Introduction to Comprehensive Developmental Neuroscience

It is broadly accepted that understanding the genetic, molecular, and cellular mechanisms of neural development is essential for understanding evolution and disorders of neural systems. Recent advances in genetic, molecular, and cell biological methods have generated a massive increase in new information. By contrast, there is a paucity of comprehensive and up-to-date syntheses, references, and historical perspectives on this important subject. Therefore, we embarked on the formidable task of assembling a novel resource entitled 'Comprehensive Developmental Neuroscience.' We hope that the books in this series will serve as valuable references for basic and translational neuroscientists, clinicians, and students.

To help with this enormous task, we invited leading experts in various subfields to select the subjects and invite appropriate authors. We were gratified by the number of busy scientists who accepted the invitation to write their articles. All the chapters have been peer reviewed by the Section Editors to ensure accuracy, thoroughness, and scholarship.

In the resulting three volumes, we cover a broad array of subjects on neural development. We organized the volumes chronologically according to the ordered steps in neural development. In addition, each volume is subdivided into three to four sections, each edited by world experts in these areas. The sections have 10–20 chapters that are written and illustrated by leading scientists.

This Volume in the series has 40 chapters devoted to the anatomical and functional development of neural circuits and neural systems, as well as chapters that address neurodevelopmental disorders in humans and experimental organisms. This volume is subdivided into three sections. The first is on the mechanisms that control the assembly of neural circuits in specific regions of the nervous system, and as a function of neural activity and critical periods. The second section concentrates on multiple aspects of cognitive development, particularly in humans. The final section addresses disorders of the nervous system that arise through defects in neural development, building on the principles that are addressed in earlier sections of the book.

Volume 1 has 48 chapters devoted mainly to patterning and cell type specification in the developing central and peripheral nervous systems (CNS and PNS). This volume is subdivided into three sections. The first is on the mechanisms that control regional specification, which generate subdivisions of the nervous system. The second is on mechanisms that regulate the proliferation of neuronal progenitors and that control differentiation and survival of specific neuronal subtypes. The third section addresses the mechanisms controlling development of non-neural cells: astrocytes, oligodendroyctes, Schwann cells, microglia, meninges, blood vessels, ependyma, and choroid plexus.

Volume 2 in the series has 56 chapters devoted to migration (cell and axonal), the formation of neuronal connections, and the maturation of neural functions. This volume is subdivided into four sections. The first is on mechanisms that control the formation of axons and dendrites. The second is on the mechanisms that regulate cell migration that disperses specific subtypes of cells along highly defined pathways to specific destinations. The third section is on the regulation of synapse formation and maintenance during development; in addition, it has chapters on synaptogenesis in the mature nervous system in response to neurogenesis, neural activity, and neural trauma. The final section is on the developmental sequences that regulate neural activity, from cell-intrinsic maturation to early correlated patterns of activity.

The Form and Functions of Neural Circuits in the Olfactory Bulb

G. Lepousez, P.-M. Lledo

Institut Pasteur, Paris, France; Centre National de la Recherche Scientifique, Paris, France

1.1 INTRODUCTION

Sensory systems are specialized biological devices by which organisms perceive the external sensory space. Sensory perception allows the deconstruction of this external world and the subsequent emergence of an internal percept. Following this Aristotelian principle, animals can discriminate and recognize an enormous range of physical and chemical signals in their environment, which may profoundly influence their behavior and provide them with vital information for reproduction and survival.

Several sophisticated sensory channels are available for that purpose, but all of them rely on a specific set of rules by which information is transposed from one dimension to another. For the chemical senses, this transposition concerns the ways in which chemical information gives rise to specific neuronal responses in a dedicated sensory organ (Ache and Young, 2005). In comparison to other sensory stimuli, odorant molecules, that is, volatile molecules that are perceived as odors, are infinite in terms of molecular formulae and cannot be classified with only objective dimensions such as frequency in the case of auditory stimuli (Laurent, 2002). The task of perceiving an odorant is made even more complex because a single odor usually is composed of many types of molecules (e.g. chocolate contains more

than 600 types) and is still perceived as one unique object, distinct from its components (a process called pattern completion). In addition, odor intensity (i.e., molecular concentration) can vary without changes in the perceived quality (a process called perceptual stability; Gottfried, 2010).

The origin of chemical detection (also called chemosensation) certainly dates back to the beginning of prokaryotes. It has evolved into distinct modalities in vertebrates to meet crucial needs such as locating potential food sources, detecting dangers such as predators, and mediating social and sexual interactions. Despite these functions, which are highly conserved throughout the evolution of species, interest in audition and vision has largely dominated the sensory research field in neuroscience, leaving behind the understanding of the more primitive chemical sense. Nevertheless, during the last two decades, neuroscience has made considerable progress in understanding how the brain perceives, discriminates, and recognizes odorant molecules so precisely. In 1991, the description of a multigene family of olfactory G-protein-coupled receptors provided a molecular basis for odor recognition (Buck and Axel, 1991). This discovery was of great significance to the neurobiology of olfaction and later was recognized with the Nobel Prize in 2004 (Mombaerts, 2004a). Since then, olfaction has attracted the attention of neuroscientists who started to investigate the different stages of chemosensory systems. As a result, converging approaches including anatomy, neurogenetics, biochemistry, cellular biology, neurophysiology, psychology, and computational neuroscience have contributed to provide a picture of how chemical information is processed in the olfactory system, starting from the periphery to higher brain regions.

Although still incomplete, today we have a fairly comprehensive picture about how chemicals interact with their cognate receptors to initiate signal transduction in the sensory receptor cells. We also know how the olfactory sensory information is first transduced in the sensory neurons located in dedicated olfactory sensory organs (Mombaerts, 2004b). Among the different elements along the olfactory pathway, local circuits in the second- and third-order central areas are key elements that process the simple monophasic sensory signal conveyed by the sensory neurons and convert it into a multidimensional content (Figure 1.1) (Gottfried, 2010; Wilson and Sullivan, 2011).

Below, we discuss how the chemical information is encoded and processed at the first central relay of the olfactory system, the main olfactory bulb, as well as the functions of the bulbar neural circuits that are relevant for triggering specific behavioral responses. In addition to the main olfactory bulb, which relays odorant information detected by sensory neurons of the olfactory epithelium, a similar structure called the accessory olfactory bulb, located in the caudal part of the olfactory bulb, relays pheromonal information detected in the vomeronasal organ. Because of space constraints, this chapter focuses exclusively on the main olfactory bulb and odor coding in rodents.

1.2 SYNAPTIC ORGANIZATION OF THE MAMMALIAN OLFACTORY BULB

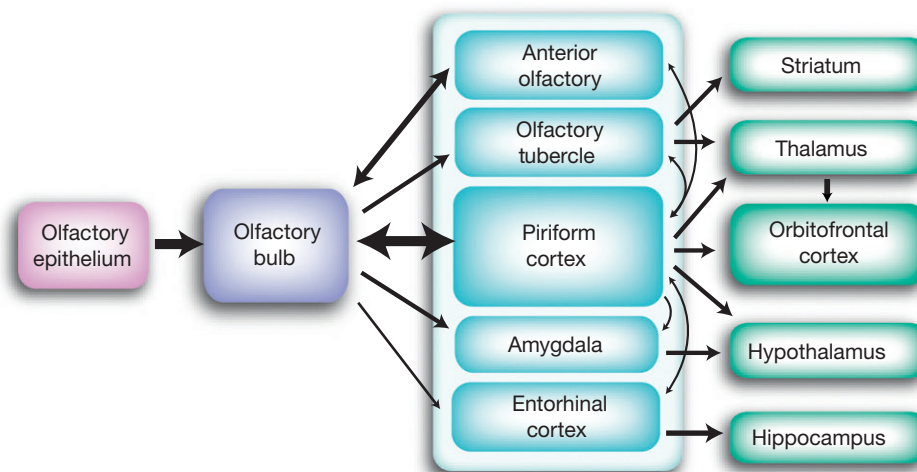
The olfactory system is responsible for correctly coding sensory information from thousands of odorous stimuli. To accomplish this complex task, odor information is


FIGURE 1.1   Schematic representation of the olfactory system. The olfactory system is composed of a sensory organ, the olfactory epithelium, followed by the olfactory bulb, the first central relay of odor information. The olfactory bulb then projects to different olfactory cortical areas involved in olfactory processing and behavior. Structures in blue that receive direct inputs from the output neurons of the olfactory bulb composed together the so-called 'olfactory cortex.'

processed through distinct units. At each of these units, a modified representation of the odor stimulus is generated. Following a bottom–up approach, we will start our description from the olfactory sensory organ located in the nasal cavity.

1.2.1 Organization of Sensory Inputs

The ability to process correctly the physical and statistical properties of chemical information is constrained by the functional architecture and the synaptic organization of some dedicated neural circuits. As our knowledge about the neurobiology of olfaction grows, it is becoming evident that the main olfactory systems of animals in disparate phyla share many striking features regarding the functional architecture and the synaptic connectivity (Bargmann, 2006; Hildebrand and Shepherd, 1997). For instance, mammals and invertebrate olfactory systems display common organizational features and functional characteristics (Wilson and Mainen, 2006). In all cases, the initial event shared by virtually all odorant detection systems is the requirement of specific interaction of odorant molecules with specific receptors expressed on the cilia of sensory olfactory neurons before conveying information to central structures (Ache and Young, 2005; Bargmann, 2006; Mombaerts, 2004b). Essentially, there are four different features that are common to all olfactory systems: (1) The presence of soluble odorant binding proteins in the mucus overlying the receptor cell dendrite, (2) the existence of G-protein-coupled receptor acting as specific odorant receptors, (3) the use of a two-step signaling cascade in odorant transduction, (4) the presence of functional anatomical structures at the first central target in the olfactory pathway called glomeruli (reviewed by Bargmann, 2006; Firestein, 2001; Mombaerts, 2004b). If these common features represent adaptive mechanisms that have evolved independently, their study might bring valuable knowledge about the way the nervous system extracts information from olfactory space.

In mammals, olfactory transduction starts with the activation of some of the thousand different types of odorant receptors located on the cilia of bipolar olfactory sensory neurons that comprise the olfactory neuroepithelium (1000–1300 genes in the mouse; Buck and Axel, 1991; Mombaerts, 2004b). It is believed that these sensory neurons recognize more than a thousand airborne volatile molecules called odorants. A general principle is that these receptors exist as separate information channels, because most sensory neurons express only one type of olfactory receptor. Because of the broad chemical tuning of these receptors (Araneda et al., 2000), the general coding principle is "one odor = one set of receptor activations" (Firestein, 2001; Mombaerts, 2004b). The olfactory epithelium then projects to the first central relay of the olfactory system: the main olfactory bulb (referred to below as the olfactory bulb). As advances in understanding olfactory transduction progressed, interest in deciphering some of the olfactory bulb functions grew concomitantly. This heightened interest has been spurred on, at least in part, by the discovery of the way in which the sensory organ connects to the olfactory bulb. We know now that the sensory neurons that express the same odorant receptor project their axons centrally to one or two spherical modules in the olfactory bulb called glomeruli (Zou et al., 2009). Here, sensory information is transmitted to higher brain centers via output neurons called mitral/tufted cells. The discrete and spherical glomeruli are morphological units made of distinctive bundles of neuropil (Figure 1.2). This terminology reflects both the homogeneity of the sensory inputs (they all express only one odorant receptor) and the degree to which the olfactory bulb neurons connected to the same glomerular unit display a similar receptive field (Dhawale et al., 2010; Tan et al., 2010). Recently, dramatic progress has been made in understanding of how olfactory sensory neurons develop and how they express only one odorant receptor. This discovery prompted the use of genetic tools to probe and manipulate specific populations of sensory neurons, resulting in several major breakthroughs

(a) (b)
FIGURE 1.2 Convergence of the olfactory sensory neuron axons into glomeruli. (a) Olfactory sensory neurons labeled in blue project their axons on the surface of the olfactory bulb (note the single glomeruli). (b) Whole-mount view of the olfactory epithelium (OE) and the olfactory bulb (OB). Olfactory sensory neurons expressing the olfactory receptor P2 in the olfactory epithelium (OE) project the axons towards a single glomerulus (red dashed circle) on the surface of the olfactory bulb (OB). *Adapted from Mombaerts P, Wang F, Dulac C, et al. (1996) Visualizing an olfactory sensory map.* Cell *87: 675–686, with permission.*

regarding axon guidance, axon sorting and axon positioning (Sakano, 2010; Zou et al., 2009).

In different species, each glomerular structure results from the convergence of 5 to 40 thousand axon terminals of sensory neurons that express the same odorant receptor (Figure 1.2). Therefore, the glomerular layer can be considered as a two-dimensional anatomical representation of the olfactory receptors' repertoire (also called 'chemotopic map'; Johnson and Leon, 2007; Wachowiak and Shipley, 2006). Because one odor can activate several olfactory neurons, odor information is first encoded by the combinatorial patterns of glomerular activation. Odorants activate a specific array of olfactory sensory neurons that lead to a chemotopically fragmented map of activated glomeruli on the surface of the olfactory bulb (Meister and Bonhoeffer, 2001). Remarkably, the precise projection pattern can be reproduced from one animal to another and even between different rodent species (Soucy et al., 2009). Distinct odorants activate different combinations of glomeruli and two odors are more difficult to discriminate when these show a greater overlap in this glomerular chemotopic map (Linster et al., 2001). Nevertheless, if such a spatial pattern coding scheme were only applicable to several odors, it would not be able to provide a sufficiently large coding space to discern between the millions of potential odors or mixtures of odor present in our environment (Laurent, 2002).

The sensory neurons project to paired olfactory glomeruli on both the medial and lateral aspects of the olfactory bulb, thus creating two mirror-symmetric maps (Mombaerts et al., 1996). As each group of glomerulus-specific output neurons is odorant receptor-specific, glomeruli form a morphological as well as functionally defined network somewhat analogous to barrels in the somatosensory cortex (Johnson and Leon, 2007). In mammals, the convergence ratio of sensory neurons to olfactory bulb output neuron is very large: about 1000:1 (Zou et al., 2009). A bulbar output neuron thus forms its responses to odors from very large numbers of converging inputs, ensuring detection of faint signals, increase signal-to-noise ratios and temporal noise average.

1.2.2 Synaptic Processing Within Olfactory Bulb Microcircuits

Because of its relatively simple anatomical organization and easy access, the olfactory bulb has been a privileged model system for deciphering the principles underlying network processing of sensory information. There, odors elicit a well-organized pattern of glomeruli activation across the surface of the olfactory bulb, but the mechanisms by which this chemotopic map is processed into an odor code by the bulbar circuitry has recently attracted more attention. With the advance in recent years of *in vitro* brain slice preparation, as well as *in vivo* recording techniques that were applied on behaving animals, the complex processing of the olfactory information is starting to be revealed. Since Cajal's pioneering studies, it has been known that the main output neurons of the bulb, the so-called mitral cells, are located in a single lamina, the mitral cell layer (Figure 1.3). A second population of output neurons, namely tufted cells, are scattered in the external plexiform layer (EPL). The primary (or apical) dendrite of mitral and tufted cells, extending vertically from its soma, contacts one glomerulus, whereas their multiple long secondary dendrites spread in the EPL.

About 50–100 output neurons (mitral/tufted cells) emanate from each glomerulus and project to a number of higher centers that compose the olfactory cortex (see Figure 1.1). Output neurons are the backbone of two serial intrabulbar microcircuits: one between primary apical dendrites and juxtaglomerular cells and the other between secondary dendrites and granule cells. The main difference between juxtaglomerular and granule cells is that the former mediate mostly interactions between cells affiliated with the same glomerulus, while granule cells mostly mediate interactions between output neurons projecting to many different glomeruli (Figure 1.3). Therefore, two potential distinct sites of odor processing can be distinguished according to the topographical organization of the bulbar circuit. The first one resides in the glomeruli where local interneurons shape excitatory inputs coming from sensory neurons. The second one lies in the EPL, where reciprocal dendro-dendritic synapses are heavily distributed between dendritic spines of local interneurons and the dendrites of output neurons. These two inhibitory microcircuits are also under the control of centrifugal fibers coming from cortical and neuromodulatory area.

1.2.2.1 Synaptic Transmission at the First Synapses

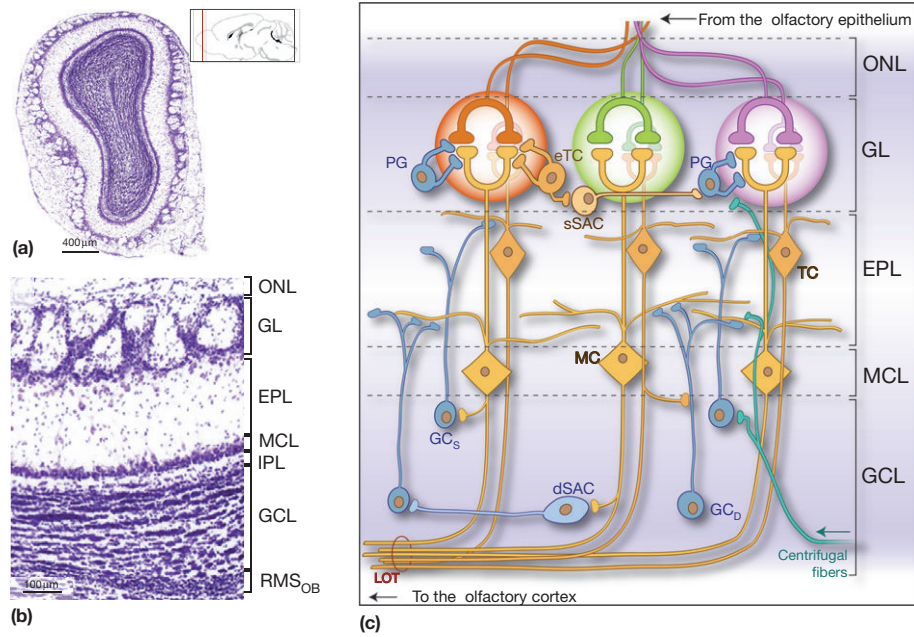
The glomerular layer constitutes a first site of integration for olfactory information. In this layer, axonal termini of olfactory sensory neurons synapse directly onto output neurons (50–100 cells per glomerulus) and also onto local neurons, namely juxtaglomerular cells (1000–2000 cells per glomerulus). The olfactory nerve-evoked excitatory responses of both neuron types comprise fast amino-3-hydroxy-5-methyl-4-isoaxozole-propionic acid (AMPA) and slow *N*-methyl-D-aspartate (NMDA) components. The latter is particularly long-lasting and may play an important role in the bulbar output by maintaining a pattern of sustained discharge of output neurons (Carlson et al., 2000).


FIGURE 1.3 Anatomical organization of the main olfactory bulb. (a) Nissl-stained coronal section of the mouse olfactory bulb showing the different concentric layers. Inset, a sagittal section showing the rostrocaudal level of the coronal section. (b) Higher magnification view. ONL, olfactory nerve layer; GL, glomerular layer; EPL, external plexiform layer; MCL, mitral cell layer; IPL, internal plexiform layer; GCL, granule cell layer; RMS OB, rostral migratory stream of the olfactory bulb. (a) Olfactory sensory neurons (OSNs) in the olfactory epithelium (OE) that express the same odorant receptors project their axons to the main olfactory bulb into one of the glomeruli that form the glomerular layer (GL). In the GL, sensory neuron terminals synapse onto the apical dendrites of output neurons, namely the mitral cell (MC) and the tufted cells (TC). In addition, periglomerular cells (PGC), superficial short-axon cells (sSAC) and external tufted cells (eTC) act on glomerular synaptic transmission exerting diverse functional effects. In the external plexiform layer (EPL), the lateral dendrites of mitral and tufted cells interact with the dendrites of granule cells (GC). Granule cells can also be subdivided into distinct subpopulations: superficial granule cells (GC$_S$), which target the superficial lamina of the external plexiform layer and synapse with tufted cells, and deep granule cells (GC$_D$), which target the deep lamina of the external plexiform layer are connected to mitral cells. The somas of mitral cells are aligned and delineate the mitral cell layer (MCL), and the somas of tufted cells are scattered in the EPL. Granule cell somas and also some deep short-axon cells (dSAC) compose the granule cell layer (GCL). Centrifugal fibers from other brains regions innervate specific layers of the olfactory bulb depending on their brain origin. Lastly, output neuron axons fasciculate to form the lateral olfactory tract (LOT). All of the cell types colored in orange are glutamatergic; GABAergic cells are in blue. ONL, olfactory nerve layer.

Juxtaglomerular cells have dendrites restricted to one glomerulus and impinge onto olfactory nerve terminals or primary dendrites of mitral/tufted cells. Juxtaglomerular cells can be subdivided into three categories (Figure 1.3). The first category is comprised by periglomerular cells, small axonless interneurons that are the main source of γ-aminobutyric acid (GABA) in the glomerular layer and which provide feedback and feedforward inhibition to output neurons (Wachowiak and Shipley, 2006). It is noteworthy that a subpopulation of these GABAergic cells is also dopaminergic (Kosaka and Kosaka, 2005). Their inhibitory action alters the strength of sensory signals as they pass out of the bulb, and it is thought to provide a mechanism of filtering of weak sensory inputs (Gire and Schoppa, 2009). In addition, periglomerular cells also exert a presynaptic regulation of sensory inputs thanks to the expression of GABA$_B$ and D$_2$ dopamine receptors on olfactory sensory terminals (Aroniadou-Anderjaska et al., 2000; Hsia et al., 1999). The second category concerns the superficial short-axon cells. This heterogeneous cell population,

comprising GABAergic and glutamatergic neurons, displays dendritic and axonal branching in several glomeruli and is thought to mediate lateral inhibition between glomeruli (Aungst et al., 2003; Kiyokage et al., 2010). The third group is composed of external tufted cells. These local glutamatergic cells, distinct from the output tufted cells, innervate periglomerular cells, short-axon cells, and mitral cells. Their spontaneous intrinsic rhythmic activity, synchronized by gap junctions and with the breathing rhythm, coordinates the activity of the cells located within each glomerulus (De Saint Jan et al., 2009; Hayar et al., 2004). In addition to direct fast excitation from OSN, external tufted cells provide a significant slow feed-forward excitation onto mitral cells (Najac et al., 2011). Moreover, activation of external tufted cells and glutamatergic superficial short-axon cells triggers lateral excitation of distant periglomerular cells, thus providing feedforward inhibition onto mitral/tufted cells of remote glomeruli (Aungst et al., 2003; Wachowiak and Shipley, 2006). This distributed inhibition mediates a globally averaged level of feedforward inhibition onto

distant mitral/tufted cells and contributes to normalization of the intensity of sensory input, a key function for constructing intensity-independent representations of stimulus quality (Linster and Cleland, 2009). It is also known that several major classes of periglomerular cells are generated in the adult through the subventricular zone (SVZ) and the rostral migratory stream (RMS) and that their respective proportions remain constant throughout life (Lledo et al., 2008).

Since extremely faint signals can be detected by the olfactory system, there may be some mechanisms that promote reliable information transmission from olfactory sensory neurons to the brain. In the absence of any presynaptic specialization such as the synaptic ribbons in the retina or the cochlea, the sustained and reliable synaptic transmission of odor information benefits from the high convergence of sensory neurons and also from a very high probability of glutamate release, reflected by a marked paired-pulse depression (Hsia et al., 1999;

Murphy et al., 2004). In addition to the synaptic mechanisms described above, glutamate spillover within glomeruli and the presence of gap junctions between output neurons connected to the same glomerulus would help in increasing the signal-to-noise ratio and normalizing the activity of output neurons (Christie et al., 2005; Linster and Cleland, 2009).

1.2.2.2 The Dendrodendritic Synapse Provides the Major Source of Inhibitory Contact to Output Neurons

In contrast to the primary dendrite, mitral/tufted cell secondary (or basal) dendrites radiate up to 1000 μm horizontally, spanning almost the entire olfactory bulb. In the EPL, mitral/tufted cell dendrites interact with the dendrites of granule cells and both contain synaptic vesicles (Figure 1.4; Price and Powell, 1970). As granule cells are the largest group of bulbar interneurons (there are about 100 granule cells for one output neuron), and
FIGURE 1.4   The dendrodendritic reciprocal synapse in the main olfactory bulb. (a) Two electron micrographs of a mitral cell dendrite (m) making a mitral-to-granule asymmetric synapse (arrow) onto a granule cell spine (g), which in turn makes a granule-to-mitral symmetric synapse (arrowhead) back onto the same mitral cell dendrite (adapted from Price JL and Powell TP (1970). The synaptology of the granule cells of the olfactory bulb. *Journal of Cell Science* 7: 125–155, with permission). (b) Serial section reconstitution of a reciprocal synapse between a lateral dendrite of mitral cell (m) and a granule cell spine (g). Green arrow, glutamatergic synapse; red arrow, GABAergic synapse (adapted from Rall W, Shepherd GM, Reese TS, and Brightman MW (1966) Dendrodendritic synaptic pathway for inhibition in the olfactory bulb. *Experimental Neurology* 14: 44–56, with permission). (c) Schematic representation of the dendrodendritic synapse. Action potentials (AP) propagating in mitral cell secondary dendrites (m, represented in orange) activate voltage-gated calcium channels (VGCC), which trigger the release of glutamate at reciprocal synapses. This glutamate locally depolarizes granule cell spines (g, represented in blue) via AMPA receptors (AMPAR) and NMDA receptors (NMDAR), which triggers calcium entry from NMDA receptors and also from voltage-gated calcium channels and calcium-induced calcium release from internal stores (CICR). This in turn causes GABA release back onto the mitral cell dendrite that activates $GABA_A$ receptors ($GABA_A$). In addition, action potentials generated in the soma of the granule cell can propagate in the dendritic tree and trigger a global release of GABA.

as they are axonless neurons, synaptic transmission between dendrites remains the dominant mode of neuronal interaction in the olfactory bulb (Schoppa and Urban, 2003; Shepherd et al., 2007).

