amplification buffer	2 µl
35 µM 5′-oligonucleotide solution	1 µl (35 pmoles)
35 µM 3′-oligonucleotide solution	1 µl
10 µCi/µl [α-^{32}P]dCTP	1 µl
human genomic DNA	10 µl (100 ng)
thermostable DNA polymerase	1–3 units
H_2O	to 20 µl

[α-^{32}P]dCTP is incorporated in the PCRs to label the amplified DNA uniformly. ^{32}P-labeled oligonucleotide primers can be used in place of [α-^{32}P]dCTP to produce an end-labeled DNA.

If possible, set up control reactions using two DNA samples known to contain alleles that differ in sequence by one or more base pairs and that are known to resolve on SSCP gels. In addition, set up a contamination control in which no template DNA is added to the reaction.

2. If the thermal cycler is not fitted with a heated lid, overlay the reaction mixtures with 1 drop (~50 µl) of light mineral oil to prevent evaporation of the samples during repeated cycles of heating and cooling. Alternatively, place a bead of paraffin wax into the tube if using a hot start protocol. Place the tubes in the thermal cycler.

3. Amplify the nucleic acids using the denaturation, annealing, and polymerization times and temperatures listed in the table. For advice on thermal cycler programs, please see Chapter 8, Protocol 1.

Cycle Number	Denaturation	Annealing/Polymerization
30 cycles	5–30 sec at 94°C	0.5–1 min at 68°C
Last cycle	1 min at 94°C	5–10 min at 68°C

These times are suitable for 50-µl reactions assembled in thin-walled 0.5-ml tubes and incubated in thermal cyclers such as the Perkin-Elmer 9600 or 9700, Master Cycler (Eppendorf), and PTC 100 (MJ Research). Times and temperatures may need to be adapted to suit other types of equipment and reaction volumes.

Preparation of the SSCP Gel

4. While the thermal cycler program is running, prepare a 5.5% polyacrylamide gel containing 10% (v/v) glycerol in 1x TBE gel buffer.

10x TBE gel buffer	10 ml
29:1% acrylamide:bisacrylamide solution	18 ml
10% ammonium persulfate	0.5 ml
glycerol	10 ml
H_2O	61.5 ml

Mix the reagents by gentle swirling or stirring.

This volume of gel solution is sufficient for one polyacrylamide gel of standard size (40 x 40-cm plates with 0.4-mm spacers). The volume of the gel solution can be increased or decreased as needed for other gel sizes.

Use the same stock of 10x TBE gel buffer to prepare enough 1x TBE gel buffer to fill the tanks of the electrophoresis apparatus.

5. Assemble and tape together two 40 x 40-cm glass electrophoresis plates with 0.4-mm spacers.

To obtain maximum resolution of single-stranded DNA conformers, it is important to use "thin-gel" spacers that are less than or equal to 0.4 mm in thickness.

6. Add 100 µl of TEMED to the gel solution. Mix the solution by gently swirling the flask, and pour the gel.

Work quickly as the acrylamide solution will polymerize rapidly. For instructions on pouring thin gels, please see Chapter 12, Protocol 8.

7. Assemble the polymerized gel into an electrophoresis apparatus at room temperature. Fill the buffer tanks with 1x TBE gel buffer made from the same stock as the gel solution.

Preparation of Samples for SSCP Electrophoresis

8. (*Optional*) If the amplified DNA fragment is to be digested with a restriction enzyme, remove the PCR tubes from the thermal cycler at the end of the run and place them on ice. Set up the following restriction enzyme digestion:

PCR solution	5 µl
10x restriction enzyme buffer	4 µl
restriction enzyme (2–50 units)	2 µl
H_2O	29 µl

Incubate for 1–2 hours at the temperature appropriate for the restriction enzyme.

The ability of SSCP gels to resolve point mutations and polymorphisms decreases as a function of the size of DNA fragment. The simplest way to resolve sequence differences in longer DNA fragments is to digest the double-stranded DNA before electrophoresis with a restriction enzyme that produces fragments 200–300 bp in length. This strategy is especially helpful when screening for polymorphisms in the introns of a gene or for detecting mutations that reside in long exons. If the DNA sequence of the fragment is known, then an appropriate restriction enzyme can be identified with ease. If the DNA sequence is not known, then a random assortment of enzymes (e.g., *Alu*I, *Dde*I, *Hae*III, *Hin*fI, *Msp*I, *Rsa*I) that recognizes 4-bp sequences may be used. Cleaving the DNA with a battery of frequently cutting enzymes will often result in the point mutation/polymorphism being located at different distances from the end of the DNA and in fragments of different sizes. Both features can affect the migration of the resulting single-stranded conformers by SSCP. Finally, digesting a 200–300-bp DNA into two or more smaller fragments followed by SSCP analysis will often resolve an otherwise undetectable mutation.

9. Dilute either 1.5 µl of the original PCR (from Step 3) or 5 µl of the restriction-enzyme-digested PCR (from Step 8) into 20 µl of sucrose gel-loading buffer. Dilute similar aliquots into 20 µl of formamide dye mix.

   The samples diluted into formamide dye mix will be denatured, whereas those diluted into sucrose gel-loading buffer will remain double-stranded and serve as controls.

10. Boil the formamide-containing samples for 6 minutes, and then plunge the tubes directly into ice.

Separation and Analysis of DNA Fragments by SSCP Gel Electrophoresis

11. Use a Pasteur pipette or a Hamilton syringe to wash out the wells of the polyacrylamide gel with 1x TBE gel buffer. With a drawn-out glass capillary tube or a micropipettor equipped with a gel-loading tip, load 2 µl of each sample on the polyacrylamide gel.

12. Apply 6–7 V/cm (~250 V [and 15 mA] for a 40 x 40-cm gel) to the gel for ~14 hours.

13. At the completion of electrophoresis, separate the glass plates, and transfer the gel to a sheet of Whatman 3MM filter paper. Dry the gel on a vacuum dryer for 30–60 minutes.

14. Subject the dried gel to autoradiography for 4–16 hours at room temperature without an intensifying screen.

    The nondenatured PCR samples (i.e., those diluted into the sucrose gel-loading buffer) will migrate through the gel as double-stranded DNAs. By contrast, the denatured samples (i.e., those resuspended in formamide dye mix and boiled) will usually migrate as a mixture of double-stranded and single-stranded DNAs. The single-stranded DNAs will generally migrate through polyacrylamide gels more slowly than the double-stranded molecules (Maxam and Gilbert 1977, 1980; Szalay et al. 1977). Only one single-stranded band will be detected if the two complementary strands of the DNA fold into conformations that cannot be resolved by SSCP. Two single-stranded DNA bands will be detected if the complementary strands fold into resolvable conformers. The PCR product of a heterozygous allele from a diploid organism should generate at least four bands, two whose mobility should be identical to that of the wild-type bands and two that are characteristic of the particular mutation. Often, however, there will be more than two bands, either as a consequence of genetic heterogeneity in the sample or because the two complementary strands of a DNA molecule each fold into more than one conformer. The patterns can be quite complex and are not easily predictable based on DNA sequence, base composition, or fragment length; however, a given pattern is often diagnostic for a particular mutation.

TROUBLESHOOTING: GEL VARIATIONS

This protocol resolves ~75% of all single-base-pair changes in DNA fragments of <300 bp. If the results are not satisfactory, there are a multitude of different gel conditions that can be used to resolve single-stranded DNA conformers. For example:

- Carry out electrophoresis for 12–16 hours at 4–6°C.
- Cast a polyacrylamide gel as described above, but with either 5% (v/v) glycerol or no glycerol. Carry out electrophoresis for 12–16 hours at 4–6°C.
- Cast a polyacrylamide gel using a high-resolution gel solution such as Mutation Detection Gel Solution (e.g., MDE Gel Solution FMC Bioproducts, Maine). This solution contains a proprietary vinyl polymer in place of acrylamide. MDE gels resolve some single-stranded DNA conformers better than polyacrylamide gels. Because double-stranded DNAs migrate more rapidly on these gels than they do on polyacrylamide SSCP gels, the single-stranded DNAs are often the only fragments detected by autoradiography. Follow the manufacturer's instructions for pouring MDE gels and note that a different strength TBE buffer is usually used.
- Load different volumes of the starting amplification reaction (after denaturation) on the SSCP gel. In some cases, loading less DNA decreases the chance that the separated single strands will reanneal with one another and will instead form intrastrand hydrogen-bonded structures that are separated on the SSCP gel.
- Dilute the PCR into an SDS-containing buffer before electrophoresis. In the above example, dilute 1.5 µl of the PCR with 8.5 µl of 0.1% (w/v) SDS in 10 mM EDTA and 10 µl of formamide dye mix. Boil the sample as described in Step 10, and analyze 2 µl of the denatured DNA on an SSCP gel. For unknown reasons, the presence of SDS sometimes facilitates the resolution of single-stranded DNA conformers.
- Substitute 1x TBE gel buffer containing 20 mM HEPES for 1x TBE gel buffer in the protocol. This simple addition greatly changes the electrophoretic mobilities of the single-stranded DNAs. Greater than 95% of conformers in DNA fragments ≤350 bp (Liu and Sommer 1998) can be resolved using two gels, one containing 1x TBE gel buffer, and the other containing 1x TBE gel buffer supplemented with 20 mM HEPES.
- Add urea (5%) or formamide (5%) to the gel buffer to prevent smearing of conformers with high contents of G+C (Glavac and Dean 1993). Addition of higher concentrations of urea produces ultrasharp bands but also a decrease in sensitivity of SSCP (Liu et al. 1999).

Protocol 9

Generation of Sets of Nested Deletion Mutants with Exonuclease III

NESTED DELETION MUTANTS LACKING PROGRESSIVELY MORE NUCLEOTIDES from one end or the other of a target DNA are used to define the boundaries of functional *cis*-acting control elements or, more rarely these days, as templates for directed DNA sequencing. The methods rely on nucleases such as BAL 31, pancreatic DNase I, or exonuclease III, which digest DNA in a predictable fashion. Of these enzymes, exonuclease III is by far the best:

- The exonucleolytic reaction proceeds at a remarkably uniform and predictable rate, making possible the simultaneous isolation both of nested deletions and of groups of deletions with tightly clustered endpoints.
- The method is not restricted to any particular vector.
- The entire series of enzymatic reactions (exonuclease digestion, treatment with nuclease S1/mung bean nuclease, and recircularization) can be carried out in a single set of tubes without purification of intermediate products (Henikoff 1984, 1987, 1990).

In the method described by Henikoff (1984), the double-stranded DNA of recombinant plasmid, phagemid, or bacteriophage M13 replicative form DNA is digested with two restriction enzymes whose sites of cleavage both lie between one end of the target DNA and the binding site of a universal primer. The enzyme that cleaves nearer the target sequence must generate either a blunt end or a recessed 3′ terminus; the other enzyme must generate a 4-nucleotide protruding 3′ terminus. Because only the blunt or recessed 3′ terminus of the resulting linear DNA is susceptible to exonuclease III, digestion proceeds unidirectionally away from the site of cleavage and into the target DNA. The exposed single strands are then removed by digestion with nuclease S1 or mung bean nuclease, and the DNA is then recircularized. If desired, a synthetic linker can be inserted at the site of recircularization.

The only significant limitation of the method is the requirement for an appropriate restriction site at one end of the target DNA that is not susceptible to attack by exonuclease III. However, in practice, this limitation is not a serious impediment. The range of cloning sites currently available in bacteriophage M13, phagemid, and plasmid vectors is so large that it is almost always possible to find a vector that is suitable for the particular target fragment under study. In those rare instances when no suitable restriction site is available, recessed 3′ termini can be protected from attack by filling with the Klenow fragment of *E. coli* DNA polymerase I and α-thiophosphate dNTPs (Guo and Wu 1983; Jasin et al. 1983). Alternatively, a protective "buffer" fragment can be

inserted between the site of cleavage and the flanking vector sequences (Haltiner et al. 1985). If the buffer fragment is long enough, the progressive removal of the target DNA by exonuclease III is unlikely to be accompanied by loss of essential sequences from the flanking vector.

For this mutagenesis procedure to be effective, it is essential that digestion of the template DNA by the appropriate restriction enzymes be complete. However, if the two restriction sites are close to each other, complete digestion may require digesting for extended times with large amounts of one or both enzymes, which may lead to nicking of the template. Because exonuclease III efficiently attacks the 3′ end of a nick (Masamune et al. 1971), deletions may then be generated in undesirable locations in both the vector and the target DNA. In our hands, this problem remains largely a theoretical possibility that occurs rarely in practice. We therefore recommend the use of a protocol based on digestion of the template DNA with two restriction enzymes, as described by Henikoff (1984).

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

dNTP solution containing dATP, dGTP, and dTTP, each at 0.5 mM in 25 mM Tris-Cl (pH 8.0)

Ethanol (100%, ice cold, and 70%, room temperature)

10x Exonuclease III buffer

660 mM Tris-Cl (pH 8.0)
66 mM $MgCl_2$
100 mM β-mercaptoethanol **<!>**

Nuclease S1 stop mixture

0.3 M Tris base
50 mM EDTA (pH 8.0)

Phenol:chloroform **<!>**

Sodium acetate (3 M, pH 5.2)

Enzymes and Buffers

Exonuclease III

The quality of exonuclease III varies from manufacturer to manufacturer and should be checked in analytical digests before large-scale preparation of nested deletion templates.

Klenow mixture (sufficient for 30 samples)

H_2O	20 µl
1 M $MgCl_2$	6 µl
0.1 M Tris-Cl (pH 7.6)	3 µl
Klenow fragment	3 units

Prepare this mixture on ice just before use.

Ligase mixture (sufficient for 24 samples)

H_2O	550 µl
10x bacteriophage T4 ligation buffer	100 µl
5 mM rATP	100 µl
polyethylene glycol (30% w/v PEG 8000) **<!>**	250 µl
bacteriophage T4 DNA ligase	5 Weiss units

Prepare this mixture on ice just before use.

Nuclease S1 reaction mixture

H_2O	172 µl
10x S1 buffer	27 µl
nuclease S1	60 units

Prepare this mixture just before use.

Mung bean nuclease can be substituted for nuclease S1 in this reaction mixture.

Restriction enzymes (two)

For a discussion on choice of enzymes and engineering their recognition sites properly into the target DNA, please see the introduction to this protocol and the information panel on **EXONUCLEASE III**.

Gels

Agarose gels (two), 1% (w/v) agarose

Nucleic Acids and Oligonucleotides

Target DNA

Analyze the sequence of the target DNA for the presence of suitable restriction sites. Clone the DNA to be digested into a plasmid or bacteriophage vector that contains as few nonessential sequences as possible. Analyze an aliquot of the preparation of recombinant plasmid DNA that is to be used as a substrate for mutagenesis by agarose gel electrophoresis in TAE buffer (please see Chapter 5, Protocol 1). The plasmid must be >90% superhelical molecules. Repurify the preparation if any linear or >10% nicked or relaxed plasmids are detected.

Because exonuclease III will initiate digestion from single-strand nicks, it is important that the template DNA consist predominantly of closed circular molecules. Purification of the template has the added advantage of removing small pieces of DNA and RNA from the closed circular DNA preparation. These can interfere with digestion by exonuclease III.

Special Equipment

Microfuge tubes (0.5 ml) or Microtiter plates with "U"-shaped wells (e.g., Baxter B1190-17)
Waterbaths preset to 30°C, 37°C, and 70°C

Additional Reagents

Step 14 of this protocol requires the reagents listed in Chapter 1, Protocol 24, 25, or 26 (for transformation).

Step 15 of this protocol requires the reagents listed in Chapter 1, Protocol 1 or 4 (for minipreparation of plasmid DNA) or in Chapter 3, Protocol 3 (for preparation of replicative form of M13 DNA).

Step 16 of this protocol requires the reagents listed in Chapter 12, Protocol 3, 4, or 5.

METHOD

1. Digest 10 µg of target DNA (recombinant bacteriophage M13 replicative form DNA, phagemid DNA, or plasmid DNA) with two restriction enzymes that cleave the polycloning site between the primer-binding site of the vector and the target DNA.

   To maximize the efficiency of cleavage, avoid using restriction sites located immediately adjacent to each other in a polycloning site. Perform the digests under conditions of low DNA concentration and large reaction volume with the appropriate buffer recommended by the enzyme's manufacturer. Digest first with the restriction enzyme that generates the blunt or recessed 3′ terminus. When all of the closed circular DNA has been converted to linear DNA, as confirmed by agarose gel electrophoresis, adjust the buffer and add the second enzyme. Alternatively, perform a standard phenol:chloroform extraction and ethanol precipitation, and set up a fresh digestion in the appropriate buffer for the second enzyme. Any DNA that escapes cleavage by the second enzyme will be digested in both directions by exonuclease III and will therefore be unlikely to generate viable

clones. The efficiency of cleavage by the second restriction enzyme can be checked by end labeling with ^{32}P the first cleavage site and checking for the subsequent loss of ~50% of the radiolabel.

If difficulties are encountered in cleaving the template DNA to completion with two restriction enzymes, we recommend using a commercial kit based on a method described by Henikoff (1990). In this procedure, single-stranded circular phagemid DNA is used as a template for extension of an oligonucleotide primer by bacteriophage T4 DNA polymerase. This reaction generates a double-stranded circular molecule containing a small nick or gap immediately 5′ to the primer. Exonuclease III is then used to resect the resulting 3′ end, and the exposed single-stranded DNA is removed by digestion with a single-strand-specific endonuclease (nuclease S1 or mung bean nuclease). The resulting set of linear nested DNA fragments have a common terminus corresponding to the 5′ end of the primer. These deleted molecules are then recircularized and used to transform cells. This method has the advantages that nested deletions can be made from any point in the target DNA and that the enzymatic reactions can be carried out sequentially in a single tube; thus, there is no need to extract the solution with organic solvents or to precipitate the DNA.

Several commercial kits are available for construction of deletion mutants using Henikoff's (1990) method (please see the information panel on **COMMERCIAL KITS FOR SITE-DIRECTED MUTAGENESIS**).

2. Purify the DNA by standard extraction with phenol:chloroform and precipitation with ethanol. Carefully remove the supernatant, and add 0.5 ml of 70% ethanol to the pellet.

   Rinsing the pellet with ethanol is important because sodium ions inhibit exonuclease III (Hoheisel 1993) (please see the information panel on **EXONUCLEASE III**).

3. Recover the washed pellet of DNA by centrifuging at maximum speed for 2 minutes at 4°C in a microfuge, and then carefully remove the supernatant. Incubate the open tube on the bench to allow the last traces of ethanol to evaporate, and then dissolve the DNA in 60 µl of 1x exonuclease III buffer. Store the dissolved DNA on ice.

4. Place 7.5 µl of nuclease S1 reaction mixture in each of 25 0.5-ml microfuge tubes or in 25 wells of a 96-well microtiter plate with U-shaped wells. Store the microtiter plate or microfuge tubes on a bed of ice.

5. Incubate the DNA solution prepared in Step 3 for 5 minutes at 37°C. Transfer 2.5 µl of the solution to the first microfuge tube or well of the microtiter plate containing the nuclease S1 reaction mixture.

6. To the remainder of the DNA solution, add 150 units of exonuclease III per pmole of recessed 3′ termini (1 unit of exonuclease III will generate 1 nmole of acid-soluble total nucleotide in 30 minutes at 37°C). Tap the tube to mix the contents and immediately return the tube to the 37°C water bath.

   Under these conditions, the amount of exonuclease III is saturating, and ~200 nucleotides per minute are removed from the blunt end or recessed 3′ terminus of each of the DNA molecules in the solution. More or less DNA can be removed by varying the intervals between successive samples. In general, the rate of exonucleolytic digestion of DNA, which determines the range of the exonuclease III digestion endpoints, varies depending on the molar ratio of enzyme to template. To ensure that all DNA templates are degraded at the same rate and that synchronicity is maintained over several kilobases of DNA fragment, exonuclease III must be present in excess in the digestion reaction.

   The rate of exonuclease digestion can also be controlled by carrying out the digestion reactions at different temperatures. Henikoff (1987) estimates that a 2°C difference in temperature in the range of 30–40°C can change the rate of digestion by 100 bases/minute.

7. At 30-second intervals, remove 2.5-µl samples of the DNA solution and place them in successive microfuge tubes or wells of the microtiter plate containing the nuclease S1 reaction mixture.

8. When all of the samples have been harvested, incubate the microfuge tubes or microtiter plate containing the nuclease S1 and digested plasmid DNA for 30 minutes at 30°C.

9. Add 1 µl of nuclease S1 stop mixture to each of the microfuge tubes or wells and incubate the reaction mixtures for 10 minutes at 70°C.

   Heating to 70°C inactivates nuclease S1 and any residual exonuclease III. For further information on these enzymes, please see the information panels on **NUCLEASE S1** in Chapter 7 and **EXONUCLEASE III** at the end of this chapter.

10. Transfer the microfuge tubes or microtiter plate to a bed of ice and analyze aliquots of each of the samples by agarose gel electrophoresis.

    Choose a concentration of agarose that will allow maximum discrimination between the original DNA and fragments that are smaller in size by up to 2 kb.

11. Pool the samples containing DNA fragments of the desired size. Add 1 µl of Klenow mixture for each 10 µl of pooled sample and incubate the reaction mixture for 5 minutes at 37°C.

12. For each 10 µl of pooled sample, add 1 µl of 0.5 mM dNTPs. Continue incubation for 15 minutes at room temperature.

    The initial brief incubation with the Klenow enzyme in Step 11 is carried out in the absence of dNTPs to allow the 3′ exonuclease activity of the enzyme to remove any remaining protruding 3′ termini from the digested DNA.

13. Add 40 µl of T4 bacteriophage ligase mixture for each 10 µl of pooled sample. Mix and continue incubation for 2 hours at room temperature.

14. Transform the appropriate *E. coli* host with aliquots of the ligated DNA.

15. Prepare minipreparations of bacteriophage M13 replicative form DNA, plasmid, or phagemid DNA from at least 24 randomly selected plaques or colonies.