Granule cells can also be subdivided into distinct subpopulations: superficial granule cells that target the superficial lamina of the EPL and are believed to establish synapses mostly with tufted cells and deep granule cells targeting the deep lamina of the EPL which are connected to the mitral cells (Figure 1.3; Mori et al., 1983; Shepherd et al., 2007). These two microcircuits (tufted/superficial granule cells versus mitral/deep granule cells) are thought to maintain different functions in odor processing. Because of their short lateral dendrites and the intrabulbar connections between mirror-symmetric glomeruli they support, tufted cells may be important for intensity perception of odorants (Lodovichi et al., 2003; Nagayama et al., 2004). By contrast, the mitral-granule cell circuit is thought to mediate complex inhibitory functions that are important for odor discrimination (Lledo and Lagier, 2006).

The synaptic interactions that play a key role in the mitral/tufted-granule cell circuits have some simple yet unusual features. Output cells and granule cells communicate via reciprocal dendrodendritic synapses (Figure 1.4; Jahr and Nicoll, 1980; Price and Powell, 1970; Rall et al., 1966; review in Schoppa and Urban, 2003). This feature also extends to periglomerular cells that synapse with mitral/tufted apical dendrites in the glomerulus. The reciprocal circuit provides inhibition that forms the basis for a reliable, spatially localized, and recurrent inhibition. Synaptic depolarization in mitral/tufted cells driven by the long-lasting excitatory inputs from sensory neurons triggers the generation of an action potential. This action potential invades the lateral dendrites (Xiong and Chen, 2002) and triggers glutamate release from output neuron dendrites onto granule cell spines. The activation of AMPA and NMDA receptors present in the spines of granule cells leads to a depolarization and a local calcium entry in interneuron dendrites and spines. This, in turn, elicits the synchronous and asynchronous release of GABA directly back onto output neurons. The release of GABA from granule cell spines is driven by calcium entry, mainly from NMDA receptors, but also from voltage-gated calcium channels and internal stores (Figure 1.4; Egger et al., 2005; Isaacson and Strowbridge, 1998; Schoppa et al., 1998). Thus, dendritic GABA release from granule cell spines might occur (1) through an action potential-independent manner, providing a local and graded form of inhibition, or (2) through an action potential-dependent manner, triggered by somatic excitatory inputs and supporting a global form of inhibition (Lledo and Lagier, 2006). Additionally, interneurons of the olfactory bulb also receive GABAergic inputs, as

classically reported in several other brain areas. Recent studies have revealed that this inhibition is mediated by inframitral interneurons called 'deep short-axon cells' (Figure 1.3), which represent an unexpectedly large and diversified population of interneurons in the olfactory bulb (Eyre et al., 2008; Pressler and Strowbridge, 2006). These deep short-axon cells receive inputs from output neurons and possibly from centrifugal fibers and provide a feedback inhibition onto granule cells (and to a lesser extent periglomerular cells) thanks to a large axonal arbor.

Since secondary dendrites have large projection fields and extensive reciprocal connections with interneurons, each local bulbar interneuron may contact the dendrites of numerous output neurons. This suggests not only that dendrodendritic interactions provide a fast and graded feedback inhibition, but that they also underlie lateral inhibition between output neurons that innervate different glomeruli. In this sense, granule cells would provide both local (recurrent) and integrated (lateral and global) inhibition to output neurons (Lledo and Lagier, 2006). How do inhibition and local microcircuits shape and encode the spatial representation of sensory inputs?

1.2.3 Sensory Processing in the Output Layer

The mitral/tufted-granule cell circuit is thought to perform three main functions: sharpening the tuning of output neurons, decorrelating sensory inputs into time-varying temporal patterns, and synchronizing activated output neuron activity. These computations are crucial for odor coding and especially for odor discrimination: reducing or facilitating inhibition between granule cells and output neurons impairs or improves odor-discrimination performance, respectively (Abraham et al., 2010).

First, olfactory information is transmitted not only vertically across the glomerular relay, between sensory neurons and output neurons, but also horizontally, through local interneuron connections that are activated in odor-specific patterns. Such a model based on lateral inhibition, originally introduced in the 1950s to explain visual contrast enhancement in the retina (see Shepherd, 2010) has been extensively characterized mathematically. Anatomical and functional characterizations of the olfactory bulb circuit have revealed the importance of lateral inhibition. Thanks to this inhibitory mechanism, activity in few stimulated output neurons may lead to the inhibition of other neighboring neurons innervating distinct glomeruli (Egger and Urban, 2006; Yokoi et al., 1995). This inhibition, which critically relies on dendrodendritic synapses, was proposed as a mechanism for sharpening the tuning of output cells compared to their inputs (e.g., Koulakov and Rinberg, 2011). For instance, examination of the responses of individual mitral cells to inhalation of aliphatic aldehydes

reveals that many individual cells are excited by one sub-set of these odorants, unaffected by a second subset, and inhibited by a third subset (Figure 1.5; Tan et al., 2010; Yokoi et al., 1995). Interestingly, the magnitude of lateral inhibition received by neighboring output neurons through the granule cell circuit is dynamically regulated, since it depends on the activity level of the postsynaptic output neuron (Arevian et al., 2008). Such interactions may underlie the limited mitral cell activation observed in animals that are awake (Koulakov and Rinberg, 2011). Because odor maps generated by different odors are ex-tensive all over the surface of the olfactory bulb and often overlap, the propagation of action potentials into the lat-eral dendrites, and the possible spread of excitation through granule cell dendrites, contributes to a contrast enhancement mechanism that sharpens the tuning of widely dispersed output neuron odorant-receptive fields. Rather than a center-surround receptive field like that in the retina, mitral cells have a more distributed and sparse receptive field (Fantana et al., 2008). Lastly, the interglomerular lateral inhibition provided by super-ficial short-axon cells in the glomerular layer described above could, to a lesser extent, provide an additional form of lateral inhibition (Aungst et al., 2003; Linster and Cleland, 2009).

Second, the long-range projections of secondary den-drites underlie fundamental computations characteristic of the nonlinear dynamical system (Laurent, 2002). In-deed, output cells respond to a constant odor exposure with odor-specific temporal spike patterns that may constitute a "temporal code" of odor identity for down-stream regions (Figure 1.6(a)). The spatially distributed pattern of activated output neurons – sometimes ambig-uous for similar odorants – evolves progressively over time and diverges from the initial pattern, following a trajectory in the coding space that is characteristic of a given odorant and a given intensity (Figure 1.6(b); Bathellier et al., 2008; Laurent, 2002; Mazor and Laurent, 2005; Stopfer et al., 2003). Within this

framework, the main function of bulbar microcircuits would be to decorrelate similar input patterns into diver-gent odor-specific temporal dynamics of output cell ac-tivity. This computation, called decorrelation, would reformat combinatorial representations by reducing the overlap between clustered input activity patterns, thus making odor representation more distinct and facil-itating their discrimination by downstream olfactory centers (Friedrich and Laurent, 2001). This temporal cod-ing scheme may also be generalized in the case of terres-trial mammals, in which active breathing introduces an additional temporal dynamic to the stimulus (Wachowiak, 2011; see respiratory traces in Figure 1.5). Odor inhalation triggers precise and reliable cell- and odor-specific temporal spike patterns, which are tightly time-locked to the sniff phase and carry sufficient infor-mation for the discrimination of odors (Cury and Uchida, 2010; Dhawale et al., 2010; Shusterman et al., 2011). The timing of mitral cell activation relative to the sniff phase has been recently highlighted as another possible mechanism for the rapid encoding of odor (Smear et al., 2011). This additional extrinsic rhythmicity imposed by the breathing cycle provides an external "clock" for the entire olfactory system that may promote spike-timing dependent coding relative to the phase of the underlying respiratory cycle (Wachowiak, 2011).

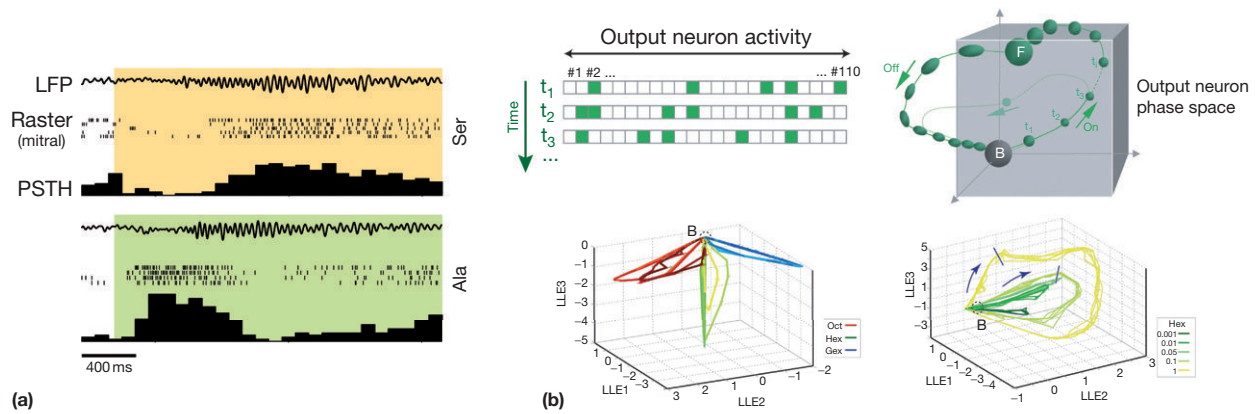
Third, the long-range projection of secondary den-drites and recurrent inhibition provided by granule cells shape the temporal patterns of output neuron activity and lead to the synchronization of the network. This synchronization gives rise to oscillations of the local field potentials (LFP) in the gamma frequency band (30–100 Hz; see LFP traces in Figure 1.6(a)), a phenome-non already described by Sir Adrian in 1942 (Adrian, 1942; see also Shepherd, 2010). Since the pioneering the-oretical work of Rall and Shepherd (Rall and Shepherd, 1968; Rall et al., 1966), experimental and computational studies have confirmed that recurrent inhibition pro-vided by the dendrodendritic reciprocal synapse is
FIGURE 1.5   Molecular receptive field property of mitral cell. (a) *In vivo* recording of mitral cell spiking activity in anesthetized rat exposed to a homologous series of aliphatic aldehydes. Top, peristimulus time histogram (PSTH), which represents the average of five single-trial responses. The bottom traces indicate the respiratory cycle. The black bar marks the period of odor presentation. Note the respiratory-driven spiking activity of mitral cell. (b) Histogram of the change in spike rates (white column = increase; black column = decrease) during odorant-stimulation compared with the spike rate during prestimulation period. Stimulus odorants are propylaldehyde (3CHO), butylaldehyde (4CHO), valeraldehyde (5CHO), hexylaldehyde (6CHO), heptylaldehyde (7CHO), octylaldehyde (8CHO), and nonylaldehyde (9CHO). *Adapted from Nagayama S, Takahashi YK, Yoshihara Y, et al. (2004) Mitral and tufted cells differ with respect to the manner in which odor maps are decoded in the rat olfactory bulb. Journal of Neu-rophysiology 91: 2532–2540, with permission.*


FIGURE 1.6 Temporal pattern and population coding of odor responses. (a) Five single-trial responses of one zebrafish mitral cell to two odor stimuli (Ala, alanine; Ser, serine). LFP, local field potential (bandpass filtered 5–50 Hz); middle, spike raster in which each tick represents the timing of one action potential from the mitral cell; bottom, peristimulus time histogram (PSTH), which represents the average of ten single-trial responses. Color shading indicates odor presentation. Note the odor-specific slow temporal response patterns. (b) The activity of the population of 99 recorded output neurons at a given time is represented as a point in a 110-dimensional space, in which each dimension represents the firing rate of one of the 110 PNs in the corresponding time bin. Each odor representation is thus represented by a multidimensional vector of output neuron states that evolves with time in a stimulus-specific manner and represents odor-evoked trajectories. Then the 110-dimensional data were analyzed with a dimensionality reduction method (namely principal component analysis) and projected in the space of the first three principal components to allow visualization. From an initial resting state (origin of the coordinate system, b), the population vector evolves through an extended trajectory to an odor-specific fixed point (F). When the pulse terminates, the population vector returns from the fixed point back to baseline via a different trajectory. Different odors evoke different trajectories for the population vector. These trajectories are highly reproducible and specific of the odor and of the odor concentration. *Adapted from Friedrich RW and Stopfer M (2001) Recent dynamics in olfactory population coding.* Current Opinion in Neurobiology *11: 468–474; Stopfer M, Jayaraman V, and Laurent G (2003) Intensity versus identity coding in an olfactory system.* Neuron *39: 991–1004; Mazor O and Laurent G (2005) Transient dynamics versus fixed points in odor representations by locust antennal lobe projection neurons.* Neuron *48: 661–673, with permission.*

crucial for establishing this network synchrony (Kay et al., 2009; Laurent, 2002; Lledo and Lagier, 2006). For example, specific modification of GABA$_A$ receptors expressed in the lateral dendrites of mitral cells disrupts the properties of gamma oscillations (Lagier et al., 2007). Such synchrony may play an important role in odor processing, especially for odor discrimination (Stopfer et al., 1997). As proposed in other brain regions, synchronization to a specific frequency would help in "binding together" remotely distributed mitral/tufted cells that participate in the encoding for the same odor, creating synchronized cell assemblies (Laurent, 2002). This synchronization also promotes temporal coincidence of spatially segregated inputs. Interestingly, downstream regions in the olfactory cortex can act as coincidence detectors (Franks and Isaacson, 2006; Franks et al., 2011).

Taking these data into account, it is clear that the interplay between local interneurons and output neurons provides a multidimensional device for the representation of olfactory information. Sparse and distributed connectivity between local interneurons and mitral output neurons may contribute to a global reformatting of odor representations in the form of an odor-specific spatiotemporal redistribution of activity across the olfactory bulb. Within this framework, two high-dimensional encoders involved in information coding within the bulbar network should be distinguished. The first is composed of the olfactory receptor repertoire expressed by the

olfactory sensory neurons, which transduces receptor activation patterns into glomerular odor maps throughout a highly reliable synaptic transmission. The secondary encoder lies in the mitral-granule cell network that extracts higher-order features from the odor maps in order to process them into temporal spiking patterns across sparse ensembles of activated output neurons. Thus, spatiotemporal pattern coding of odors provides a large coding space that scales to the millions of discernible odors of our environment.

An important issue concerning odor coding theories relates to how downstream regions can read odor representations built in the olfactory bulb neuronal circuit. One important particularity of the olfactory system is that it is the only sensory pathway through which peripheral olfactory information can propagate towards cortical regions without any relay via the thalamus (Figure 1.1). The axons of bulbar output neurons project directly to different cerebral cortical structures that compose the so-called olfactory cortex (Wilson et al., 2006). The olfactory cortex includes the anterior olfactory cortex (also called the anterior olfactory nucleus), which connects the two olfactory bulbs through a portion of the anterior commissure (Kikuta et al., 2010), the piriform cortex (this region receives the major part of olfactory bulb projection and is considered to be the primary olfactory cortex), the olfactory tubercle, the cortical nucleus of the amygdala, and the entorhinal cortex, which

in turn projects to the hippocampus (Figure 1.1). From the olfactory cortex, olfactory information is ultimately relayed to the thalamus and to the neocortex, notably to the orbitofrontal cortex, the region of cortex thought to be involved in the conscious perception of smell (Gottfried, 2010). The general topographic organization of the olfactory bulb is not conserved in the downstream structures. Mitral cells from the same glomerulus project broadly in the entire piriform cortex without any apparent spatial correlation (Ghosh et al., 2011; Sosulski et al., 2011). Pyramidal cells of the piriform cortex receive convergent inputs from distinct glomeruli (Apicella et al., 2010; Davison and Ehlers, 2011; Miyamichi et al., 2011) and respond to multiple odorants (Poo and Isaacson, 2009; Stettler and Axel, 2009). This high degree of overlap between distributed bulbar projections to higher olfactory centers may constitute the anatomical basis for a combinatorial coding and a crosstalk between information strands emanating from different odorant receptors. This characteristic probably helps to integrate multiple modules of olfactory information into a synthetic representation of a particular scent made of numerous chemical compounds. Alternatively, the synaptic organization of olfactory bulb inputs to the olfactory cortex and the local inhibition within the olfactory cortex that enforces coincidence detection in pyramidal cells suggest that spike-timing-dependent coding of odor representation is an important element of the processing carried out by the olfactory cortex (Poo and Isaacson, 2009; Stokes and Isaacson, 2010).

1.2.4 Centrifugal Fibers from Higher Brain Structures Profusely Innervate the Olfactory Bulb

In addition to sensory inputs from the olfactory epithelium, the olfactory bulb receives a large number of centrifugal inputs from a variety of cortical and noncortical structures (Figure 1.3). Thus, rather than a simple bottom–up odor coding of olfactory signals, the olfactory bulb also deeply integrates top–down information, which modulates the odor representation depending on the internal state or experience of the animal. These direct centrifugal inputs include (1) glutamatergic fibers from olfactory cortex, mainly from the piriform cortex and the anterior olfactory cortex, and (2) modulatory projections from the locus coeruleus (noradrenaline), the horizontal limb of the diagonal band of Broca (acetylcholine and GABA), and the dorsal raphe nucleus (serotonin).

Most of the glutamatergic centrifugal fibers synapse onto granule cell somas, creating a trisynaptic loop between the olfactory cortex and the olfactory bulb. These excitatory inputs tune the excitability of granule cells, modulating the mitral cell–granule cell microcircuit

and the associated processes mentioned above, such as synchronization (Mouret et al., 2009; Strowbridge, 2009). For instance, repetitive excitatory inputs can produce a large depolarization in the granule cell soma sufficient to relieve the Mg^{2+} blockade of NMDA receptors at distal dendrodendritic synapses, thereby promoting recurrent and lateral dendrodendritic inhibition in the olfactory bulb (Balu et al., 2007). The presence of these dense centrifugal inputs clearly suggests that olfaction processing does not involve simple feed-forward pathways. Rather, feedback loops involving long-range axonal projections from downstream regions of the olfactory cortex to the olfactory bulb continually reset the network and provide a dynamic processing of odor.

In addition to the massive glutamatergic innervation from the olfactory cortex, the bulb receives diffuse inputs from neuromodulatory regions. It has been difficult to correlate cellular results and behavioral experiments, especially because these neuromodulators exert multiple and sometimes opposite effects on olfactory bulb neurons depending on the receptor and ligand concentration.

Acetylcholine is released in all the layers of the olfactory bulb by cholinergic fibers originating from the horizontal limb of the diagonal band of Broca and exerts multiple effects on the activity of both output neurons and local interneurons via the expression of different nicotinic and muscarinic receptors (Castillo et al., 1999). At the functional level, changes of behavioral state are partly mediated by changes in the level of acetylcholine tone (Tsuno et al., 2008). Disruption of this cholinergic tone affects output cell receptive fields, gamma oscillations, and olfactory discrimination (Chaudhury et al., 2009; Tsuno et al., 2008).

Serotoninergic fibers extend from the dorsal raphe nuclei and densely innervate the glomerular layer. Recently, serotonin has been shown to regulate sensory inputs to the olfactory bulb indirectly by promoting GABA release from periglomerular cells (Petzold et al., 2009). Noradrenergic fibers from the locus coeruleus are present in the deeper layers, in the granule cell layer, and also in the EPL. Noradrenaline exerts multiple effects on both partners of the dendrodendritic synapse, which may result in the modulation of output cell activity (Jahr and Nicoll, 1982; Nai et al., 2009). Both serotonin and noradrenaline levels increase after odor presentation, and both have been involved in odor preference in young animals and odor discrimination in adults (review in Mandairon and Linster, 2009).

Thus, neuromodulatory innervation is thought to promote flexible and context-dependent changes in the information-processing mode of local neuronal circuits. As will be discussed at greater length later in this chapter, neuromodulators play a major role in the plasticity of the olfactory bulb cells and circuits.

1.3 CIRCUIT DEVELOPMENT: A LESSON FROM ADULT NEUROGENESIS

In contrast to other sensory modalities, the olfactory system exhibits lifelong turnover of both peripheral sensory neurons and central interneurons of the olfactory bulb. In these two places, the addition of new neurons represents another means, in addition to molecular, synaptic or morphological alterations within individual cells, by which circuits can change their own functional organization. This cell-level renovation is neither static nor merely restorative. The process of neuron production during adulthood (called hereafter adult neurogenesis) constitutes an adaptive response to challenges imposed by an animal's environment and/or by its internal state (hormones, stress). Adult neurogenesis in the sensory organ and in the olfactory bulb also raises a number of important questions concerning the role of neurogenesis in olfaction.

1.3.1 Neurogenesis of Sensory Neurons in the Adult Olfactory Epithelium

Facing continuous environmental assaults due to their relatively unprotected position in the nasal cavity, olfactory sensory neurons of the olfactory epithelium are continuously renewed throughout adult life. This site of neurogenesis is made possible by the presence of multipotent progenitors found deep in the olfactory epithelium, near the basal lamina that separates the epithelium from the underlying lamina propria. This progenitor population is mainly composed of globose basal cells and, to a lesser extent, horizontal basal cells. Globose basal cells include transient amplifying precursors and immediate neuronal precursors that express specific markers such as Mash1 and neurogenin-1 and give rise to all the different cell types of the epithelium, including sensory neurons (Cau et al., 1997). During their journey towards the bulb, sensory neuron axons are enveloped by a class of glial cells called ensheathing glial cells, which may act as an extrinsic orientation cue (Sakano, 2010). The progressive generation of mature neurons is relatively rapid and takes only 8–10 days after lesion or toxin exposure. The turnover of sensory neurons, and by extension, the rate of neurogenesis in the olfactory epithelium, is normally regulated by environmental factors. Indeed, the mitotic rates of sensory neurons can be bidirectionally regulated: Naris occlusion reduces sensory neuron turnover and progenitor division, whereas naris reopening, chemical lesions of the epithelium, or olfactory bulb ablation stimulates progenitor activity, restoring the sensory neuron population (review in Schwob, 2002). It is noteworthy that differentiated neurons send back regulatory signals to inform progenitor cells about the number of new neurons that need to be produced to maintain cell population homeostasis. Thus, neurogenesis of sensory neurons depends on a proper balance of positive regulatory factors that stimulate proliferation and differentiation and negative regulatory molecules produced by mature sensory neurons to inhibit additional neuron production. There has been considerable interest in growth factors that control neurogenesis, differentiation, and apoptosis, such as transforming growth factor, fibroblast growth factor, and bone morphogenetic protein (Schwob, 2002). This adult neurogenesis in a peripheral organ, coupled with the fact that there are a limited number of cell classes in the olfactory epithelium, makes this area attractive for studying mechanisms that control the rate of formation of neurons and their death throughout adulthood.

What could be the functional meaning of this never-ending rejuvenation of the sensory organ? Mature sensory neurons that have been damaged by exposure or by pathogens and immature sensory neurons that cannot find adequate synaptic targets in the olfactory bulb are two obvious candidates to support the existence of this peripheral neurogenesis. Once mature, sensory neurons must extend along a long route to the correct glomerulus. As odor quality remains constant throughout life, the glomerular array must remain constant to a certain degree. Axon guiding through preexisting axons and guidance cues present in the olfactory bulb allow for correct targeting to the olfactory bulb (Sakano, 2010; Zou et al., 2009). Moreover, apoptotic cell death has been observed in cells throughout all stages of regeneration, implying apoptotic regulation of neuron numbers and targeting at all levels of the neuronal lineage. It remains to be determined whether the newly generated sensory neurons indeed bring unique features (such as high probability of glutamate release, lack of adaptation, etc.) to the targeted olfactory bulb circuits.