16. Linearize the DNAs by digestion with an appropriate restriction enzyme and analyze their sizes by electrophoresis through a 1% agarose gel. Include the original plasmid or bacteriophage DNA that has been linearized by restriction enzyme digestion as a marker. Choose clones of an appropriate size for sequencing (Chapter 12) or additional restriction enzyme mapping.

    Approximately 80–90% of the deletions will typically retain a universal or reverse primer-binding site and can be sequenced using the appropriate oligonucleotides. For DNA sequencing, it is best to select clones that differ in size by ~400 bp to ensure that an overlapping set will be analyzed. For appropriate DNA sequencing protocols using the religated and retransformed DNAs, see Chapter 12.

Protocol 10

Generation of Bidirectional Sets of Deletion Mutants by Digestion with BAL 31 Nuclease

IN THIS METHOD, THE NUCLEASE BAL 31 (purified from the marine bacterium *Alteromonas espejiana* BAL 31) is used to make uni- or bidirectional deletions in a segment of cloned DNA. BAL 31 is a complex enzyme and tends to digest a population of double-stranded DNA targets in an asynchronous fashion (please see the information panel on **BAL 31**). The resulting deletions are therefore far more heterogeneous in size than those created by processive enzymes such as exonuclease III (please see Protocol 9).

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

5x BAL 31 buffer
- 2.5 M NaCl
- 62.5 mM $CaCl_2$
- 62.5 mM $MgCl_2$
- 100 mM Tris-Cl (pH 8.0)

dNTP solution of all four dNTPs, each at 0.5 mM
EGTA (0.5 M, pH 8.0)
Ethanol
Phenol:chloroform (1:1, v/v) **<!>**
Sodium acetate (3 M, pH 5.2)
Sucrose gel-loading buffer
TE (pH 7.6)

Enzymes and Buffers

Bacteriophage T4 DNA polymerase
BAL 31 nuclease
Klenow fragment of E. coli *DNA polymerase I*
Restriction endonucleases
Please see Steps 3, 23, and 31.

Gels

Agarose gels
Please see Steps 3 and 32.
Agarose gel (0.8%) containing 0.5 μg/ml ethidium bromide <!>
Please see Step 11.
Agarose gel cast in TBE containing 0.5 μg/ml ethidium bromide
Please see Step 25.
Preparative agarose gel
Please see Step 27.

Nucleic Acids and Oligonucleotides

Marker DNA for gel electrophoresis

Special Equipment

Stopwatch
Water baths preset to 65°C and to the appropriate temperature(s) for restriction endonuclease digestion

Additional Reagents

Step 1 of this protocol requires the reagents listed in Chapter 1, Protocols 17–19, or the reagents listed in Chapter 3, Protocol 6.
Step 2 of this protocol requires the reagents listed in Chapter 1, Protocol 9.
Step 27 of this protocol requires the reagents listed in Chapter 5, Protocol 4, 5, 6, or 7.
Step 30 of this protocol requires the reagents listed in Chapter 1, Protocols 23–26, or the reagents listed in Chapter 3, Protocol 6 or 8.
Step 31 of this protocol requires the reagents listed in Chapter 1, Protocol 1, or the reagents listed in Chapter 3, Protocol 3.
Step 34 of this protocol requires the reagents listed in Chapter 12, Protocol 3, 4, or 5.

METHOD

Preparation of Target DNA for Digestion by BAL 31

1. Clone the target fragment into an appropriate plasmid or bacteriophage M13 vector.

   If deletion mutants are to be constructed from both termini of the target DNA, it will be necessary to clone the parental target DNA in both orientations with respect to the polycloning site in an appropriate vector.

2. Purify the closed circular recombinant DNA(s) by column chromatography on Qiagen columns (or their equivalent) and precipitation with ethanol. Redissolve the DNA in the smallest practical volume of Tris/EDTA.

   It is essential to use highly purified closed circular DNA (i) to minimize the contribution of contaminating RNA and small fragments of *E. coli* chromosomal DNA to the total concentration of termini in the reaction and (ii) to eliminate nicked circular molecules, which are degraded by BAL 31 from the site of the nick.

3. Digest 30 μg of the closed circular DNA to completion with a restriction endonuclease that cleaves at one end of the target DNA. This site defines the common point from which the nested deletions will begin. Use agarose gel electrophoresis to verify that digestion with the restriction endonuclease is complete.

4. Purify the DNA by extraction with an equal volume of phenol:chloroform. Separate the aqueous and organic phases by centrifugation at maximum speed for 3 minutes at 0°C in a microfuge, and then transfer the aqueous phase to a fresh microfuge tube.
5. Add 0.1 volume of 3 M sodium acetate (pH 5.2) and 2 volumes of ice-cold ethanol. Store the tube for 10 minutes at 0°C, and then recover the DNA by centrifugation at maximum speed for 10 minutes at 4°C in a microfuge.
6. Remove the supernatant, and wash the pellet of DNA carefully with 70% ethanol at room temperature. Dry the pellet at room temperature, and dissolve it in TE (pH 7.6) at a concentration of 1 µg/µl. Store the DNA at –20°C.

Assaying BAL 31 Activity

Most commercial preparations of BAL 31 contain two kinetically distinct forms of the enzyme: a fast form and a slow form (please see the information panel on **BAL 31**). The slow form is a proteolytic degradation product of the fast form. The rate at which BAL 31 digests DNA is a function of the proportion of the fast and slow forms in the particular preparation of the enzyme used. Pure preparations of the fast form are available (Wei et al. 1983), but they are expensive and, in any case, they frequently decay into the slow form during storage. To preserve BAL 31 in the fast form, do not freeze the enzyme, and store it at 4°C.

Because the ratio of fast and slow forms of BAL 31 varies from preparation to preparation, it is essential to assay the activity of the particular batch of enzyme that will be used to generate deletions.

7. In a microfuge tube, mix:

linearized DNA (1 µg/µl)	4 µl
H_2O	48 µl
5x BAL 31 buffer	13 µl

Dispense 9 µl of this mixture into each of seven separate microfuge tubes.

8. Make a series of seven twofold dilutions of BAL 31 in 1x BAL 31 buffer. Enzyme dilution is best carried out by placing seven aliquots (2 µl) of 1x BAL 31 buffer on the surface of a piece of Parafilm lying on a bed of ice or on a cold block. Use a disposable micropipette tip to mix 2 µl of the BAL 31 preparation under test with the first drop. Use a fresh tip to transfer 2 µl of the mixture to the next drop, and again mix. Continue in this fashion until the enzyme has been added to all of the drops. Working quickly, add 1 µl of each of the last six dilutions to six of the microfuge tubes containing the linear DNA being tested. Do not add enzyme to the seventh tube.

   Most commercial preparations of BAL 31 are supplied at a concentration of ~1 unit/µl; 0.05–0.1 unit of most commercial preparations of BAL 31 is sufficient to digest 1 µg of a 2-kb segment of linear DNA to fragments <200 bp in length.

9. Incubate all of the microfuge tubes (including the tube that received no enzyme) for 30 minutes at 30°C.
10. Add 1 µl of 200 mM EGTA (pH 8.0) to each tube, and then heat the tubes for 5 minutes at 65°C.

    BAL 31 requires Ca^{2+} for activity and is therefore completely inhibited by EGTA. The enzyme is also inactivated by heating for 5 minutes at 65°C.

11. Mix each of the samples with 3 µl of agarose gel-loading buffer and analyze the size of the DNAs by electrophoresis through a 0.8% agarose gel containing 0.5 µg/ml ethidium bromide.

12. Examine the gel by UV illumination, and determine the dilution of enzyme just sufficient to digest the DNA to the point where only a smear of small (200-bp) fragments is detectable. This dilution of BAL 31 will be used in the large-scale digestion (Step 15).

    Another way to check the progress of the BAL 31 digestion is to set up a large-scale digestion with BAL 31 and to withdraw aliquots at various times. Each of these aliquots is then digested with a restriction enzyme that cleaves the target fragment several times. As the digestion with BAL 31 proceeds, the restriction fragments disappear in a defined order. Knowing the size and map positions of the restriction fragments, it is possible to estimate the rate of BAL 31 digestion. The amount of enzyme added to the large-scale digest (below) should be sufficient to digest <20% of the length of the target fragment in the first 5 minutes of the reaction.

Large-scale Digestion with BAL 31

13. Mix:

linearized DNA (1 µg/µl)	20 µl
H_2O	240 µl
5x BAL 31 buffer	65 µl

    Incubate the mixture in a water bath at 30°C.

14. While the mixture is warming to 30°C, prepare a set of eight microfuge tubes, each containing 5 µl of 200 mM EGTA (pH 8.0). Label the tubes 1.5 minutes, 3.0 minutes, 4.5 minutes, etc.

15. Add 36 µl of the appropriate dilution of BAL 31 (please see Step 12) to the reaction mixture prepared in Step 13. Quickly mix the enzyme by tapping the side of the tube, and then return the tube to the water bath set at 30°C and start a stopwatch.

16. At 1.5-minute intervals, transfer 45 µl of the reaction mixture to the appropriately labeled microfuge tube. Store the tubes on ice until all of the samples have been collected.

17. Heat the tubes for 5 minutes at 65°C to inactivate the BAL 31.

18. Add 5 µl of 3 M sodium acetate (pH 5.2) to each tube, followed by 100 µl of ice-cold ethanol. Mix the solution by vortexing, and store the tubes on ice for 20–30 minutes.

19. Recover the DNAs by centrifugation at maximum speed for 10 minutes at 4°C. Remove the supernatants, and wash the pellets with 200 µl of ice-cold 70% ethanol. Centrifuge for a further 2 minutes.

20. Carefully remove the supernatants, and stand the open tubes at room temperature until all of the ethanol has evaporated. Dissolve each of the pellets in 23 µl of TE (pH 7.6).

Isolation of Truncated Target Fragments

21. Add to each of the DNA preparations:

0.5 mM dNTP solution	3 µl
10x polymerase buffer	3 µl
bacteriophage T4 DNA polymerase (~5 units)	1 µl

    Incubate the reactions for 15 minutes at room temperature, and then add ~1 µl (~5 units) of the Klenow fragment. Continue the incubation for a further 15 minutes at room temperature.

The use of two different DNA polymerases in the repair reaction results in an approximately three-fold increase in recovery of mutants.

22. Purify the DNAs by extraction with phenol:chloroform, and then precipitate the DNAs with ethanol as described in Steps 18–20. Dissolve each of the DNAs in 16 µl of TE (pH 7.6).

23. To each DNA, add 2 µl of the appropriate 10x restriction enzyme buffer and 8 units of a restriction enzyme that will separate the target DNA from the vector. Incubate the reactions for 1 hour at the appropriate temperature.

24. At the end of the incubation, transfer an aliquot (3 µl) from each digest to a fresh microfuge tube. Store the remainder of the digests on ice until needed in Step 27.

25. Add 1 µl of sucrose gel-loading buffer to each 3-µl aliquot, and load the contents of each tube into the wells of an agarose gel cast in 0.5x TBE and containing 0.5 µg/ml ethidium bromide. The wells at the sides of the gel should contain markers of the appropriate size.

    Cast the gel with a percentage of agarose that allows separation of the target fragment and the vector (please see Table 5-2, in the introduction to Chapter 5).

26. Separate the target fragments from the vector DNA by electrophoresis. Examine the gel by UV illumination, and determine which of the samples has been digested to an appropriate size by BAL 31.

27. Pool the samples (from Step 24) containing target DNA of the appropriate size, and isolate the target fragments by preparative gel electrophoresis. Recover the target DNA fragments from the gel using one of the methods described in Chapter 5, Protocols 4–7.

28. Estimate the amount of purified target DNA from the intensity of ethidium-bromide-mediated fluorescence (please see Appendix 8).

Cloning of Deleted Target Fragments

29. Ligate the deleted target fragments with a plasmid, phagemid, or bacteriophage M13 vector (please see Chapter 1 or 3) that carries one blunt end and one terminus that is compatible with the restriction enzyme used in Step 23.

    The exact composition and volume of the ligation reaction will depend on the amount of target DNA available. If possible, use between 50 and 100 ng of target DNA, and make sure that the molar ratio of vector DNA to target DNA is at least 5 (to minimize the number of recombinants that contain more than one fragment of target DNA). To maximize the formation of recombinants, the ligation reaction should be carried out under conditions that favor blunt-end ligation, i.e., in a small volume in the presence of high concentrations of bacteriophage T4 DNA ligase and polyethylene glycol and low concentrations of ATP. For details on ligation conditions, please see Chapter 1, Protocol 19.

30. Transform (plasmids or phagemids) or transfect (bacteriophage M13 replicative form DNA) competent *E. coli* of an appropriate strain with small aliquots or dilutions of the ligation mixture. The next day, grow small-scale cultures of 12 transformed colonies or bacteriophage M13 plaques, chosen at random.

31. Purify plasmid, phagemid, or bacteriophage M13 replicative form DNA from each of the 12 cultures by using one of the methods described in Chapter 1 or 3. Digest the DNAs with a restriction enzyme(s) that will liberate the target fragment from the vector.

32. Analyze the size of the target fragment liberated from each of the DNAs by agarose gel electrophoresis, using size markers of an appropriate size.

33. If the results are satisfactory (i.e., if the target fragments fall within the desired size range), pick a large number of individual transformed colonies or plaques and determine the size of the inserts as described above. Preserve those cultures that carry recombinants of the desired size.

34. Determine the exact endpoints of the deletion in each mutant by DNA sequencing (please see Chapter 12, Protocol 3, 4, or 5).

BAL 31

BAL 31, isolated from the marine bacterium, *Alteromonas espejiana* sp., is a calcium-dependent nuclease whose predominant activity against DNA is exonucleolytic. Magnesium ions are also required for full activity. BAL 31 contains:

- ***A 3′→5′ exonuclease activity*** that removes mononucleotides from double-stranded DNA (Zhou and Gray 1990).
- ***A 5′→3′ exonuclease activity*** that works efficiently on single-stranded DNA (Gray and Lu 1993).
- ***An endonuclease that digests single-stranded DNA*** slowly and cleaves a variety of torsionally strained DNA substrates, including negatively supercoiled DNA, junctions between left- and right-handed DNA (B-Z junctions), and superhelical DNAs carrying apurinic sites or covalent cross-links (Legerski et al. 1977, 1978; Lau and Gray 1979; Kilpatrick et al. 1983; Wei et al. 1984).

The combination of the two exonuclease activities causes both strands of double-stranded DNA to be shortened from both ends. BAL 31 will also digest single-stranded RNA and double-stranded RNA, the latter much less efficiently than double-stranded DNA (Bencen et al. 1984). In molecular cloning, the exonucleolytic reaction of BAL 31 has been used:

- ***To produce uni- and bidirectional deletion mutations at specific sites in cloned DNAs.*** Unidirectional deletions are best generated in target DNAs cloned between two unique restriction sites in a plasmid or phagemid vector. Bidirectional deletions can be generated from a unique internal restriction site in the target DNA (please see Figures 13-7 and 13-8).
- ***As an aid to restriction mapping of cloned DNAs*** (Legerski et al. 1978; Hauser and Gray 1991). When linear duplex DNA is digested with BAL 31, the terminal restriction fragments are destroyed first, followed by the subterminal fragments and so on. The order of restriction fragments in an unmapped segment of cloned DNA can therefore be ascertained from the order in which restriction fragments disappear from samples that have been digested with BAL 31 for increasing periods of time.

So far, the functions of >200 genes and the organization of at least 100 *cis*-acting sequences have been analyzed by assaying the function of deletion mutants created by BAL 31. In addition, unidirectional deletions generated by BAL 31 have been used to create sets of nested templates for sequencing long segments of DNA cloned in bacteriophage M13 vectors (Poncz et al. 1982).

Properties of BAL 31

Most commercial preparations of BAL 31 contain two kinetically distinct forms of the enzyme, a fast (F) form with a molecular weight (M_r) of 105,000 and a slow (S) form (M_r = 85,000). The S form is a proteolytic degradation product of the F form and is generated by a protease in the supernatant of *Alteromonas* cultures. The F form itself appears to be a degradation product of an even larger protein (Hauser and Gray 1990).

The two forms of BAL 31 degrade single-stranded DNA at approximately equal rates, but they differ markedly in the activity that generates uni- and bidirectional deletions, i.e., the 3′→5′ exonucleolytic degradation of double-stranded DNA. The rate of the reaction of the F form is described by the equation of Wei et al. (1983):

$$F(v_o,[S]) = F(V_{max}^{app}, [S] + K_m^{app}) \quad (1)$$

where v_o is the initial reaction velocity, [S] is the initial substrate concentration expressed in mole/liter of duplex termini, V_{max}^{app} is the apparent maximum velocity at the concentration of enzyme used, and K_m^{app} is the apparent Michaelis constant. The value of K_m^{app} is ~58 nM when the initial length of the duplex substrate is in the range of 2.0–2.5 kb (Gray and Lu 1993).

At high substrate concentrations and working at maximum velocity, one unit of the F form releases 2.1 nmoles of nucleotide/liter/minute from duplex DNA molecules. This value of V_{max}^{app} applies to DNAs whose content of (G+C) is between 52 and 67 Mol%. However, because the activity of the F form of BAL 31 on double-stranded DNA increases slightly as the (G+C) content of the substrate decreases, V_{max}^{app} should be increased by interpolation by a factor of 1.7 as the (G+C) content decreases from 52 to 37 Mol% (Gray and Lu 1993).

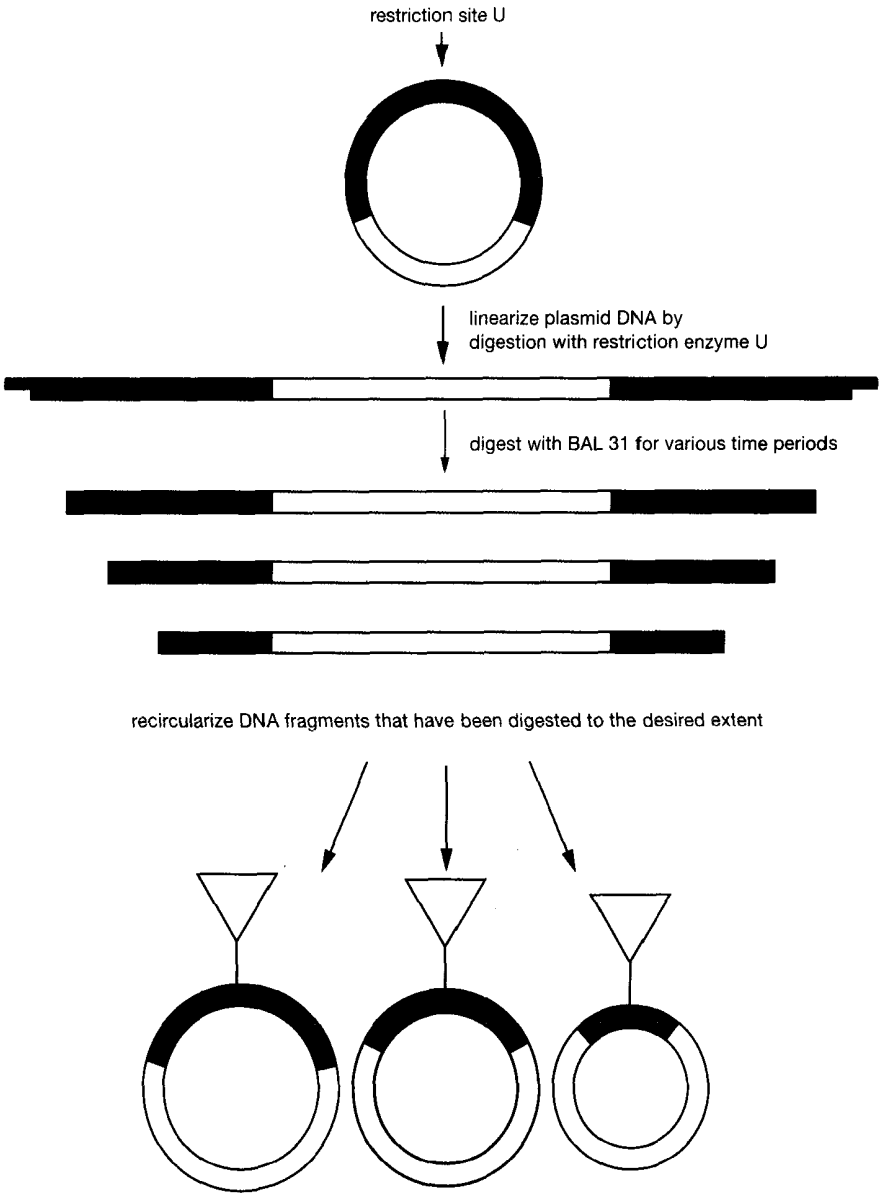

FIGURE 13-7 Generation of Bidirectional Deletions by Digestion with BAL 31

Digestion proceeds from a site within the target.

Equation 1 cannot be used to predict the kinetics of degradation for the S form of BAL 31 because the values of K_m^{app} for this enzyme are larger than the highest concentration of substrate that can be assembled in the reaction (Gray and Lu 1993). However, since $[S]$ is much less than K_m^{app}, a plot of v_o versus $[S]$ yields a straight line. The term on the right-hand side of Equation 1 reduces to $F(V_{max}^{app}, K_m^{app})$, which is constant at fixed enzyme concentration.

Because this term is the slope of the plot of v_o versus $[S]$, it is possible to calculate $F(v_o, [S])$ for any given concentration of the S form of BAL 31 and to extrapolate results from one enzyme concentration to another. For example, if x units of the S form catalyze the release of 0.5 residue/minute from a certain concentration of double-stranded substrate, then $2x$ units will catalyze the release of 1.0 residue/minute.

In general, the S form of BAL 31 truncates linear duplex DNA 20–30-fold more slowly than the F form (Wei et al. 1983). However, by contrast to the F form, the activity of the S form on double-stranded DNA

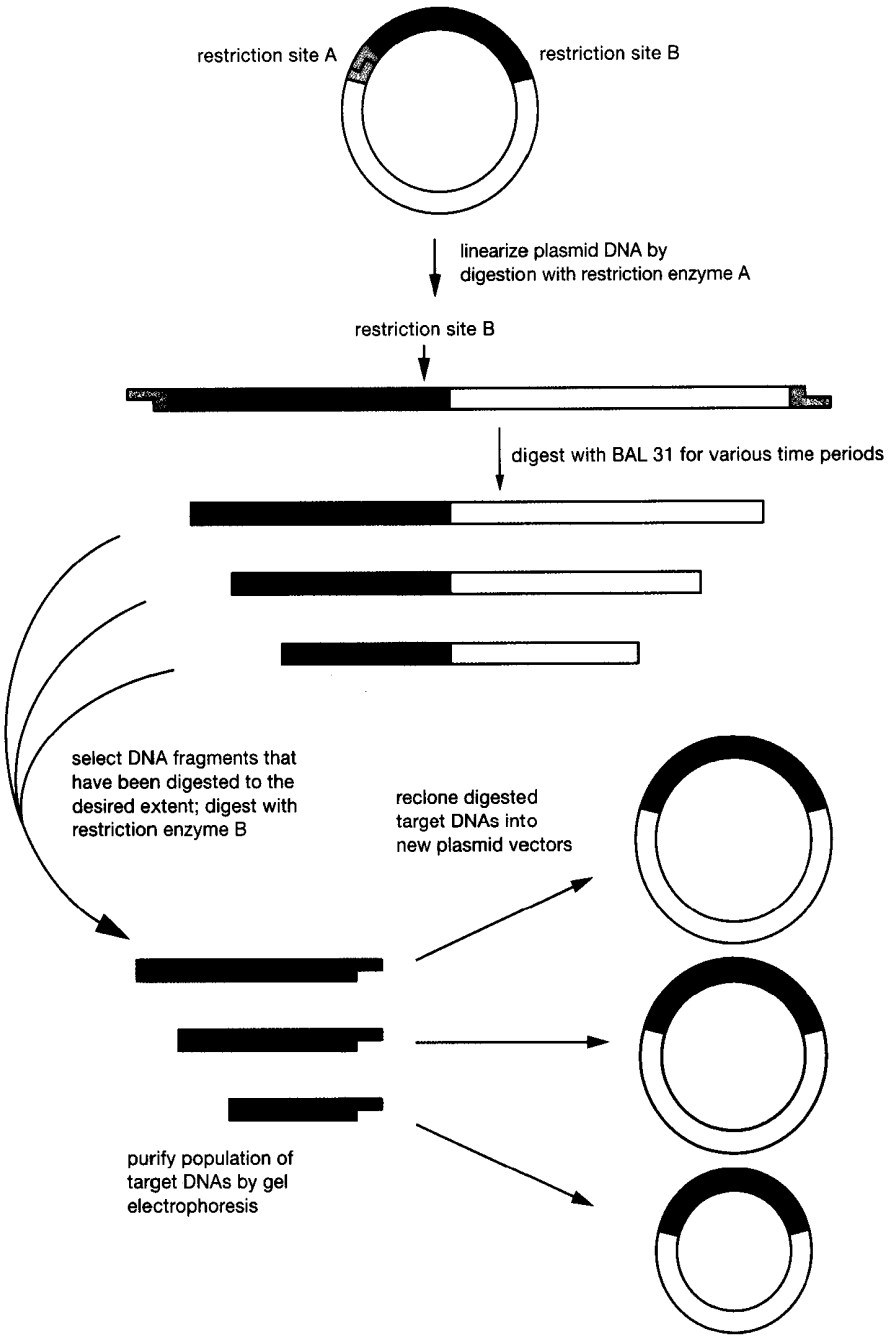

FIGURE 13-8 Generation of Unidirectional Deletions by Digestion with BAL 31

Digestion proceeds from each end of the target.

decreases markedly with increasing G+C content, with a 4.2-fold change in $F(v_o, [S])$ over the range 37–66 Mol% G+C (Legerski et al. 1978; Gray and Lu 1993). The dependence of $F(v_o, [S])$ on G+C content can be estimated from the following equation:

$$F(v_o,[S]) = 16.85 - 0.546P + 0.00456P^2 \quad (2)$$

where P is the Mol% G+C, and the value of $F(v_o, [S])$ corresponds to an enzyme concentration of 1 unit/ml. The desired value of $F(v_o,[S])$ can be calculated by multiplying the quantity obtained from Equation 2 by

the concentration of the S form to be used in the experiment (Gray and Lu 1993). Because of these complications, the F species is the enzyme of choice for controlled shortening of duplexes whose base composition shows wide local variation.

When the products of BAL 31 digestion are to be ligated, it is important to consider that the average length of single-stranded tails created by digestion of linear double-stranded DNA is dependent on the ratio of F and S forms and on their concentration. The average length of the protruding 5′ tails decreases with increasing enzyme concentration (Zhou and Gray 1990). High concentrations of the F or S form (>2 and 10 units/ml, respectively) will generate DNA molecules that carry an average of seven nucleotides of single-stranded DNA per terminus; 2–4% of these molecules can be blunt-end-ligated to one another without further treatment. Low concentrations of either form (below ~1 and 5 units/ml of the F and S nuclease, respectively) will generate long single-stranded termini whose efficiency of blunt-end ligation is very low. Thus, a low concentration of F enzyme in a preparation may be compensated in this regard by a relatively high concentration of S form. However, repair with bacteriophage T4 DNA polymerase (or, in some cases, the Klenow fragment) is obligatory at low concentrations and desirable at high concentrations of BAL 31.

Although pure preparations of the F and S forms of BAL 31 are commercially available, they are very expensive. Results using mixed preparations will vary, depending on the relative amounts of the two forms in the initial preparation. However, mixed preparations of the enzyme work perfectly well for most purposes, although it is necessary to carry out preliminary experiments to determine the concentration of enzyme and the time of digestion that give the desired results.

Preparations rich in the F form are preferred for such tasks as removal of long (>1000 bp) segments from the termini of double-stranded DNA, degradation of double-stranded RNA, and mapping of restriction sites, B-Z DNA junctions, and lesions in double-stranded DNA. The S form of the enzyme is best suited for removal of short segments (10–100 bp) from the termini of double-stranded DNA. Mixed preparations of the enzyme can be used for any of these tasks, although the results will vary as mentioned above.

Facts and Figures

- Digestions with BAL 31 are usually carried out at 30°C in a buffer (pH 8.0) containing between 0.4 and 0.6 M NaCl and 12.5 mM of both Ca^{2+} and Mg^{2+}.
- The DNA should be purified by chromatography on Qiagen columns (or their equivalent), concentrated by precipitation with ethanol, resuspended in the smallest practical volume of Tris/EDTA, and then diluted into the reaction mixture to a final concentration of >20 mg/ml (for a fragment ~2 kb in length).
- The amount of enzyme used should be calculated to digest <20% of the length of the target fragment in the first 5 minutes of the reaction.
- Aliquots withdrawn from the reaction at various times should be stored at 4°C in 20 mM EGTA.
- A good way to check the progress of the BAL 31 digestion is to digest an aliquot of the samples taken at various times with a restriction enzyme that cleaves the target fragment several times. As the digestion proceeds, the fragments disappear from the digest in a defined order. Knowing their size and map positions, it is possible to estimate the rate of BAL 31 digestion.

Historical Footnote

BAL 31 was discovered accidentally by Horace Gray when he was an assistant professor at the University of Houston in the early 1970s. At this time — several years before molecular cloning of DNA became possible — the only source of milligram amounts of prokaryotic closed circular duplex DNA was the bacteriophage PM2, which had been discovered by Romilio Espejo, a Chilean microbiologist. Espejo was a peripatetic visitor to the California Institute of Technology, where Gray was a postdoctoral fellow in Jerry Vinograd's laboratory. Gray and others in Vinograd's laboratory were interested in the hydrodynamic properties of closed circular DNA and so needed to purify bacteriophage PM2 on a large scale. The bacteriophage was routinely grown on *Alteromonas espejiana*, a marine bacterium that had also been isolated by Espejo some years before. Espejo originally characterized it as a *Pseudomonas*. However, when it was reexamined and found to fit the small genus *Alteromonas*, the authors of that paper (Chan et al. 1978) named it after Espejo.

Pursuing studies on PM2 DNA at the University of Houston, Gray was surprised to find that some batches of the bacteriophage particles lysed in preparative CsCl gradients, releasing their viral DNA, which then sedimented to the bottom of the centrifuge tubes. The released DNA was a mixture of closed circular and linear forms and Gray and his colleagues were excited by the possibility that a restriction enzyme might be present either in the bacteriophage particles or in lysates of *Alteromonas*. However, they soon noticed that the linear DNA produced from closed circular DNA became progressively shorter during incubations with *Alteromonas* culture supernatants and realized that the *Alteromonas* lysate contained an exonuclease (the source of lysis was never discovered). The exonuclease was given the name BAL 31 and Gray spent a good part of the next 15 years working out its biochemistry and structure. Almost everything that we know about the enzyme is due to the work carried out in his laboratory in Houston. Espejo returned to Chile but lost contact with former colleagues in the United States when he was forbidden to travel from Chile during the 1970s.

EXONUCLEASE III

Exonuclease III of *E. coli* removes 5′ mononucleotides from the 3′-hydroxyl ends of duplex DNA, leaving protruding 5′ termini (Richardson and Kornberg 1964; Richardson et al. 1964). At 37°C, a limited number of 5′ mononucleotides are removed during each binding event. Resection of DNA molecules therefore occurs in a distributive and quasi-synchronous fashion. The favorable kinetics of digestion and the immunity of single-stranded 3′ termini to attack led to the development of methods (1) to generate single-stranded templates for DNA sequencing (Smith 1979; Guo and Wu 1982; Sorge and Blinderman 1989; Li and Tucker 1993) and (2) to produce unidirectional sets of progressive deletions in populations of linear DNA molecules with one resistant (3′ protruding) terminus and one susceptible (blunt or 5′ protruding) terminus (Henikoff 1984, 1987, 1990; Hoheisel and Pohl 1986). 3′ termini that are resistant to exonuclease III can be generated by digestion with certain restriction enzymes (see Table 13-2), by digestion with λ exonuclease, or by "tailing" with terminal deoxynucleotidyl transferase.

TABLE 13-2 Substrate Specificity of Exonuclease III

Type of Termini	Resistant or Sensitive to Exonuclease III	References
Blunt-ended	Sensitive	Richardson et al. (1964)
Recessed 3′	Sensitive	Richardson et al. (1964); Weiss (1981)
Protruding 3′ termini with <4 unpaired bases	Sensitive	Henikoff (1984)
Protruding 3′ termini with >3 unpaired bases	Resistant unless the terminal base is C. Most 4-base protruding 3′ termini generated by restriction enzymes are resistant to exonuclease III. However, termini generated by *Apa*I, *Ban*II, *Bsp*1286I, *Hae*II, and *Kpn*I, which cleave 3′ to a C residue, are sensitive to the enzyme. These enzymes should therefore be avoided when designing templates for exonuclease-III-based deletion and DNA sequencing.	Henikoff (1984); Hoheisel (1989, 1993)
3′ termini filled with α-thio deoxynucleotides	Resistant	Putney et al. (1981); Olsen and Eckstein (1990)

Exonuclease III is a 31-kD globular protein, encoded by the *xth* gene of *E. coli*, which has been sequenced (Saporito et al. 1988). Surprisingly for such a small protein, exonuclease III possesses multiple catalytic activities.

- ***A 3′→5′ exonuclease*** that degrades double-stranded DNA (Richardson et al. 1964).
- ***A 3′ phosphomonoesterase*** (Richardson and Kornberg 1964; Brutlag and Kornberg 1972) that removes a number of 3′ termini from double-stranded DNA, including 3′ phosphoglycoaldehyde and 3′ phosphoglycolate residues (for review, please see Doetsch and Cunningham 1990).
- ***A nucleotidyl hydrolase*** cutting 5′ to apurinic/apyrimidimic sites in DNA (Weiss 1976, 1981; Weiss et al. 1978).
- ***A powerful exonucleolytic ribonuclease H*** (Keller and Crouch 1972; Weiss et al. 1978).

This constellation of activities, which are catalyzed by a single active site (Weiss 1976, 1981), is consistent with genetic data indicating that exonuclease III acts within the cell as part of the prokaryotic base-excision repair pathway (Rogers and Weiss 1980).

Exonuclease III supplied from most commercial manufacturers is purified from a strain of *E. coli* containing a chimeric plasmid (pSGR3) that carries a 3-kb fragment of the *E. coli* genome encompassing the *xth* gene (Rao and Rogers 1978). Exonuclease III contains a bound divalent cation that is required for activity. The purified enzyme does not require Mn^{2+} or Mg^{2+} in the reaction buffer unless it has been exposed to EDTA. Ca^{2+} can partially substitute for Mg^{2+} for the exonucleolytic activity of exonuclease III (Kow 1989). The mechanism by which exonuclease III degrades DNA exonucleolytically is affected by temperature, the concentration of monovalent cation, and the concentration and structure of the 3′ termini (please see Table 13-3).

Arrhenius plots of the temperature dependence of the rate of exonucleolytic digestion by exonuclease III in the presence of Mg^{2+} show a transition at 25–30°C (Henikoff 1987; Kow 1989; Hoheisel 1993), suggesting that the enzyme exists in two conformational states. In one state, which predominates at temperatures <25°C, exonuclease III binds tightly to DNA and works in a processive fashion. At temperatures >30°C, the enzyme has a lower activation energy and hydrolyzes populations of 3′ termini in a distributive fashion (Hoheisel 1993). Ca^{2+} ions stabilize exonuclease III in its low-temperature conformation (Kow 1989). The activity of exonuclease III is inhibited at temperatures in excess of 46°C (Hoheisel 1993). Table 13-4 lists some of the applications of the enzymatic activities of exonuclease III to molecular cloning.

TABLE 13-3 Exonucleolytic Activities of Exonuclease III

Reaction Conditions	Enzymatic Activity	References
70 mM NaCl at 5°C	Exonuclease III removes six nucleotides from the end of a duplex and remains bound as a stable complex.	Donelson and Wu (1972)
50 mM NaCl at 5°C	An initial burst of exonucleolytic activity removes six nucleotides from the end of a duplex. This is followed by a slower rate of progressive hydrolysis.	Donelson and Wu (1972)
23–28°C	Exonucleolytic digestion is synchronous for ~250 nucleotides and is processive. At saturating enzyme concentrations, 5′ mononucleotides are removed at a rate of ~100 nucleotides/min/3′end.	Wu et al. (1976); Hoheisel (1993)
37°C	Exonucleolytic digestion is distributive and quasi-synchronous. At saturating enzyme concentrations, 5′-mononucleotides are removed at a rate of ~400 nucleotides/min/3′ end.	Thomas and Olivera (1978); Hoheisel (1993)

Exonuclease III is inhibited by NaCl and displays maximal activity in buffers containing 15 mM Tris-Cl (pH 8.0) and 6.6 mM $MgCl_2$. No enzymatic activity is detectable in buffers containing 300 mM NaCl (Hoheisel 1993).

Production of Nested Deletions by Digestion with Exonuclease III

Henikoff (1984) described a method whereby the double-stranded DNA of recombinant plasmid, phagemid, or bacteriophage M13 replicative form DNA is digested with two restriction enzymes whose sites of cleavage both lie between one end of the target DNA and the binding site for universal primer. The enzyme that cleaves nearer the target sequence must generate either a blunt end or a recessed 3′ terminus; the other enzyme must generate a 4-nucleotide protruding 3′ terminus. Because only the blunt or recessed 3′ terminus of the resulting linear DNA is susceptible to exonuclease III (please see Table 13-3), digestion proceeds unidirectionally away from the site of cleavage and into the target DNA. The exposed single strands are then removed by digestion with nuclease S1 or mung bean nuclease, and the DNA is then recircularized. If desired, a synthetic linker can be inserted at the site of recircularization.

The major defect of this method is that it requires two unique restriction sites immediately adjacent to the point from which deletions originate. In most cases, these sites are located in the polycloning site to one side of the target sequence. For the procedure to be effective, it is essential that digestion of these two sites by the appropriate restriction enzymes be complete. However, if the two sites are close to each other, this can be achieved only by digesting for extended times with large amounts of one or both enzymes, which can lead to nicking of the template. Because exonuclease III efficiently attacks the 3′ end of a nick (Masamune et al. 1971), deletions may be generated in undesirable locations in both the vector and the target DNA.

To solve this problem, Henikoff (1990) described a method in which a single-stranded circular phagemid DNA is used as a template for extension of an oligonucleotide primer by bacteriophage T4 DNA polymerase. This reaction generates a double-stranded circular molecule containing a small nick or gap

immediately 5′ to the primer. Exonuclease III is then used to resect the resulting 3′ end, and the exposed single-stranded DNA is removed by digestion with a single-strand-specific endonuclease (nuclease S1 or mung bean nuclease). The resulting set of linear nested DNA fragments have a common terminus corresponding to the 5′ end of the primer. These deleted molecules are then recircularized and used to transform cells. This method has three advantages:

- Nested deletions can be made from any point in the target DNA.
- Restriction enzymes are not used.
- The enzymatic reactions can be carried out sequentially in a single tube, and there is no need to extract the solution with organic solvents or to precipitate the DNA.

Another method to control the extent of resection is to label the DNA randomly with thionucleotides before digestion with exonuclease III. Because thio-containing nucleotides are resistant to hydrolysis by exonuclease III, digestion will stop at the first place the enzyme encounters a thio-substituted nucleoside. By controlling the amount of α-thio incorporation, investigators can more readily obtain sets of resected DNA fragments of the desired size (King and Goodbourn 1992).

Making Templates for Dideoxysequencing with Exonuclease III

Sequencing strategies based on digestion of double-stranded DNA templates with exonuclease III have been in use since 1982 when Guo and Wu (1983) developed a method in which the DNA sequence was obtained by resynthesis of the resected strand. This method eliminated the need for a primer-binding site, but it required knowledge of the restriction map of the target DNA. Although improvements were made (Guo and Wu 1983), exonuclease III was not used extensively to prepare templates for DNA sequencing until 1984, when Henikoff's protocol to create nested deletions was published. However, this method is labor-intensive and, in addition to enzymatic resection, requires much subcloning, growth of bacterial cultures, and purification of nucleic acids. In addition, a new deletion is needed for each 300–500 nucleotides of sequence.

LINKER-SCANNING MUTAGENESIS

Linker-scanning mutagenesis (McKnight and Kingsbury 1982) is designed to locate and identify functional elements in promoters, replication origins, and other *cis*-acting regulatory regions. A canon of mutants is generated in which short segments of the target DNA are replaced in a systematic fashion with a "neutral" DNA sequence. Replacing the natural DNA sequence with a sequence of the same length will usually destroy the function of a particular regulatory element, but it will not change the spacing, torsional topology, or orientation of functional elements within the domain. The phenotypes of individual mutants can therefore be mapped with some confidence to specific locations within the regulatory region. Because all mutants carry the same neutral sequence, comparison of their phenotypes is valid in most cases.

In the original linker-scanning method (McKnight and Kingsbury 1982), 5′- and 3′-deletion mutants were first generated by resection with exonuclease III (please see the information panel on **EXONUCLEASE III**). The termini of these mutations were then precisely mapped to identify pairs of mutants whose endpoints differed by precisely the number of nucleotides present in the neutral synthetic linker. Pairs of mutants were then yoked together through a synthetic linker (please see Figure 13-9). This sounds simple in theory, but it is extremely laborious and time-consuming in practice. To obtain a usable set of linker-scanning mutants by this method, a large number of 5′ and 3′ deletions must be constructed, sequenced, and matched. In their original paper, McKnight and Kingsbury (1982) used 43 5′ and 42 3′ deletions to obtain a canon of 15 linker-scanning mutants. Although the method was later streamlined (e.g., please see

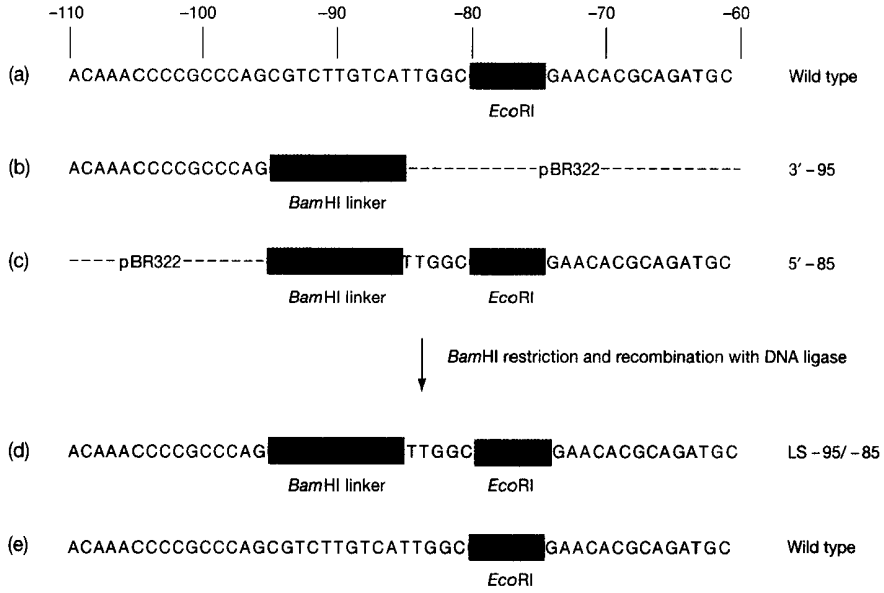

FIGURE 13-9 Construction of a Linker-scanning Mutant

(*a*) Nucleotide sequence of the normal HSV *tk* gene between 60 and 110 residues upstream of the transcription initiation site is shown on the top and bottom lines. This sequence is referred to as wild type. (*b, c*) Nucleotide sequences of two linker deletion mutants 3′–95 and 5′–85. (*d*) Linker-scanning mutant –95/–85 was constructed by recombining 3′–95 and 5′–85 at the *Bam*HI restriction site. The nucleotide residues of the *tk* gene that are substituted by this procedure are shown in bold type. (Redrawn, with permission, from McKnight and Kingsbury 1982 [©AAAS].)