1.3.2 Adult-Born Interneurons in the Olfactory Bulb

The second adult region where ongoing neuronal addition/replacement takes place is the olfactory bulb (Figure 1.7). In this case, the ongoing neuronal production of olfactory bulb neurons occurs mainly in the SVZ under normal conditions. There, astrocytes in the adult SVZ, which line the border between the striatum and the lateral ventricle, act as slow-dividing adult primary neural stem cells, capable of generating a progeny of neuroblast precursors. Stem cell astrocytes (also called type-B cells) divide and generate rapidly dividing type-C transit-amplifying cells that in turn give rise to type-A migrating neuroblasts (reviewed in Doetsch, 2003; Figure 1.7). Once generated, these neuroblasts proceed
FIGURE 1.7 The subventricular zone – olfactory bulb neurogenic pathway in the adult rodent. The center panel is a schematic diagram of a sagittal section of the rodent forebrain. The subventricular zone (SVZ) lies in the walls of the lateral ventricle (LV), below the corpus calosum (CC). After their generation in the SVZ, neuroblasts migrate tangentially along the RMS to their final destination in the olfactory bulb (OB). Left panel shows the neurogenic niche. Separated from the lateral ventricle by a monolayer of ependymal cells (E), slow-dividing astrocytic stem cells (red, type-B cells) divide to generate transit-amplifying cells (blue, type-C cells), which in turn give rise to neuroblasts (in green, type-A cells) that start to migrate in chain to the rostral migratory stream (RMS). Right panel illustrates the sequence of morphological maturation, from the migrating neuroblast in the RMS (5 days after birth) to their final differentiation into interneurons (mainly granule cells, here represented in blue) and their integration into the network. Adult-born granule cells first receive somatic glutamatergic inputs from centrifugal fibers (CF) before establishing dendrodendritic synapse with mitral cells (MC).

towards the olfactory bulb along an intricate path of migration, up to 5 mm long in rodents, called the RMS (Lois and Alvarez-Buylla, 1994). Along the RMS, another population of astrocytes forms a glial tunnel that guides the chain migration of neuroblasts from the SVZ to the olfactory bulb. More than 30 000 neuroblasts exit the rodent SVZ for the RMS each day and reach the center of the olfactory bulb within 6 days (Doetsch, 2003). In the olfactory bulb, neuroblasts detach from these chains and migrate radially from the RMS. Finally, after 1–3 weeks, neuroblasts mature into olfactory inhibitory interneurons of two main types, granule cells (90% of the adult-born cells) and juxtaglomerular cells (5% of the adult-born cells), found in their respective olfactory bulb layers (Lledo et al., 2008; Petreanu and Alvarez-Buylla, 2002. Interneuron identity is specified at birth and is not specified within the olfactory bulb. Progenitors within the various domains of the SVZ are heterogeneous and are preprogrammed at birth to generate different subsets of olfactory bulb interneurons (Lledo et al., 2008; Merkle et al., 2007).

Using replication-incompetent viral vectors to transduce newly generated neurons in the SVZ and label them with GFP, the morphological and functional properties of these newborn bulbar neurons during their migration and differentiation have been characterized (Lledo et al., 2006). Morphologically, newly generated cells become more complex within the first week after their birth and they become fully mature morphologically as early as 4 weeks of age (Petreanu and Alvarez-Buylla, 2002; Whitman and Greer, 2007; Figure 1.7). After starting migration, neuroblasts express functional GABA and glutamate receptors (Platel et al., 2007). Upon reaching the olfactory bulb, they receive GABAergic and glutamatergic synaptic contacts, notably from centrifugal fibers (Figure 1.7). Then, as they progressively become excitable,

they become spiking neurons and start to release GABA onto output cell dendrites (Bardy et al., 2010; Belluzzi et al., 2003; Carleton et al., 2003). Thus, the formation of synaptic contacts before their activation and GABA release would prevent any network perturbations due to aberrant contacts. Interestingly, of the neurons that successfully mature, only 50% survive to the first month (Petreanu and Alvarez-Buylla, 2002). Therefore, new neurons are intensively selected early in their life.

Although the ongoing bulbar neurogenesis has been extensively documented at the cellular level, the functional consequences are not yet clear. Ablation of adult neurogenesis using genetic, pharmacological, or radiation methods results in faint olfactory phenotype alterations, notably in short-term and long-term olfactory memory (reviewed in Lazarini and Lledo, 2010); however, all previous behavioral analysis has indicated that adult-born neurons might be recruited in short-term or long-term odor memory, two phenomena that may involve neural plasticity (see Section 1.4.2).

1.4 STRUCTURAL AND EXPERIENCE-INDUCED PLASTICITY IN THE OLFACTORY BULB

1.4.1 Activity-Dependent Plasticity in the Olfactory Bulb: Cell Properties and Transmitters

The mammalian olfactory system is known for undergoing experience-dependent plasticity. In the olfactory bulb, granule cells are the major sites of synaptic plasticity. In contrast to many axodendritic synapses described in the brain, the major synaptic interaction in the olfactory bulb, the dendrodendritic transmission between output

neurons and granule cells, does not exhibit a strong activity-dependent form of synaptic plasticity, but rather seems to be functionally hard-wired (although a form of short-term plasticity has been described, see Dietz and Murthy, 2005). On the contrary, plasticity at the dendro-dendritic synapse is under the control of neuromodulatory inputs originating from brain regions known to be involved in attention and learning processes. As mentioned above, neuromodulators such as acetylcholine and noradrenaline are known to modulate the synaptic properties of the dendrodendritic synapse (Tsuno et al., 2008). From a general point of view, neuromodulators can have important and long-lasting effects on odor discrimination, learning, and memory, providing the olfactory system with a high degree of plasticity. The neuromodulators act at two distinct, yet complementary functional levels: cell excitability and synaptic activity. By acting on both inhibitory local interneurons and mitral/tufted output neurons (reviewed in Mandairon and Linster, 2009), they have profound effects on both odor processing at the first central relay and odor representation.

In addition to neuromodulatory top–down projections, feedback projections from the olfactory cortex to granule cells are the major source of synaptic plasticity in the olfactory bulb (Gao and Strowbridge, 2009; Nissant et al., 2009; Stripling and Patneau, 1999). In addition to different forms of short-term plasticity, tetanic stimulation of centrifugal excitatory inputs onto granule cells produces a long-term potentiation (LTP) of synaptic strength. Moreover, the same tetanic stimulation that triggers LTP in granule cells also produces a long-lasting enhancement of inhibition onto mitral cells (Gao and Strowbridge, 2009). This form of plasticity is thought to play a role in the long-term modification of the mitral–granule cell network and may shape the spatial and temporal firing patterns of output cell activity. Indeed, the activity of individual output cells can change dramatically depending on the odor context or during learning (Doucette and Restrepo, 2008; Fletcher and Wilson, 2003; Kay and Laurent, 1999; Pager, 1983).

The most thoroughly documented region of the olfactory system exhibiting synaptic plasticity is the olfactory cortex (Wilson et al., 2006). Synaptic contact between the olfactory bulb and the olfactory cortex occurs within the piriform cortex and through recurrent associative connections (Best and Wilson, 2004), as well as from distant and higher order areas, such as the orbitofrontal cortex (Cohen et al., 2008). In the piriform cortex, the massive recurrent connections as well as inputs from distant and high-order areas, such as the orbitofrontal cortex, provide the anatomical structure of an associative network (Best and Wilson, 2004; Cohen et al., 2008; Wilson and Sullivan, 2011).

Lastly, thanks to the accessibility of the olfactory epithelium, responses to naris closure or destruction of olfactory epithelium have highlighted how general decreases in sensory inputs can induce long-term activity-dependent structural plasticity in a sensory network. These experiments reveal how sensory deafferentation mainly affects interneuron populations, interneuron number and phenotype (notably dopamine expression) in particular, as well as the reorganization of the dendritic arbor and synapse density (Leo et al., 2000; Saghatelyan et al., 2005).

1.4.2 Adult-Born Neurons Are Substrates for Experience-Induced Plasticity

The continuous arrival of new interneurons provides another major source of plasticity in the bulbar network. In addition to bringing new building blocks and new connections into the network, adult-generated neurons have unique functional properties compared to neurons generated during early life. These attributes increase their functional impact in the network relative to more mature neurons. By using viral labeling approaches to distinguish adult-born granule cells from preexisting ones, LTP of glutamatergic synapses was found specifically in adult-born cells shortly after their arrival in the olfactory bulb, but this property progressively faded after several weeks (Nissant et al., 2009). Thus, adult-born granule cells may be particularly sensitive to synaptic plasticity but may also potentiate the LTP of cortical glutamatergic inputs to the olfactory bulb. LTP of cortical inputs – specifically to adult-born granule cells – provides an intriguing mechanism to regulate the spatial and temporal firing patterns of output neurons. A role for this synaptic plasticity in olfactory learning remains to be found. Interestingly, olfactory activity influences the maturation and the survival of newborn neurons. Anosmic mice exhibit a strong decrease in the survival of newly formed granule cells (Petreanu and Alvarez-Buylla, 2002), whereas enrichment of the olfactory environment potentiates the survival and accelerates the formation of glutamatergic synapses onto newborn cells (Kelsch et al., 2009; Mouret et al., 2008; Rochefort et al., 2002). Postprandial sleep has been recently shown to promote newborn cell death, possibly though the action of top–down inputs from the olfactory cortex (Yokoyama et al., 2011). Together, these results suggest that postnatal neurogenesis in the olfactory bulb is part of a plasticity mechanism coupled to sensory experience. Moreover, the link between the rate of neuronal survival and olfactory activity suggests that it constitutes a way for the system to adapt to the olfactory environment.

It takes about 2–3 weeks for an adult-generated neuron to become part of the existing olfactory bulb circuit

(Lledo et al., 2006). In this network, the presence of young evolving neurons brings special functions that the preexisting bulbar neurons cannot achieve. Since it takes time for new neurons to mature and become synaptically integrated, adult neurogenesis may contribute to slow, long-term adjustments of the olfactory bulb circuitry, rather than to fast and acute plastic changes. In contrast, the action of centrifugal fibers into the bulb may mediate the faster adaptive changes that adult neurogenesis cannot support. Interestingly, adult-born survival is also controlled by the concerted action of neuromodulators and feedback excitatory projections (Mouret et al., 2009). Therefore, the structural plasticity achieved through adult neurogenesis can be seen as a very long-term form of metaplasticity in the olfactory bulb network: Synaptic plasticity at centrifugal inputs facilitates further integration of long-lasting plastic elements provided by adult neurogenesis.

1.5 CONCLUDING REMARKS

Studies of architectural and functional organization of bulbar circuits have both revealed a wide range of distinct neuronal functioning. This diversity reflects the complex task that neuronal networks have to fulfill in order to process a high-dimensional sensory space. Obviously, information is encoded across neuron assemblies in the olfactory bulb that cannot be extracted by simply averaging the firing frequency. GABAergic inhibition is crucial for olfactory coding, but the functional architecture of dendrodendritic inhibitory microcircuits differ from conventional networks described in other sensory systems. In addition, odor representation is dynamic and highly complex, therefore requiring a unique mechanism of neuronal plasticity. Adult neurogenesis and the actions of centrifugal projections to the olfactory bulb are among the most prominent processes that allow for adaptive mechanisms of plasticity.

Functional Circuit Development in the Auditory System

D.B. Polley[1], A.H. Seidl[2], Y. Wang[2], J.T. Sanchez[2]

[1]Eaton-Peabody Laboratory, Massachusetts Eye and Ear Infirmary & Dept. of Otology and Laryngology, Harvard Medical School, Boston, MA, USA; [2]Virginia Merrill Bloedel Hearing Research Center & Dept. of Otolaryngology, Head and Neck Surgery, University of Washington, Seattle, WA, USA

OUTLINE

2.1 INTRODUCTION TO AUDITORY SYSTEM DEVELOPMENT

2.1.1 A Neurobiological Approach to Studying Auditory System Development

The auditory system undergoes a series of profound changes from the time neural circuits begin forming in the fetal brain to the day, years later, when a child first comprehends a complete sentence. The processes unfolding during this period are a fascinating mixture of intrinsic molecular orchestration and activity-dependent refinement. In humans, auditory perceptual development is a protracted process that begins late in the second trimester when the fetus first shows discriminative changes in heart rate to variations in specific sound features. Progressive improvements in the ability to resolve variations in frequency, temporal patterns and spatial positions of sounds are observed throughout infancy and early childhood, and these changes often parallel an increasing capacity to discriminate phonological units of a child's native language (Werker, 2005). While a greater understanding of the processes at work in human auditory development is of paramount importance, these efforts are often complicated by an inability to isolate the contributions of sensory system development from other cognitive and physical factors.

The use of model systems such as birds and rodents has provided researchers with direct access to central and peripheral auditory circuits, and has elucidated many of the basic mechanisms that underlie their changes during ontogeny. Songbirds and chickens have long been popular model systems due to the greater ease of studying and manipulating the embryo in the egg (*in ovo*) rather than *in utero*. As a result, we can now draw information from an extensive corpus of work detailing the organization of brainstem and forebrain pathways, and the similarities by which songbirds acquire their song and humans acquire speech, particularly in their dependence on auditory feedback during sensitive periods of development. Interestingly, birds begin hearing approximately eight days before hatching, around embryonic (E) day 11, while altricial mammals such as mice, rats and gerbils do not respond to airborne sound until the second postnatal (P) week of life. The relatively late onset of hearing in rodents has aided research into the cellular and molecular changes that underlie abrupt changes in circuit development in the days before and after the onset of hearing.

Recent studies suggest that molecular cues, whose expression is genetically controlled, play an essential role in the formation of topographically ordered connections in the auditory system. It is also evident that factors linked to the flux of ions across the cell membrane during and following the action potential also support neuron survival and regulate the growth and topographic specificity of axons and dendrites within auditory brain areas. In some brain areas, instructive electrical signals generated through the "closed-loop" spontaneous activity is sufficient to promote normal neural circuit development, whereas higher levels of the auditory pathway require structured activity patterns arising from acoustic signals to guide their final stages of assembly. The influence of each activity-dependent and activity-independent factor waxes and wanes within defined windows of development, and piecing together the chronology and mechanisms behind each epoch of auditory system development represents one of the fundamental challenges for researchers in this field. The chapter describes the current state of knowledge concerning the interplay of these factors in the establishment of functional circuits from the cochlea to the cerebral cortex.

2.1.2 Basic Concepts of Cochlear Transduction

The encoding of auditory information begins with a highly specialized receptor organ known as the cochlea in mammals and the basilar papilla in birds. In mammals, pressure waves are delivered into the fluid filled cochlea via the middle ear bones, setting the cochlear partition into motion. The cochlear partition consists of the basilar membrane (BM), the organ of Corti, and the tectorial membrane (Figure 2.1(a)). As a result of this motion and the mechanical properties of these structures, a relatively crude spectral analysis is performed by a vibratory pattern that occurs along the partition, a passive process referred to as the traveling wave (Von Békésy, 1960). This traveling wave results in a vibratory pattern such that high frequency sounds produce maximum displacement near the beginning (base) of the partition, while low frequency sounds vibrate maximally near the end (apex) of the partition.

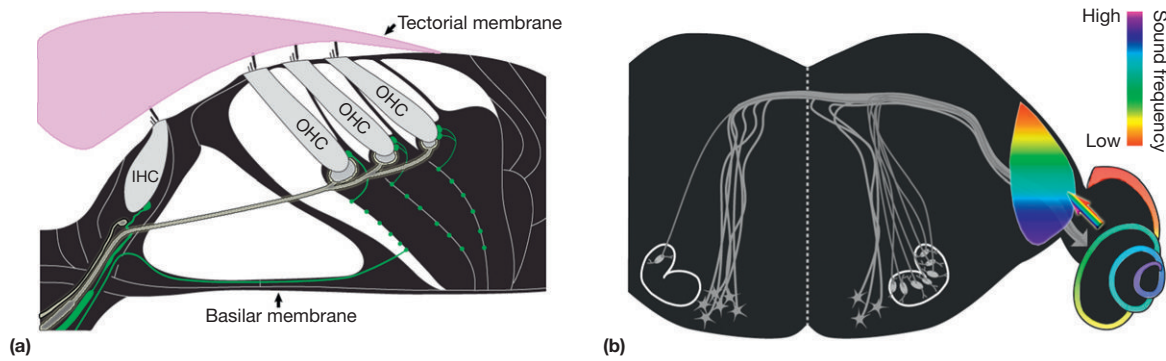
The sensory receptors in mammals responsible for transducing these hydro-mechanical vibrations are located in the organ of Corti and are known as inner and outer hair cells (IHC and OHC, respectively). Both types of receptors are polarized epithelial cells that contain mechano-sensitive organelles located on their apical surface. These actin-filled hair-like processes are termed stereocilia and contain mechanotransducer channels near the tips of the ciliary bundles. The bundles are deflected as a result of partition movement, opening the channels and depolarizing the hair cell due to an influx of potassium (K^+). This unconventional form of depolarization activates voltage gated calcium (Ca^{2+}) channels, which triggers the release of the excitatory neurotransmitter glutamate. Glutamate binds to postsynaptic receptors located on first-order spiral


FIGURE 2.1 **Connections within the adult auditory system**. Schematics illustrate the position of cell bodies and their interconnections in mammalian Organ of Corti (a) and initial components of the auditory pathway (b). (a) Two classes of mechanical sensory receptors, inner hair cells (IHC) and outer hair cells (OHC) are innervated by dendrites that carry afferent signals to the brain (green) and efferent axons that convey signals to the brain (gray). (*B*) Sounds of varying frequencies maximally excite particular regions along the basilar membrane (BM). Maximal sensitiveness are mapped systematically across the length of the BM, such that high frequency vibrations excite the base of the BM and low frequencies excite the apex. This tonotopic organization of frequency preference is preserved through topographically ordered projections to the central auditory system. Distinct populations of cells on both sides of the brainstem send efferent projections to the cochlea.

ganglion neurons (green dendrites, Figure 2.1(a)), initiating saltatory conduction of action potentials to auditory nuclei in the brainstem.

The generic description above for sensory transduction holds true for all hair cells in both birds and mammals. However, the separation into IHCs and OHCs, and their differences, are remarkable and unique to mammals. The IHCs are the true sensory receptor, receiving approximately 95% of afferent innervation. In contrast, OHCs receive only around 5% of afferent contacts, suggesting a minor role in sensory transduction. Despite this dichotomy, OHCs are thought to have highly-specialized "motor" functions. One such active function is to enhance the bundle displacement caused by the vibration of the cochlear partition, acting as a positive feedback on the bundle and the consequent amplification of its displacement. A second active function involves an elongation and contraction of the OHC itself. As the OHC changes length, it feeds back mechanical force onto its surrounding environment, a process termed electromotility. This results in a highly significant and spatially segregated enhancement of the basilar membrane vibratory amplitude. Accordingly, the relatively crude sensitivity and frequency selectivity of the basilar membrane that arises through its passive biomechanical properties is substantially refined through hair cell active amplification. Not only do hair cells transmit signals to the central nervous system, they are also innervated by efferent axons from the brain, which communicate with OHCs to extend the dynamic range of hair cell signaling and protect the Organ of Corti from acoustic overexposure (Figure 2.1(b)). For detailed reviews of auditory transduction and the distinct mechanisms that create active cochlear amplification in mammals versus birds, readers are referred to (Hudspeth, 2008; Dallos, 2006)

2.1.3 Scope of this Chapter

A functional circuit can be defined as the connection between one or more cells or nuclei that transmit – and often transform – a signal. As such, topics relating to the proliferation, delamination and migration of cells and the development of their connecting projections in the auditory system are touched upon only briefly. Rather, this chapter is primarily concerned with describing the relative contributions of intrinsic molecular events, spontaneous action potentials and sound-evoked action potentials in the assembly of functional circuits within the peripheral and central auditory pathways.

This chapter is divided into three principal sections. The first section covers the ontogeny of local circuits within the cochlea and as well as the development of afferent and efferent circuits connecting the cochlea to the brain. The second section describes the establishment of circuits within the developing auditory brainstem and the influence of signaling from the auditory periphery. The final section addresses the formation of functional circuits in the auditory midbrain and cortex. When appropriate, we have cited notable seminal research papers, breakthrough findings and comprehensive review materials so that the interested reader may avail themselves of these more focused sources of information.

2.2 DEVELOPMENT OF PERIPHERAL CIRCUITS

2.2.1 Developing Networks Within the Cochlea

Cochlear hair cells initiate the process of hearing by converting mechanical deflections of their stereocilia bundles into electrochemical signals that are distributed

throughout the rest of the auditory system. Before mature and normal transduction can occur, a number of critical developmental events take place between hair cells and non-sensory cells within the cochlea. The specialized function of IHCs and OHCs depends in part upon developing networks of non-sensory supporting cells within the organ of Corti and the lateral wall of the cochlea.

The precision of mechanoelectrical transduction can be attributed, in part, to the unusual electrical potential and ionic milieu in the endolymphatic space surrounding the apical surface of the hair cell. Prior to and during the first week of hearing, an endocochlear potential is established between the endolymph and surrounding perilymph, which increases from 0 mV to +80 mV. The ramping up of the electrical potential is complemented by the accumulation of high levels of K^+ in the endolymphatic space, which further exaggerates the electrical gradient across the negative resting potential of the hair cell membrane. The combination of high extracellular K^+ and the positive endocochlear potential work synergistically to effectively drive ionic currents through open mechanotransducer channels, creating the large and rapid receptor potential changes that mediate glutamate release at the synapse between the hair cell and the auditory nerve. The endocochlear potential is established through the development of tight cellular junctions between local networks of epithelial cells, connective tissue and supporting cells that completely partition the endolymph from the surrounding perilymph. These tightly bound networks also efficiently recycle K^+ from the hair cell back into the endolymphatic space where they can once again be used in sensory transduction.

The spontaneous generation of action potentials from sensory receptors is considered essential for normal neural circuit development throughout the brain. In the developing auditory system, the mechanisms responsible for spontaneous action potential activity are still unresolved but recent reports suggest that this spontaneous activity is generated by IHCs of the cochlea. The cartoon of the IHC region in the immature Organ of Corti represents one proposed set of developmental changes that occur in cochlear circuitry (Figure 2.1(a)). Compared to IHCs in mature animals, which are surrounded by one or two supporting cells (see Figure 2.1(a)), the pre-hearing Organ of Corti features a structure known as the greater epithelial ridge, or Kollikers organ (Ko). This structure consists of non-neuronal inner supporting cells (ISCs) that are present up to the onset of hearing. However, by the time of hearing onset, Ko undergoes programmed cell death and subsequent removal of the majority of ISCs. Despite this dramatic change in the structure of the organ of Corti, recent studies have identified a potential role for ISCs in the initiation of electrical signaling within the auditory nerve (Tritsch, 2007). One to two weeks prior to the onset of hearing, the elongated
FIGURE 2.2 **Transient microcircuits in the developing Organ of Corti**. (a) Schematic of the region surrounding the inner hair cell in the pre-hearing rodent. Compared to the same region in the adult cochlea (Fig. 2.1(a)), the immature cochlea features a proliferation of elongated inner supporting cells called Kölliker's organ (Ko, in purple) and inner pillar cells (IPC). (b) Inner supporting cells in Ko (ISC, purple) release ATP prior to hearing onset. ATP binds to purinergic receptors (black ellipses) to promote Ca^{2+}-dependent glutamate release from ribbon synapses within the inner hair cell (IHC, gray) and action potentials in auditory nerve fibers (green).

ISCs within Ko begin to spontaneously release adenosine tri-phosphate (ATP) into the extracellular space (Figure 2.2(b)). ATP activates purinergic receptors on neighboring IHCs, peripheral processes of the auditory nerve and on the ISCs themselves. Binding of ATP on the IHC depolarizes the membrane potential, inducing Ca^{2+}-dependent glutamate release and bursts of action potentials in auditory nerve fibers. ATP release is local and desynchronized along the length of the cochlea. In this manner, spatially and temporally independent volleys of electrical signals initiated by non-sensory neurons entrain the firing patterns of SG and, ultimately, central auditory neurons. This process is thought to play a role in the strengthening of functional circuits prior to the onset of hearing.

Despite this role of ATP release from Ko, it remains uncertain how early action potential activity is patterned and whether ATP binding drives IHC membrane voltage or provides weaker modulatory control. More recent data suggests that during the first postnatal week of life, developing IHCs intrinsically generate the voltage changes that elicit action potentials in SG neurons. The frequency and pattern of this spontaneous action potential activity varies between regions of the cochlea (i.e., high-frequency versus low-frequency) and are modulated in multiple ways by the release of acetylcholine (ACh) and ATP near the IHCs (Johnson, 2011). It has been proposed that this pattern of action potential activity, along with ACh and ATP modulation, could be important for guiding tonotopic organization and the refinement of sensory information along the central auditory pathways before the occurrence of experience-drive information becomes relevant.