Haltiner et al. 1985; Luckow et al. 1987; Südhof et al. 1987; Luckow and Schütz 1991), it remained a daunting proposition until synthetic oligonucleotides became available at reasonable cost. Since then, many methods have been described to generate linker-scanning mutants by oligonucleotide ligation (Hobson et al. 1996) or PCR (e.g., please see Gustin and Burk 1993; Li and Shapiro 1993; Viville 1994; Harlow et al. 1996; Schanke 1997; Barnhart 1999). These methods save much labor by eliminating the need to generate two sets of deletions with exonucleases. In addition, they allow the investigator to define the length of the linkers and to place them with precision in predetermined locations within the target DNA. However, PCR methods can be both laborious and extensive. For example, the technique described by Gustin and Burk (1993) requires four oligonucleotide primers, three PCRs, and two ligations for each mutant.

More efficient PCR-based methods are based on variations on overlap extension PCR (Higuchi et al. 1988; Ho et al. 1989; Harlow et al. 1994), megaprimer PCR (Schanke 1997), or, for longer scanning mutations, a combination of circular PCR and linker insertion (Barnhart 1999). Figure 13-10 shows two methods based on overlap extension that work efficiently and require two partially complementary mutagenic oligonucleotides per mutation and two common oligonucleotides that are used to amplify all mutants in the canon.

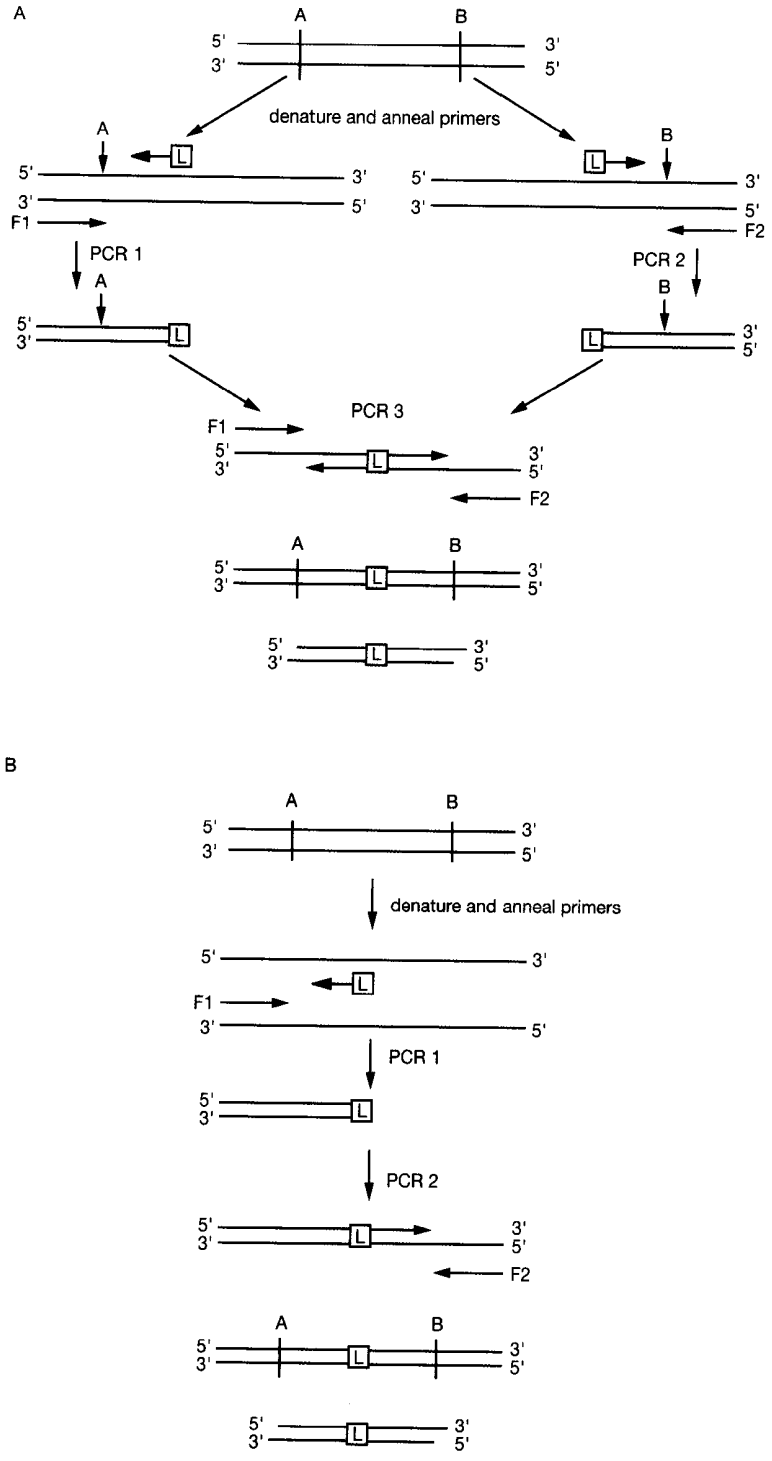

FIGURE 13-10 Linker Scanning

Generation of linker-scanning mutations by PCR. (*A*) In the overlap method, two complementary oligonucleotides carrying linker sequences at the 3′ termini are used to prime PCR 1 and PCR 2. In each case, the second primer (F1 or F2) is complementary to sequences lying outside unique restriction sites (shown as A and B). The products of PCR 1 and PCR 2 are mixed and denatured and used as templates in PCR 3, which is primed by the two flanking oligonucleotides (F1 or F2). The PCR product is then cleaved with restriction enzymes A and B and cloned into a suitable vector. (*B*) In the asymmetric method, PCR is primed by F1 and another primer carrying linker sequences at its 3′ terminus. The products of the reactions are purified and used, together with oligonucleotide F2, to prime PCR 2. The product of PCR 2 is cleaved with restriction enzymes A and B and cloned into a suitable vector. (Modified, with permission, from Harlow et al. 1994.)

RANDOM MUTAGENESIS

Four methods are used to construct multiple mutations into a defined region of cloned DNA: chemical mutagenesis, cassette mutagenesis, misincorporation mutagenesis, and mutagenesis with doped or spiked oligonucleotides.

Chemical Mutagenesis

Chemical mutagenesis, the most venerable method of local randomized mutagenesis, involves exposing a short fragment (<200 bp) of double-stranded DNA to a mutagen, such as nitrous acid, hydroxylamine, bisulfite, or hydrazine (please see Table 13-5). The population of mutagenized fragments is then used to create a small library of recombinant clones that contain a mutagenized fragment in place of the homologous wild-type sequence. Individual recombinants carrying mutations that generate a novel phenotype are identified by appropriate functional tests. The exact location and specific characteristics of the mutations(s) can be ascertained by any one of a number of methods, including DNA sequencing (please see Protocol 7).

Unfortunately, the frequency at which mutants are recovered by chemical mutagenesis can be unacceptably low (Chu et al. 1979; Solnick 1981; Busby et al. 1982; Kadonaga and Knowles 1985). Furthermore, as shown in Table 13-5, most commonly used chemical mutagens react with bases in a specific manner, so that the spectrum of mutations obtained with a single mutagen may be too narrow to allow a comprehensive analysis of a particular segment of a protein (Shortle and Nathans 1978; DiMaio and Nathans 1980; Peden and Nathans 1982). Finally, chemical mutagenesis of double-stranded DNA is highly nonrandom, with regions prone to denaturation being the most vulnerable. This problem can be alleviated, but not

TABLE 13-5 Mode of Action of Commonly Used Chemical Mutagens

MUTAGEN	MODE OF ACTION
Nitrous acid	Reacts with the amines of purines and pyrimidines to generate diazonium derivatives that are rapidly hydrolyzed in aqueous solution to ketonic products. Because the rates of these deamination reactions increase with decreasing pH, mutagenesis with nitrous acid is usually carried out at pH 5.2. guanine→xanthine, which pairs with thymine adenine→hypoxanthine, which pairs with cytidine cytosine→uracil, which pairs with adenine Nitrous acid therefore generates transition mutations, where purines are replaced by purines and pyrimidines are replaced by pyrimidines. Of the three bases, cytosine is deaminated most efficiently and guanine the least efficiently. The relative rates of reaction of cytosine:adenine:guanine are 6:2:1 (Schuster 1960).
Hydroxylamine	Deaminates cytosine at low pH (<pH 2.5) and converts it to uracil. ^{me}5-cytosine, however, is resistant to deamination. At pH 6.0, the deamination of cytosine is incomplete and a stable intermediate product (hydroxyaminocytosine) is formed that can pair with adenine (Lawley 1967). In both cases, the result is a transition mutation where C-G base pairs are converted to A-T.
Bisulfite	Reacts almost exclusively with cytosine, which it deaminates to uracil (Shapiro et al. 1973). Bisulfite and hydroxylamine therefore generate the same type of transition mutations.
Hydrazine	Cleaves the heterocyclic rings of cytosine and thymidine, which leads to hydrolytic depyrimidation of DNA at the site of attack (Brown et al. 1966) The higher the monovalent cation concentration in the reaction, the greater the preference of hydrazine for cytosine. During DNA replication, any of the four bases can be inserted into the daughter strand opposite the apyrimidinic site.

entirely eliminated, by using single-stranded DNAs as substrates for mutagenesis (Greenfield et al. 1975; Shortle and Botstein 1983). The yield of mutants can be increased by transfecting chemically mutagenized DNA into an *ung*$^-$ strain of *E. coli* that lacks uracil *N*-glycosylase and is therefore unable to remove uracil residues generated by deamination (Pine and Huang 1987).

Myers et al. (1985b) introduced methods to treat single-stranded DNA with chemicals that damage all four bases. Here, single-stranded DNA of a recombinant M13 bacteriophage is exposed under defined conditions to chemicals (nitrous acid, formic acid, and hydrazine) that modify bases in single-stranded DNA without breaking the phosphodiester backbone. After removal of the chemicals, a universal sequencing primer and a DNA polymerase are used to synthesize the complementary strand of DNA. When the polymerase encounters damaged bases in the template strand, it incorporates nucleotides essentially at random. Because all possible nucleotides can be incorporated at a single position, there is a 75% probability of mutation at every site of damage. Furthermore, because transversions are generated twice as frequently as transitions, the resulting mutations generate DNAs (and subsequently proteins) with a wide spectrum of changes. After the extension reaction is completed, the double-stranded target fragment is excised and recloned into an appropriate vector. Mutants can be identified directly by DNA sequencing of random clones.

The major problem with Myers' method is the frequency with which useful mutations can be isolated. To prevent the formation of unacceptable numbers of multiple mutants, it is necessary to limit carefully the length of time the single-stranded DNA is exposed to damaging chemicals. However, this requirement means that many of the template strands escape modification altogether. Therefore, the best that can be achieved by this method is a frequency of single mutations of 10–15%. This problem can sometimes be alleviated by using denaturing gradient gel electrophoresis to purify fragments of DNA that carry mutations (Myers et al. 1985b,c) or by using a screening method such as single-stranded DNA conformation analysis (Orita et al. 1989b) to identify rapidly clones that carry mutations. For a comprehensive discussion of methods used in chemical mutagenesis, please see Walton et al. (1991).

Cassette Mutagenesis

In the simplest form of cassette mutagenesis (Wells et al. 1985), a small section of DNA is removed from the wild-type gene and replaced by a synthetic segment of DNA that carries one or more mutations. Cassette mutagenesis can therefore be used to introduce single or multiple amino acids within the target zone. In theory, the method is capable of, for example, generating a canon of mutants encoding all possible amino acid residues at a particular codon or inserting or deleting amino acids at every position.

There are many ways to design pools of oligonucleotides that carry mutations at the desired site(s). A particularly efficient method is to synthesize one strand of the cassette as a pool of oligonucleotides with equal mixtures of all four nucleotides in the first two positions of the target codon and an equal mixture of G and C in the third position (Reidhaar-Olson and Sauer 1988). This composition produces a truncated version of the genetic code that contains only 32 codons and yet encodes the entire set of amino acids (Scott and Smith 1990; Reidhaar-Olson et al. 1991). The second strand of the cassette is synthesized with inosine at each target position. Inosine is able to form base pairs with each of the four conventional bases (Martin et al. 1985). The two strands are then annealed, and the population of mutagenic cassettes is ligated into the open-jawed vector.

The resulting population of doped cassettes will include codons specifying each of the 20 amino acids at each target site(s). However, because of redundancy in the code, some amino acids will be represented more frequently than others, and it may be necessary to sequence many candidates to obtain a complete collection of cassettes. If only a subset of amino acid substitutions is required, it would be worthwhile to consider doping schemes that generate oligonucleotides encoding specific subsets of amino acids and excluding others (e.g., please see Arkin and Youvan 1992).

In cassette mutagenesis, the frequency of particular mutations and of double and triple mutations usually deviates from theoretical predictions. This deviation is probably a result of inequalities in the efficiency with which the four nucleotide precursors are incorporated into the mutagenic cassettes. However, these deviations only become serious when the aim is to isolate a complete sampling of mutations. In this case, it may be better to harvest most of the mutations from the pool and then to complete the set by conventional site-directed mutagenesis.

Misincorporation Mutagenesis

In the early 1980s, suites of mutants were generated by enzymatic incorporation of nucleotide analogs or by misincorporation of normal nucleotides (Müller et al. 1978; Shortle et al. 1982; Zakour and Loeb 1982; Shortle and Botstein 1983; Shortle and Lin 1985). However, the rate of recovery of useful mutations was too low and the distribution of the mutations too biased to allow the assembly of a complete library of mutants. More recently, however, misincorporation mutagenesis has been revived in a more efficient form.

Misincorporation of bases occurs when one of the four nucleotides in an in vitro DNA synthesis reaction is present in a limiting amount (usually 1–10% of the normal concentration). The DNA polymerase, starved of the correct nucleotide, stalls briefly and then inserts one of the three available nucleotides. The synthetic reaction can be catalyzed either by a thermolabile polymerase such as the Klenow fragment (e.g., please see Lehtovaara et al. 1988) or, more efficiently, in a PCR catalyzed by an error-prone thermostable polymerase such as *Taq*. In the latter case, four PCRs are carried out, each depleted for a different nucleotide but containing high concentrations of dITP (Spee et al. 1993; Kuipers 1996). The thermostable DNA polymerase therefore has the option of incorporating an inosine residue at sites requiring the depleted nucleotide or of incorporating one of the three available conventional nucleotides. Because all four natural bases can form base pairs with inosine, there is a theoretical probability of 75% that a mutation will arise during the next PCR cycle at the site of incorporation of inosine. The combination of both types of mutageneses elevates the frequency of mutation approximately tenfold over the already high basal rate of *Taq* polymerase (5×10^{-4}). The frequency of mutation can be further elevated by including Mn^{2+} at a concentration of 0.5 mM in the PCR buffer (Leung et al. 1989).

Spiked Oligonucleotide Primers

Random mutations in short (<80-nucleotide) regions of DNA can be constructed using spiked oligonucleotides as primers in the classic method of oligonucleotide-mediated mutagenesis (e.g., please see Hermes et al. 1989; Dale et al. 1991; Dale and Belfield 1996). Spiked oligonucleotides are synthesized on an automated DNA synthesizer by mixing each of the phosphoamidite precursors with a mixture of the other three bases. The frequency of mutations depends on the degree of spiking oligonucleotide primers, which can be adjusted by the investigator (Dale and Belfield 1996). In theory, spiked oligonucleotide primers should generate a truly random distribution of mutations. In practice, this degree of perfection is not achieved, perhaps because oligonucleotides that differ in sequence — even by as little as one nucleotide — prime with different efficiencies, perhaps as a consequence of differences in secondary structure.

ALANINE-SCANNING MUTAGENESIS

Alanine-scanning mutagenesis is a scheme to change the surface residues of a protein while preserving its underlying three-dimensional structure. The technique was originally designed to map the surfaces of a protein that are involved in interactions with other proteins or small ligands (Cunningham and Wells 1989; Bass et al. 1991; Wells 1991). The amino acid sequence of the protein was surveyed for clusters of highly charged residues, typically Arg, Lys, Asp, and Glu. The side chains of these residues are usually exposed to solvent on the surface of proteins where they can contribute to interactions with substrates, inhibitors, and other ligands, including proteins. Site-directed mutagenesis was then used to delete (or truncate) these wild-type side chains and replace them with a chemically inert side chain that does not extend beyond the β-carbon. The substitution of innocuous alanine for charged residues on the surface generally does not disrupt folding of the core of the protein. However, the absence of polar groups from critical locations may severely compromise functions of the protein that involve residues on the surface.

Alanine-scanning mutagenesis of charged amino acids generates a systematic set of mutant proteins that can be assayed for loss of function and avoids the necessity of generating, sequencing, and characterizing a large library of random mutants. Even so, the number of mutants generated by a comprehensive alanine scan can be formidable. For example, scanning the surface of tissue-plasminogen activator, a 527-amino-acid protein, involved the conversion of some 134 charged amino acids to alanine residues (Bennett et al. 1991). To reduce the amount of work, charged amino acids were collected into arbitrary clusters. Each cluster contained Arg, Lys, Asp, Glu, and His residues that lie within five residues of each other in the primary sequence. The charged amino acids in each of these clusters were simultaneously changed to alanine residues by oligonucleotide-mediated site-directed mutagenesis. This strategy generated a total of 64 mutants (12 single mutants, 35 doubles, 12 triples, and 5 quadruples), which were then expressed and assayed. The decision to include histidine residues in this alanine scan is questionable. Although its pK is near neutrality, the charged group of histidine is often involved in binding the buried charge of another reactive group (Richardson and Richardson 1989). Substitution of histidine by alanine may therefore destabilize the protein or result in other undesirable structural changes in the mutant protein.

Alanine scanning is not for the faint-hearted. The surveying power of the method depends on the breadth of its synoptic coverage. However, comprehensive scrutiny of charged residues, or even of charged clusters, on the surface of a moderate-sized protein may require the generation, expression, and assay of many mutants. Perhaps for this reason, alanine scanning of entire proteins has been used chiefly by commercial companies. Genentech developed a technique whereby alanine scanning is used to define functional motifs involved in catalysis and substrate binding of yeast cAMP-dependent protein kinase (Gibbs and Zoller 1991), to identify residues required for binding of interleukin 8 to its receptor (Hébert et al. 1991), to identify hormone-binding determinants in the human growth hormone receptor (Bass et al. 1991; for review, please see Wells 1996), to map antigenic epitopes on human growth factor (Jin et al. 1992), and to assign certain functions to particular structural domains of tissue-plasminogen activator (Bennett et al. 1991).

Academic laboratories have used the technique in a more limited way, for example, to produce detailed maps of functional residues in individual domains or subdomains of proteins and to evaluate the contribution of different side chains to the stability and folding of particular domains in proteins of known structure. For purposes such as these, alanine scanning remains the method of choice; papers founded on the technique continue to be published at the rate of several a month.

MUTAGENIC OLIGONUCLEOTIDES

All methods for site-directed mutagenesis require the use of one or more mutagenic oligonucleotides to alter the target sequence. If these oligonucleotides are correctly designed, the desired mutants will be produced with ease and efficiency. If not, the yield of mutants may be unacceptably low. Oligonucleotides used for conventional (non-PCR) site-directed mutagenesis must:

- ***Be complementary to the appropriate strand of the target DNA.***
- ***Be sufficiently long (>20 nucleotides) to anneal specifically to the target sequences.*** Primers carrying two or more base substitutions should be at least 25 nucleotides in length.
- ***Carry the mismatched base(s) in the center,*** thus providing 10–15 bases on either side that perfectly match the template strand. Efficient introduction of insertions, deletions, or substitutions >3 nucleotides in size require primers that have as much as 30 nucleotides complementary to the template on each side of the mutation's site. Whenever possible, the calculated thermal stabilities of the duplexes formed between the target DNA and the 5′- and 3′-terminal regions of the mutagenic oligonucleotide should be equal to one another. For information on calculating the melting temperature of oligonucleotides, please see the introduction to Chapter 10.
- ***Contain a 5′-terminal region that forms a perfect hybrid with the template,*** so that DNA synthesis initiated from an upstream primer does not easily displace the mutagenic oligonucleotide. Approximately eight to ten perfectly matched nucleotides are required to suppress displacement of the oligonucleotide by the Klenow fragment. Displacement can also be prevented by using enzymes such as bacteriophage T4 DNA polymerase (Nossal 1974; Kunkel 1985), which have no 5′-3′ exonuclease activity, or Sequenase (Schena 1989), which cannot readily remove the hybridized mutagenic primer from its template.
- ***Form a hybrid sufficiently stable to allow efficient priming of DNA synthesis*** from the 3′ terminus of the oligonucleotide. If the mismatched nucleotide is too close to the 3′ terminus, the 3′ segment of the oligonucleotide will be unable to form a stable hybrid with the target DNA and will therefore be susceptible to exonucleolytic degradation if, for example, the Klenow fragment is used in the primer-extension reaction (Gillam and Smith 1979a,b). In addition, an increase in the frequency of priming at incorrect locations might occur because the unhybridized 3′ region of the mutagenic oligonucleotide is now free to anneal to incorrect sites on the template. To suppress these effects, between 10 and 15 perfectly matched nucleotides are required at the 3′ terminus of the mutagenic oligonucleotide.
- ***Be free of palindromic, reiterated, or self-complementary sequences*** that might form stable structures. The greater the potential for such structures, the lower the efficiency with which the oligonucleotide will hybridize to its target sequence in the template DNA. In extremely rare cases, the secondary structure of the oligonucleotide (or its complementary target sequence) is so great that mutants cannot be obtained. Under such circumstances, it may be necessary to carry out mutagenesis with a much longer synthetic oligonucleotide whose 5′ and 3′ termini extend well beyond (15–20 nucleotides) the problem region. Screening recombinants for the desired mutants is then carried out with a much smaller oligonucleotide (17–19 nucleotides) that carries the potentially mismatched bases in the central position.

The same general guidelines apply when designing primers for use in PCR-based methods of site-directed mutagenesis. However, an additional design feature is required when using a DNA polymerase such as *Taq* that catalyzes the template-independent addition of a nucleotide (usually adenosine) to the 3′ terminus of the amplified product (please see the information panel on **TAQ DNA POLYMERASE** in Chapter 8). In many cases, the additional nucleotide will not be complementary to the template strand. To restore the correspondence between the PCR product and the target DNA, the oligonucleotide should be designed so that its 5′ end is immediately preceded on the template strand by a deoxythymidine residue (Kuipers et al. 1991). An adenosine residue added by the DNA polymerase does not change the amino acid sequence and does not interfere with the use of the amplified DNA as a megaprimer in a subsequent round of PCR.

In many cases, mutagenic oligonucleotides can be designed so as to introduce a new restriction site or eliminate an existing site located close to the site of mutation. This strategy allows candidate clones to be screened by restriction enzyme cleavage and thereby facilitates identification of mutants. A computer pro-

gram entitled Primer Generator permits investigators to determine whether an oligonucleotide can be designed that both introduces a desired mutation and alters a nearby restriction site (Turchin and Lawler 1999). An alternative more powerful option that is independent of the DNA sequence near the site of mutation uses two primers: one to mutagenize the target site and another to remove a nonessential unique restriction site in the flanking vector sequences (Deng and Nickoloff 1992). This method can be extended to build both mutations into a single long "megaprimer" that can be used in a second PCR to generate a large amount of mutated double-stranded DNA (Kammann et al. 1989; Landt et al. 1990; Sarkar and Sommer 1990, 1992; Ke and Madison 1997).

The sequence of mutagenic oligonucleotides should be analyzed for the ability to form fortuitous, stable hybrids with regions of the template molecules other than the target sequences. Most commonly available programs for computer analysis of DNA sequences can be used to scan potential mutagenic primers for features such as hairpin formation, dimer formation, potential false annealing sites, position and number of mutations/insertions, melting temperature, and stability of 5′ and 3′ ends. Some programs can calculate the predicted stability (ΔG) of 5-bp windows across the length of an oligonucleotide-template hybrid. Oligonucleotides whose 3′ pentamers have ΔG values between −6 and −10 kcal/mole usually provide the maximum yield of mutations (Piechocki and Hines 1994), presumably because the hybrids formed by their 3′ ends (1) are stable enough to compensate for the mismatch(es) in the center of the oligonucleotide but (2) are sufficiently unstable to suppress false priming from unwanted sites.

If necessary, the specificity of hybridization of the mutagenic oligonucleotide can be checked either in a DNA-sequencing reaction in which the oligonucleotide is used as a primer or by extending the primer in the presence of a small amount of one labeled dNTP and four unlabeled dNTPs and then digesting the product with appropriate restriction enzymes. The pattern of radioactive bands will reveal whether priming has occurred at the desired site and the length to which the primer has been extended (Zoller and Smith 1984). However, tests of this type are generally carried out only when difficulties are encountered in obtaining the desired mutation.

In general, the larger the size of the mutation to be constructed, the lower the efficiency of oligonucleotide-directed mutagenesis. For example, large deletions (i.e., deletions of several hundred nucleotides) are generated with ~50-fold lower efficiency than mutations involving only local changes in sequence. This inefficiency stems from two sources. First, the ability of the mutagenic oligonucleotide to form stable hybrids with two separate sequences on the template DNA decreases as a function of the distance between the two sequences. Second, there is an increased probability that the oligonucleotide will hybridize to incorrect sequences on the template DNA. The consequence of these effects is that the efficiency of "loop-in/loop-out" mutagenesis is far lower than the efficiency of mutagenesis of one or two contiguous nucleotides. Furthermore, the proportion of clones that carry alterations at ectopic sites is greatly increased. For these reasons, it is often necessary to screen putative loop-in/loop-out mutants by hybridization with oligonucleotides that are complementary to the desired deletion/insertion junction ("positive probes") and with oligonucleotides that are complementary to the deleted sequence or the starting insertion point ("negative probes") (please see Thigpen and Russell 1992). Finally, because of the high frequency with which incorrect mutations are created, it is essential to determine the complete sequence of the mutagenized DNA (not just the region that is the planned target).

SELECTING AGAINST WILD-TYPE DNA IN SITE-DIRECTED MUTAGENESIS

The frequency of mutations generated by oligonucleotide-mediated mutagenesis varies from >0.1% to nearly 50%, depending on the complexity of the mutation and the underlying efficiency of the method used. In classical oligonucleotide-mediated mutagenesis, a fraction of the wild-type bacteriophage M13, phagemid, or plasmid DNA will escape mutation and will generate nonmutant colonies or plaques, sometimes in considerable numbers. A similar problem arises in PCR-based mutagenesis when double-stranded plasmid DNAs are used as templates (e.g., please see Weiner and Costa 1994; Weiner et al. 1994; Costa et al. 1996).

To alleviate these difficulties, methods have been developed to destroy nonmutant DNAs selectively in vitro or suppress the growth of wild-type clones. In both cases, the net effect is to increase the proportion of mutant clones in the recombinants recovered after site-directed mutagenesis. These selective methods are of particular value when attempting to isolate "difficult" mutants that are generated with low efficiency in primer extension or PCRs (e.g., large deletion mutants and multiple point mutants) or when using pools of oligonucleotides to generate many mutants simultaneously at a defined location in the target DNA.

Selection In Vitro

Destruction of Parental Template with DpnI

The restriction enzyme *Dpn*I cleaves double-stranded DNA specifically at the methylated sequence $G^{m6}ATC$ (Lacks and Greenberg 1975, 1977; Geier and Modrich 1979). Plasmid and bacteriophage DNAs isolated from almost all commonly used strains of *E. coli* have been fully methylated in vivo by the endogenous Dam methylase and are therefore sensitive to cleavage by *Dpn*I (McClelland and Nelson 1988). Hemimethylated DNAs are cleaved by *Dpn*I at somewhat lower efficiency. By contrast, DNA synthesized in vitro using the four conventional deoxynucleotides is unmethylated and therefore completely resistant to cleavage. Consequently, *Dpn*I can be used at the end of site-directed mutagenesis to degrade residual methylated wild-type templates and to enrich for unmethylated DNAs synthesized in vitro. Selective destruction of parental templates by *Dpn*I is used chiefly as a method to disinfect double-stranded DNAs synthesized during PCR-based mutagenesis (e.g., please see Ponce and Micol 1992; Weiner and Costa 1994; Costa et al. 1996; Wang and Malcolm 1999).

Another way to achieve biochemical discrimination against the template strand is to incorporate methylated nucleoside triphosphate into the mutant strand during synthesis in vitro. The mutant strand will then be protected against digestion with restriction enzymes such as *Hha*I, *Sau*3AI, and *Msp*I, which will degrade the unmodified parental template DNA into small fragments (e.g., please see Vandeyar et al. 1988; Hofer and Kühlein 1993).

Destruction of Parental Template with Uracil-DNA Glycosylase: The Kunkel Method

Single-stranded templates of bacteriophage M13 DNA, generated in a strain of *E. coli* carrying *ung*$^-$ *dut*$^-$ mutations (please see the panels on ***DUT*** and ***UNG***) contain 20–30 uracil residues in place of thymines (Sagher and Strauss 1983). When this DNA is used as a template in a classical mutagenesis procedure, the product is a heteroduplex molecule with uracil in the wild-type strand and thymine in the strand synthesized in vitro. Exposure of the heteroduplex to uracil-DNA glycosylase, either in vitro or after transfection of the DNA into an *ung*$^+$ strain, results in removal of the uracil and cleavage of the phosphodiester backbone at the resulting apyrimidinic sites. These lethal lesions result in selective and efficient destruction of the template strand and a reduction in infectivity of approximately five orders of magnitude. A large proportion (up to 80%) of the bacteriophage plaques are therefore derived by replication of the transfecting, uracil-free (–) strand. Because synthesis of this strand is primed by the mutagenic oligonucleotide, many of the progeny bacteriophages carry the desired mutation.

The Kunkel method has changed very little since its introduction (Kunkel 1985; for review, please see Kunkel et al. 1991). Perhaps the one significant improvement is the extension of the technique to include double-stranded templates derived from phagemids (McClary et al. 1989; Wang et al. 1989; Liu et al. 1990; for review, please see Hagemeier 1996) and plasmids (Jung et al. 1992). This improvement eliminates the need to subclone the fragment of interest into single-stranded vectors before mutagenesis. However, the

yield of mutants is generally rather low and additional steps are often required to reduce the backround of wild-type phagemids or plasmids. In addition, because the inserts that can be propagated in double-stranded vectors are larger, significantly more DNA sequencing may be required to confirm the mutation(s) of interest and to verify that no mutations have arisen anywhere else within the target DNA.

DUT

The *dut* gene of *E. coli* encodes dUTPase, a zinc-containing tetrameric pyrophosphatase (M_r = 64,000) (Shlomai and Kornberg 1978; Lundberg et al. 1983). In *dut* mutants, the cell's ability to convert dUTP to dUMP is impaired. This decrease results in a 25–30-fold increase in the intracellular pool of dUTP. The elevated ratio of dUTP:dTTP leads to an increase in the frequency of misincorporation of dUTP at a random subset of the sites normally occupied by thymine.

The *dut*$^-$ mutants of *E. coli* used in the Kunkel method all contain a trace of dUTPase activity (Konrad and Lehman 1975; Hochhauser and Weiss 1978), perhaps because a complete lack of the enzyme is lethal (el-Hajj et al. 1988). Viable *dut*$^-$ mutants show increased rates of recombination and spontaneous mutation, which result from the temporary strand breaks and gaps in DNA caused by excision of the uracil residues by uracil-DNA glycosylase, encoded by the *ung* gene.

UNG

Uracil residues incorporated into DNA in *E. coli* are normally removed by the small monomeric enzyme uracil-DNA glycosylase (deduced M_r = 25,664) which cleaves the *N*-glycosydic bond between the base and the deoxyribose phosphate backbone, generating an apyrimidinic site (Lindahl 1974; for review, please see Lindahl 1982; Tomilin and Aprelikova 1989). The phosphodiester backbone at these sites is cleaved by endonucleases (exonuclease III or endonuclease IV) (for review, please see Lloyd and Linn 1993) and then repaired by DNA polymerase I and ligase. Cells deficient in uracil-DNA glycosylase cannot cleave the *N*-glycosydic bond and display increased rates of spontaneous mutation which are biased toward G:C→A:T transitions (Duncan and Miller 1980; Duncan and Weiss 1982).

The *ung* gene of *E. coli* has been cloned (Duncan and Chambers 1984), as have highly conserved *ung* genes from many other organisms including yeast, humans, and herpesviruses (for references, please see Olsen et al. 1991; Lloyd and Linn 1993). These genes probably evolved to remove mutagenic deaminated cytosine residues from DNA.

Unique Restriction Site Elimination

Unique site elimination (USE) is employed in classical oligonucleotide-directed mutagenesis to digest unmutated double-stranded plasmid DNAs that carry a unique restriction site in a nonessential region (Deng and Nickoloff 1992). In this method, two primers are hybridized simultaneously to the denatured template DNA and one primer introduces the desired mutation in the target DNA; the other destroys the unique restriction site in the plasmid. After the in vitro mutagenesis reaction is completed, the plasmid DNA is used to transform a strain of *E. coli* that is deficient in correcting mismatched bases, for example, a strain carrying a *mutS*$^-$ mutation. The mismatched base pairs in the heteroduplex DNA are resolved by replication, rather than repair. The plasmid DNA prepared from pooled transformants is then digested with the restriction enzyme that cleaves wild-type DNA at the unique site. Plasmids that have escaped mutagenesis will be cleaved by the enzyme into linear DNA, which transforms *E. coli* inefficiently. Mutant plasmids, on the other hand, are resistant to digestion, retain full transforming ability, and are efficiently recovered after transformation of a *mutS*$^+$ strain of *E. coli* (Deng and Nickoloff 1992; Ogretman et al. 1996).

The USE method works with increased efficiency if the two mutations can be combined into a single primer, which may be synthesized de novo or, more commonly, generated by PCR. This application is especially useful (1) if the restriction site used for selection is *Bam*HI, *Bgl*II, or *Pvu*II; the restriction site selection based on these enzyme recognition sites, for unknown reasons, does not work well when two separate mutagenic primers are used or (2) if the plasmid used as template is large (>6 kb). For more information, please see instructions provided by the manufacturers of USE mutagenesis kits (e.g., Amersham-Pharmacia) (please see the information panel on **COMMERCIAL KITS FOR SITE-DIRECTED MUTAGENESIS**).

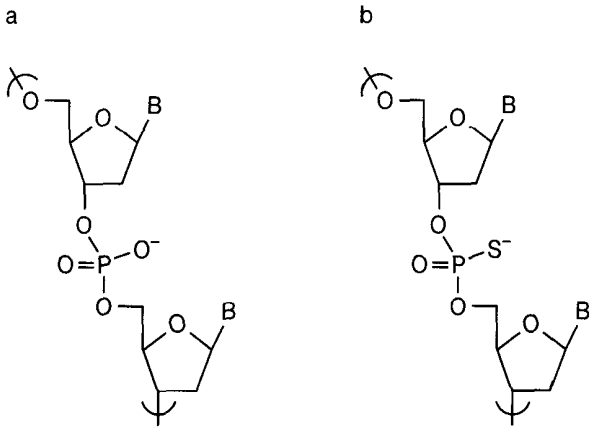

FIGURE 13-11 Structure of Phosphorothioate-containing Oligonucleotide

Phosphorothioate analogs of DNA and RNA contain a sulfur atom in place of oxygen in the phosphodiester linkage between bases. (*a*) Structure of the normal phosphodiester linkage; (*b*) structure of the phosphorothioate-containing linkage. (Redrawn, with permission, from TriLink BioTechnologies, Inc.)

Incorporation of Phosphorothioate Analogs into the Mutant Strand

Phosphorothioate analogs of DNA and RNA contain a sulfur atom in place of a nonbridging oxygen at one or more of the linkages between adjacent nucleotides (for review, please see Eckstein 1985; Zon and Geiser 1991). Nucleic acids containing phosphorothioate internucleotide links can be synthesized in vitro by DNA and RNA polymerases in reactions containing nucleoside phosphorothioates as substrates (available from Synthegen or Applied Biosystems). When supplied with S_p-diastereomers of dNTP-S or NTP-S, both types of polymerases efficiently catalyze the formation of phosphorothioate internucleotide linkages exclusively in the R_p-diastereomeric configuration (for review, please see Eckstein and Gish 1989). Incorporation of nucleoside phosphorothioates into a growing DNA or RNA chain therefore involves net inversion of configuration at the bridging phosphorus atom (please see Figure 13-11) (Eckstein 1985).

Phosphorothioate-containing DNAs and RNAs are very similar in structure to conventional nucleic acids. However, the presence of a sulfur atom with a larger van der Waals radius, lower electronegativity, and reduced ability to form multiple bonds results in useful changes in chemical properties that can be harnessed for a variety of purposes in molecular biology and molecular cloning. For example, because of the reduced electrophilicity of the sulfur atom, phosphorothioate linkages in DNA and RNA are resistant to hydrolysis by certain nucleases, with the degree of resistance being dependent on the particular nuclease, the stereochemistry of the phosphorothioate linkage, its distance from the scissile bond, and the type of metal cofactor required by the enzyme.

Phosphorothioates may be used to increase the efficiency of oligonucleotide-directed mutagenesis of both single-stranded templates (Taylor et al. 1985; Nakamaye and Eckstein 1986; Sayers et al. 1988a,b, 1992; Sayers and Eckstein 1989, 1991, Sugimoto et al. 1989) and double-stranded templates (Olsen and Eckstein 1990, 1991). In the case of single-stranded templates, a mismatched oligonucleotide primer is annealed to a single-stranded DNA template as described by Zoller and Smith (1983). The primer is extended by a polymerization reaction catalyzed by bacteriophage T7 DNA polymerase or the Klenow fragment. In this reaction, one of the conventional dNTPs (usually dCTP) is replaced by the corresponding dNTP-S. The resulting heteroduplex therefore consists of a template strand whose backbone contains conventional phosphodiester bonds and a mutated (+) strand that carries phosphorothioate internucleotidic linkages to the 5′ side of all dC residues apart from those contributed by the mutagenic oligonucleotide primer. Incubation of the heteroduplex with a restriction enzyme (usually *NciI* or *AvaI*) results in a partial reaction in which the template strand is selectively nicked. The strand carrying phosphorothioate residues is resistant to digestion by the restriction enzyme. The nicks in the template strand are extended by reaction with an exonuclease (exonuclease III, T7 exonuclease, or λ exonuclease). The gap generated in this way is then filled in a second

polymerization reaction in which the mutant (+) strand is used as a template. Because the mutation is now carried on both strands of the DNA, >90% of the plaques generated after transfection consist exclusively of the desired mutant.

When this technique was first developed, the choice of restriction enzymes was limited to those that generated nicked heteroduplexes when presented with substrates that had been asymmetrically labeled with phosphorothioates (Sayers et al. 1988a). However, the number of suitable enzymes is enlarged when the nicking reaction is carried out in the presence of ethidium bromide. Under these conditions, many restriction enzymes introduce nicks into the strand consisting of conventional phosphodiester bonds but are unable to cleave the strand containing phosphorothioate residues (Sayers et al. 1988b; Sayers and Eckstein 1991).

When oligonucleotide-directed mutagenesis is carried out on double-stranded DNA templates, exonuclease digestion is used to generate a region of single-stranded DNA to which the mutagenic oligonucleotide can efficiently anneal. Following polymerization in the presence of three dNTPs and one dNTP-S, a restriction enzyme is used to introduce nicks into the wild-type strand, which contains only conventional phosphodiester bonds. After the nick has been expanded as described above, a second round of polymerization is used to generate a homoduplex that carries the desired mutation in both strands (Olsen and Eckstein 1990, 1991).

Selection In Vivo

Two primers are hybridized simultaneously to the denatured template DNA; one primer introduces the desired mutation in the target DNA and the other repairs a mutation in an antibiotic resistance gene carried in the vector. After the in vitro mutagenesis reaction is completed, the resulting heteroduplex DNA is used to transform a strain of *E. coli* that is deficient in correcting the mismatched base, for example, a strain carrying a *mutS*$^-$ mutation. The mismatched base pairs in the heteroduplex DNA are resolved by replication, rather than repair. A fraction of the plasmids recovered from the *mutS*$^-$ transformants will then carry the desired mutation and a newly functional antibiotic resistance gene. These plasmids are then recovered in a second round of transformation — this time into a mismatch-repair competent host — with selection for the restored antibiotic resistance gene (Lewis and Thompson 1990; Hashimoto-Gotoh et al. 1995; Postina and Fahrenholz 1995; Bohnsack 1996).

N^6-METHYLADENINE, DAM METHYLASE, AND METHYLATION-SENSITIVE RESTRICTION ENZYMES

Methylation of Adenine Residues by Dam Methylase

In *E. coli*, adenine residues embedded in the sequence $^{5'}$.....GATC.....$^{3'}$ carry a methyl group attached to the N^6 atom (Hattman et al. 1978). More than 99% of these modified adenine bases, which are found on both strands of the palindromic recognition sequence, are formed by action of DNA adenine methylase (*dam*), a single-subunit nucleotide-independent (type II) DNA methyltransferase that transfers a methyl group from *S*-adenosylmethionine to adenine residues in the recognition sequence (Geier and Modrich 1979; for reviews, please see Marinus 1987; Palmer and Marinus 1994).

The recognition sites of several restriction enzymes (including *Pvu*I, *Bam*HI, *Bcl*I, *Bgl*II, *Xho*II, *Mbo*I, and *Sau*3AI) contain the sequence $^{5'}$.....GATC.....$^{3'}$, as do a proportion of the sites recognized by *Cla*I (~1 site in 4), *Xba*I (1 site in 16), *Mbo*II (1 site in 16), *Taq*I (1 site in 16), and *Hph*I (1 site in 16). The transfer of a methyl group to the N^6 atom of adenine places a bulky alkyl substituent in the major groove of B-form DNA and completely prevents cleavage in vitro by some restriction enzymes (e.g., *Mbo*I; Dreiseikelmann et al. 1979). Other restriction enzymes will at best cleave a subset of their recognition sites. For example, *Cla*I recognizes the sequence $^{5'}$ATCGAT$^{3'}$. If this sequence is preceded by G, followed by C, or both, either or both of the A residues will be methylated and the site protected from cleavage. However, methylation does not endow the sequence GATC with absolute immunity from cleavage by any and all restriction enzymes. For example, the restriction enzyme *Sau*3AI, an isoschizomer of *Mbo*I, cleaves –GATC– sequences regardless of

their state of adenine methylation, whereas the enzyme *Dpn*I specifically cleaves fully methylated –G^{me6}ATC– sequences (Lacks and Greenberg 1975, 1977; Geier and Modrich 1979). DNAs modified by *dam* methylase in vitro also remain sensitive to restriction by the *E. coli mcr* and *mrr* systems. Mammalian DNA is not methylated at the N^6 position of adenine and therefore can be cleaved to completion by restriction enzymes that are sensitive to *dam* methylation of prokaryotic DNA.