2.2.2 Development of the Place Code

The basilar membrane acts as a spectral analyzer that translates vibration frequencies within the cochlear fluid

pressure waves into positions of maximal displacement along its length. In mature animals, the BM is relatively narrow and taut at its base (violet region, Figure 2.1(b)) compared to the apex, which is wider and more mobile (red region, Figure 2.1(b)). As previously mentioned, this structural gradient confers a smooth shift of preferred vibration frequency along its length, with high frequencies maximally activating basal regions of the BM and low frequencies maximally activating apical areas. As with the visual and somatosensory pathways, the spatial organization of the receptor organ is maintained through topographic connections between the receptor epithelia and successive levels of the central sensory pathways. In the auditory system, the one-dimensional tonotopic arrangement of preferred frequency along the length of the BM is preserved in tonotopic maps of preferred frequency within the central auditory nuclei.

In nearly every respect, the development of basal (high frequency) regions of the cochlea occurs before apical (low frequency) regions; apical hair cells are the last to differentiate and the last to be innervated by afferent and efferent nerve fibers that convey signals to and from the brain. Therefore, one would predict that sensitivity to high frequency sounds would emerge before low frequencies in development. Interestingly, behavioral and neurophysiological hearing assessments in dozens of avian and mammalian species show just the opposite: high frequency sensitivity is the last to mature. This developmental mismatch implies that either tonotopic connections between the periphery and central auditory system are undergoing large-scale rewiring, or that developmental changes within the cochlea cause a given position along the BM to vibrate at progressively higher frequencies during the early period of hearing. Direct neurophysiological recordings from first-order auditory ganglion neurons that innervate a fixed point within the basal cochlea provide clear support for this latter scenario (Echteler, 1989). Basal cochlear regions were found to be maximally sensitive to low frequencies at the onset of the hearing and then become gradually responsive to higher frequencies. This developmental shift in the cochlear place code has been traced to a progressive maturation of OHC mechanics (Norton, 1991).

2.2.3 Development of Afferent and Efferent Circuits

The mature functional circuit linking the auditory periphery to the brain has four essential processing stations: 1) sensory hair cells in the auditory periphery, 2) first-order spiral ganglion cells (SG) that send a peripheral dendrite to the IHCs and OHCs and a central axon to the brain (i.e., the auditory nerve), 3) the cochlear nucleus (CN), a second-order auditory brain nucleus that is heavily innervated by auditory nerve fibers, and 4)

brainstem neurons whose efferent projections innervate IHCs, OHCs and neurons of the CN (Figure 2.3(a)). The two types of sensory receptors in the mammalian cochlea (IHCs and OHCs) are each innervated by two types of SG neurons: Type I and Type II. Type I afferents comprise approximately 95% of all SG neurons and each contact a single IHC. A single IHC, in turn, can be innervated by 10–20 Type I afferents, providing parallel and topographically specific information transfer from a single IHC to the CN. By contrast, a single Type II SG neuron contacts 30–60 OHCs, providing a weaker, spatially integrated signal to CN neurons. Although the OHCs contribute comparatively little afferent input to the brain, they are the predominant targets of efferent axons from the medial olivocochlear neurons (MOC) in the brainstem. In mature animals, the central processes of the auditory nerve terminate in the CN. In some cases, one or two auditory nerve fibers contact a single CN neuron via a massive axosomatic synapse called the endbulb of Held. The process through which this circuit achieves its mature form reflects an interplay of molecular processes and intrinsic activity-dependent processes that can be broken down into three phases.

Phase 1: Well Before Hearing Onset

In rodents, the peripheral processes of SG neurons innervate basal regions of the cochlea approximately five days before birth, or approximately 17 days prior to hearing onset (Figure 2.3(b)). Within a day of growing into the peripheral epithelia, afferents can be sorted into Type I or Type II morphologies. It is generally agreed that there are no gross errors or widely exuberant connections between SG dendrites and sensory hair cells. However, the exact precision of longitudinal (basal to apical) and radial (IHC to OHC) innervation patterns by Type I afferents is not entirely understood. Genetic fate mapping studies have described highly precise and rapid initial targeting (Koundakjian, 2007), while ultrastructural and histochemical studies find that Type I afferents initially innervate multiple IHCs and OHCs (Echteler, 1992). The weight of evidence favors this latter characterization. ACh-releasing efferent fibers grow into the sensory epithelia at the same time or slightly before afferent fibers. Compared to afferent innervation, however, efferent fibers show a clear developmental shift in their spatial targeting, as olivocochlear efferent fiber innervation is initially biased towards IHCs rather than OHCs (Pujol, 1978).

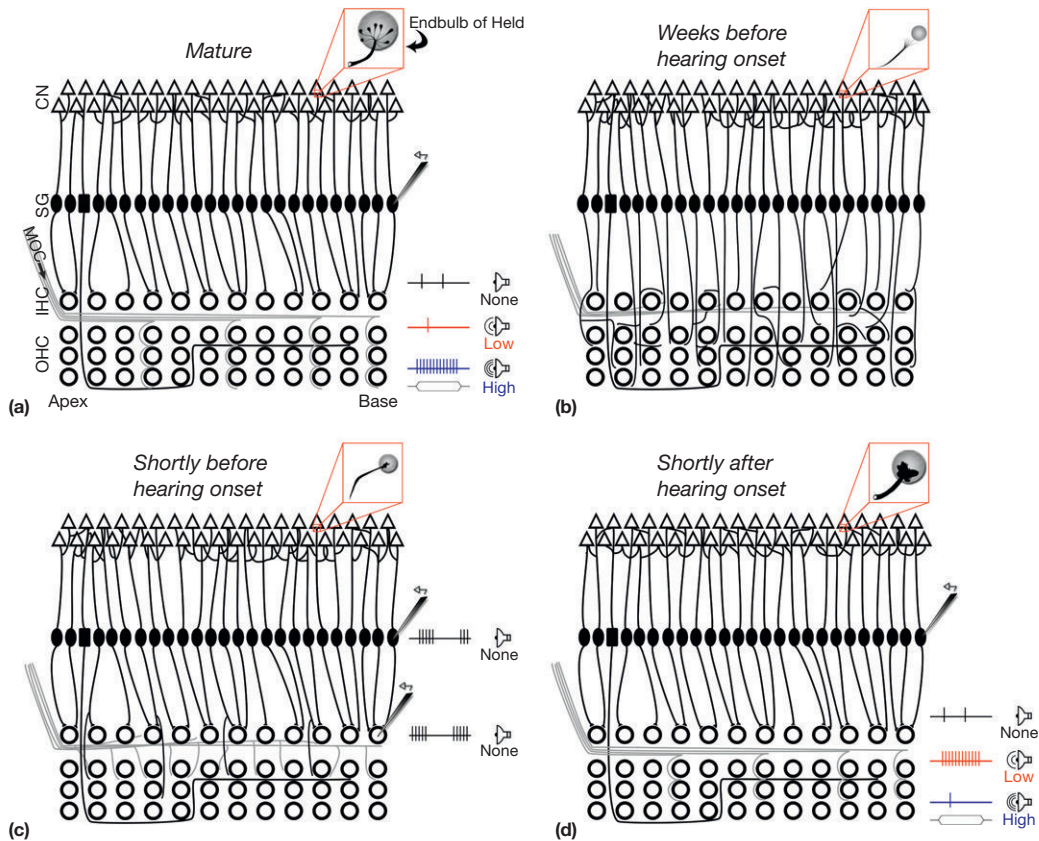
The central projections of SG neurons reach their targets in the CN approximately one day before their peripheral dendrites innervate the sensory epithelia. Despite the fact that the cochlear nucleus is still forming at this stage, projections from the SG are remarkably precise and demonstrate a clear spatial organization long before intrinsic or sensory-evoked action potential signaling begins. Although little is known about the


FIGURE 2.3   Development of afferent and efferent circuits linking the periphery and the brain. (a) In mature mammals, Type I (ellipse) and Type II (rectangle) spiral ganglion neurons (SG) extend a peripheral processes to a single row of inner hair cells (IHC) or three rows of outer hair cells (OHC), respectively. The central projection of SG neurons form elaborate axosomatic synapses called endbulbs of Held on specific types of neurons within the cochlear nucleus (CN, triangle). Efferent axons from medial olivocochlear (MOC) neurons innervate OHCs. Recording from a SG neuron innervating to the base of the cochlea would reveal occasional action potentials in the absence of sound or in response to low frequency sounds but elevated firing rates in response to high frequency sound (sound onset and offset represented by the trapezoidal stimulus). (b) Weeks before hearing onset, patterns of peripheral, central and efferent connections have been established, but lack the precise organization seen in mature animals. (c) In the days leading up to hearing onset, Type I/ II and MOC connections are sorted into their correct hair cell targets and rhythmic trains of Ca^{2+} spikes initiated in IHCs entrain the firing patterns of Type I SG neurons. Endbulb synapses are beginning to form. (d) In the days following hearing onset, peripheral innervation patterns are largely mature and central projection are approaching the topographic specificity and synaptic structure observed in mature animals. SG neurons innervating basal regions of the cochlea are responsive to low frequency tones, rather than high, due to immature basilar membrane and stereocilia mechanics.

molecules or cellular interactions participating in the establishment of auditory nerve fiber topography, several growth factors and receptors are expressed at approximately the time that connections are being established. In particular, differential distribution of the Eph/ephrin family of receptor tyrosine kinases in the auditory nerve and CN suggests an axon guidance mechanisms that shapes the formation of topographic connectivity within the auditory brainstem (Cramer, 2005).

Phase 2: Shortly Before Hearing Onset

Following the initial period of exuberant connectivity, the dendrites from Type I ganglion cells begin to coalesce around individual IHCs (Figure 2.3(c)). Conversely, efferent MOC fibers are in a transitional state during which immature connections to IHCs are maintained alongside newly formed connections with OHCs. IHC

mediated spontaneous spiking is robust during this period and electrophysiological recordings reveal temporally patterned IHC Ca^{2+} spikes that are mimicked by the firing patterns of SG neurons (Tritsch, 2010). In addition, functional synapses between SG and CN neurons are established, but the shape and overall size of endbulbs in the CN are still quite immature.

Phase 3: Shortly After Hearing Onset

At this stage, peripheral innervation of the receptor epithelia is essentially mature with Type I and Type II afferent endings making appropriate contacts with IHCs and OHCs, respectively. MOC efferents drop their IHC connection and make nearly exclusive contact with OHCs. Rhythmic spontaneous bursting gives way to stochastic spontaneous action potentials intermingled with temporall and topographically structured sound-evoked

responses. However, recordings from SG neurons innervating basal IHCs reveal an immature preference for low frequency sounds, as described in the section on place code development above. The topography from the SG neurons to the CN is initially very precise. However, more recent findings in mammals show that subtle topographic refinement continues around the onset of hearing and continues for several months, suggesting a combination of intrinsic and extrinsic activity-dependent mechanisms (Leake, 2002). Additionally, endbulb synapses continue to undergo clear structural modifications. Though they do not yet reach the state of a fully developed calyx that engulfs most of the CN cell body in mature animals, the axon terminals increase in diameter by an order of magnitude relative to the pre-hearing period (Jhaveri, 1982; Ryugo, 1982).

2.2.4 Conclusions

In a matter of weeks, what began as an outpocketing of epithelial cells near the embryonic hindbrain becomes an exquisite functional circuit, capable of encoding mechanical vibrations spanning three orders of magnitude in frequency, a 120 dB dynamic range for amplitude encoding (a million-million-fold change in signal energy), and sensitivity to sub-atomic stereocilia displacements with microsecond mechanical response times. The physical attributes of sound are captured by a tonotopically-organized array of sensory hair cells, which form topographic connections with neurons in the CN to initiate the psychological experience of hearing. This complex circuitry arises through the interaction of sensory and non-sensory supporting cells within the developing cochlea in addition to afferent and efferent connections that link the cochlea to the brain. Other than a modest topographic refinement in the spatial distribution of central projections to the CN and a fairly dramatic transformation of the endbulb synaptic terminal shape and overall size, these circuits reach a mature form independent of sensory input. Instead, maturation appears to reflect the dominant influence of genetic programming and molecular guidance cues with a subordinate role for cell-cell interactions that may include - but are not limited to – internally generated action potential patterns.

In humans, the development of peripheral circuitry is paralleled by enormous changes in infant phonological perception. The earliest stages of perceptual refinement can be attributed, at least in part, to the physical maturation of the outer ear, middle ear and cochlea. However, the scope of perceptual processes that continue to come online after peripheral circuits have matured as well as their dependence upon normally patterned sensory input both point toward the essential role of central auditory circuits in the development of hearing.

2.3 DEVELOPMENT OF BRAINSTEM CIRCUITS

2.3.1 Functional Circuit Assembly in the Brainstem

The assembly of functional circuits within the auditory system has been the subject of intense study over the past 30 years. Auditory brainstem nuclei are derived from progenitor cells within the hindbrain that migrate to their appropriate positions shortly before hair cells in basal regions of the cochlea are born. Like the central projection of SG neurons to the CN, guidance of embryonic brainstem neurons and assembly of their interconnections are thought to be mediated by the Eph/ephrin signaling, although the detailed signaling pathways have yet to be defined (Cramer, 2005). Axonal connections into second- and third-order nuclei are fully formed several days before hearing onset in birds and rodents. Direct electrical stimulation of the afferent axons in pre-hearing animals reveal that these connections form functional synapses shortly after they innervate their target nuclei (Jackson, 1982). The tonotopically organized connection between the auditory spiral ganglion neurons and the CN is preserved in projections to higher-order nuclei. That this topography is initially present from the time connections are formed further supports the influence of activity-dependent mechanisms on circuit formation in the auditory system.

Functional circuits in the auditory brainstem of mammals (Figure 2.4(a)) and birds (Figure 2.4(b)) can be separated into three functional divisions: 1) an excitatory projection from the second-order auditory nucleus (green), 2) inhibitory inputs (red), and 3) third-order nuclei that establish binaural sensitivity by integrating these excitatory and inhibitory inputs (white).

In mammals, CN neurons receive afferent input from the SG and project ipsilaterally to the lateral superior olive (LSO) and contralaterally to the medial nucleus of the trapezoid body (MNTB). The medial superior olive (MSO) gets binaural excitatory inputs from both the ipsilateral and contralateral CN. The MNTB extends a glycineric (inhibitory) projection ipsilaterally to the MSO and LSO.

In birds, cochlear ganglion neurons extend a central process into two second-order brainstem nuclei, nucleus magnocellularis (NM) and nucleus angularis (NA). NM neurons make bilateral projections to nucleus laminaris (NL), a third-order nucleus analogous to the MSO in mammals. Whereas the mammalian MSO receives a powerful direct inhibitory input from MNTB, the inhibitory brainstem nucleus in birds, SON, modulates the convergent excitatory strengths of bilateral inputs to NA, NM, and NL.
FIGURE 2.4   **Organization of mammalian and avian brainstem circuitry**. Schematic coronal sections of the auditory brainstem nuclei in rodents (A) and chicken (B). Brainstem circuits feature central projections from the primary sensory ganglion neurons (1) to 2nd order auditory nuclei in the brainstem (2). 3rd order brainstem nuclei (4) integrate inputs from 2nd order nuclei and local inhibitory nuclei (3). Excitatory projections are shown in green, inhibitory in red, nuclei in grey. For mammals, SG = spiral ganglion, CN = cochlear nucleus, LSO = lateral superior olive, MSO = medial superior olive, MNTB = medial nucleus of the trapezoid body. For birds, BP = basilar papilla, CG = cochlear ganglion, NA = nucleus angularis, NM = nucleus magnocellularis, NL = nucleus laminaris, SON = superior olivary nucleus. For both schematics, the dorsal surface of the brainstem is facing up.

2.3.2 Development of Fine-Scale Connectivity in the MSO

The spatial position of a visual or tactile stimulus can be encoded according to where, along the two-dimensional layout of the retina or skin, activity is greatest. In the auditory system, the functional layout of the cochlea is reduced to a single dimension mapped to sound frequency. The horizontal position of a sound source in space must be computed centrally, by neurons sensitive to differences in the loudness or timing of sounds arriving to each ear. Neurons in the MSO of mammals (NL in birds) are specialized to extract microsecond differences in the timing of excitatory inputs from the CN (or NM) associated with each ear. In mammals with low frequency hearing, such as gerbils, this precise tuning to interaural time differences (ITDs) appears to be enhanced by developmental changes in the subcellular positioning of inhibitory glycinergic inputs from the MNTB (Werthat, 2008). Glycinergic terminals from MNTB are evenly distributed across the dendrites and cell bodies of MSO neurons round the time of hearing onset. In the days and weeks that follow, the less effective inhibitory synapses on the distal ends of the dendritic tree are eliminated, sparing the

proximal axosomatic inhibitory synapses (Figure 2.5). Alterations at the subcellular level are paralleled by a progressive refinement in the overall topographic breadth of presynaptic axon innervation across the topographic map in MSO.. These anatomical changes are associated with increased temporal precision and efficacy of synaptic inhibition onto MSO neurons as well as sharpening of neural ITD tuning functions in the auditory brainstem, suggesting a direct link between physiological maturation and its structural underpinnings. Taken together, the developmental shifts in the topographic and subcellular distribution of inhibitory inputs to the MSO work synergistically to sharpen the spatial and temporal sensitivity of MSO neurons to the excitatory CN inputs arriving from each side of the brain.

FIGURE 2.5 **Correlation between development of inhibitory inputs and ITD tuning**. Before hearing onset, inhibitory glycinergic synapses (red dots) and excitatory glutamatergic synapse (green dots) on MSO neurons are distributed over soma and dendrites. After hearing onset, the glycinergic synaptic inputs get refined to the cell body. This refinement depends on meaningful acoustic experience and can be interrupted by the exposure of omnidirectional white noise during hearing onset. White noise exposure at an adult stage has no effect on glycine receptor distribution. ITD tuning responses in the auditory brainstem correlate with the development of inhibitory inputs to MSO. When animals were exposed to white noise between P10 and P25, ITD tuning responses recorded were found to have the same characteristics as right after hearing onset, when neuronal responses to ITDs are immature and coarse. Under control conditions, i.e. with normal exposure to sound, ITD sensitivity developed normally. White noise exposure in adult animals has no effect on ITD tuning.

2.3.3 Development of Fine-Scale Connectivity in the LSO

LSO neurons are sensitive to interaural sound level differences via tuning to the relative strength of excitatory inputs from the ipsilateral ear and inhibitory inputs from the contralateral ear. Unlike the MSO, contralateral inputs are only expressed indirectly, via a local inhibitory connection from the MNTB. The sharp binaural tuning of LSO neurons is thought to arise from the integration of tonotopically matched excitatory inputs from the ipsilateral CN and MNTB. By contrast to MSO synapses, which are predominantly remodeled after hearing onset, topographic plasticity in the LSO proceeds in two phases: a functional silencing of MNTB inhibitory inputs prior to hearing onset followed by a structural pruning of MNTB axon terminals after the onset of hearing.

The pre-hearing functional refinement phase takes place contemporaneously with the period of ATP-induced Ca^{2+} spikes in IHCs. Accordingly, recordings from MNTB neurons at this age reveal spontaneous action potential bursts with the same rhythmic patterns observed in SG neurons (Tritsch, 2010). These activity patterns also depend upon an intact connection with IHCs, which may indicate that intrinsic spontaneous "test patterns" generated in the Organ of Corti prior to hearing onset may play a role in both peripheral and central circuit formation. During this 3–4 day period, the spatial spread of MNTB-derived inhibition shrinks by approximately 75%, considerably sharpening the breadth of inhibition along the tonotopic axis (Kim, 2003).

The onset of hearing ushers in a phase of structural refinement. In the week following hearing onset, dendritic arbors of postsynaptic LSO neurons increase in branching complexity yet are culled to more confined space within the topographic map. These postsynaptic modifications are accompanied by the physical elimination of tonotopically misaligned presynaptic axon terminals from the MNTB. For a more detailed description of inhibitory circuit development the reader is referred to Chapter 131 of this volume by K. Kandler et. al.

2.3.4 Afferent Regulation of Cochlear Nucleus Development

These functional and structural changes in the brainstem synaptic networks during the weeks surrounding hearing onset provide correlational evidence that spontaneous and sensory-evoked events are needed to achieve the elegant organization of neurons and connectivity observed in mature animals. The strong test of this hypothesis has been carried out by dozens of studies over the last sixty years that examine age-dependent deviations from normative development following

disruption or complete elimination of afferent input from the cochlea. The seminal study by Rita Levi-Montalcini (Levi-Montalcini, 1949) removed the otocyst (the precursor of hair cells and ganglion neurons) of chicks at an early stage of embryonic development, thereby depriving auditory brainstem nuclei of cochlear input. She noted that neurons in NA and NM developed normally until E11 (the approximate time of hearing onset in the chick), at which point the size and overall number of surviving neurons rapidly declined. This observation suggested a dependence of CN neuron survival upon an intact connection with the periphery and has inspired a number of researchers to delve deeper into the role of afferent signaling in the formation and maintenance of brainstem circuitry.

Subsequent studies in the chick and rodents have further characterized the nature and timing of CN degeneration following deafferentation. Unilateral otocyst removal at E3 or cochlea removal prior to sexual maturity in chicks or cochlear destruction shortly after birth in rodents produces a variety of changes, including: 1) the CN on the ablated side has significantly fewer neurons than the intact side and the surviving neurons have smaller soma and neuropil area; 2) an ectopic – yet tonotopically aligned – projection from the normally innervated CN grows into the CN on the deafferented side; and 3) in mammals, the endbulb of Held development described in Figure 2.3 never reaches the fully mature state (reviewed in Harris, 2006).

In most animals, these plasticity effects are strictly limited to a developmental critical period. As noted above, the effects of otocyst removal in the E3 chick are not apparent for another eight days, when active connections with the periphery are first established. The critical period for CN neuron survival ends as abruptly as it begins, as cochlear destruction in gerbils during the first postnatal week causes 45-90% of CN cells to die, yet has no effect on the number of surviving neurons when the same manipulation is performed at P9, just prior to the onset of hearing (Tierney, 1997). The remarkably rapid changes in susceptibility of CN neurons to deprivation appears to reflect a differential weighting of factors that promote versus inhibit cell death.

Collectively, studies of CN development demonstrate that the proliferation, migration and formation of appropriate topographic connections are complete before action potentials begin to appear in auditory nerve fibers. The arrival of normal spontaneous and sound-evoked afferent action potentials has little effect on cellular morphology or topographic specificity. However, pathological deviations from the normal developmental trajectory (e.g., cochlear removal) that occur within a defined critical period window radically alter CN organization, leading to pronounced cell death and atrophy of surviving cells. The cellular mechanisms that close the critical period of CN vulnerability are not yet fully established, but gene array analyses suggest that glial proliferation and up-regulation of immunity-related genes may play an important role.

In addition to deafferentation-induced cell death and atrophy, hearing loss also induces a long-term enhancement of neuronal excitability. *In vitro* measurements of neurons in acute slices of the CN demonstrate a shift towards enhanced excitation and diminished inhibition. The loss of balanced excitation and inhibition arises from an abnormal sorting of membrane-bound ligand-gated neurotransmitter receptors and voltage-gated ion channels. Ongoing research is exploring the hypothesis that this pathological over-excitability in the brainstem and other stations of the central auditory pathways may be the source of tinnitus, the perception of phantom sounds that can accompany hearing loss.

2.3.5 Afferent Regulation of 3rd-Order Brainstem Nuclei

All auditory-evoked signals in the brain are initially routed through the CN. Therefore, alterations in CN morphology resulting from cochlear ablation could also impact the organization of downstream nuclei. Indeed, the post-hearing structural refinement of axon terminals from the MNTB to the MSO and LSO described previously is substantially diminished without a connection to an intact cochlea. Moreover, unilateral cochlea removal before hearing onset enhanced an otherwise weak physical connection between the normally innervated CN and the opposing side of the MSO.

Unlike the inhibitory projections from the MNTB to the LSO and MSO, excitatory projections from the CN undergo considerably less developmental refinement and are largely insensitive to cochlear removal. The CN, for example, forms a giant excitatory synapse onto MNTB neurons called the calyx of Held. This calyx is the largest synapse in the mammalian brain and features glutamatergic CN terminals that almost completely envelop the MNTB neuron, ensuring high-fidelity transmission necessary for sharp interaural time- and level-dependent tuning observed in the MSO and LSO, respectively. In mature brains, one calyx innervates a single MNTB neuron. Although the calyx undergoes substantial changes in shape during the first weeks of postnatal development, the one-to-one connectivity is present from the time CN projections initially arrive in the MNTB and is established with or without spontaneous or evoked action potential from the auditory nerve (Hoffpauir, 2006).

The effects of deafferentation have been extensively studied in NL of the chicken. The intrinsic organization and connectivity patterns within NL lend themselves to

studies of afferent regulation of individual dendrites. First, NL exhibits a clear gradient of dendritic geometry that varies from small, short and stubby to large, long and elaborate across the high-to-low tonotopic map. This gradient appears to begin to form around the time of hearing onset. Second, NL neurons have two sets of symmetrical dendrites, one set oriented dorsally to contact glutamatergic inputs from the ipsilateral NM, the other ventrally to contact glutamatergic inputs from the contralateral NM. This organization permits researchers to directly compare the effects of unilateral manipulations (which would affect the dorsal dendrites on the ipsilateral NL and the ventral dendrites on the contralateral NL) to transection of the NM axons at midline (which would affect the ventral dendrites on both sides of the brain).

Using both of these approaches, researchers have discovered an interesting dichotomy in the afferent regulation of intrinsic features versus functional circuit properties. Removal of synaptic input to one side of NL induces a progressive retraction of dendrites on the corresponding side on a surprisingly short timescale (Figure 2.6). Tracking these changes over time reveals that retraction begins within 1 hour, can last over 2 weeks, and can amount to as much as a 60% reduction in length, demonstrating that NL neurons can rapidly regulate significant amounts of membrane surface devoted to specific excitatory inputs (Deitch, 1984). By contrast to the rapid calibration of dendritic length allocated to the dorsal versus ventral NM inputs, the short-to-long gradient of relative dendrite length across the tonotopic axis of NL is largely unaffected by cochlear removal.

FIGURE 2.6   **Compartment-specific regulation of afferent activity on dendritic structure in the chick nucleus laminaris** (**NL**). NL neurons have bipolar dorsal and ventral dendrites (black), receiving highly segregated excitatory inputs by an axon from either the ipsilateral or contralateral ear via the nucleus magnocellularis (NM). (*Left*), Under normal physiological conditions, the two dendritic domains receive balanced inputs (green), each elicited by one ear, and their dendrites are of similar length. (*Middle*), Following the deafferentation of the inputs to one domain, e.g. when axons from one side of the brain get cut, deprived dendritic branches rapidly retract, while the length of the other dendrite remains unchanged. (*Right*) Physiological stimulation of the axon inputs to one set of dendrites (red lightning bolt), but not the other, leads to a growth of the stimulated dendritic branches and a retraction of unstimulated dendritic domain.

2.3.6 Influence of the Source and Pattern of Afferent Activity on Brainstem Circuits

The effects of cochlear removal on brainstem circuits point towards a panoply of developmental events that depend upon afferent signals from the periphery. Cochlear removal eliminates both spontaneous and sound-evoked action potentials in addition to the physical degeneration of SG neurons. Because the dependence on afferent activity is most commonly observed after hearing onset, one might assume that sound-evoked activity provides important signals for the fine-tuning of brainstem circuits. An alternative explanation holds that any afferent action potential signaling, be it spontaneous or evoked, could be sufficient for normal assembly of brainstem circuits.

To isolate the relative contributions of spontaneous action potentials versus sound-evoked activity, researchers have compared the effect of pharmacologically silencing all afferent action potentials versus simply blocking the transduction of acoustic signals. The effects of tetrodotoxin infusion into the inner ear at the time electrical signaling first begins were indistinguishable from the effects of cochlear removal: approximately 40% of the neurons died with widespread neuronal atrophy in the survivors (Born, 1988). On the other hand, simply blocking sound-evoked activity (by disrupting the sound transmission mechanisms of the outer or middle ear) without eliminating spontaneous activity in auditory nerve did not cause atrophy or cell death in the CN (Tucci, 1985). These results suggest that action potentials, or more probably the voltage-gated changes in glutamate and calcium signaling, provide a necessary source of trophic support during the critical period of CN development. Although the particular patterning of sound-evoked action potentials was not necessary for the normal cellular maturation of this second-order nucleus, it had a significant impact on stimulus selectivity and circuit formation in downstream nuclei. For instance, rearing animals in omnidirectional noise interferes with low frequency signals necessary to calculate interaural time differences. Absent these instructive environmental signals, the MSO fails to develop at a normal pace and features widely branching axodendritic MNTB synapses rather than the topographically focused axosomatic synapses found in normally reared animals (Seidl, 2005); Figure 2.5). Similarly, interaural level difference tuning in brainstem neurons is significantly altered when owls are reared with an earplug that deprives them of normally calibrated binaural cues (Mogdans, 1994).

2.3.7 Conclusions

In summary, functional circuit development and refinement in the auditory brainstem is thought to reflect

an interplay between molecular cues coupled with spontaneous and evoked action potential activity. Factors such as connectional topography in the LSO and spatial gradients of dendritic length in NL appear to be governed by intrinsic, activity-independent mechanisms and form prior to the onset of hearing. Cochlear action potentials before and after the onset of hearing predominantly regulate the size and subcellular positioning of synaptic contacts. The development of precise connectivity is less categorical: the proper development of axonal projections from the MNTB to MSO and LSO is dependent upon afferent signaling after hearing onset, the topographic specificity of SG connections into the CN are subtly modified by afferent signaling, while excitatory projections from the CN to their ipsilateral and contralateral brainstem targets develop independently of cochlear signaling (although they make aberrant connections should one cochlea be removed).

Compared to peripheral circuits, which have matured in many respects by hearing onset, brainstem circuits undergo additional refinement after sound-evoked activity is introduced to the system. These phenomena are likely to contribute to the progressive improvement in infant auditory perceptual acuity in humans and animals. For example, human infants become increasingly capable of resolving the fine positioning of sounds along a horizontal plane, which may reflect the developmental calibration of synaptic properties within the MSO and LSO. Other aspects of phonological development, including the neural specializations that underlie the acquisition of language, can only be understood by examining the development of functional circuits in higher levels of the central auditory system.

2.4 DEVELOPMENT OF AUDITORY MIDBRAIN AND FOREBRAIN CIRCUITS

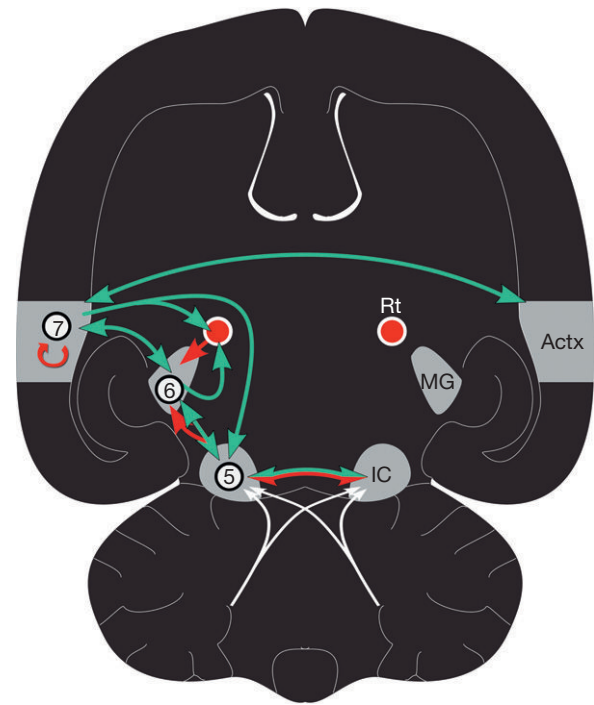
Higher auditory circuits are assembled from a diverse set of excitatory and inhibitory connections arising from three critical sources: 1) the inferior colliculus (IC), a midbrain auditory brain structure, 2) the medial geniculate (MG) and reticular (Rt) divisions of the thalamus, and 3) the auditory cortex (Actx) (Figure 2.7). These nuclei are interconnected through a complex array of feedforward, feedback and intrinsic connections. Inputs from the two ears are heavily intermixed, given the feedforward binaural inputs from the MSO and LSO as well as interhemispheric connections between each IC and Actx. Both the IC and MG are obligatory relays for auditory signals reaching the Actx and, consistent with brainstem circuits, a tonotopic organization within these connections is evident 5-7 days before birth in rodents, long before the initiation of afferent signaling from the periphery.


FIGURE 2.7 **Organization of higher auditory circuits**. Schematic of a horizontal section through a rodent brain. Convergent bilateral input from the brainstem (white arrows) projects to the inferior colliculus (IC), an auditory midbrain structure (5). The IC connects to the auditory thalamus (6) and cortex (7) through a complex chain of feedforward, feedback and intrinsic excitatory (green) and inhibitory (red) connections. MG = medial geniculate body, Rt = reticular nucleus of the thalamus, Actx = auditory cortex. Top of the figure is rostral (i.e., anterior), bottom is caudal (i.e., posterior).

2.4.1 Development of Thalamocortical Subplate Circuitry

Compared to the wealth of studies in NL, LSO and MSO, functional circuit developments in higher auditory brain areas have yet to be characterized in detail at the cellular level. One emerging exception is the observation of a transient microcircuit linking the neonatal thalamus and cortex. Cortical neurons originate from the ventricular zone and reach their final positions within the six-layered cortical plate via local radial migration or, in the case of several classes of inhibitory interneurons, via long-distance horizontal migration along the rostral stream (additional information on patterning and neural migration within the cerebral cortex can be found in Rubenstein and Rakic, 2013). Subplate neurons (SPN) reside in the white matter beneath the cortical plate, physically interposed between the ascending MG axons and the incipient circuits forming in the more superficial layers of the cerebral cortex (for a comprehensive review of subplate neurons, see (Kanold, 2010)).

SPN development occurs at an accelerated pace compared to the other cortical neurons; SPNs are among the

first neurons to appear in the cerebral cortex, the first cortical neurons to fire action potentials, and are almost completely eliminated around the time of hearing onset. SPNs have elaborate dendritic trees that integrate excitatory inputs from the MG and local inhibitory inputs. SPN axon terminals ramify extensively in the same layers of the cerebral cortex that will receive the bulk of direct axonal input from the MG in subsequent stages of development. SPNs have high input resistances, relatively depolarized resting membrane potentials and are electrically coupled to one another via gap junctions, making them a sensitive and potent source of excitatory input to Actx prior to hearing onset.

Their precocious morphological and biophysical development combined with their physical position between MG and Actx make SPNs ideal interlocutors in the postnatal assembly of thalamocortical circuits. Indeed, as represented in Figure 2.8, MG axons innervate the subplate days before birth and wait there for days or weeks (depending on the species) before innervating the middle cortical layers. During this waiting period, SPNs make excitatory glutamatergic projections to excitatory and inhibitory neuron subtypes within Actx, potentially providing a source of activity-dependent synaptic refinement before connections are established with the MG.

2.4.2 Postnatal Development of Local Cortical Circuits

Cortical circuits undergo a subsequent wave of refinement during the second postnatal week, after the majority of SPNs have been eliminated. At the onset of hearing, sound-evoked responses in Actx are restricted to frequencies at the center of the hearing range presented at high sound levels. Over the following 2–3 days, response thresholds decrease and sensitivity to a broader range of sound frequencies begins to emerge. Following this brief period of change, which almost certainly reflects peripheral maturation, recordings from Actx neurons reveal a gradual improvement in their ability to synchronize action potential timing to rapid modulations of an incoming sound source. This improvement in cortical temporal processing is a hallmark feature of central auditory development and thought to be essential for the accurate encoding of important environmental sounds such as speech.

Through targeted recordings of excitatory and inhibitory neuron subtypes in Actx using an *in vitro* brain slice preparation, researchers have discovered that the progressive elimination of temporal "sluggishness" towards the end of the second postnatal week is associated with a confluence of synaptic and intrinsic changes in Actx neurons. In addition to afferent input from MG, acetylcholine (ACh)-positive axon terminals from neurons located in the basal forebrain begin innervating the Actx in postnatal week 1 and reach adult levels by postnatal week 2. The maturation of cholinergic terminals coincides with significant changes in the levels or composition of nicotinic ACh receptors and NMDA receptors (nAChRs and NMDARs, respectively) in Actx (Metherate, 2003). Although ACh does not excite Actx neurons directly, it can enhance excitatory transmission indirectly by binding to nAChRs, which in turn modulate glutamatergic NMDARs. The decline of nAChRs
FIGURE 2.8 **Subplate neurons form a transient microcircuit linking the auditory thalamus and cortex**. Subplate neurons (SPNs, squares) mediate excitatory signaling from the medial geniculate nucleus of the thalamus (MG, diamond) to excitatory (triangle) and inhibitory (circle) cells in the auditory cortex (Actx, triangle). Shortly after birth (left), SPNs are believed to be the exclusive source of subcortical input to Actx. In the days hearing onset (middle), SPNs mediate direct excitatory projections to Actx before they are eliminated, shortly thereafter (right). Green ellipses=glutamate receptor, red ellipses=GABA receptor, black ellipses=electrical synapse.

in Actx by postnatal week 3 works synergistically with changes in AMPA and NMDA glutamate receptor subunit composition to reduce the duration and increase the amplitude of excitatory postsynaptic currents in Actx (Figure 2.7(a)). Thus, the transient appearance of nAChRs during postnatal week 2 represents a critical period during which ACh can prolong the time course of NMDA-dependent synaptic excitation around the period of hearing onset.

The sharpening of synaptic excitation in Actx around the time of hearing onset is mirrored by a progressive enhancement of synaptic inhibition. Presynaptically, the voltage-gated K^+ channel subtypes present in GABAergic interneurons change significantly over the first three weeks of postnatal development to adjust the resting membrane potential and shorten the refractory period following an action potential. These biophysical changes are complemented by the progressive loss of $GABA_B$ receptors on presynaptic interneurons, enabling higher sustained firing rates without fatiguing. Postsynaptically, the $GABA_A$ receptor subunit composition in excitatory Actx neurons changes over the first weeks of development to eliminate the α3 subunit in favor of the α1 and β2/3, both of which are associated with faster inhibitory synaptic current rise times (Figure 2.9(a)). Collectively, these intrinsic and synaptic changes in the time course of excitatory and inhibitory synaptic

transmission endows Actx neurons with an improved ability to track rapid temporal fluctuations in sound signals with high fidelity (for review see Sanes, 2009).

2.4.3 Afferent Regulation of Higher Auditory Circuit Development

Detailed characterizations of auditory brainstem circuit development in the absence of cochlear signaling have revealed a combination of activity-dependent and activity-independent processes. To assess the generality of these principles throughout the central auditory pathways, researchers have also examined the role of an intact periphery on the maturation of IC and Actx circuits. The potentially confounding influence of CN degeneration has been avoided in this type of experiment by bilaterally removing the cochleae after the critical period for CN cell death, but before the onset of hearing, such that higher auditory circuits have the potential to be shaped by spontaneous – but not sound-evoked – action potentials.

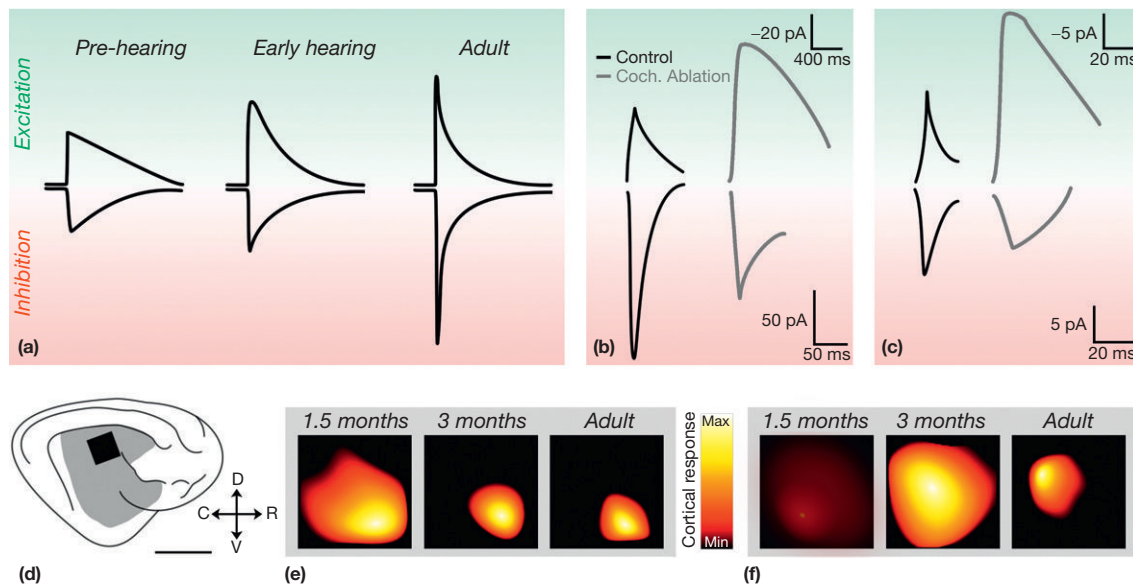
Recordings made in the acute brain slice preparation weeks after cochlear ablation reveal dramatic alterations in the strength and time course of excitatory and inhibitory synaptic currents in the IC (Figure 2.9(b)) and Actx (Figure 2.9(c)). Compared to control slices taken


FIGURE 2.9 **Afferent regulation of higher auditory circuits**. (a-c) Black lines represent excitatory (upward) and inhibitory (downward) synaptic currents recorded from brain slices containing auditory cortex (a, c) or inferior colliculus (b) neurons. Auditory cortex neurons display faster and stronger synaptic currents over development based on changes in intrinsic and synaptic properties. This process is arrested following bilateral cochlear ablation, wherein neurons are hyperexcitable and display immature temporal dynamics. Current amplitude is plotted on the vertical axis. (d) Lateral surface of the cat brain. Gray denotes total area of auditory cortex in normal cats. Black square denotes area from which neurophysiological signals are measured in panels e and f. D = dorsal, R = rostral, V = ventral C = caudal. Horizontal bar = 1 cm. Inward negative EPSCs are plotted upwards, and outward positive IPSCs are plotted downwards, by convention. (e-f) Areal extent of neural responses in auditory cortex evoked from activation of a stimulating electrode implanted proximal to the auditory nerve fibers in acutely deafened (e) or congenitally deaf (f) cats. Current traces in (b) and (c) are adapted from data presented in Sanes and Bao, 2009.

from normally hearing animals, neurons in cochlear-ablated slices areas show weaker, prolonged inhibition that is qualitatively similar to activity found in normal animal prior to hearing onset. Synaptic excitation is also prolonged in a similar fashion to pre-hearing animals, yet the amplitudes are far greater than those observed in the course of normal development, suggesting that deafferentation tips the homeostatic balance between excitation and inhibition towards greatly enhanced excitability, in a similar fashion to the CN (Kotak, 2005).

Recent studies have identified a combination of intrinsic and synaptic factors that may explain the failure of synaptic inhibition to mature normally. In terms of intrinsic biophysical mechanisms, the first postnatal weeks are marked by a substitution of voltage-gated K^+ channels that mediate faster membrane kinetics as well as the appearance of a K^+-dependent intracellular chloride transporter, KCC2. During the first week of postnatal development, when KCC2 expression levels are low, intracellular chloride concentrations are higher than the electrochemical equilibrium potential and GABA release from inhibitory neurons induces a depolarization of the membrane potential in postsynaptic neurons, rather than the expected hyperpolarization. As levels of membrane-bound KCC2 increase in the second week of postnatal development, greater amounts of intracellular chloride are extruded into the extracellular space, thereby lowering the equilibrium potential and establishing the normal hyperpolarizing influence of GABA. This developmental process is arrested in the IC of cochlea-ablated animals, where the inhibitory reversal potential can be elevated by as much as 24 mV above normally hearing age-matched controls, reducing the hyperpolarizing effect of GABA binding. Although overall expression levels of KCC2 are not affected, pharmacological experiments reveal that cochlear ablation arrests the normal age-dependent maturation of KCC2 function, contributing to reduced levels of inhibitory signaling (Vale, 2003).

A synaptic piece of the puzzle was discovered through a comparison of GABA$_A$ receptor subunit composition in the Actx of normal and deafferented animals. Recall from the description above that GABA$_A$ receptors composed of the α1 and β2/3 subunits appear during the second postnatal week and are partially responsible for the transition to shorter, larger-amplitude inhibitory synaptic currents. Following bilateral cochlear ablation, juvenile Actx neurons fail to express the mature form of the membrane-bound GABA$_A$ receptor, thereby preventing the sharpening of the inhibitory postsynaptic currents observed in age-matched controls (Kotak, 2008). Taken together, these results demonstrate a broad spectrum of intrinsic and synaptic events that fail to develop in the absence of sound evoked-activity. The sum total of these events render IC and Actx neurons incapable of tracking rapid fluctuations in sound properties, an essential characteristic of normal hearing.

2.4.4 Developmental Regulation over Reinstating Hearing in the Deaf

Synaptic transmission studies in the brain slice preparation shed some light on the molecular targets of afferent signaling and help to identify the complications and possibilities associated with reinstating hearing in deaf individuals. Unlike birds, and other non-mammalian vertebrates, which can regrow hair cells throughout life, mammals are born with all the cochlear hair cells they will ever have. Nevertheless, hearing is a possibility for profoundly deaf individuals through the use of the cochlear implant, a neural prosthetic device that bypasses the dysfunctional transduction machinery within the cochlea and reinstates afferent signals through direct electrical stimulation of auditory nerve fibers. Approximately 200,000 individuals have been fitted with cochlear implants over the past 40 years and it was discovered early on that the age of surgical implantation plays a crucial role in the quality of hearing experienced by cochlear implant users. While post-lingually deaf individuals often recover acceptable hearing and speech recognition whether they are implanted as children or adults, congenitally deaf individuals stand the best chance of experiencing the full benefit of the cochlear implant if they undergo the implantation procedure at an early age, typically by the time they are 7 years old (Dorman, 2007).

Through careful study of cochlear implants in a special breed of congenitally deaf cats, researchers have begun to understand how auditory brain areas represent signals delivered through the cochlear implant and the manner by which these representations are shaped through development and experience. As an experimental control, normally hearing cats are acutely deafened with an ototoxic drug and immediately fit with a cochlear implant. Neural recordings are made from the Actx of acutely or congenitally deaf cats at various ages in response to brief electrical pulses delivered the auditory nerve (Figure 2.9(d)). A comparison of activation patterns across development in acutely deafened cats reveals an exuberant spatial spread of neural activity across the Actx in young kittens that is culled to a topographically restricted activation area by 3 months of age (Figure 2.9(e)). By contrast, activating the implant in congenitally deaf kittens at 1.5 months evokes a weak cortical response (Figure 2.9(f)). At 3 months postnatal, deaf cats show the exuberant activation patterns comparable to normally hearing kittens at 1.5 months and these activation areas are not consolidated until early adulthood (Kral, 2005). The hyper-excitability of the Actx in congenitally deaf cats at three months may stem from

the diminished synaptic inhibition and augmented synaptic excitation observed in brain slices of rodents that undergo cochlear ablation in infancy (Figure 2.9(c)).

Although the mechanisms governing the recovery of hearing in cochlear implant users remain unclear, one possible clue has been found through analyzing the endbulb of Held synapse in deaf cats that began hearing through chronic use of the cochlear implant at an young age. As described previously, the endbulb synapse fails to develop normally in the absence of cochlear signaling. Strikingly, the endbulb synapse from cats using the cochlear implant for 3 months beginning at an early age was largely indistinguishable from normally hearing cats (Ryugo, 2005). Therefore, reinstating afferent activity to the central auditory system in early life can rescue the progressive synaptic degradation observed at several levels of the central auditory system.

2.4.5 Experience-Dependent Influences on Functional Circuit Development

For the most part, the influence of afferent signaling on neural circuit development has been described in the context of all-or-nothing manipulations; comparisons to normally hearing animals are made through cochlea removal, genetic deafness, or pharmacological silencing of the auditory nerve. However, many facets of auditory perceptual development depend upon the specific patterns of auditory experience rather than its presence or absence. For example, before a child utters a first word in its native language, it will have been exposed to hundreds of thousands of words that bear the phonemic structure specific to that language. One school of developmental cognitive psychology has argued that this repeated auditory exposure to speech sounds, when appropriately timed during childhood development, "primes" the auditory and vocal motor areas of the brain to specialize in the nuances of a given language. A half century of inspired neurobiology and neuroethology research has shown that the processes through which songbirds learn their vocal repertoire offers a striking parallel to human language acquisition. Song and speech learning both involve a complex interplay between innate predispositions and experience, both forms of learning are shaped by developmental critical periods, both require skilled control over the motor vocal apparatus, and both depend upon precisely calibrated auditory feedback (for a review of song learning, the reader is referred to (Brainard, 2002).

Although the circuitry underlying song acquisition is more closely linked to sensorimotor integration than auditory processing *per se*, auditory experience has also been found to exert a profound influence over the development of dedicated auditory circuitry within IC and Actx. In rodents, a tonotopic map of preferred sound frequency tuning can be readily delineated from the primary field of the auditory cortex (AI), which is visible along the lateral surface of the brain (Figure 2.10(a)). In mature animals, the tonotopic map features an orderly low-to-high gradient of frequency tuning across the posterior-to-anterior extent of AI, with similar tuning organized into orthogonal iso-frequency contours (Figure 2.10(b)). Most recording sites feature closely matched frequency tuning for tones presented to each ear, albeit tuning evoked from contralateral stimuli is more robust than the weaker, high-threshold tuning for tones presented to the ipsilateral ear. By contrast to the adult map, AI recordings made shortly after the onset of hearing (P11-14) reveal narrowly tuned, high threshold responses restricted to the middle frequency regions of the tonotopic map (Figure 2.10(c)).