Lists of restriction enzymes whose pattern of cleavage is affected by *dam* methylation have been assembled by Kessler and Manta (1990) and McClelland and Nelson (1988); additional information may be found in the brochures of most commercial suppliers of enzymes and in a database of restriction and modification enzymes (REBASE) accessible via the Internet at:

http:// www.neb.com/rebase/rebase.html

When it is necessary to cleave prokaryotic DNA at every possible site with restriction enzymes that are sensitive to dam methylation, the DNA must be isolated from strains of *E. coli* that are *dam*$^-$ (Marinus 1973; Backman 1980; Roberts et al. 1980; McClelland and Nelson 1988). These strains (e.g., GM2163 is available from New England Biolabs and JM110 from the ATCC) exhibit a quirky phenotype, including elevated rates of spontaneous mutation and recombination, increased sensitivity to UV irradiation, high rates of recombination, and increased rates of induction of lysogenic bacteriophages (for discussion, please see Marinus 1987; Palmer and Marinus 1994). *dam*$^-$ strains are generally less robust than wild-type K-12 strains because deficiency of *dam* impairs the ability of the mismatch repair system to correct errors in the progeny strand of newly replicated DNA (Lu et al. 1983; Pukkila et al. 1983; for reviews, please see Modrich 1989; Palmer and Marinus 1994). The absence of *dam* methylation therefore leads to increased rates of spontaneous mutation. *dam*$^-$ strains may also exhibit aberrant regulation of certain classes of genes and a reduced efficiency of initiation of DNA replication. Because of these problems, *dam*$^-$ strains should not be grown for long periods in continuous culture or stored on plates or stab cultures for long periods. Instead, these strains should be stored in small aliquots at –70°C. In some *E. coli* strains, maintenance of the *dam* mutation is enhanced by growing the cells in the presence of chloramphenicol or kanamycin. In these strains, the *dam* gene was inactivated by insertion of the transposon Tn*9*, which encodes chloramphenicol resistance (Marinus et al. 1983), or by replacement of part of the gene with a DNA fragment carrying a *kan*^{r} marker to inactivate the *dam* gene (Parker and Marinus 1988). A list of commonly used *dam*$^-$ strains has been published by Palmer and Marinus (1994).

Unmethylated and Hemimethylated Adenine Residues in GATC

In some strains of *E. coli*, a small fraction (~0.2% or less) of the estimated 18,000 $^{5'}$.....GATC.....$^{3'}$ sequences are unmethylated (Ringquist and Smith 1992). These unmodified sites appear to be preferentially located near the origin of replication or in regions of genomic DNA that are protected from *dam* methylation in vivo by DNA-binding proteins (e.g., cAMP receptor protein) (Ringquist and Smith 1992; Wang and Church 1992; Hale et al. 1994).

The unique origin of replication in the chromosome of *E. coli* (*oriC*) is highly enriched in GATC sequences. The time of initiation of DNA synthesis is controlled by a number of factors, including the state of methylation of these sequences (for review, please see Crooke 1995). Punctual and timely initiation requires that these *oriC*-proximal GATC sequences be fully methylated by the Dam nuclease. Semiconservative replication generates hemimethylated GATC sequences, which become bound to the bacterial membrane, where they are no longer accessible to Dam methylase. Before the next round of DNA synthesis is initiated, the *oriC* region is released from the membrane and the local GATC sites once again become fully methylated. How these processes are coordinated is not fully understood.

GLYCEROL

Glycerol (please see Figure 13-12) is used for several purposes in molecular cloning, including:

- ***For stabilization of enzymes.*** Most enzymes are supplied by commercial manufacturers in buffers containing 50% glycerol, which allows the preparations to be stored at –20°C without freezing. Glycerols and other polyols are thought to exert their effects by stabilizing protein-protein interactions. Glycerol is therefore widely used to generate continuous density gradients for the analysis of the composition and molecular weights of protein complexes.
- ***In gel-loading buffers.*** Glycerol is used to increase the density of gel-loading buffers and thereby facilitate the loading of nucleic acids and proteins into the slots of agarose and polyacrylamide gels.

  High concentration of glycerol (>8%) in samples applied to DNA sequencing gels, however, generate bends in the sequencing tracks and blurring of bands >300 bases in size (Tabor and Richardson 1987). This smearing is almost certainly because glycerol reacts with boric acid in the gel-running buffer to form negatively charged esters that migrate through the gel during electrophoresis (Böeseken 1949). This problem can be solved in several ways (Pisa-Williamson and Fuller 1992):

  Diluting the DNA polymerase into buffers that do not contain glycerol.

  Replacing boric acid in the gel and in the running buffer with taurine, a weak aminosulfonic acid with a pK_a similar to that of boric acid. Taurine/EDTA/Tris buffer consists of 1.78 M Tris, 0.57 M taurine, and 0.01 M EDTA. A 20x solution therefore contains 216 g of Tris, 72 g of taurine, and 2 g of EDTA per liter.

  Precipitating the products of the sequencing reaction with ethanol before loading onto the gel.

- ***In polyacrylamide gels.*** Glycerol is included in some types of nondenaturing polyacrylamide gels to improve the electrophoretic separation of conformers of single-stranded DNA molecules during analysis of mutations by SSCP (Glavac and Dean 1993).

  The reasons for the beneficial effects of glycerol, which are most evident when SSCP gels are run at room temperature, are unclear. Kukita et al. (1997) showed that the pH of the gel buffer is lowered from 8.4 to 7.7 by the addition of glycerol, which reacts with the borate ions in TBE. However, it is difficult to see how this effect could explain the temperature-dependent improvement in resolution of single-stranded conformers. Hayashi (1991) proposed that glycerol and other polyols such as sucrose and polyethylene glycol (Markoff et al. 1997) are weak denaturants, whose polar OH groups disrupt the filigree of hydrogen bonding in single-stranded conformers. This explanation is consistent with the observation that glycerol preferentially increases the mobility of conformers that are rich in purines.

- ***For glycerol boosts that increase the efficiency*** of transient expression and transformation of mammalian cells. Transfected cultures are exposed briefly to 15–20% glycerol in isotonic saline (Frost and Williams 1978; Parker and Stark 1979). Glycerol is toxic, but the speed and efficiency of its poisonous effects vary widely from one type of cell to another. The optimal time, length, and intensity of treatment must therefore be determined empirically for each cell line.

- ***In glycerol step gradients*** (Vande Woude et al. 1979), which are used as a faster and cheaper alternative to CsCl step gradients (Yamamoto et al. 1970) in the large-scale purification of bacteriophage λ particles. Pure glycerol has a density of 1.26 g/ml, which is hardly sufficient to support bacteriophage λ particles (density ~1.40 g/ml). Glycerol step gradients are therefore centrifuged only for sufficient time to concentrate the virus particles at one of the steps.

- ***For long-term storage of bacterial stocks.*** Bacterial cultures can be stored indefinitely at –70°C without significant loss of viability in media containing 15% (v/v) of glycerol.

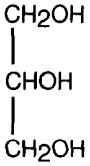

FIGURE 13-12 Structure of Glycerol

MUTATION DETECTION

Detection of mutations is essential for the molecular analysis of inherited diseases of humans, for positional cloning of the genes that cause such diseases, and more generally, to correlate phenotype with genotype in organisms as diverse as mice and slime molds. In mutation detection, proband DNAs are tested for differences from a reference (wild-type DNA). At present, DNA sequencing is the only method capable of detecting and identifying single-base mutations with certainty and precision. However, because sequencing of kilobase lengths of DNA is expensive, slow, and dreary, many different techniques have been developed to localize mutations and hence reduce sequencing to a minimum. The existing tests differ widely in their power of ascertainment, accuracy, speed, and cost, and each only detects a subset of mutations. At present, therefore, detection and localization of uncharacterized mutations often require the sequential application of two or more tests, followed by confirmatory DNA sequencing. Tests to detect mutations can be divided into two categories: scanning methods and specific methods.

Scanning methods are used to search segments of DNA for uncharacterized mutations. Three types of scanning tests are in common use:

- ***Tests based on differences*** in electrophoretic migration between mutant and reference (wild-type) DNAs. Included in this class are denaturing gradient gel electrophoresis (DGGE) and single-stranded conformational polymorphism (SSCP). These tests, which are simple and cheap, are typically used to localize mutations to segments of DNA ~200 bp in length.
- ***Tests based on detection*** of sequence changes in concert with electrophoretic migration differences. Two fingerprinting strategies have been described that use SSCP to resolve differences generated either by the creation or loss of a dideoxy termination site, known as dideoxy fingerprinting (ddF) or bidirectional dideoxy fingerprinting (Bi-ddF), or by the creation or loss of a restriction endonuclease recognition site, known as restriction endonuclease fingerprinting (REF). In general, the fingerprinting methods are more difficult and expensive, but they are capable of mapping mutations with a resolution of ~10 bp, and thus are easily confirmed by sequencing.
- ***Tests based on chemical cleavage*** of mismatched bases (CCM) in heteroduplexes formed between reference and mutant nucleic acids. Such mismatches can be cleaved by enzymes such as RNases, DNA repair enzymes, and resolvases or by chemicals such as hydroxylamine and osmium tetroxide. These tests can be used to scan segments of nucleic acids up to 1.5 kb in length and can ascertain the position of the mutation with accuracy. However, enzymatic tests detect different types of mismatches with different efficiencies, and the extent of cleavage is often dependent on local context. CCM is more dependable but requires toxic chemicals, which must be handled in an appropriately vented chemical fume hood.

Specific methods are used to ascertain whether a previously characterized mutation is present in a particular proband DNA. These methods include hybridization to allele-specific oligonucleotides (ASO), allele-specific amplification (amplification refractory mutation system [ARMS], or competitive oligonucleotide priming [COP]), oligonucleotide ligation assay (OLA), or base-specific primer extension. For mutations that alter restriction sites, additional methods are available, including restriction fragment length polymerase (RFLP)/PCR.

Table 13-7 catalogs the commonly used tests to screen mammalian genes for mutations. The strengths and weaknesses of many of these tests have been extensively reviewed (e.g., please see Cotton 1989, 1992; Rossiter and Caskey 1990; Condie et al. 1993; Grompe 1993; Prosser 1993; Saleeba and Cotton 1993; Smooker and Cotton 1993; Dean 1995; Forrest et al. 1995; Liu and Sommer 1995; Liu et al. 1997).

TABLE 13-7 Summary of Methods Commonly Used to Detect Mutations

Method and Acronym	Principle	Strengths/Limitations	Key References
Protein truncation test (PTT)	PTT is used to search coding sequences for mutations that result in premature chain termination of a specific target protein. PCR is first used to detect a mammalian sequence for initiation of translation, and a sequence unique for the segment of DNA to be amplified, in-frame with the initiating ATG. PCR products are then used without purification in a coupled transcription-translation system. The resulting radiolabeled polypeptides are analyzed by SDS-PAGE. Chain-terminating mutations will generate truncated products.	PTT detects chain-terminating mutations in 1–2-kb segments of amplified cDNA or a single large exon of genomic DNA. Overlapping PCR from cDNA templates must be used to ensure that mutations near the beginning of exons are ascertained. PTT does not localize the underlying mutation precisely and is not useful for small exons since very short protein fragments are easily lost by degradation or during SDS-PAGE.	Powell et al. (1993); Roest et al. (1993); Prosser et al. (1994)
Denaturing gradient gel electrophoresis (DGGE)	When double-stranded DNA migrates through increasing concentrations of urea and formamide, the complementary strands will dissociate in a domain-dependent fashion. The dissociation causes an abrupt decrease in the mobility of the fragment in polyacrylamide gels. The presence of a mutation may change the stabilty of its local domain and hence alter its pattern of migration. When preparing DNA for analysis by DGGE, PCR is used to attach an ~40-bp G-C clamp to one end of the fragment. This clamp provides a highly stable, denaturation-resistant domain that allows mutations in lower melting domains to be ascertained (Sheffield et al. 1989). Heteroduplexes between a wild-type strand and a potential mutant strand will be destabilized by the single base-pair mismatch and will therefore migrate more slowly than either homoduplex. Heteroduplexes generated during PCR amplification of heterozygous genomic DNA can therefore greatly assist in the detection of mutations. A variation of DGGE (constant denaturant gel electrophoresis or CDGE) uses a temperature gradient and a gel containing a constant concentration of denaturant (Rosenbaum and Riesner 1987; Riesner et al. 1989; Borreson et al. 1991a,b; Hovig et al. 1991).	DGGE/CDGE is used to analyze PCR-amplified, G-C clamped segments of DNA <500 bp in length. The technique is best suited to scanning multiple samples for mutations in the same DNA fragment. An experienced investigator can detect close to 100% of single-base mutations, assign them to a domain, and make an intelligent guess about the nature of the mutation. A change from A/T to G/C usually increases the stability of the local domain; a change from G/C to A/T usually has a destabilizing effect. The exact position and nature of the mutation must be confirmed by DNA sequencing. DGGE requires specialized equipment and a distinctly user-unfriendly computer program, which is needed to select sequences for oligonucleotide primers.	Fischer and Lerman (1983); Myers et al. (1987); Sheffield et al. (1989) Rosenbaum and Riesner (1987); Riesner et al. (1989); Borreson et al. (1991a,b); Hovig et al. (1991)

Single-strand conformational polymorphism (SSCP)	Intrastrand base pairing causes single-stranded DNA molecules to form complex secondary structures. Alteration of the nucleotide sequence of the molecule by as little as a single base can reshape the secondary structure, with consequent changes in electrophoretic mobility. SSCP exploits the differences in mobility between wild-type and mutant strands of DNA. In most cases, the material analyzed by SSCP has been amplified by PCR from genomic DNA (PCR-SSCP) and is 50–400 bases in length. The DNA is denatured with alkali and then analyzed by electrophoresis under nondenaturing conditions at neutral pH. With a wild-type molecule, two bands are generally seen on the gel, corresponding to each of the single strands of the PCR product. However, additional bands, corresponding to different conformations, may sometimes be seen. The PCR product of a heterozygous allele should generate at least four bands, two of which should be identical in mobility to the wild-type bands and two that are characteristic of the particular mutation.	SSCP requires no specialized equipment and is the fastest and simplest of all the techniques to scan DNA fragments for the presence of mutations. Like DGGE, however, SSCP assigns mutations to a region but does not define them or map them precisely. Close to 100% of mutations can be detected in fragments of 100–300 bases if the analysis is performed under several different gel-running conditions (e.g., 0.5x TBE at 4°C with and without 5% glycerol). The use of longer fragments leads to decreasing efficiency of detection.	Orita et al. (1989a,b, 1990); Ainsworth et al. (1991); Dean and Gerrard (1991); Condie et al. (1993); Glavac and Dean (1993)
RNase cleavage of mismatches	Mismatches in RNA:RNA heteroduplexes formed between a reference wild-type RNA and a putative mutant RNA are cleaved by ribonuclease A. Mismatches in RNA:DNA heteroduplexes are cleaved by RNase I or by a combination of ribonuclease T1 and ribonuclease A. After digestion, the size of the probe strand is assayed by denaturing polyacrylamide gel electrophoresis. The reference and probe nucleic acids are generated by amplifying individual exons of genomic DNA or cDNA encoded by the target gene. The upstream primer contains a consensus sequence for the bacteriophage T7 promoter which can be used to generate RNA templates. A variation, known as the nonisotopic RNase cleavage assay (NIRCA) is based on the ability of RNase A to cleave both strands of a duplex RNA target carrying mismatched base pairs (Goldrick et al. 1996). Cleavage products of duplex RNA, generated by in vitro transcription of the amplified target DNA, are resolved by electrophoresis and detected by staining.	Some mismatches in heteroduplexes, particularly those with purines in the probe strand, are cleaved poorly by RNase A and RNase T1; cleavage is often context-dependent and nonspecific cleavages are common. Between 30% and 60% of single-base substitutions go undetected by this assay (Cotton 1992; Prosser 1993). RNase I (Murthy et al. 1995) may be a better alternative since it has a broader specificity. At its best, however, the method is capable of scanning 1-kb tracts of DNA and of localizing the position of the mutation with accuracy. In the alternative assay (NIRCA), the transcription reaction produces target RNA sufficient to detect cleavage products directly in the gel, thus bypassing the need to synthesize and purify a radiolabeled probe. Reagents required for the NIRCA protocol are available as a kit (MisMatch Detect II from Ambion).	Freeman and Huang (1981); Gibbs and Caskey (1987); Winter et al. (1985); Myers et al. (1985a, 1988); Rojas et al. (1995); Murthy et al. (1995); Goldrick et al. (1996)

(*Continued on the following pages.*)

TABLE 13-7 (*Continued*)

METHOD AND ACRONYM	PRINCIPLE	STRENGTHS/LIMITATIONS	KEY REFERENCES
Detection of point mutations with DNA mismatch repair enzymes	The *E. coli mutY* gene encodes an enzyme that cleaves the adenine residue in G:A mismatches. HeLa cell thymidine glycosylase cleaves the thymine residue in G:T mismatches. For mutation detection, heteroduplexes formed in vitro between proband DNA and wild-type DNA are cleaved by a combination of mismatch repair enzymes. The size of cleavage products is then ascertained by denaturing PAGE.	The method, which is used on PCR-amplified exons of genomic DNA, is claimed to detect as little as 1% mutant sequences in a mixture of mutant and wild-type DNAs; all possible single-base mismatches can be detected, albeit with varying efficiencies. The location of the mutation is determined with accuracy. Nonspecific cleavage by *mutY* and thymidine glycosylase is a possible problem.	Lu and Hsu (1992); Hsu et al. (1994) Marshal et al. (1995); Youil et al. (1995)
Cleavage of mismatches with bacteriophage resolvases (T4 endonuclease VII and T7 endonuclease I)	Resolvases recognize mismatched bases in double-stranded DNA and cut the DNA at the mismatch. For mutation detection, heteroduplexes are formed in vitro between proband DNA and wild-type DNA and cleaved by resolvases. The size of cleavage products is ascertained by denaturing PAGE.	Nearly all possible mismatches are cleaved, albeit with varying efficiencies. The location of the mutation is determined with accuracy. In the test series reported by Youil et al. (1995) and Marshal et al. (1995), two single-base mismatches (G:A and A:T) went undetected, suggesting that context may affect the efficiency of cleavage. Nonspecific cleavage by resolvases is also a possible problem.	
Dideoxy fingerprinting (ddF and Bi-ddF)	ddF is a combination of SSCP and Sanger dideoxy sequencing. A conventional dideoxy sequencing reaction is carried out with a single dideoxy terminator and the products are analyzed by electrophoresis under nondenaturing conditions. The banding patterns (fingerprints) obtained from ddF resemble a rather blurry sequencing gel. Mutations, which are detected by comparing fingerprints generated from reference and probe sequences, can result in gain or loss of a termination site, a change in mobility of the products of the reaction, or both. In most cases, the templates for ddF are RNAs generated by in vitro transcription of amplified genomic DNAs. However, any sequencing protocol could be adapted to ddF.	Unlike SSCP, ddF provides information about the position of the mutation within the fragment under analysis. With experience in reading gels, mutations can be localized with an accuracy of ~10 bp when segments of 200 bp are analyzed. Larger segments of DNA can be amplified and then screened in 200-bp segments by primer walking. When ddF reactions are carried out in both directions (bidirectional or Bi-ddF), heterozygous mutations can be detected with high efficiency (Liu and Sommer 1994; Blaszyk et al. 1995; Liu et al. 1997). Detection rates approaching 100% for homozygous mutations have been reported and the method has been adapted for use with automated DNA sequencers (Ellison et al. 1994). ddF requires ~50% more effort and costs about twice as much as SSCP performed under one condition.	Sarkar et al. (1992); Ellison et al. (1994); Liu and Sommer (1994); Blaszyk et al. (1995); Liu et al. (1997)
Restriction endonuclease fingerprinting (REF)	Similar in concept to ddF, REF is used to detect mutations in target fragments that result in the creation or loss of a restriction endonuclease recognition site. A set of overlapping segments of DNA is created by amplification of the target segment, and, after individual digestion with a member of a reference group of restriction endonucleases, the target sequences are resolved by SSCP and then confirmed by DNA sequencing.	REF is best used for detecting mutations in large exons or in many small introns, for example, in fragments ranging from 1.5 to 2 kb in length. Selecting the optimal group of restriction endonucleases is facilitated by the use of special software designed for this application. The REF Select program is available from ssomers@smtplink.coh.org. Detection rates approaching 100% for a 1.9-kb segment of DNA have been reported (Liu et al. 1997).	

CDI modification	Water-soluble carbodiimide reacts with the imino sites of mispaired guanine and thymine residues forming a bulky adduct that (1) subtly alters the electrophoretic mobility of heteroduplexes containing single-base mismatches, (2) can be cleaved with piperidine, and (3) prevents extension of a primer by *Taq* DNA polymerase. In the latter case, the truncated product is detected by PAGE.	Piperidine cleavage of CDI adducts can detect most, if not all, mispaired guanine and thymine residues in heteroduplexes, albeit with varying efficiency. Using inhibition of primer extension, only ~50% of mispaired guanine residues are detected. Problems encountered include internal priming and nonspecific modification by CDI. The method, which does not identify the location of mutations precisely, needs careful optimization before it can be applied routinely.	Novack et al. (1986); Ganguly et al. (1989); Ganguly and Prockop (1990)
Chemical cleavage of mismatch (CCM)	A labeled heteroduplex molecule between a wild-type sequence and a potential mutant is treated with either hydroxylamine (which modifies mismatched cytosine residues), osmium tetroxide (which modifies mismatched thymine residues), or both reagents. The chemically modified bases are then cleaved with piperidine, and the resulting fragments of DNA are analyzed by PAGE.	100% of mutations can be ascertained when heteroduplexes are end-labeled on the coding and noncoding strands, respectively, and are modified in parallel reactions by both hydroxylamine and osmium tetroxide. Heteroduplexes >1 kb in size can be analyzed, and mutations can be localized with high precision. The major drawback of the chemical cleavage method is that it uses hazardous chemicals, is labor-intensive, and is not easily automated. However, the use of strand-specific fluorophores as end labels instead of radioactive isotopes (Verpy et al. 1994) opens the possibility that the products of chemical cleavage reactions could be analyzed on automated DNA sequencers.	Cotton et al. (1988); Cotton (1992); Condie et al. (1993); Smooker and Cotton (1993); Verpy et al. (1994)
RFLP/PCR	RFLP is used to detect mutations (small deletions, insertions, and single-base changes) that render restriction sites resistant to cleavage. Wild-type genomic DNA is eliminated from the sample by restriction digestion and the resistant DNA is then amplified by PCR, using primers that lie upstream and downstream from the restriction site.	RFLP/PCR can detect specific mutations with high sensitivity. This is because the PCR step suppresses background caused by the presence of wild-type DNA. However, the method is of limited value since it can be applied only to sequences that harbor a known restriction site. The method therefore cannot be used to establish the entire spectrum of mutations in a gene.	Pourzand and Cerutti (1993)
Allele-specific oligonucleotides (ASO)	Allele-specific oligonucleotides, usually 14–17 bases in length, can be used as hybridization probes to distinguish between wild-type and a known mutant allele. Hybridization and washing conditions are established that (1) preserve perfect hybrids between the oligonucleotide probe and its target sequence and (2) eliminate hybrids that contain a mismatched nucleotide. Originally carried out on total genomic DNA (Conner et al. 1983; for review, please see Cotton 1989), ASO is now used exclusively to establish the presence or absence of specific mutations in PCR-amplified fragments of genomic DNA. In the so-called reverse ASP system, a range of different oligonucleotides representing different mutations are bound to a solid matrix and labeled PCR products of proband DNAs are hybridized to them.	ASO can only be used when the mutation of interest has been mapped precisely and ascertained by sequencing. Design of the oligonucleotide is the key to success, with the mutant bases being placed in the center of the oligonucleotide, where they exert maximum destabilizing effect when they are mispaired.	Saiki et al. (1986)

(Continued on the following page.)