A series of studies over the past decade demonstrate that experimentally modifying the ambient acoustic environment experienced by young animals during critical periods of higher auditory circuit development can dramatically alter the normal developmental sequence described in Figures 2.10(b) and 2.10(c). For example, rearing litters of rodents in a sound environment dominated by the repeated presentation of a single tone at a fixed frequency more than doubles the area of the tonotopic map tuned to that exposure frequency (Figure 2.10(d)). As illustrated in Figure 2.10(d), exposure to a repetitive middle frequency tone for just 96 hours beginning at the onset of hearing is associated with an expansion of the corresponding area within the tonotopic map at the expense of flanking frequency representations. The tonotopic map retains this distorted organization into adulthood despite the fact that animals hear normal acoustic stimuli from P16 onwards. Conversely, rearing animals older than P16 to the repeated single frequency has no effect on the map regardless of the length of exposure time (de Villers-Sidani, 2007). Similar effects of tone rearing have been reported in the IC.

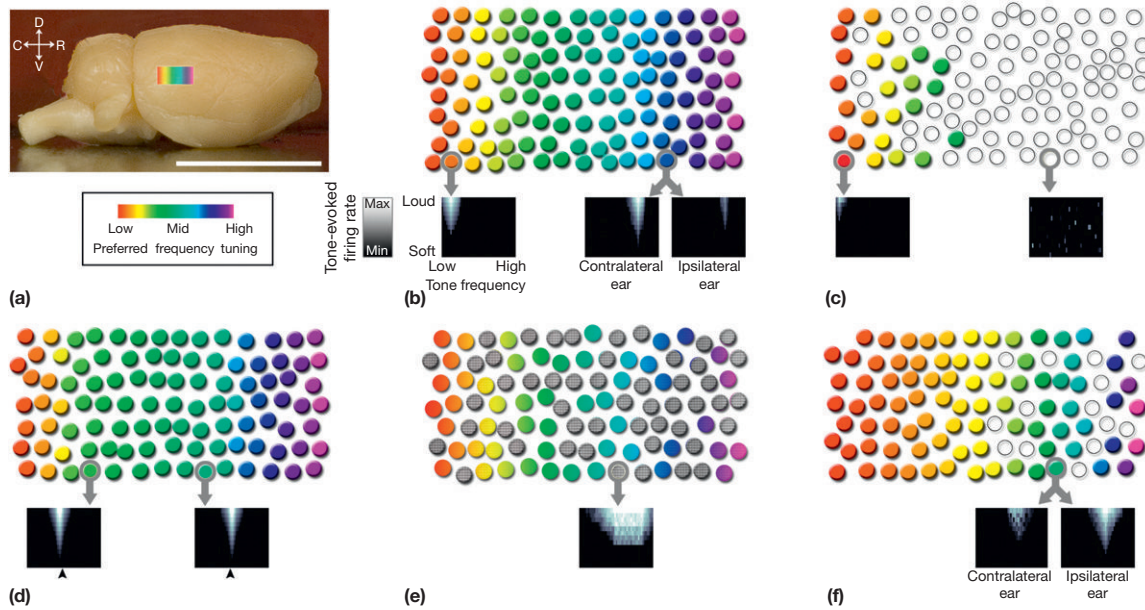
Whereas rearing animals in fixed frequency tone environments induces a region-specific reallocation of territory within the cortical map, rearing animals in broad-spectrum noise is associated with a degeneration of Actx tonotopy and an abundance of recording sites with abnormally broad tuning (Figure 2.10(e)). Similar to the extended visual cortex critical periods observed in animals reared in total darkness, the critical period for the effects of single tone exposure is abnormally prolonged in animals reared in white noise. Thus, deprivation of patterned acoustic input postpones the flip of a molecular switch that normally limits the critical period, and the effects of singe tone exposure can distort the map many weeks after the critical period would normally have closed (Chang, 2003). That a critical period normally observed in infancy can be delayed


FIGURE 2.10 **Experience-dependent map reorganization in the developing auditory cortex**. (a) Photograph of the lateral surface of the rat-brain. Color gradient denotes the position and orientation of the tonotopic map within the primary auditory cortex (AI). Horizontal line = 1 cm. (b-f) Schematics of tonotopic maps reconstructed from microelectrode recordings of tone-evoked action potentials at approximately 100 different points within AI. At each recording site, the frequency response area (grayscale surface plots) is determined by presenting tones at various frequencies and levels and identifying the frequency to which the neuron is tuned at its threshold intensity (indicated by the color of each dot). (B) Normal adult animals display a smooth and orderly tonotopic gradient in which neurons at the caudal and rostral boundaries of AI prefer low and high frequency tones, respectively. Neurons are tuned to the same frequency for sounds presented to each ear, yet responses to the contralateral ear are more robust than the ipsilateral ear. (c) Tonotopy at the onset of hearing is narrow, high-threshold and restricted to low frequency areas of the map. Open circles denote recordings sites with no evoked response. (d) Rearing rodents in acoustic environments dominated by presentation of a single middle frequency tone (represented by green colors and vertical arrows on surface plots) show an over-representation of that tone frequency within the tonotopic map such that recording sites at distant points within the map have similar tuning. (e) Rearing rodents in continous white noise is associated with a disrupted tonotopic map featuring numerous recording sites with abnormally broad frequency tuning (represented by gray dots). (f) Reversibly closing the contralateral ear during critical periods of development is associated with an over-representation of low frequency tones, the loss of contralateral tuning at several points (open circles) and an enhancement of tuning strength to tones delivered to the developmentally unobstructed ipsilateral ear.

into adulthood supports the possibility that progressive development of auditory feature representation in Actx may be more closely linked to an experiential timeline, rather than a strict chronological timeline.

A parallel can also be drawn between the reversible lid suture method used extensively in studies of visual cortex development and the effects of reversible ear canal ligation on Actx and IC development. Ligating the ear canal temporarily interferes with the transmission of acoustic signals to the middle ear, and ultimately the brain, particularly at high frequencies. By reopening the ear canal prior to recording from the contralateral AI, researchers have observed a degraded tonotopic map populated by weak high-threshold responses to contralateral tones and the occasional absence of contralateral tuning in higher frequency regions of the map (Popescu, 2010). By contrast to the contralateral bias observed in normal animals (Figure 2.(10)b), the quality of tuning for stimuli delivered to the ipsilateral ear is often superior to the normally dominant contralateral ear (Figure 2.10 (f)). Interestingly, ipsilateral inputs were only enhanced when the ear canal was ligated in infant and juvenile animals, but not in adulthood. Collectively, these results indicate that the allocation of representational resources within the Actx and IC is quite dynamic and can be adaptively reassigned to the inputs that are most prominent during critical periods of early postnatal development.

2.4.6 Conclusions and Directions for Future Research

Compared to the periphery and brainstem, the assembly of circuits in higher auditory brain areas appears to be particularly sensitive to sound-evoked patterns of afferent action potentials. Eliminating hearing or even perturbing the normal balance of signals between the ears or across various frequency channels can dramatically alter auditory signal processing. This plasticity has been documented at multiple levels of analysis, ranging from the synaptic transmission between two neurons up to the coordinated arrangement of frequency tuning across

hundreds of thousands of neurons. Although circuit re-organization at higher levels of the auditory system is striking, additional information on the normative course of development in the IC, MG and Actx as well as a deeper mechanistic understanding about the contributions of transient microcircuits such as the SPN to circuit assembly prior to hearing onset will greatly aid efforts to understand how the stable networks that underlie normal hearing are constructed. Absent data that bridge the gap between synapses and neural networks in normally developing animals, it is difficult to know whether activity- or experience-dependent modifications derail normal development or introduce an abnormal outcome following the conclusion of normal maturation.

The past fifty years of auditory developmental research have revealed a great deal about the interplay between intrinsic molecular events and dynamic electrical signaling in functional circuit maturation. The scope of research in the coming years may widen to include other biological factors that help to shape functional circuits. Although neurons are the central players in functional circuits, they do not operate in isolation. Networks of developing non-sensory glial cells, cells that form the developing vasculature and the molecules that form the extracellular matrix play may key roles in modulating neural signaling and providing a physical substrate for growth. As we have seen in the cochlea, the non-sensory cells that make up Kölliker's organ may act as the catalyst for electrical signaling throughout the pre-hearing auditory system and it is probable that exciting new connections between neural development and the non-neural cells and molecules that support them remain to be discovered. On the other end of the spectrum, it will be important to link the observations made at a neurobiological level to their potential behavioral consequences measured at the level of the whole organism. Demonstrations of abnormal circuit connectivity or map organization are worthwhile and interesting in their own right, but take on additional importance when they can be associated with changes in perceptual abilities. Studies that bridge the gaps between these various levels of analysis and stations of processing along the auditory pathway promise to reveal more about the etiology and therapeutic possibilities for treating hearing impairment, and may teach us a great deal about the fundamental principles of neural development.

Development of the Superior Colliculus/Optic Tectum

B.E. Stein, T.R. Stanford

Wake Forest School of Medicine, Winston-Salem, NC, USA

3.1 NOMENCLATURE

Anatomically, the *tectum* is that portion of the mesencephalon, or midbrain, sitting between the hindbrain and the forebrain. The name is the Latin word for *roof* and reflects the view of early anatomists that the tectum formed a roof over the fluid-filled cerebral aqueduct and the tegmentum. In mammals, it sometimes is referred to as the *tectal plate* (or *quadrigeminal plate*) and is composed of two pairs of bumps or colliculi (*collis* means hill in Latin), one on each side of the midbrain. The more rostral pair is referred to as the *superior colliculi*, and the more caudal pair is known as the *inferior colliculi*.

However, the reader should be aware that there is some confusion in the nomenclature. The term *optic tectum* (OT) properly refers to the nonmammalian homolog of the superior colliculus (SC), and its name reflects its preeminent visual role in these animals. Thus, discussions of the OT are generally specific to the major central nervous system visual nucleus in birds, reptiles, amphibians, and fish, animals from which much has been learned about the function of the OT. But while the mammalian homolog of the OT is called the *superior colliculus*, projections to and from it are called *tectopetal* (e.g., *retinotectal*, *corticotectal*) and *tectofugal* (e.g., *tectoreticular*, *tectospinal*), respectively. The confusing nature of this

nomenclature is compounded by the tendency of some to refer to the SC as the OT and of others to use *colli-culo(ar)* for *tecto(al)*.

The primary subject of the following discussion is the SC; however, the OT and SC have fundamental functional similarities, and research on the OT will be referred to when it is instructive for understanding SC organization, function, or both.

3.2 FUNCTIONAL ROLE

Although the SC, like its nonmammalian counterpart, is clearly visually dominant, it is not strictly visual, and neither is the OT. Furthermore, the role of the SC is not restricted to visuomotor behavior (nor is the OT). Rather, it is a multisensory structure that contains visual, auditory, and somatosensory representations, all of which contribute to its role in initiating orientation and localization behaviors that involve multiple sensory organs. Thus, although the visuomotor role in gaze shifts (i.e., movement of the eyes with or without corresponding movement of the head) is well known (Sparks, 1986), it also is involved in orientation of the ears (Stein and Clamann, 1981) and limbs (Stein and Gaither, 1981; Stuphorn et al., 2000). It is best to think of the SC as involved in the transformation of sensory signals (visual, auditory, and somatosensory) into motor commands.

Its ability to represent salient stimuli and engage in sensorimotor transduction so that the organism can initiate rapid orientation to the initiating event is critical to survival. The rapid maturation of the SC compared with that of the cortex reflects its importance in minimizing early ecological vulnerabilities as neonates develop greater independence. This is especially evident in altricial species, whose birth at an early stage of maturation makes observation of neural development far easier than in their precocial counterparts. However, in the adult stage of both altricial and precocial species, the communication between the cortex and SC reaches its apex, and their complementary and interdependent functions become linked through their reciprocal connections.

Before discussing the developmental features that render the SC capable of performing its adult role or how its inherent plasticity is reflected in changes resulting from sensory experience, trauma, or both, it first is necessary to describe its overall structure and function in the mature brain. A discussion of the major features of this remarkable structure follows.

3.3 GENERAL ANATOMICAL ORGANIZATION OF THE SUPERIOR COLLICULUS

The SC is a laminated structure, composed of seven alternating fibrous and cellular layers (Kanaseki and Sprague, 1974), as shown in the illustration of a cat in Figure 3.1. Operationally, however, it is divided into two broad regions: superficial (I–III) and deep (IV–VII) layers (Edwards, 1980; Harting et al., 1973; Stein, 1984). The former is strictly visual. It receives a substantial direct projection from the retina, as well as many visual projections indirectly from a host of other subcortical and cortical structures (Edwards et al., 1979). Its outputs ascend the neuraxis via the sensory thalamus and are relayed from there to the extrastriate cortex. Its descending projections pass through the deeper layers to target another visual site, the parabigeminal nucleus.

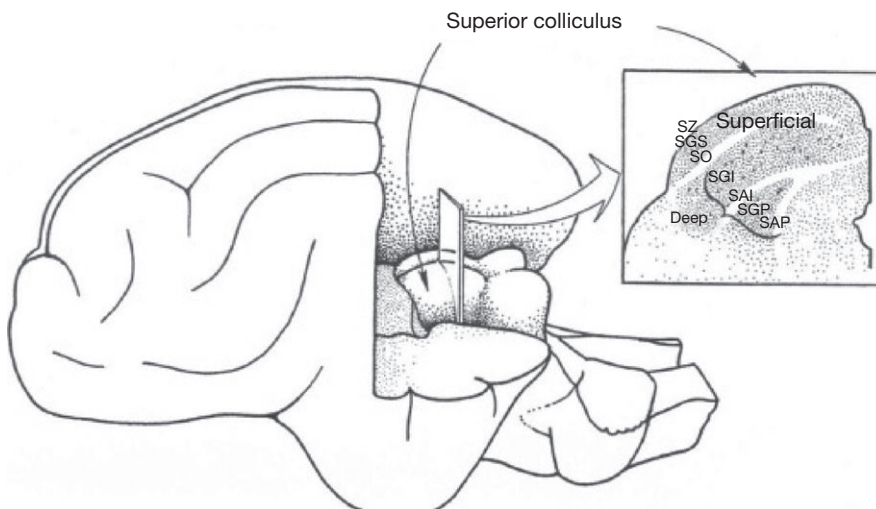
In contrast, the deep layers of the SC contain a much more heterogeneous group of neurons, which includes recipients not only of visual inputs (few come directly from the retina, but many are relayed from other brain regions, especially the cortex) but also of inputs from


FIGURE 3.1 Lateral view of the cat brain and superior colliculus (SC). A portion of cortex has been removed to reveal the SC and IC (unlabeled). A coronal section of the SC to the right shows its layers: SZ, stratum zonale; SGS, stratum griseum superficiale; SO, stratum opticum; SGI, stratum griseum intermediale; SAI, stratum album intermediale; SGP, stratum griseum profundum; SAP, stratum album profundum. *Reproduced from Stein BE, Meredith MA (1993) The Merging of the Senses. Cambridge, MA: MIT Press.*

the auditory, somatosensory, and motor systems (Stein and Meredith, 1993). In keeping with their role in sensorimotor transformation, the deeper layers send heavy descending projections to the regions of the brainstem and spinal cord that control movements of the eyes, ears, head, and limbs, as well as outputs to nonspecific sensory and motor areas of the thalamus (Edwards, 1980; Edwards and Henkel, 1978; Edwards et al., 1979; Harting, 1977; Harting et al., 1973, 1980; Moschovakis and Karabelas, 1985; Redgrave et al., 1985, 1986a,b; Rhoades et al., 1987; Sommer and Wurtz, 1998, 2004a,b; Stein and Edwards, 1979; Weber et al., 1979). It is the deep layers that are most closely associated with the sensorimotor roles for which the SC is best known; because they contain neurons responsive to multiple sensory modalities, they are referred to as the multisensory layers.

3.4 SPATIAL TOPOGRAPHIES, MULTISENSORY INTEGRATION, AND MOTOR OUTPUT

3.4.1 Visuotopy

Physically, the SC is aligned with the general axis of the brain, so its rostral pole points forward and its caudal pole points backward. Neurons in its superficial visual layers are arranged in a visuotopic (i.e., retinotopic) map of contralateral visual space and the map in the cat SC (e.g., see Feldon et al., 1970) is generally representative of those in animals having forward-facing eyes (see Cynader and Berman, 1972 for a description in monkeys). SC neurons having receptive fields in central visual space are located rostrally in the structure and are the smallest. Thus, this portion of the map has the greatest spatial resolution. Neurons having receptive fields progressively more peripheral (i.e., temporal) in space are located progressively more caudal in the structure and are the largest. This portion of the map has the lowest spatial fidelity. In short, the horizontal meridian from central to peripheral visual space runs roughly rostrocaudal. The vertical meridian is roughly orthogonal to the horizontal meridian, with superior visual space represented medial and inferior space represented lateral. The central visual point (i.e., the fovea in primates and area centralis in carnivores) is the point at which the horizontal and vertical meridians cross.

The central representation of visual space is expanded in the SC. Thus, for example, the central 10° of space occupies more than a third of the tissue devoted to the map in the cat SC and more than half the tissue in monkey SC. In some species, such as the cat, neurons located rostral to the vertical meridian extend the map to represent up to 10° of the ipsilateral hemifield. This nasal representation is essentially nonexistent in monkeys (Cynader and Berman, 1972), but is much larger in animals such as rats, which have eyes on the sides of their head (e.g., see Siminoff et al., 1966).

A retinotopic organization is also characteristic of the OT, although in some nonmammalian species, the vertical and horizontal meridians are not always as well aligned with the brain's rostrocaudal axis as they are in mammals (e.g., see Gaither and Stein, 1979). The ubiquity of a retinotopy likely represents the ease of using a map to determine the location of a visual event and of transforming the visual cues it provides into motor coordinates for orientation responses. However, this sensorimotor transduction is primarily a function of the deep (i.e., multisensory) layers of the SC, which also contain a map of the visual space.

The retinotopy in the deep layers is similar to that of the overlying superficial layer map; however, the source of visual afferents differs somewhat. Receptive fields are considerably larger than those in the overlying layers, and as a result, there is lower spatial resolution in this visual map (McIlwain, 1975, 1991; Meredith and Stein, 1990). Yet, it has a better representation of the far periphery and also extends a bit further into the ipsilateral hemifield than does the superficial layer map (Meredith and Stein, 1990). Shifts in receptive field size follow the same trend as those in superficial layers, with central visual fields being the smallest and far peripheral receptive fields being the largest. But the visual map in the multisensory layers is only one of three overlapping spatiotopic sensory representations in this region of the structure.

3.4.2 Somatotopy

The somatosensory representation in the multisensory SC is largely of the cutaneous surface and its maplike representation is called 'somatotopic.' Its relationship to the visuotopic representation has also been studied most extensively in cats (see Meredith et al., 1991; Stein et al., 1975; but see also Benedetti and Ferro, 1995; Dräger and Hubel, 1975; McHaffie et al., 1989). Like the visual representation, it is formed from comparatively large receptive fields that are organized into a map of the body, with a geometric expansion of the representation of the face and head. The face representation is made up of the smallest receptive fields, is located rostrally, and roughly overlaps the representation of central visual space. The body and rump are represented more caudal and the limbs extend laterally, so that the upper body space is represented medially to coincide with the representation of upper visual space and the lower body space is represented laterally to coincide with the representation of lower visual space. Given that the SC also receives inputs from pathways

carrying information about potentially harmful stimuli, it is not surprising to find that it also has neurons responsive to noxious stimuli (Stein and Dixon, 1978, 1979). These neurons have many of the same properties found in structures better known for dealing with nociceptive information (Larson et al., 1987; Rhoades et al., 1983). Although this representation has been studied only in rodents and is largely restricted to the face and forelimb (McHaffie et al., 1989; see also Auroy et al., 1991), it incorporates the same general topographic features employed by the other sensory maps (Stein and Meredith, 1993).

3.4.3 Audiotopy

Unlike the visual and somatotopic maps, which are formed directly via afferents from different regions of the retina or skin (albeit with some geometrical distortions), the spatiotopic nature of the auditory representation must be derived via neural computation based on comparisons of the timing, intensity, and frequency of the sound signals at the two ears. Although the term 'audiotopic' is not commonly used and hence seems a bit awkward, it is as appropriate as 'retinotopic' and 'somatotopic' in this context. Its properties have also been examined closely in cats and follow the same general organizational features of the maps that have been outlined earlier. Forward auditory space is represented in the rostral aspect of the structure, temporal auditory space in its caudal aspect, and superior–inferior space is laid out along its mediolateral axis (Middlebrooks and Knudsen, 1984; see also Palmer and King, 1982; King and Palmer, 1983).

3.4.4 Multisensory Integration

The alignment of SC sensory maps is evident in the overlap among modality-specific receptive fields of multisensory SC and OT neurons. Indeed, the individual maps are largely a reflection of the receptive field properties of multisensory neurons that, in cats at least, comprise the majority of sensory responsive neurons in the deep layers. Each multisensory neuron has at least two receptive fields, one for each of the sensory modalities to which it responds (e.g., see Stein and Meredith, 1993 for a review). For example, a visual–auditory neuron with a visual receptive field in central visual space will have an auditory receptive field in an overlapping region of central visual space, so that only visual and auditory cues from roughly the same locations will affect that neuron.

A key element of SC function is derived from the ability of multisensory neurons to integrate the influences of the different sensory modalities and the nature of such integration hinges strongly on map alignment. While much of the information about multisensory integration comes from studies of single neurons in cat SC, similar observations have also been made in the SC and OT of other species (see, e.g., Bell et al., 2001, 2005; Gaither and Stein, 1979; Hartline et al., 1978; King and Palmer, 1978; Stein and Gaither, 1981; Van Wanrooij et al., 2009; Wallace et al., 1996; Zahar et al., 2009). Operationally defined, 'multisensory integration' is the process by which stimuli from different senses combine (i.e., *cross-modal*) to produce a response that differs from those produced by the component stimuli individually. At the level of the single neuron, integration corresponds to *a statistically significant difference between the number of impulses evoked by a cross-modal combination of stimuli and the number evoked by the most effective of these stimuli individually* (see Stein and Stanford, 2008 for discussion). This difference can be manifested as either a response increase or decrease, depending on how the stimuli are configured in space. Cross-modal stimuli that signal a common event (they are in the same place at the same time) impinge on overlapping modality-specific receptive fields, and the integration of their influences yields response enhancement. Conversely, modality-specific cues emanating from disparate locations affect nonoverlapping regions of their respective sensory maps; disparate cues thus fail to produce enhancement and, in some instances, produce response depression (Kadunce et al., 1997). Examples of multisensory integration that yield response enhancement and response depression are shown in Figure 3.2.

Remarkably, convergence of inputs from different senses alone is not sufficient for multisensory integration in the SC. A matching set of converging unisensory inputs from association cortex is required (primarily from the anterior ectosylvian sulcus (AES); Alvarado et al., 2009; Fuentes-Santamaria et al., 2008a, 2009; Stein et al., 1983 but also inputs from the rostral–lateral suprasylvian sulcus (rLS) play a role – see Jiang et al., 2001). Without these cortical inputs, SC neurons respond to individual cues from different senses but do not integrate them to yield (Alvarado et al., 2007, 2008, 2009; Jiang et al., 2001; Wallace and Stein, 1994). Rather, the neural response to cross-modal stimulation is no greater than that to the best of the stimulus components alone, a finding that is mirrored by an absence of the multisensory advantages that are typical of SC-mediated behaviors (Jiang et al., 2002, 2006, 2007; Wilkinson et al., 1996). The requirement for cortical input has implications for the development of SC multisensory integration and the behaviors it supports, as will be discussed later in this chapter.