TABLE 13-7 (*Continued*)

METHOD AND ACRONYM	PRINCIPLE	STRENGTHS/LIMITATIONS	KEY REFERENCES
Amplification refractory mutation system (ARMS) and competitive oligonucleotide priming (COP)	ARMS can be used to distinguish between wild-type and a known mutant allele. An oligonucleotide carrying a base that forms a mismatch with the template strand primes DNA synthesis with very low efficiency in PCRs. In ARMS, two pairs of primers are used. One oligonucleotide of each pair contains either the wild-type or mutant base at its 3′ end. The PCR will work efficiently only when the 3′ base of the oligonucleotide forms a perfect hybrid with the template DNA, i.e., wild-type DNA with the normal oligonucleotide and mutant DNA with the mutant oligonucleotide. In COP, a wild-type oligonucleotide and a mutant oligonucleotide, labeled with different fluorophores, compete for the same sequence on the template DNA. Amplification occurs only when the oligonucleotide perfectly matches the template. The potentially mismatched base is placed in the center of the oligonucleotide, where its destabilizing effect on the hybrid is maximal.	ARMS is the more useful of these two techniques. By contrast to COP, which requires an automated sequencer to detect which fluor has been incorporated into the PCR product, ARMS requires no special equipment. Mandatory controls in both systems include the use of wild-type and previously validated mutant templates.	Newton et al. (1989); Sommer et al. (1989); Gibbs et al. (1989)
Oligonucleotide ligation assay (OLA)	Two oligonucleotides are positioned on the template with the 5′ base of one oligonucleotide abutting the 3′ base of the other. If these two bases form perfect hybrids with the target DNA, the oligonucleotides can be ligated together by DNA ligase. If a thermostable ligase is used, the reaction can be carried out for multiple cycles, much like a linear PCR. This greatly enhances the ratio of signal to noise.		Wu and Wallace (1989); Barany (1991a,b); Landegren (1993)
Primer extension	This method relies on extension by one labeled nucleotide of an oligonucleotide primer that binds to sequences immediately adjacent to the site of a previously defined mutation. Each labeled [α-^{32}P]dNTP is used in a separate PCR, and the products of all four reactions are analyzed by electrophoresis through a 20% polyacrylamide gel.	This method ascertains previously defined mutations in genomic DNA with high accuracy. Other primer extension methods have been developed, but these are less accurate and/or technically more demanding.	Sokolov (1990)

Chapter 14

Screening Expression Libraries

SUCCESSFUL SCREENING OF CDNA EXPRESSION LIBRARIES requires probes that bind to target proteins with high specificity and dissociate from them slowly. Discussed below are three classes of probes that fit these criteria.

- ***Antibody Probes.*** Antibodies that recognize antigenic determinants or epitopes specific for the protein of interest are used to screen protein imprints of cDNA expression libraries. Because of their ability to react with cognate epitopes when the surrounding protein is malfolded or denatured, antibodies are the reagents of choice for primary screening of expression libraries when no nucleic acid probes are available for the gene of interest (for reviews, please see Helfman and Hughes 1987; Mierendorf et al. 1987; Young and Davis 1991; Hurst 1997). Since 1983, when Young and Davis (1983a,b) introduced immunological screening, cDNA clones encoding hundreds of different proteins have been isolated by this method.

Immunological screening does not depend on the expression of a functional protein, merely on the synthesis of an immunologically reactive epitope. Although some epitopes are complicated topological structures formed by the folding of noncontiguous regions of one or more polypeptide chains, others consist of short tracts of adjacent amino acids from a single polypeptide chain (Geysen et al. 1987). Such localized epitopes can be formed in foreign proteins expressed in bacteria even though the protein as a whole may be malfolded and nonfunctional. Simple epitopes can also form in fusion proteins, which will therefore display at least a part of the characteristic immunological reactivity of the entire target protein.

cDNA libraries suitable for immunological screening are occasionally constructed in plasmid vectors (Helfman et al. 1983; Helfman and Hughes 1987), but, more commonly, they are constructed in bacteriophage λ expression vectors such as gt11 (Huynh et al 1985) and its close relatives: λgt18-23, λZAP, λZAP Express, and λZAPII. For further information about these expression systems, please see the information panel on **PLASMID AND BACTERIOPHAGE λ EXPRESSION VECTORS** at the end of this chapter.

- ***Oligonucleotide Probes.*** Double-stranded synthetic oligonucleotides of defined sequence are used to screen protein imprints of expression libraries for cDNA clones that express sequence-specific DNA-binding proteins (Schleif 1988; Singh et al. 1988; Vinson et al. 1988; Singh 1993). Screening can be laborious because the mRNAs for many proteins of this class are rare and because screening is generally carried out in a serial fashion with oligonucleotide probes that (1) correspond to the wild-type consensus binding sequence and (2) carry a mutated version of the binding sequence with reduced affinity for the transcription factor. Despite these disadvantages, screening expression libraries with DNA ligands has proven to be a remarkably rewarding technique. The rich harvest of clones encodes mammalian transcription factors containing several types of DNA-binding motifs including helix-turn-helix, zinc fingers, leucine zippers, and helix-loop-helix domains (for reviews, please see Singh et al. 1989; Singh 1993).

- ***Specialized Probes.*** Listed below are more specialized probes used to screen protein imprints of expression libraries.

  Labeled proteins or small organic molecules. For example, ^{125}I-labeled calmodulin has been used to isolate cDNA clones encoding proteins that bind to calmodulin (Sikela and Hahn 1987; Mutzel et al. 1990), whereas radiolabeled cAMP has been used as a probe to isolate cDNAs encoding cAMP-binding proteins (Lacombe et al. 1987). This type of interaction cloning has also led to the isolation of cDNAs encoding, for example, proteins involved in signal transduction pathways (Skolnik et al. 1991) and heterodimeric transcription factors (Blanar and Rutter 1992). However, such successes are rare, probably because the sensitivity of the technique is too low. These days, yeast two- and three-hybrid procedures would be the methods of choice to isolate cDNAs encoding interacting proteins (please see Chapter 18).

  Short RNA probes have been used to isolate cDNAs encoding proteins that interact with the probe in a sequence-specific manner and with high affinity ($K_b > 10^9\ M^{-1}$) (Qian and Wilusz 1993; for reviews, please see Bagga and Wilusz 1999; Webster and Macdonald 1999).

  Apurinic DNA has been used as a probe to identify cDNA clones expressing DNA-repair proteins (Lenz et al. 1990).

- ***Antibodies specific for phosphotyrosine residues.*** Tyrosine residues of recombinant proteins expressed in bacteria can be phosphorylated by cognate kinases in posttranslational modification reactions. Antibodies directed against phosphotyrosine residues can therefore be used to screen protein imprints of mammalian cDNA libraries for clones encoding peptides rich in phosphotyrosine residues that are substrates for a particular kinase (e.g., please see Kornbluth et al. 1988; Lindberg et al. 1988).

Among the reagents that have been used to detect antibody bound to its antigen on nitrocellulose filters are the following:

- ^{125}I-labeled antibodies reactive with species-specific determinants on the primary antibodies (Helfman et al. 1983; Helfman and Hughes 1987).
- Protein A of *Staphylococcus aureus* radiolabeled with ^{125}I (Kemp and Cowman 1981; Johnson et al. 1985).
- Second antibodies conjugated directly to horseradish peroxidase (HRP) (de Wet et al. 1984). Alternatively, HRP coupled to avidin may be used to detect a second antibody coupled to biotin (Young et al. 1985; French et al. 1986).
- Second antibodies conjugated to alkaline phosphatases (AP) (Mierendorf et al. 1987).
- Radiolabeled ligand, which binds to a divalent antibody that is attached monovalently to antigen on the nitrocellulose filter (Chao et al. 1989). This method can be used only in those rare circumstances when pure ligand is available in quantity.

Although a systematic comparison of these reagents has not been published, enzymatic methods of detection are generally more sensitive and give lower backgrounds than do radiochemical methods. In addition, enzymatic methods produce signals directly on the nitrocellulose filter (rather than on a sheet of X-ray film), so that positive plaques can be located more accurately.

Antibodies coupled to either HRP or AP that react with species-specific determinants on the primary antibodies are available commercially, and both have been used successfully to isolate cDNA clones from expression libraries constructed in bacteriophage λ vectors. Both enzymes catalyze the formation of an insoluble colored precipitate on the surface of a nitrocellulose filter at the site of an antigen-antibody complex (Towbin et al. 1979; Hawkes et al. 1982; Blake et al. 1984; Knecht and Dimond 1984; Towbin and Gordon 1984; Hawkes 1986). AP, however, offers some potential advantages: The enzyme remains active for several hours, during which the end product of the reaction — a dark-blue precipitate of diformazan (McGadey 1970) — continues to accumulate and intensify in color. By contrast, although HRP-conjugated antibodies can efficiently detect antigen-antibody complexes on the surfaces of nitrocellulose filters (Mierendorf et al. 1987), the yellow-brown color fades over the course of time. Some protocols also require the use of a carcinogenic chromogen, *o*-dianisidine, which requires special handling and disposal.

In addition to probes that bind to target proteins, expression libraries can of course be screened in the conventional manner with labeled DNA or RNA probes. Screening by hybridization does not require expression of the target protein, merely the presence in the recombinant clone of a DNA sequence encoding all or part of the protein. The technique may therefore be used to screen DNA imprints of any type of library constructed in any type of vector. For further details, please see Chapters 1 and 2.

In this chapter, we describe methods for the immunological screening of bacteriophage λ and plasmid cDNA expression libraries, methods for the purification of antibody probes, procedures for antibody-based screening of expression libraries, and methods for the production and analysis of fusion proteins in bacteriophage λ recombinants.

Genetics tells us almost nothing about ourselves that we did not know before... . Genetics answers all the questions about the human condition, except for the interesting ones.

Steve Jones

Protocol 1

Screening Expression Libraries Constructed in Bacteriophage λ Vectors

IN A TYPICAL IMMUNOLOGICAL SCREENING EXPERIMENT, a library constructed in a bacteriophage λ expression vector is plated on an appropriate *Escherichia coli* strain in the absence of isopropyl-thio-β-D-galactoside (IPTG). The absence of inducer ensures that no fusion proteins toxic to the host are synthesized until plaque formation is well under way. After 2–4 hours, the plates are moved from 42°C to 37°C to stabilize any fusion proteins that are temperature-sensitive, and filters impregnated with IPTG are laid on top of the developing plaques to collect an imprint of the induced fusion proteins. After incubation for a further 2–4 hours, the filters are removed and probed with antibody as described in the protocol. The plates are then stored at 4°C until the results of immunological screening are available. Positive plaques are recovered and analyzed further as described in detail in Protocols 7, 8, and 9 of this chapter and in Chapter 2.

Three alternative methods to detect bound antibodies are discussed: radiochemical screening, chromagenic screening, and chemiluminescent screening. The advantages and disadvantages of these methods are discussed in the introduction to this chapter.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Blocking buffer

10 mM Tris-Cl (pH 8.0)
150 mM NaCl
0.05% (v/v) Tween-20
20% (v/v) fetal bovine serum

Alternative blocking buffers are 5% (w/v) nonfat dried milk or TNT buffer containing 1% (w/v) gelatin and 3% (w/v) bovine serum albumin. Opinion of the relative virtues of these blocking agents varies from laboratory to laboratory. We recommend that the investigator carry out preliminary experiments to determine which of them works best with the primary and secondary antibodies that will be used for screening. Blocking buffer can be stored at 4°C and reused several times. Sodium azide **<!>** should be added to a final concentration of 0.05% (w/v) to inhibit the growth of microorganisms.

Chloroform <!>

IPTG (10 mM)

Just before use in Step 4, dissolve 0.6 g of solid IPTG in 250 ml of H_2O. Sterilize the solution by passage through a 0.25-μm filter.

Reagents for detection of antigen-antibody complexes:

Reagents for chromogenic screening with alkaline-phosphatase-conjugated antibody

Reagents for chromogenic screening with horseradish-peroxidase-conjugated antibody

Reagents for chemiluminescent screening

For a list of reagents needed for the desired screening method, please see Step 15. For information on commonly used methods to detect antibodies, please see the information panel on **USING ANTIBODIES IN IMMUNOLOGICAL SCREENING** at the end of this chapter. For further details, please see the information panels in Appendix 9.

SM

Store SM at room temperature in 50-ml aliquots. Discard each aliquot after use to reduce the possibility of contamination.

TNT buffer

10 mM Tris-Cl (pH 8.0)
150 mM NaCl
0.05% (v/v) Tween-20

Approximately 1 liter of TNT buffer is required per 10 filters screened. Store TNT buffer at room temperature.

Washing buffers:

TNT buffer containing 0.1% (w/v) bovine serum albumin

TNT buffer containing 0.1% (w/v) bovine serum albumin and 0.1% (v/v) Nonidet P-40

These buffers should not contain sodium azide.

Radioactive Compounds

^{125}I-labeled protein A or ^{125}I-labeled immunoglobulin (optional) <!>

Radioiodinated secondary antibody <!>

Use this antibody if detecting the antigen-antibody complexes with a radiolabeled secondary antibody in Step 15.

RADIOIODINATION OF IgG

▲ **WARNING** Perform this procedure behind appropriate shielding in a correctly vented chemical fume hood.

This method can be used to radiolabel an IgG fraction for use as a secondary antibody.

1. Prepare IgG from antiserum by protein A–Sepharose chromatography as described by Harlow and Lane (1999). Dilute the IgG with 50 mM sodium phosphate (pH 7.5) to obtain a final concentration of 1 mg/ml.
2. To 50 μl of the diluted IgG, add 4 μl of ^{125}I (sodium ^{125}I, 10 mCi/ml).
3. Add 15 μl of chloramine T (2 mg/ml in 50 mM sodium phosphate [pH 7.5]).
4. Incubate the reaction for 90 seconds at room temperature.
5. Add 50 μl of sodium metabisulfite (5 mg/ml in 50 mM sodium phosphate [pH 7.5]).
6. Apply the solution to a 5-ml column of Sephadex G-25 (equilibrated in 50 mM sodium phosphate [pH 7.5]) (please see Appendix 8).
7. Collect 0.5-ml fractions until all of the radioactivity has been eluted (~3 ml).
8. Pool the radioactive material.

   Usually, >95% of the radiolabel is incorporated, and the specific activity of the radiolabeled antibody exceeds 10^8 cpm/mg. Do not store radiolabeled antibody for prolonged periods before use.

Antibodies

Primary antibody

For advice on choosing primary and secondary antibodies, please see the information panel on **USING ANTIBODIES IN IMMUNOLOGICAL SCREENING** at the end of this chapter.

Media

LB agar plates

Each 90-mm Petri dish should contain 30–35 ml of agar medium, whereas each 150-mm plate should contain ~50 ml. The plates must be dry; otherwise, the top agarose will peel off when the nitrocellulose filter is removed. Usually, 2-day-old plates that have been dried for an additional 1–2 hours at 37°C with their lids slightly open work well. LB agar plates without ampicillin are used in the screening procedure because *E. coli* Y1090*hsdR* grows slowly in the presence of the antibiotic.

LB top agarose

Melt the top agarose by microwaving for a short period of time and then cooling to 47°C. Dispense the molten top agar as 3-ml aliquots (for 90-mm plates) or 7.5-ml aliquots (for 150-mm plates) in sterile tubes. Place the aliquots in a 47°C heating block or water bath to prevent the top agar from gelling.

Special Equipment

Air incubator preset to 42°C

Culture tubes (sterile 13 x 100 mm)

Forceps, blunt-ended

Needle (18-gauge) and syringe filled with waterproof black drawing ink (India Ink)

Nitrocellulose filters

Filters suitable for binding protein and immunoblotting include nitrocellulose filters free of Triton X-100 (Millipore HATF or equivalent), and supported nitrocellulose derivatives such as Hybond-C extra (Amersham Pharmacia Biotech). Nylon membranes and charged nylon membranes should not be used for immunological screening because of their poor retention of proteins and high backgrounds.

Number the filters with a soft-lead pencil or ballpoint pen, wet them with water, and sandwich them between dry Whatman 3MM papers. Wrap the stack of filters in aluminum foil, and sterilize them by autoclaving at 10 psi (0.70 kg/cm^2) on liquid cycle.

Additional Reagents

Step 1 of this protocol requires the reagents listed in Chapter 2, Protocol 1.

Step 17 of this protocol requires the reagents listed in Chapter 2 Protocol 2.

Vectors and Bacterial Strains

Bacteriophage λ expression library

Construct a cDNA library in an appropriate expression vector as described in Chapter 11 or purchase the library from a commercial supplier. Before beginning the screening experiment, determine the titer of the bacteriophage solution as described in Chapter 2, Protocol 1.

E. coli

Different bacterial host strains used in expression screening require different growth media. For example, *E. coli* Y1090*hsdR*, which is commonly used as a host strain for cDNA libraries constructed in λgt11, carries a mutation in the *lon* gene which encodes an ATP-dependent protease. Fusion proteins expressed in these strains are often more stable than those expressed in strains lacking this mutation. This strain also carries a plasmid (pMC9) that encodes the *lac* repressor and prevents synthesis of potentially toxic fusion proteins from the β-galactosidase promoter. This plasmid also carries a selectable marker (*amp*^{r}). To ensure against loss of the plasmid, grow *E. coli* strain Y1090*hsdR* in media containing 50 μg/ml ampicillin (except when screening, please see note with LB agar plates above).

E. coli strains BB4 and XL1-Blue, which are used for immunological screening of libraries constructed in λZAP and its derivatives, carry a *lacI*^{q} gene and a *tet*^{r} marker on an F′ factor. These strains should be grown in media containing 12.5 μg/ml tetracycline.

Before plating the host strain to be used, become familiar with its genotype and any unique growth requirements.

METHOD

Plating Bacteriophage λ

1. Using a single colony of the appropriate strain of *E. coli* as inoculum, prepare a plating culture as described in Chapter 2, Protocol 1.

2. Calculate the number of plates that will be required to screen the library, assuming 0.5×10^4 to 2×10^4 plaques per 90-mm plate or 0.5×10^4 to 5×10^4 plaques per 150-mm plate. Arrange a set of sterile tubes (13 x 100 mm) in a rack; use a fresh tube for each plate. In each tube, mix 0.1 ml of the plating bacteria with 0.1 ml of SM containing the desired number of plaque-forming units of the bacteriophage λ expression library. Incubate the infected bacteria for 20 minutes at 37°C.

   Immunological screening works best when the density of plaques is low. The color produced by the chromogenic reaction is most intense at the expanding edge of the plaque. Well-isolated immunopositive plaques therefore display a characteristic ring-like pattern. When plaques crowd against one another, their morphology becomes fragmented, and the intensity of color at the common border between adjacent plaques is greatly reduced. However, immunopositive plaques can still be recognized as long as some portions of their borders do not make contact with the borders of neighboring plaques. When the density exceeds ~500 plaques/cm^2, the borders between neighboring plaques disappear and antigen-positive plaques become increasingly difficult to identify. The number of plaques per plate given in this step should therefore be regarded as the upper limit for immunological screening.

3. Add to each tube 2.5 ml (90-mm plate) or 7.5 ml (150-mm plate) of molten top agarose, and immediately pour the mixture onto an LB agar plate. Incubate the infected plates for 3.5 hours at 42°C.

   An incubation temperature of 42°C is used to ensure inactivation of the λ repressor protein (encoded by the *cIts*857 allele) and activation of the lytic program of bacteriophage λ development.

Induction of Protein Expression on Filters

4. Number the nitrocellulose filters with a soft-lead pencil or a ballpoint pen. Use gloves to handle the filters because skin oils will prevent the transfer of proteins. Soak the filters in 10 mM IPTG for a few minutes. Use blunt-ended forceps (e.g., Millipore forceps) to remove the filters from the solution, and allow them to dry at room temperature on a pad of Kimwipes.

5. Remove one plate at a time from the incubator, and quickly overlay it with an IPTG-impregnated nitrocellulose filter. Do not move the filter once contact is made with the plate. Put the plate in the 37°C incubator and repeat the above procedure until all plates contain a nitrocellulose filter.

   The easiest way to place the filter on the plate without trapping air bubbles is to hold it by its edges, bending it slightly so that the middle of the filter makes contact with the center of the plate. Wetting action then pulls the filter onto the plate.

   It is important to place filters on the plates one at a time so that the temperature of the plates does not drop below 37°C. The growth of bacteriophages is severely retarded at temperatures <30°C.

6. Incubate the plates for at least 4 hours at 37°C.

   During primary screening of a library, it is often difficult to distinguish immunoreactive plaques from false positives. The frequency with which false positives appear depends on several factors, including the care taken in handling the filters, the characteristics of the particular antiserum, and the method used to detect antigen-antibody complexes. In general, chromogenic methods of detection yield fewer false positives than radiochemical methods and chemiluminescent methods. Even

under the best conditions, however, false positives arise at a frequency of approximately one per plate. To avoid the labor and expense of screening large numbers of plaques for a second time, we recommend that primary screening be carried out in duplicate.

If the library is not to be screened in duplicate, the original filter can be left on the plate for 10–12 hours. If duplicate filters are required, please see the panel following Step 9.

7. Remove the lids from the plates and continue the incubation for a further 20 minutes at 37°C. This step strengthens the bond between the soft agarose and the agar plate.

8. Move the plates in small batches to room temperature. Use an 18-gauge needle attached to a syringe containing waterproof black ink to mark each filter in at least three asymmetric locations by stabbing through it and into the agar underneath.

9. Use blunt-ended forceps to peel the filters off the plates and immediately immerse them in a large volume of TNT buffer. Rinse away any small remnants of agarose by gently agitating the filters in the buffer. The speed of the shaking incubator should be high enough to prevent the filters from sticking to one another.

   If large areas of the top agarose stick to the nitrocellulose filters, chill the plates for 30 minutes at 4°C or 5 minutes at –20°C before peeling the filters off the surface of the agarose.

To Prepare Duplicate Filters

a. Remove the lids from the plates 30 minutes before removing the first filter.
b. Chill the plates for 30 minutes at 4°C or 5 minutes at –20°C.
c. Mark each filter with waterproof black ink.
d. Remove the filters and immediately immerse them in TNT buffer.
e. Overlay each of the plates with a second filter impregnated with IPTG.
f. Incubate the plates for a further 4–6 hours at 37°C.
g. Meanwhile, process the first set of filters as described in Step 10 onward.
h. After the second batch of filters has been incubated on the plates for 4–6 hours, mark them with ink, immerse them in TNT buffer, and process them as described in Step 10 onward.

10. After all of the filters have been transferred to the TNT buffer, wrap the plates in plastic film and store them at 4°C until the results of the immunological screening are available.

Detection of Plaques Expressing Fusion Protein

▲ **IMPORTANT** Do not allow the filters to dry out during any of the subsequent steps. Antibodies bound nonspecifically and reversibly to wet filters become permanently attached if the filters dry out. It is also essential that the filters do not stick to one another when they are immersed in the various buffers and antibody solutions. This problem can be minimized by dividing the filters into small batches (e.g., five filters per batch) and using a separate large Petri dish or crystallizing dish for each batch. The Petri dishes can be stacked on top of one another on a slowly rotating platform shaker.

11. When all of the filters have been rinsed, transfer them one at a time to a fresh batch of TNT buffer. After transfer, agitate the buffer and filters gently for a further 30 minutes at room temperature.

    If necessary, the filters may be removed from the buffer at this stage, wrapped in Saran Wrap, and stored for up to 24 hours at 4°C.

12. Use blunt-ended forceps to transfer the filters individually to a glass tray(s) containing blocking buffer (7.5 ml for each 82-mm filter, 15 ml for each 138-mm filter). When all of the filters have been submerged, agitate the buffer and filters slowly on a rotary platform for 30 minutes at room temperature.

13. Use blunt-ended forceps to transfer the filters to a fresh glass tray(s) containing the primary antibody diluted in blocking buffer (7.5 ml for each 82-mm filter, 15 ml for each 138-mm filter). Use the highest dilution of antibody that gives acceptable background yet still allows detection of 50–100 pg of denatured antigen. When all of the filters have been submerged, agitate the solution gently on a rotary platform for 2–4 hours at room temperature.

    The antibody solution can be stored at 4°C and reused several times. Sodium azide should be added to a final concentration of 0.05% (w/v) to inhibit the growth of microorganisms.

14. Wash the filters for 10 minutes in each of the buffers below, in the order given. Transfer the filters individually from one buffer to the next. Use 7.5 ml of each buffer for each 82-mm filter and 15 ml for each 138-mm filter.

    TNT buffer containing 0.1% bovine serum albumin
    TNT buffer containing 0.1% bovine serum albumin and 0.1% Nonidet P-40
    TNT buffer containing 0.1% bovine serum albumin

15. Detect the antigen-antibody complexes with the chosen radiochemical, chromogenic, or chemiluminescent reagent.

RADIOCHEMICAL SCREENING

Use ~1 μCi of ^{125}I-labeled protein A or immunoglobulin per filter. Radiolabeled protein A is available from commercial sources (specific activity 2–100 μCi/μg). Radioiodinated secondary antibody is available commercially or can be prepared as described in the panel on **RADIOIODINATION OF IgG** above in Materials.

a. Dilute radiolabeled ligands in blocking buffer (7.5 ml for each 82-mm filter, 15 ml for each 138-mm filter).

b. Incubate the filters for 1 hour at room temperature, and then wash them several times in TNT buffer before establishing autoradiographs as described in Appendix 9.

Continue at Step 16.

CHROMOGENIC SCREENING

Antibodies coupled to horseradish peroxidase (HRP) or alkaline phosphatase (AP) that react with species-specific determinants on primary antibodies are available from commercial sources and should be used at the recommended dilution in accordance with the manufacturer's instructions. Typically, 5 μl of conjugated antiserum is used for each 82-mm filter in 7.5 ml of blocking buffer (without sodium azide). For further details on HRP or AP, please see the information panels in Appendix 9.

Antigen-Antibody-Antibody-AP Complexes Located Using BCIP and NBT

Materials for Chromogenic Screening with AP-conjugated Antibodies

Alkaline phosphatase-conjugated anti-immunoglobulin antibodies
AP buffer
    100 mM Tris-Cl (pH 9.5)
    100 mM NaCl
    5 mM $MgCl_2$
5-Bromo-4-chloro-3-indolyl phosphate (BCIP)
Dimethylformamide <!>
Nitro blue tetrazolium (NBT)

a. Gently agitate the filters for 1.5–2 hours at room temperature in the solution of AP-conjugated antibody.

b. Wash the filters as described in Step 14.

c. Prepare stock solutions of BCIP (50 mg/ml in 100% dimethylformamide) and NBT (50 mg/ml in 70% dimethylformamide). These solutions are stable when stored in the dark.

d. Prepare the BCIP/NBT developing solution just before use as follows:

   i. Add 33 µl of the NBT solution to 5 ml of AP buffer and mix well.

   ii. Add 16.5 µl of the stock solution of BCIP. Mix again. Protect the solution from strong light and use it within 1 hour.

e. Blot the washed filters on paper towels.

f. Incubate the filters (Step d) in the BCIP/NBT developing solution (7.5 ml for each 82-mm filter, 15 ml for each 138-mm filter) for several hours at room temperature.

g. Rinse the filters briefly in two changes of H_2O. An intense purple color will develop at the site of antigen-antibody complexes.

Continue at Step 16.

Antigen-Antibody-Antibody-HRP Complexes Located Using 4-Chloro-1-Naphthol

Materials for Chromogenic Screening with HRP-conjugated Antibodies
4-Chloro-1-naphthol
H_2O_2 (30%) **<!>**
HRP-conjugated anti-immunoglobulin antibodies
Methanol **<!>**
NaCl (5 M)
Tris-Cl (1 M, pH 7.5)
Tris-Cl (10 mM, pH 7.5) containing 150 mM NaCl

a. Gently agitate the filters in the HRP-conjugated antibody solution for 1.5–2 hours at room temperature.

b. Wash the filters as described in Step 14.

c. To prepare developing solution, dissolve 60 mg of 4-chloro-1-naphthol in 20 ml of ice-cold methanol. Just before use, mix the solution with 100 ml of 10 mM Tris-Cl (pH 7.5), 150 mM NaCl containing 60 µl of 30% H_2O_2.

d. Blot the washed filters on paper towels and wash them briefly in 10 mM Tris-Cl (pH 7.5) containing 150 mM NaCl.

e. Incubate the filters for 15–20 minutes at room temperature in the 4-chloro-1-naphthol developing solution (10 ml for each 82-mm filter, 25 ml for each 138-mm filter).

f. Wash the filters in two changes of H_2O. An intense purple color will develop at the site of antigen-antibody complexes.

Biotinylated species-specific antibodies and avidin-conjugated HRP are available from commercial sources. They should be diluted according to individual manufacturer's instructions and used for immunological screening as described above for HRP-conjugated antibodies.

Clones of bacteriophage λ can be recovered directly from stained filters after chromogenic screening (Alter and Patrie 1990). The amounts of infectious particles recovered by the recommended method — scraping the filters with a scalpel blade — are highly variable, ranging from <100 to $>10^4$ pfu per stained imprint. The scrapings from each imprint are mixed with 20-μl aliquots of SM, stored overnight at 4°C, and then replated in a series of dilutions on the appropriate strain of *E. coli*. Of course, much greater quantities of bacteriophages can be recovered by the traditional method of aligning the stained filters with the original plaques. However, large quantities of bacteriophage are not necessarily an advantage since the next step is to plaque-purify the recombinant bacteriophage.

If the scraping method is used, we recommend continuing the traditional method of keying the filters to the plaques, especially when screening large cDNA libraries. This extra effort provides insurance if the desired recombinants fail to be recovered by scraping.

Continue at Step 16

CHEMILUMINESCENT SCREENING

Chemiluminescence is the most sensitive method for detecting immunopositive plaques. The secondary antibody is typically conjugated to either AP or HRP. Use of AP-conjugated antibodies requires substrates such as 1,2-dioxetane phosphates that emit light at a maximum wavelength of 466 nm upon dephosphorylation. HRP-conjugated antibodies oxidize the substrate luminol, which in the presence of hydrogen peroxide and phenol emits an intense light emission with a maximum at 428 nm. With either system, the light emission can be captured by autoradiography. Chemiluminescent detection is quick, produces a permanent record of the screened filter (an X-ray film or phosphoimage), and is sensitive (1–10 pg of antigen in a plaque can be detected). Two potential drawbacks are the inflated cost of the reagents and the need to identify positives on the original agar plate by comparison to an autoradiogram. A typical protocol follows.

Materials for Chemiluminescent Screening

AP- or HRP-conjugated anti-immunoglobulin antibodies
Chemiluminescent substrates (commercially available from, e.g., Tropix)
Saran Wrap

a. Gently agitate the filters for 1.5–2 hours in the AP- or HRP-conjugated antibody solution at room temperature.

b. Wash the filters as described in Step 14.

c. Prepare the chemiluminescent substrates according to the manufacturer's instructions.

d. Incubate the washed filters in the chemiluminescent substrates for 1–5 minutes (again, consult the manufacturer's recommendations for optimal exposure times).

e. Drain the excess solution from the filters, and immediately wrap the filters in Saran Wrap. Do not allow the filters to dry out.

f. Establish an autoradiogram (please see Appendix 9). Typically, the initial exposure is 1 minute. This interval provides enough information to establish the proper exposure time.

Continue at Step 16.

16. Identify the locations of positive plaques or, if made, compare the duplicate filters, searching for coincident signals. For screens involving radiolabeled or chemiluminescent probes, compare the resulting autoradiograms with the agar plates on a light box. For screens involving chromogenic reagents that leave a visible positive residue on the filter, carry out the following steps:

    a. Lay a sheet of Saran Wrap or Mylar film over the filters.

    b. On the surface of the Saran Wrap, mark the locations of the holes in the filters and the locations of antigen-positive clones with different colored waterproof markers. Label the Saran Wrap to identify the plates from which the filters were derived.

    c. Place the sheet of Saran Wrap on a light box, and align the plates containing the original bacteriophage λ plaques on top of it.

    d. Identify the area containing the positive plaque, and remove a plug of agar from this area using the large end of a Pasteur pipette. Transfer the plug to 1 ml of SM containing 2 drops of chloroform.

    e. Keep the sheet of Saran Wrap, which provides a permanent record of the locations of the positive plaques. The colored spots on the original filters fade quite rapidly.

17. Allow the bacteriophage particles to elute from the agar plug for several hours at 4°C. Measure the titer of the bacteriophages in the eluate, and then replate them so as to obtain ~3000 plaques per 90-mm plate. Rescreen the plaques as described above (from Step 4 onward), and repeat the process of screening and plating until a homogeneous population of immunopositive recombinant bacteriophages is obtained.

VALIDATION OF CLONES ISOLATED BY IMMUNOLOGICAL SCREENING

The identification of immunoreactive clones from expression libraries cannot be taken as proof that the cDNA of interest has been isolated. The specificity of antibodies is never absolute and the epitope(s) recognized on the protein is usually undefined. Further tests are therefore required to validate the identity of the initial isolates. In decreasing order of stringency, these tests include:

- ***Demonstration that the protein encoded by the cloned cDNA displays the correct biological or enzymatic activity.*** This test usually requires the isolation of full-length cDNA clones and expression in prokaryotic or eukaryotic vectors that do not generate fusion proteins. In only a few cases has it been possible to demonstrate the appropriate enzymatic activity in fusion proteins synthesized in bacteriophage λgt11 vectors (e.g., firefly luciferase [de Wet et al. 1984] and cat brain glutamate decarboxylase [Kaufman et al. 1986]).
- ***Comparison of the amino acid sequence of the protein with the amino acid sequence deduced from the sequence of the cloned cDNA.*** At present, this test can rarely be applied, since there is usually no amino acid sequence available for proteins whose genes are cloned by immunological screening. However, as the catalog of human genes is completed, this test should become routine.
- ***Demonstration that the fusion protein expressed by the clone can block the interaction between the purified protein of interest and a specific antibody.*** For example, the fusion protein could protect an enzyme from inactivation by an antibody. Alternatively, the fusion protein can be used as a ligand in affinity purification of an antibody (e.g., please see Earnshaw and Rothfield 1985). The affinity-purified antibody is then used as a probe in western blots of purified antigen. Finally, the fusion protein may be used as an immunogen to raise antibodies that can be tested for their ability to bind to, or inhibit the activity of, the protein of interest. For the preparation of fusion proteins, please see Protocols 7, 8, and 9 in this chapter and Chapter 15.

These tests are by no means the only ones that may be used to validate clones isolated by immunological screening. Regardless of the method used, it is essential to devise independent tests that do not rely on the same immunological reagents used to identify the clone in the first place.

TROUBLESHOOTING

A variety of problems are encountered when using antibodies to screen an expression library in a bacteriophage λ vector. Consider the following if "cursed" with no positive clones or "blessed" with an abundance of positives. General texts on immunochemistry can provide insights and solutions to certain problems (Johnstone and Thorpe 1982; Harlow and Lane 1999).

- The antibody used may not recognize the antigen when the latter is expressed in *E. coli*. This problem can occur when screening for eukaryotic cell surface proteins that have an abundance of posttranslational modifications such as carbohydrates, lipids, and disulfide bonds. Each of these modifications are antigenic and not generally present on proteins expressed in bacteria. Monospecific polyclonal antibodies that recognize fully denatured, deglycosylated proteins should be used whenever possible to avoid these problems.
- Use a TNT buffer that does not contain Tween. Nonionic detergents can disrupt the binding of low-affinity antibodies to an antigen. Omitting Tween can, however, lead to the detection of an abundance of false positive clones due to the accompanying reduction in stringency.
- The use of excess primary or secondary antibody in the screening reactions can lead to the detection of too many "positive" clones. These clones are presumed to result from binding of antibody to proteins that are related to the two targets, but are not identical to them. Diluting the antibody may eliminate or reduce cross-reactions without significantly affecting the binding of the antibody to its two targets.
- Too many positives can sometimes reflect a problem with the blocking reagent. Try one of the other blocking reagents suggested under the blocking buffer entry in the Materials list. Alternatively, increase the concentration of Tween or try another nonionic detergent such as Nonidet P-40 in the rinsing and washing buffers. The temperature at which the blocking, rinsing, and washing steps are carried out can be increased to as high as 50°C.
- If positive plaques are not detected, vary the incubation times in the protocol. For example, the incubation of the IPTG-soaked filters on the agar plates can be varied between 2 and 10 hours. Snyder et al. (1987) reported that an 8–10-hour incubation yields a signal that is 5–10 times stronger than a 2-hour incubation. Similarly, an overnight incubation with primary antibody or incubation at 4°C works better for some antibodies, especially those with low affinity for antigen.

Protocol 2

Screening Expression Libraries Constructed in Plasmid Vectors

MOST CDNA LIBRARIES CONSTRUCTED IN PLASMIDS TODAY USE EXPRESSION vectors of the pUC, pUR, or pEX series (please see Chapters 11 and 15 and Appendix 3). In the pUC and pUR vectors, the cDNA is inserted into polycloning sites that lie within the amino-terminal region (pUC) or the carboxy-terminal region (pUR) of the *E. coli* β-galactosidase gene. Although libraries constructed in both pUR and pUC vectors have been screened successfully with antibodies (e.g., please see Helfman et al. 1983), pUR vectors have some advantages. First, because the polycloning site is available in all three translational reading frames, any open reading frame of a sequenced fragment of cDNA can be easily inserted in the appropriate frame for expression. Second, fusion proteins in which the foreign sequences are located in the carboxy-terminal region of β-galactosidase are more stable than fusion proteins with insertions in the amino-terminal region (Stanley 1983). In at least some cases, fusion proteins synthesized from recombinants constructed in pUR vectors retain β-galactosidase activity (Rüther and Müller-Hill 1983), which can serve as a useful marker during protein purification (please see Chapter 15, Protocol 1, and Chapter 17, Protocol 7). Expression of fusion proteins in both pUC and pUR plasmids is controlled by the upstream *lac* promoter and is therefore repressed in strains of bacteria that overproduce the *lac* repressor (I^q strains). Continual repression is important to prevent constitutive expression of foreign proteins, which are frequently toxic to *E. coli* (Amann et al. 1983; Gething and Sambrook 1983). Plasmids encoding toxic proteins can therefore be propagated and amplified under conditions that allow only minimal expression of the fusion protein. Maximal synthesis of the fusion protein is transiently induced by exposing the culture to IPTG before immunological screening is undertaken. Several expression plasmids have been described that carry their own copy of the $lacI^q$ gene (e.g., please see Stark 1987). Expression of sequences cloned in these plasmids is tightly regulated, regardless of the strain of bacteria used.

The pEX family of plasmids also contains polycloning sites in all three reading frames at the 3′ terminus of a fusion gene composed of bacteriophage λ *cro* sequences and *E. coli lacZ* sequences (Stanley and Luzio 1984). Expression of *cro*-β-galactosidase fusion proteins is controlled by the bacteriophage λ p_R promoter, which can be repressed during growth and amplification of the plasmid by the bacteriophage λ *cI* gene product. The pEX vectors are normally grown at 30°C in a bacterial strain carrying a defective bacteriophage λ prophage that synthesizes a temperature-sensitive *cI* gene product. Transient expression of the fusion protein is induced by raising the temperature of incubation to 42°C before immunological screening.

Although quantitative comparisons have not been carried out, it is clear that each of these three families of plasmids can efficiently direct the synthesis of large quantities of fusion proteins

(up to 40% of the total extractable cellular protein). Within any one system, smaller fusion proteins are expressed to higher levels than larger fusion proteins and are degraded less rapidly by cellular proteases, perhaps because they more readily form precipitates (known as inclusion bodies; please see Chapter 15, Protocol 8) within the cell (Stanley and Luzio 1984).

Three alternative methods to detect bound antibodies are discussed: radiochemical screening, chromagenic screening, and chemiluminescent screening. The advantages and disadvantages of these methods are discussed in the introduction to this chapter.

MATERIALS

CAUTION: Please see Appendix 12 for appropriate handling of materials marked with <!>.

Buffers and Solutions

Please see Appendix 1 for components of stock solutions, buffers, and reagents. Dilute stock solutions to the appropriate concentrations.

Blocking buffer

10 mM Tris-HCl (pH 8.0)
150 mM NaCl
0.05% (v/v) Tween-20
20% (v/v) fetal bovine serum

Alternative blocking buffers are 5% (w/v) nonfat dried milk or TNT buffer containing 1% (w/v) gelatin and 3% (w/v) bovine serum albumin. Opinion of relative virtues of these blocking agents varies from laboratory to laboratory. We recommend that the investigator carry out preliminary experiments to determine which of them works best with the primary and secondary antibodies that will be used for screening. Blocking buffer can be stored at 4°C and reused several times. Sodium azide **<!>** should be added to a final concentration of 0.05% (w/v) to inhibit the growth of microorganisms.

Chloroform **<!>**

Lysis buffer

100 mM Tris-Cl (pH 7.8)
150 mM NaCl
5 mM $MgCl_2$
1.5% (w/v) bovine serum albumin
1 µg/ml pancreatic DNase I
40 µg/ml lysozyme

Add DNase I and lysozyme to this buffer just before use in Step 11.

Reagents for detection of antigen-antibody complexes:

Reagents for chromogenic screening with alkaline-phosphatase-conjugated antibody
Reagents for chromogenic screening with horseradish-peroxidase-conjugated antibody
Reagents for chemiluminescent screening

For a list of reagents needed for the screening method, please see Step 19. For information on commonly used methods to detect antibodies, please see the information panel on **USING ANTIBODIES IN IMMUNOLOGICAL SCREENING.** For further details, please see the information panels in Appendix 9.

SM

Store SM at room temperature. Discard each aliquot after use to reduce the possibility of contamination.

TNT buffer

10 mM Tris-Cl (pH 8.0)
150 mM NaCl
0.05% (v/v) Tween-20

Approximately 1 liter of TNT buffer is required per 10 filters screened. Store TNT buffer at room temperature.

Washing buffers:

TNT buffer containing 0.1% (w/v) bovine serum albumin
TNT buffer containing 0.1% (w/v) bovine serum albumin and 0.1% (v/v) Nonidet P-40

These buffers should not contain sodium azide.

Radioactive Compounds

^{125}I-labeled protein A or ^{125}I-labeled immunoglobulin (optional) <!>

Radioiodinated secondary antibody <!>

Use this antibody if detecting the antigen-antibody complexes with a radiolabeled secondary antibody in Step 19.

RADIOIODINATION OF IgG

▲ **WARNING** Perform this procedure behind appropriate shielding in a correctly vented chemical fume hood.

This method can be used to radiolabel an IgG fraction for use as a secondary antibody.

1. Prepare IgG from antiserum by protein A–Sepharose chromatography as described by Harlow and Lane (1999). Dilute the IgG with 50 mM sodium phosphate (pH 7.5) to obtain a final concentration of 1 mg/ml.
2. To 50 µl of the diluted IgG, add 4 µl of ^{125}I (sodium ^{125}I, 10 mCi/ml).
3. Add 15 µl of chloramine T (2 mg/ml in 50 mM sodium phosphate [pH 7.5]).
4. Incubate the reaction for 90 seconds at room temperature.