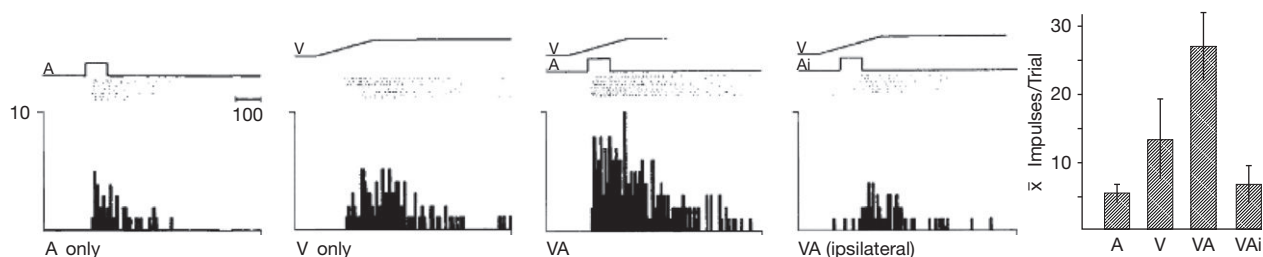
Insofar as the magnitude of activity within SC sensory maps corresponds to the physiological salience of an external stimulus, and thus the likelihood that it will generate a motor response, the implications of multisensory integration for behavior are quite clear. Enhanced


FIGURE 3.2 Multisensory enhancement. Left: A square-wave broadband auditory stimulus (A, 1st panel) and a moving visual stimulus (ramp labeled V, 2nd panel) evoked unisensory responses from this neuron (illustrated below the stimulus by rasters and peristimulus time histograms). Each dot in the raster represents a single impulse; each row, a single trial. Trials are ordered from bottom to top. The 3rd panel shows the response to auditory and visual stimulus presentation at the same time and location, which is much more robust than either unisensory response. Yet, when the auditory stimulus was moved into ipsilateral auditory space (Ai) and out of the receptive field, its combination with the visual stimulus elicited fewer impulses than did the visual stimulus individually. This 'response depression' is illustrated within the 4th panel. Right: The mean number of impulses/trial elicited by each of the four stimulus configurations. Note the difference between multisensory enhancement (VA) and multisensory depression (VAi). *Reproduced from Stein and Rowland, 2011,* Progress in Brain Research.

activity for spatially concordant cues corresponds to an increased likelihood of stimulus detection and an associated motor response to orient to that stimulus. In contrast, the multisensory depression that results from stimuli at competing locations would have an opposing effect (Calvert et al., 2004; Gillmeister and Eimer, 2007; Spence et al., 2004; Stein and Stanford, 2008). In either case, sensory-related activation must be transformed into motor commands, which, like their sensory counterparts, assume the form of a topographically organized map.

3.4.5 Mototopic Representation

Many of the neurons in the deep/multisensory layers are output neurons that project to one or more brainstem and spinal cord regions responsible for moving the eyes, ears, whiskers, head, and limbs (Coulter et al., 1979; Edwards and Henkel, 1978; Grantyn and Grantyn, 1982; Harting, 1977; Holcombe and Hall, 1981a,b; Huerta and Harting, 1982a,b; Moschovakis et al., 1998; Weber et al., 1979; see Gandhi and Katnani, 2011; Hall and Moschovakis, 2004; Sparks, 1986; Sparks and Mays, 1990 for reviews). The term 'mototopic,' like 'audiotopic,' is not in common usage but, once again, seems equally appropriate in this context, given the more commonly used terms 'visuotopic' and 'somatotopic.' By far, the most is known about the motor topography for producing gaze shifts and for movements of eyes (or the eyes and head) to place stimuli of interest into the line of sight. Accordingly, the motor map for gaze shifts is in register with the visual, auditory, and somatosensory topographies; therefore, the sensory evoked activity represents the distance and direction of a stimulus from the current line of sight, and the motor activity at that site represents a command for shifting gaze to the corresponding distance and in the corresponding direction.

The SC motor map is two-dimensional, with gaze amplitude (from small to large) represented along its rostrocaudal axis and gaze direction (from upward to downward) represented along its mediolateral axis (du Lac and Knudsen, 1990; Goldberg and Wurtz, 1972; Pare et al., 1994; Robinson, 1972; Schiller and Stryker, 1972; Wurtz and Goldberg, 1972). In a manner analogous to sensory receptive fields, constituent neurons of the SC motor map have *movement fields*, such that they respond most vigorously in association with gaze shifts within a particular range of amplitude and direction, and gaze shifts are produced consequent to the activity of their premotor activity. Figure 3.3 illustrates a typical SC movement field for a neuron recorded from the right SC of a monkey. This neuron discharges most vigorously (peak of the 3D plot) for saccades having a direction of approximately 190° (leftward and slightly downward) and having an amplitude of approximately 7° of visual angle (i.e., deviation of eye from the straight ahead position). Considered in the context of the motor map of the right SC, this neuron would be located toward the rostral pole (small movements) and slightly lateral (downward). Thus, like the SC sensory maps, which constitute 'place codes' for stimulus location in sensory space, the SC motor map is a 'place code' for movement vector, such that the locus of activation determines the amplitude and direction of an impending movement.

3.4.6 Maintaining Sensory and Motor Map Alignment

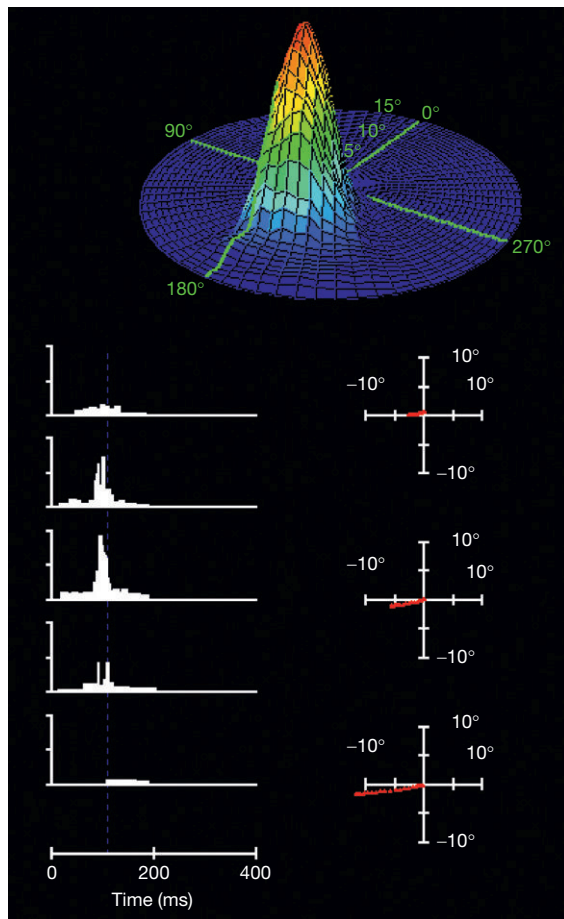
The overlap among the sensory and motor maps is unlikely to be serendipitous, as it appears to be the most straightforward way to coordinate the cross-modal sensory cues and movements of the various sensory organs toward a salient event. Nevertheless, given the ability to move the different sensory organs independently, retaining the registry of their midbrain maps presents


FIGURE 3.3 Superior colliculus movement field. Neurons in the SC have movement fields and discharge most for movements within particular ranges of amplitude and direction. The 3D polar plot (above) illustrates the movement field of an SC neuron that discharges for relatively small and slightly downward saccadic eye movements. Below left, the premotor activity profiles are shown aligned on the onsets of saccades (blue dotted line) of five different amplitudes (top to bottom) and representing a 'slice' through the peak of the movement field along the line of best direction. Representative saccade trajectories are shown to the right of the activity profiles. Note that maximum activity corresponds to a slightly downward saccade having amplitude corresponding to roughly 7° of visual angle. *Reproduced from Stanford and Sparks, unpublished observations.*

a nontrivial problem. The problem is partially solved by the nonstatic nature of these maps. Studies in various species show that shifting the eyes voluntarily or inducing long-term shifts in the optical axis via surgical or prismatic means produces a corresponding shift in the SC auditory map (Brainard and Knudsen, 1998; Hartline et al., 1995; Jay and Sparks, 1984; King et al., 1988; Peck et al., 1995). A similar shift may also be initiated in the somatosensory map (Groh and Sparks, 1996). These observations suggest that the different senses are linked to an oculocentric coordinate system, though compensatory shifts in the nonvisual maps do not completely compensate for large ocular misalignments

(Metzger et al., 2004). Maintaining intermap registry ensures that any visual, auditory, or somatosensory cue (and any combination of them) derived from the same location in space activates neurons in approximately the same SC location. This, in turn, accesses the same point in the motor map to produce coordinated orientation of all the sensory organs toward the location of the initiating event. This not only helps determine the nature of that event but also puts the animal in an appropriate position to evaluate it.

3.5 THE MATURATION OF THE SUPERIOR COLLICULUS

3.5.1 The Neonate

In altricial species, such as cats, the ability of the SC to use sensory information to initiate overt behaviors is poorly developed at birth. Unlike primates, ungulates, and other precocial species, the newborn carnivore (rodent, lagomorph, marsupial, etc.) is poorly equipped to deal with its sensory environment. Its eyes are closed, there is a vascular network around the lens that impedes the transmission of light (Bonds and Freeman, 1978; Thorn et al., 1976), and it is functionally blind. Similarly, its ear canals are still sealed, and it is deaf. The only sensory inputs that activate SC neurons at this time are tactile. These inputs are already functional prenatally but are only weakly effective and stay that way for some time after birth (Stein et al., 1973a,b). The newborn carnivore's motor capabilities are also poorly developed, and it depends heavily on its mother for things like warmth and protection, and even the initiation of feeding (Larson and Stein, 1984; Rosenblatt, 1971). The immaturity of the newborn cat's SC makes it a good model for exploring how sensory responses develop, how the different sensory representations become established, and how multisensory integration develops so that SC neurons can use the available sensory information synergistically to optimize SC-mediated behavior.

3.5.2 Sensory Chronology

As noted, somatosensory responsiveness in some cat SC neurons precedes birth and provides the structure with its first source of information about the world. Auditory responses begin to appear in some SC neurons at 5 days postnatally, and neurons develop visual responsiveness last (Stein et al., 1973a,b). Interestingly, visual responses develop in two sequential phases, first appearing from top to bottom in the most superficial (i.e., visual) layers of the structure and then in a similar manner in neurons in its multisensory (deeper) layers. These phases are widely separated in time, with neurons in the

most superficial strata of the superficial layers beginning to respond to visual stimuli at about 6 postnatal days, and those in the multisensory layers not showing responsiveness to visual stimuli for several weeks (Kao et al., 1994).

3.5.2.1 Retinotectal Inputs and the Development of a Superficial Layer Visuotopy

Because of the visually dominant role of the SC, the development of its visual inputs (especially those coming directly from the retina) has received a great deal of attention. Once again, cats have been one of the primary sources of this information, along with rodents, opossums, and monkeys. Given the functional immaturity of the newborn cat's SC (there is no visual responsiveness yet), it is surprising to note the advanced state of its retinotectal topography during late embryonic development (Graybiel, 1975; Williams and Chalupa, 1982). Although, at this point, the retinotectal projections appear to be restricted to the superficial layers of the SC, segregation of inputs from the contralateral and ipsilateral eyes is already apparent several days before birth (Figure 3.4(b); embryonic day 56), and by embryonic day 61 (Figure 3.4(c)) further refinement leads to an almost adult-like patterning of inputs. This advanced pattern of retinal projections is achieved by sculpting it from a far more widespread projection that is evident at approximately embryonic day 38 (Figure 3.4(a)). At that point, the projections from the two retinas are intermingled and distributed across the entire rostrocaudal and mediolateral extent of the SC. This pattern is progressively altered so that by embryonic day 61 (4–7 days before parturition) the pattern of ipsilateral and contralateral retinotectal inputs closely resembles the pattern characteristic of the adult. Although the timing is different, similar developmental processes have been noted in monkeys (Rakic, 1977), hamsters (Frost et al., 1979), rats (Land and Lund, 1979), and opossums (Cavalcante and Rocha-Miranda, 1978).

Data from a variety of nonmammalian and mammalian models have suggested that chemoaffinity cues provide the basis for the fundamental topographical order of retinotectal projections and that this coarse representation is subsequently refined by activity-dependent mechanisms (Drescher et al., 1997; Fraser, 1992; Ruthazer and Cline, 2004; Ruthazer et al., 2003; Sperry, 1963; Walter et al., 1987). There is good reason to assume that similar processes are involved in determining the adult-like pattern of sensory afferents to the multisensory layers of the SC, but observations of the development of its retinotectal projections are hampered by weak input, and less attention has been directed toward the maturation of nonvisual inputs. Nevertheless, it has been noted that somatosensory tectopetal afferents are already widespread in the multisensory layers of the SC at birth, and they too appear to have an adult-like configuration (McHaffie et al., 1986, 1988).

The apparent maturity of the representation of tectopetal sensory afferents (inputs) at birth stands in contrast to the significant immaturity in at least one of its tectofugal efferent (output) sensory projections, namely, those to the lateral geniculate nucleus (LGN). This transient

FIGURE 3.4 Retinotectal projection patterns to the superficial superior colliculus are highly developed in cats before birth. Shown are photographic illustrations of the distribution of a tracer (horseradish peroxidase shown as dark regions) from one eye to both colliculi approximately 17 ((a), at E38) and 9 days before birth ((b), at E56). Sections are ordered from rostral (bottom) to caudal (top), with the contralateral SC on the left. The calibration bar is 1 mm. Note that the projection has largely withdrawn from the ipsilateral SC and changed its distribution in the contralateral SC by E56. Several days later, ((c), at E61), an almost adult-like pattern input is apparent. *Adapted from Williams RW, Chalupa LM (1982) Prenatal development of retinocollicular projections in the cat: An anterograde tracer transport study.* Journal of Neuroscience 2:604–622.

tectogeniculate projection is topographic and is part of the ascending wing of the SC's visual projection that eventually reaches the cortex via polysynaptic pathways. In adults, the tectogeniculate projection is confined to the ventral C layers, but in neonates it extends across all layers of the LGN as well as into the medial interlaminar nucleus. It is retained for approximately 3 postnatal weeks, long after visual function has been initiated, and is eliminated by mechanisms that are not yet fully understood (Stein et al., 1985). Its immaturity contrasts with the more rapidly maturing tectofugal pathways involved in motor functions (Stein et al., 1982, 1984).

Despite the adult-like pattern of retinotectal projections at birth, the visual system is not yet functional. Visual responsiveness begins in superficial layer SC neurons at 6 days of age. At this time, the eyelids are still closed (they open naturally at 7–11 days postnatal) and visually responsive neurons are rare, which are clustered together between ineffective loci (Kao et al., 1994; Stein et al., 1973a). This reflects a random onset of visual activity via random functional coupling of retinotectal afferents and their SC target neurons and/or the random openings in the vascular networks around the lens that begin at about the time of eye opening (Freeman and Lai, 1978). Most active sites are located in the middle portion of the structure and in its most superficial aspect. Nevertheless, the general topographic organization established by the afferent projections is apparent at this time (Kao et al., 1994; Figure 3.5).

Curiously, the initial visual activity is restricted not only across the horizontal aspect of the SC, but also, as noted earlier, in its vertical aspect. Neurons in the most superficial portion of the SC, where inputs from retinal W cells terminate, begin responding earliest. Neurons deeper in the superficial layers, where Y-cell inputs dominate, develop later, and visual responsiveness in the subjacent multisensory layers develops last (Kao et al., 1994; Wallace and Stein, 1997). The bases for this particular pattern of functional development remain obscure, but it occurs at the same time that the number of active loci across the horizontal aspect of the structure increases to yield a continuous retinotopy that underlies its visuotopic organization (Figure 3.6).

These early responsive neurons are functionally immature and have many properties that typify functionally immature neurons elsewhere in the nervous system. Their receptive fields are very large and require either long-duration flashed stationary targets or very slowly moving stimuli for activation. They fatigue readily with repeated stimulation, require very long interstimulus intervals to respond to sequential stimuli, and have very long latencies (Kao et al., 1994; Stein et al., 1973b). They also lack binocularity and direction selectivity, properties that characterize these neurons when

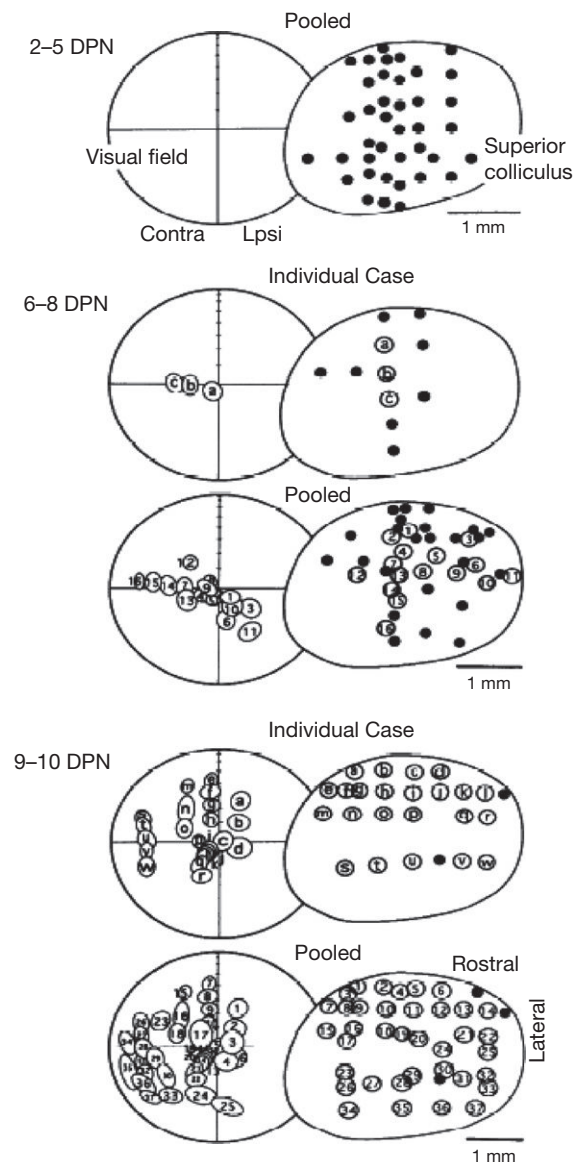

FIGURE 3.5   The maturation of the visuotopic map in the superficial superior colliculus. Data from three age groups are shown. Each contains a diagram of the visual field on the left and a schematic of the dorsal surface of the SC on the right. Circles on the SC represent electrode penetrations (filled, no visual activity, open, visual activity). Correspondence between the electrode penetrations and visual receptive fields are shown by numbers and letters (only the 'best area' of a receptive field was mapped). No visual activity was encountered before 6 days postnatal (dpn) but was already represented in a maplike pattern when first encountered. Adjacent electrode penetrations in the SC yielded visual activity at adjacent sites in visual space. By 9–10 dpn, most SC locations had become responsive to visual stimulation. *Reproduced from Kao CQ, Stein BE, Coulter DA (1994) Postnatal development of excitatory synaptic function in deep layers of SC.* Abstracts – Society for Neuroscience *20: 1186.*

mature and are believed to facilitate orientation to moving targets. These properties develop over a 6- to 8-week period. It is not clear what, if any, visual behaviors these early responding neurons can support, as overt visual
FIGURE 3.6 During maturation, superior colliculus visual activity progresses from the top to the bottom of the superficial layers. Vertical lines illustrate electrode penetrations through coronal sections of the SC in each age group. Sections are arranged rostrocaudally. Each region of visual activity is represented by a thick vertical black line spanning the distance between the first and last location of visually active neurons. Note that the visually active spans increase with age so that by 9–10 dpn, visual activity is evident throughout the depths of the superficial layers. No deep-layer visual activity was present at this time. *Reproduced from Kao CQ, Stein BE, Coulter DA (1994) Postnatal development of excitatory synaptic function in deep layers of SC.* Abstracts – Society for Neuroscience *20: 1186.*

function is not observed in cats until 2–3 weeks after birth, by which point they have already matured considerably (Fox et al., 1978; Stein et al., 1973a). Nevertheless, the physiological maturation of the receptive field properties of these superficial layer neurons takes 2 months or more to reach their adult status. This reflects, in part, the physiological maturation of visual tectopetal afferents, especially those from the cortex (e.g., see Stein and Gallagher, 1981).

Although sensory experience is critical for the formation of many neural properties in the central nervous system, the fundamental features of SC visuotopy and the responsiveness of its constituent neurons appear to progress in a manner independent of visual experience. Superficial layer and deep (multisensory) layer neurons in dark-reared cats show robust visual responses and adult-like resistance to fatigue with repeated stimulation, although their receptive fields remain comparatively large and their more sophisticated properties develop more gradually. Similarly, in the newborn monkey, the ocular properties are far more mature than those of the cat, and SC neurons already show a well-ordered and continuous superficial layer visuotopy. Although the receptive fields of its neurons are also larger than

those in the adult and their visual latencies are longer, the neurons respond robustly to visual stimuli and already have many adult-like response properties (Wallace et al., 1997). The maturational differences in the newborn monkey and cat SC likely reflect both the shorter gestational period in the cat and its higher dependence on corticotectal inputs for construction of its neuronal response properties (Stein, 1984).

3.5.2.2 Development of Deep Layer Sensory Topographies

Attention to the maturation of neurons in the deep layers has been focused on their functional properties rather than their topographies. Thus, much of what is known about this feature of their development has to be inferred. The somatosensory and auditory receptive fields of neonatal neurons are, like their visual counterparts, extremely large. Neonatal somatosensory receptive fields cover much of the contralateral body and early auditory receptive fields are 'omnidirectional,' having receptive fields that encompass the whole of the contralateral auditory space. They gradually shrink in size over the first few months of life, and in the absence of evidence that neurons have receptive fields that

are 'mislocated,' it is assumed that the resolution of their maps gradually increases as individual receptive fields contract. The functional changes that ensue in these layers as a consequence of development are discussed in the section on the maturation of multisensory integration. Examples of receptive field development are also provided.

3.5.3 The Development of Multisensory Neurons

Although a great deal of effort has been expended on understanding the maturation of the superficial layer visuotopy to understand the maturation of SC-mediated orientation behaviors, as noted earlier, it is actually the deep (multisensory) layer visual responsiveness that is most closely linked to this function. Also, these layers are slower to develop. Because the maturation of these neurons has been most closely studied in cats, unless otherwise stated, the descriptions in what follows relate to this species.

Because neurons in the multisensory layers become responsive to visual cues only after 3 postnatal weeks (Kao et al., 1994; Wallace and Stein, 1997), it is obvious that neither the weak direct retinal projection to these layers (Beckstead and Frankfurter, 1983; Berson and McIlwain, 1982) nor the relay of visual input from active neurons in the superficial layers (e.g., Behan and Appell, 1992; Grantyn et al., 1984; Moschovakis and Karabelas, 1985) are capable of activating these neurons before this time. Yet somatosensory- and auditory-evoked neuronal activity is already apparent, though the responsive neurons also have the large receptive fields and tendency toward fatigue that are characteristic of neonatal neurons. This developmental chronology (somatosensory first, auditory second, visual last) parallels the development of sensory-evoked orientation behaviors (Fox et al., 1978; Norton, 1974; Villablanca and Olmstead, 1979).

At this time, there is a gradual increase in the number of SC neurons that can respond to multiple sensory inputs. Thus, each of the different possible convergence patterns of responsiveness to visual, auditory, and/or somatosensory inputs becomes evident. One of the hallmark features of multisensory SC neurons, however, is their ability to use information from the different senses synergistically. This process of integrating cross-modal inputs markedly facilitates SC-mediated behavior and begins at about the fourth postnatal week.

3.5.4 Superficial Layer and Deep (Multisensory) Layer Maturational Delay

As noted earlier, visual responsiveness occurs comparatively early in superficial layer neurons, beginning before the end of the first week, and comparatively late in the multisensory layers, where it begins in the third or fourth postnatal week. This maturational delay relative to superficial layer visual activity underscores the significant maturational difference between the sensory-specific properties of superficial-layer neurons and their multisensory counterparts in the deep layers. Synthesizing information from multiple senses is surely a more complex process than responding to any one of them individually and therefore requires greater maturational time. These superficial–deep-layer differences also extend to the functional roles to which their information processing contributes. Although both neuronal populations probably share functions related to perception and overt behavior, superficial layer visual neurons are believed to contribute more to the former and deep-layer multisensory neurons to the latter.

Developing the ability to integrate cross-modal inputs is a multistep process. Neurons first develop responsiveness to a single sensory input, then to at least two different (i.e., cross-modal) inputs, and can finally develop the ability to integrate the information carried in multiple sensory channels.

The maturation of the various possible multisensory convergence patterns follows closely the chronology of unisensory maturation. Thus, somatosensory–auditory neurons are the first multisensory neurons to appear. They become evident 10–12 days post parturition, and visual–nonvisual neurons become evident at approximately the third postnatal week, as soon as visual responsiveness begins in the multisensory layers. Yet, it still takes many weeks of maturation before the adult-like incidence of the various modality-convergence patterns is reached and the adult-like incidence of neurons capable of multisensory integration is achieved. As might be suspected from their unisensory counterparts, the receptive fields of the initial multisensory neurons are very large. They contract over several months, thereby progressively increasing the spatial resolution of the individual sensory maps to which they contribute and enhancing their spatial register with one another (Figure 3.7). The changes in receptive field size are accompanied by an increase in response vigor and reliability, as well as by a decrease in response latency. These functional changes reflect a combination of developmental factors taking place in afferent systems, as well as within the internal circuitry of the SC.

3.5.5 The Development of Multisensory Integration

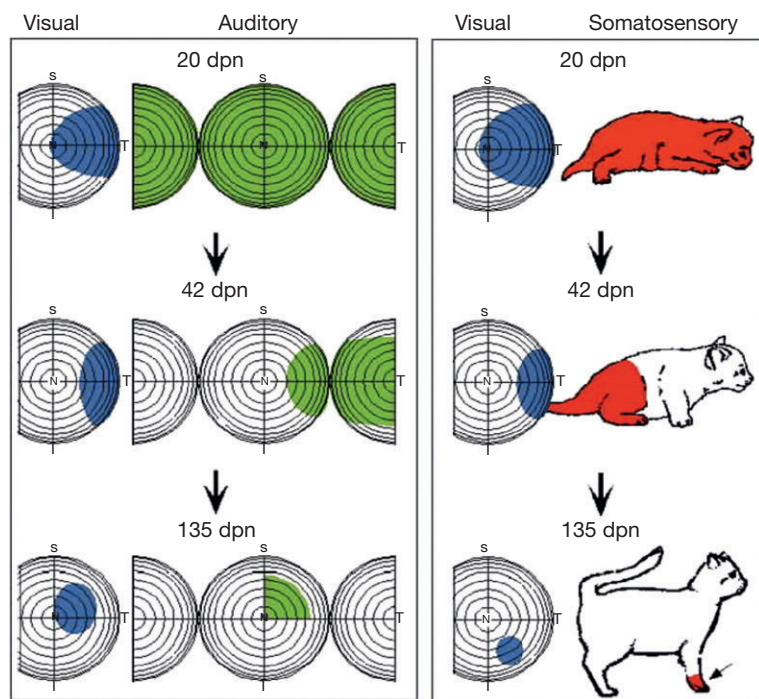
The ability to integrate cross-modal inputs is delayed until at least 1 month after birth (Wallace and Stein, 1997), and before it develops, the cross-modal responses of multisensory neurons look like the responses elicited


FIGURE 3.7 The maturation of multisensory receptive fields. Shown are exemplar SC receptive fields from visual–auditory (left) and visual–somatosensory (right) neurons that were mapped in animals aged 22–135 dpn. Note that receptive fields become progressively smaller at older ages, increasing their spatial resolution and their register with one another. *Adapted from Wallace MT and Stein BE (1997) Development of multisensory neurons and multisensory integration in cat superior colliculus.* Journal of Neuroscience 17: 2429–2444 *(see also Stein and Rowland, 2011).*

by one (the more effective) of the component stimuli alone. At this age, however, some neurons respond to cross-modal stimuli with responses that significantly exceed the presumptive unisensory responses, but such neurons are rare at this time. The incidence of these integrative neurons progressively increases with age, but the mature condition is not reached until the animal is several months old and has had a great deal of sensory experience.

The absence of an ability to integrate cross-modal inputs in the neonatal cat's SC is not due to the general immaturity of these neurons. The macaque monkey is born much later in development than the cat. Its eyes and ears are open at birth and it sees and hears quite well, and unlike the cat, it already has multisensory SC neurons in its SC. But they cannot integrate their cross-modal inputs to produce response enhancement (Wallace and Stein, 2001) and, therefore, respond to these stimuli very differently than do their adult counterparts (Wallace et al., 1996). The likely reason is that they have not yet had the necessary sensory experience. Apparently, postnatal sensory experience is not critical for the appearance of multisensory neurons, but these observations strongly suggest that it is necessary for them to integrate their different sensory inputs. Observations from experiments with human subjects are consistent with this hypothesis (e.g., Gori et al., 2008; Neil et al., 2006; Putzar et al., 2007), though critical direct observations showing that the newborn cannot yet use cross-sensory cues synergistically are not yet available. Nevertheless, newborn human infants

are capable of engaging in a host of multisensory tasks, the best known of which is cross-modal matching (see Stein et al., 2010 for further discussion).

3.5.6 The Impact of Sensory Experience on the Maturation of Multisensory Integration

As noted earlier, when discussing multisensory integration, inputs from association cortex (e.g., primarily from the anterior ectosylvian sulcus, or AES, in cats) have been found to be essential for SC multisensory integration. Thus, one might expect that the functional coupling of this input with multisensory SC neurons is a necessary precondition for the development of SC multisensory integration, and this appears to be the case. Anatomically, the corticotectal projections from AES have already grown into the multisensory layers of the SC prior to birth and long before SC neurons are responsive to multiple sensory inputs (McHaffie et al., 1988). However, they are unlikely to be functional at this time. Their critical contribution to multisensory integration becomes obvious as soon as a neuron in the SC exhibits this capability. As noted earlier, this first happens for some rare neurons at about 1 month of age. Deactivating AES at this stage eliminates that capacity as effectively as it does in adulthood. The neurons' responses to the cross-modal stimulus combination are now no longer significantly different from those to the most effective component stimulus (Wallace and Stein, 2000; Figure 3.8).
FIGURE 3.8   The maturation of multisensory integration parallels the functional coupling of AES-SC projections. The developmental increase in the incidence of SC neurons capable of multisensory integration is paralleled by the effectiveness of AES deactivation in blocking the expression of this capability. Nearly all SC neurons lost this ability during AES deactivation, regardless of age (the number of neurons tested at every time point is shown in parentheses). The small proportion of SC neurons whose multisensory integration capability was unaffected by AES deactivation likely depended on an adjacent area of association cortex (i.e., the rostrolateral suprasylvian cortex, see Jiang W, Wallace MT, Jiang H, Vaughan JW, Stein BE (2001) Two cortical areas mediate multisensory integration in superior colliculus neurons. *Journal of Neurophysiology* 85: 506–522). *Reproduced from Wallace MT and Stein BE (2000) Onset of cross-modal synthesis in the neonatal superior colliculus is gated by the development of cortical influences.* Journal of Neurophysiology 83:3578–3582.

Although the association cortex component of the SC circuit appears to be critical for multisensory integration, it is not sufficient. Appropriate sensory experience is also a key factor.

During this early phase of life, the brain is learning about external events and the statistical relationships among stimuli that are derived from the same event. Cross-modal stimuli that are produced by the same event are temporally and spatially coincident, or at least proximate in space and time. These relationships must be learned (e.g., via Hebbian learning rules) and somehow represented in the underlying circuitry responsible for multisensory integration. Given the arbitrary nature of many cross-modal relationships, it is difficult to conceive of an effective scheme for incorporating this information without actual experience. Experience with cross-modal stimuli establishes a principled way of interpreting and interacting with external events so that only a select group of cross-modal stimuli will produce multisensory integration. For example, the brain learns to expect that some visual and auditory cues are linked

to the same event, based on their location and timing. This information is used to establish principles for categorizing cross-modal stimuli derived from the same, or different, events.

To test the hypothesis that sensory experience plays a key role in the development of multisensory integration capabilities, cats were raised in darkness in order to preclude visual–nonvisual experiences. Normally, the physiology of SC multisensory integration is reached at 3–4 months of age (Wallace and Stein, 1997), and these dark-reared animals were not studied until at least 6 months of age. Visual experience was not essential for the appearance of visually responsive neurons, and such neurons were common in these dark-reared animals, as well as in newborn monkeys (Wallace and Stein, 2001). Each of the modality-convergence patterns was also well represented among the neurons encountered (Wallace et al., 2004). However, their receptive fields were still quite large and more typical of the neonate than the mature animal (Figure 3.9). The failure to contract their receptive fields was indicative of their physiological immaturity and this was most apparent in their inability to integrate cross-modal cues. As shown in Figure 3.9, their multisensory response to a cross-modal visual–nonvisual stimulus was approximately equal to their response to the visual component stimulus alone. Multisensory responses that approximate the response to the most effective component stimulus are typical of neonatal neurons that have not yet developed their capacity for multisensory integration and of adult multisensory neurons deprived of the critical input from association cortex.

Human subjects who have had their early vision compromised by congenital cataracts also show persistent visual–nonvisual integration deficits even many years after the cataracts have been removed (Putzar et al., 2007). These observations support the hypothesis that cross-modal experience is a critical factor in the maturation of the capacity to integrate multisensory cues (Figure 3.10), but they do not provide information about whether the nature of that early experience determines the principles that govern this process. To test this possibility, animals were reared from birth to 6 months of age in a dark room in which pairs of visual and auditory stimuli were periodically presented, but these stimuli were always spatially disparate (Wallace and Stein, 2007). The properties of their multisensory SC neurons were then assessed.

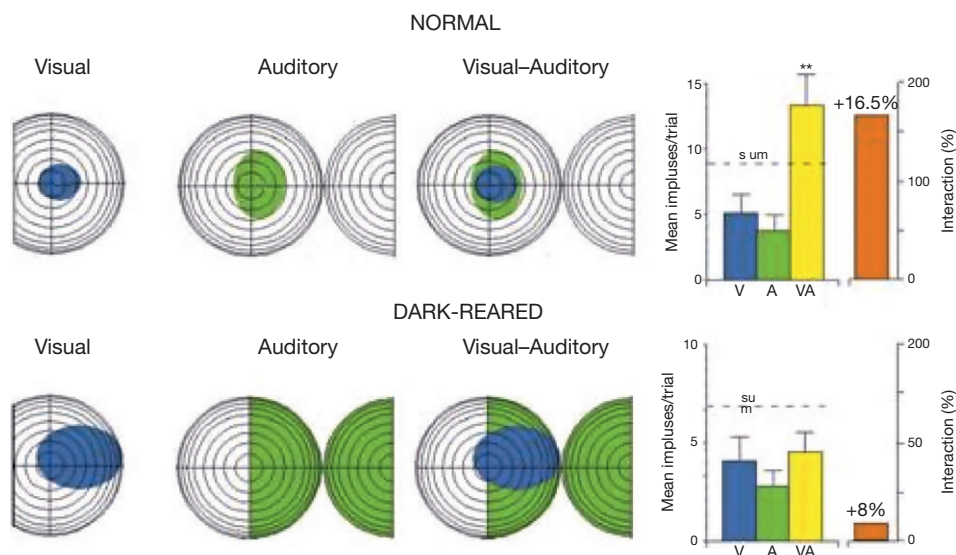
Once again, visually responsive neurons were common, as were visual–nonvisual neurons. Yet, the majority of visual–auditory neurons appeared to have been unaffected by the experience with the disparate visual–auditory cues and had properties characteristic of neonates. Their receptive fields were very large and were unable to integrate these cross-modal cues. But there


FIGURE 3.9 Multisensory neurons have large receptive fields and lack multisensory integration capabilities after dark rearing. The visual and auditory receptive fields and the multisensory responses of a typical normal SC multisensory neuron are shown at the top. The bar graph to the right shows the characteristic enhanced response to the cross-modal pair of stimuli in spatial and temporal register. In contrast, the neuron below, from the SC of a dark-reared animal, has much larger receptive fields and shows no evidence of multisensory response enhancement to the cross-modal stimulus. V, visual stimulus; A, auditory stimulus; VA, cross-modal stimulus. *Adapted from Wallace MT, Perrault TJ, Jr., Hairston WD, Stein BE (2004) Visual experience is necessary for the development of multisensory integration 1.* Journal of Neuroscience *24: 9580–9584.*

FIGURE 3.10 Multisensory enhancement is evident in the human superior colliculus using fMRI. Coronal (left) and sagittal (right) sections reveal high degrees of enhanced SC multisensory activity (red indicates elevated BOLD responses). Elevated activity is in response to visual–auditory as opposed to the best of these stimuli (i.e., visual) individually. *Adapted from Calvert GA, Hansen PC, Iversen SD, Brammer MJ (2001) Detection of audio-visual integration sites in humans by application of electrophysiological criteria to the BOLD effect.* Neuroimage *14: 427–438.*

was a substantial minority of such neurons that did appear to have incorporated the visual–auditory experience. Their receptive fields were somewhat smaller (but still quite large) and were in poor spatial register with one another. Some neurons had visual and auditory receptive fields that were elongated along their horizontal axes and had only small portions overlapping one another. In other cases, there was no receptive field overlap, a configuration that is highly unusual in normal animals, but one that was consistent with the early visual–auditory experience of these animals. Most important in the present context was that they could integrate visual–auditory stimuli. But the cross-modal stimuli had to be spatially disparate in order to fall within their respective receptive fields simultaneously. An example of such a neuron is shown in Figure 3.11.

Collectively, the data reveal that experience is essential for the development of multisensory integration and that the nature of the experience directs the formation of the underlying neural circuit through which this integration is achieved. Although the specifics of that circuit remain to be fully explored (e.g., see Fuentes-Santamaria et al., 2006, 2008a,b, 2009), the cortex is known to play a critical role (e.g., see Alvarado et al., 2009; Jiang et al., 2001; Stein, 2005; Wallace and Stein, 1994) and its ablation early in life precludes the maturation of SC multisensory integration (Jiang et al., 2006, 2007). It appears that early experience is essential for the brain to learn the statistics of cross-modal events, and there is good reason to suspect that this experience exerts its critical impact on the AES-SC (anterior ectosylvian sulcus-superior colliculus) projection.

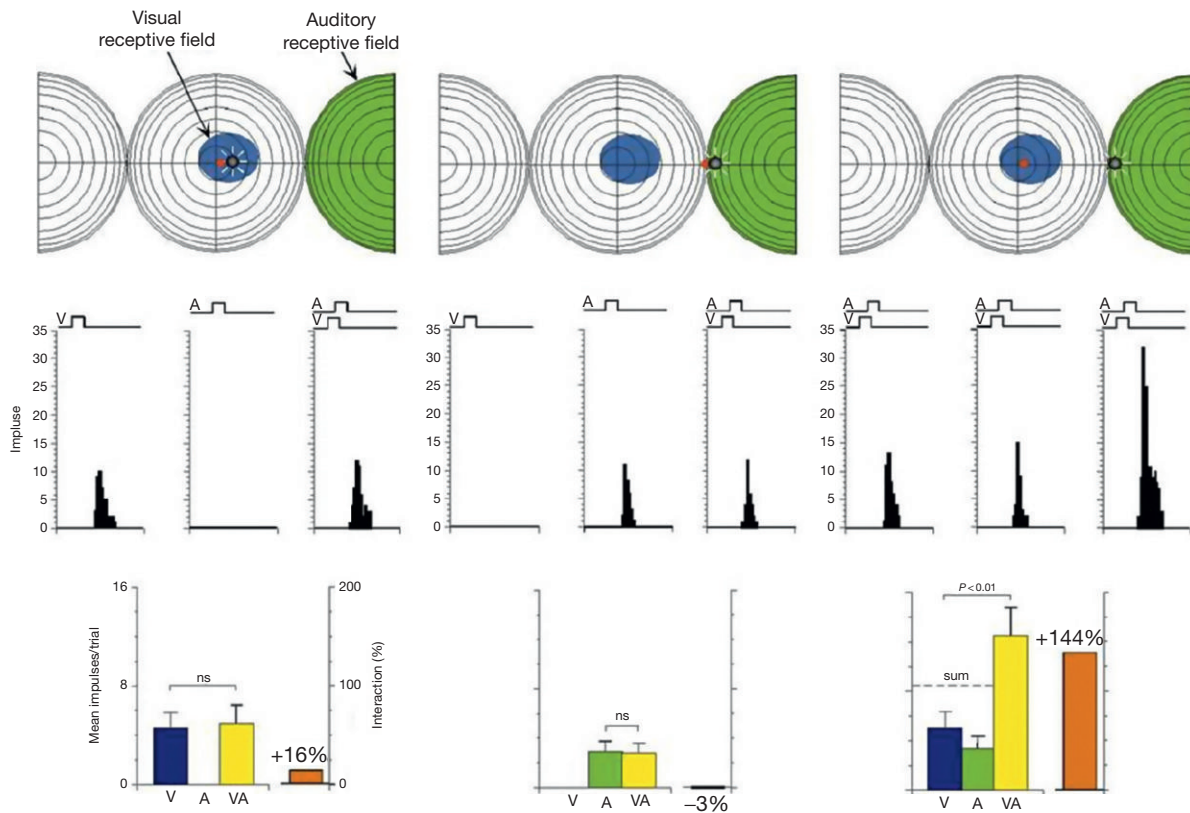
This possibility was explored by Rowland et al. (2005) and Stein et al. (2008), who deactivated AES and adjacent association cortex ipsilaterally during the period in which SC multisensory integration normally develops. This deprived the cortex of cross-modal experience but did not compromise the responsiveness of SC


FIGURE 3.11 Early experience with spatially disparate visual–auditory stimuli results in atypical requirements for their integration. Shown is an SC neuron from an animal reared from birth to 6 months of age with simultaneous but spatially disparate visual–auditory cues. The neuron's visual and auditory receptive fields were atypical by being nonoverlapping. When visual–auditory stimuli were spatiotemporally coincident and within the visual (left) or auditory (center) receptive fields, the multisensory response was no greater than that evoked by the most effective component stimulus. But, when the two stimuli were disparate in space and simultaneously presented within their respective receptive fields, they elicited a significantly enhanced multisensory response. Thus, the neuron integrated spatially disparate visual–auditory stimuli as normal animals integrate spatially concordant visual–auditory stimuli, a seeming 'reversal' of the spatial principle. *Adapted from Wallace MT and Stein BE (2007) Early experience determines how the senses will interact.* Journal of Neurophysiology 97: 921–926.

neurons to these stimuli via many other input channels. Chronic deactivation was accomplished by implanting muscimol-infused pledgets of Elvax (a polymer) over the association cortex. The GABAa agonist was slowly released from the polymer, deactivating underlying neurons. When the polymer was depleted or removed, cortical activity returned rapidly and was once again responsive to environmental stimuli. Behavioral and physiological studies were then conducted when the animals had reached 1 year of age. Although experiments are still ongoing, the preliminary data reveal that the animals appeared normal in their ability to respond to visual stimuli in both visual fields. They also benefited from visual–auditory cues in the ipsilateral hemifield as much as normal animals. However, they were severely compromised in their multisensory responses to crossmodal stimuli in their contralateral hemifield. Crossmodal stimuli in this hemifield were no more effective in facilitating SC-mediated behavior than was the visual stimulus alone. Thus, as expected, the inability of association cortex to monitor the statistics of visual–auditory

events compromised the maturation of the circuit necessary for SC multisensory integration. This was also evident in the inability of multisensory neurons in the ipsilateral SC to integrate visual–auditory information.

That these deficits in multisensory integration were apparent long after the cortex was once again active (a period far longer than that required for its normal acquisition in early life) could be interpreted as reflecting a 'critical' or 'sensitive' period for instantiating this process. If the former were the case, this capacity would never develop. This possibility was examined in some of these same animals that were retained for several years. These animals were then tested as before. Their behavior appeared to be normal, indicating that they acquired the ability to integrate visual–auditory cues later in life. That this acquisition likely involved multisensory SC neurons was indicated by the finding that the multisensory responses of ipsilateral SC neurons, while not completely normal, did exhibit multisensory response enhancement to spatiotemporally coincident visual–auditory stimuli.

3.5.6.1 Motor Development

Much less is known about the development of the motor than the sensory properties of SC neurons. Although there is little doubt that the fundamental properties involved in gaze shifts are not species-specific, most of the available information comes from studies in one preparation: the alert monkey trained to make gaze shifts. For obvious reasons, technical limitations make conducting such studies in neonates quite difficult, especially making any direct correlations with the maturation of sensory properties in the primary sensory developmental model, the cat. Nevertheless, for neonatal SC sensory responses to have any direct impact on behavior, their efferents to the brainstem and/or spinal cord must be in place and capable of carrying tectofugal signals.

These pathways can be seen exiting the SC and contacting targets involved in eye movements within hours of birth in the cat. The target areas include the central gray overlying the oculomotor nucleus, an area into which oculomotor dendrites project, as well as segments of the pontine and medullary reticular formation that connect to the abducens nucleus (Stein et al., 1982). Tectofugal projections also reach the cervical spinal cord. This region is involved in controlling head and limb movement, and these projections are detailed in adults by Huerta and Harting (1982a,b).

Using electrical stimulation of the SC, this motor pathway has already been demonstrated to have functional capabilities in 2-day-old cats (Stein et al., 1980), days before natural auditory stimuli can activate multisensory layer neurons and weeks before visual stimuli are effective. Such electrical stimulation elicits eye, ear, neck, whisker, and limb movements, albeit with a higher threshold and lower reliability than in adults. Furthermore, the motor topography in the SC is already evident. Stimulation of homotopic loci in each SC produces mirror-image eye movements. Nevertheless, many SC stimulation sites proved to be ineffective at this stage of maturation. Presumably, this is due to the immaturity of the SC, as direct stimulation of the oculomotor nucleus evoked reliable eye movements. It is not yet known, however, whether tactile stimuli, which can already activate SC neurons in preterm kittens, can initiate SC-mediated movements in neonates. If, on the other hand, the SC is organized in motor coordinates, as has been suggested by some investigators (e.g., see Sparks, 1986; Sparks and Porter, 1983), it could indicate that early motor function could influence later auditory and visual organization. It would also be consistent with the idea (e.g., see Hein et al., 1979) that eye-movement-generated movement of an image across the retina is necessary for interpreting that visual image and that during development, the former precedes the latter (though spontaneous or vestibular cues could produce the necessary eye movements in neonatal cats; Fish and Windle, 1932; Windle and Fish, 1932).

3.6 SUMMARY

It is important to acknowledge that this chapter has focused on certain anatomical and physiological aspects of SC development for which functional implications are readily apparent. Thus, for example, the formation of topographic representations and the development of multisensory integrative capabilities have obvious implications for producing behavioral output and behavioral correlates in developing animals. In doing so, however, voluminous bodies of literature on, for example, the chronology of synapse formation and the appearance of histochemical markers that parallel SC functional development have been ignored. Likewise, with few exceptions, the focus has been primarily on the SC, but there is also a wealth of comparative data pertaining to the OT from studies of a wide array of nonmammalian species. While the same general principles of development apply, maturational differences dictated by the varied and specialized environmental niches that these animals occupy would require a discussion that is beyond the scope of this chapter. Lastly, it is important to point out what already may be obvious: knowledge of SC development disproportionately favors aspects relevant to its sensory capabilities. This weighting belies the truly integrated sensorimotor function of the SC and highlights a rather substantial gap in the knowledge of how the SC develops to play its adult role. It can only be hoped that future studies will address this imbalance to provide a more complete picture of the SC developmental chronology.

Multisensory Circuits

A.J. King

University of Oxford, Oxford, UK

4.1 INTRODUCTION: MULTISENSORY PERCEPTION AND BEHAVIOR

As they interact with their surroundings, humans and other animal species typically experience multiple stimuli that are registered by different sense organs. These signals may provide complementary information about the same object or event. This is likely to be the case if the stimuli occur at more or less the same time and originate from the same location in space or – in the case of more complex signals, such as the auditory and visual components of speech – if they are semantically related. The capacity of the central nervous system to merge and integrate input from different sensory modalities can have profound effects on perception and behavior. This can be seen as an improvement in an animal's ability to detect or discriminate objects, or determine where they are located, and a reduction in the time required to react to them (reviewed by Alais et al., 2010; Calvert et al., 2004).

In addition to enhancing perceptual judgments, particularly when the stimulus information supplied by one or more sensory modalities is weak or ambiguous, crossmodal interactions can induce various illusions if the different sensory inputs provide conflicting cues. These illusions provide further evidence of how the brain attempts to merge multisensory inputs so that they are perceived as if they originate from the same external event. One of the most striking examples involves the effect of vision on speech perception. Being able to view the speaker's face improves speech comprehension so long as the audiovisual cues are congruent (Ma et al., 2009; Sumby and Pollack, 1954), but watching the speaker articulate a different speech sound from the one that is being presented results in the perception of a third sound that represents a combination of what was seen and heard (the "McGurk effect"; McGurk and MacDonald, 1976). Another well-known example of the influence of vision on auditory perception is provided by the "ventriloquism effect." Although spatially aligned visual cues can improve the accuracy of auditory localization (Shelton and Searle, 1980; Stein et al., 1988), misaligned visual cues can bias or capture the perceived location of a sound source (Howard and Templeton, 1966; Slutsky and Recanzone, 2001).

In addition to their effects on the perceived identity and location of stimuli, interactions between the senses can determine when those stimuli are perceived to occur. For example, if a single light flash is accompanied by multiple auditory beeps, subjects report seeing multiple

flashes (Shams et al., 2000). Similarly, sounds can alter the perceived timing of visual events (Fendrich and Corballis, 2001; Recanzone, 2003). Thus, whereas vision tends to dominate audition in the spatial domain, the reverse is true for temporal tasks (Welch and Warren, 1980). This is because in many species, including humans, the spatial resolution of the visual system is superior to that of the auditory system, whereas temporal sensitivity is much greater for audition (King and Nelken, 2009). However, this relationship between the senses is not fixed because the ventriloquism effect can work in reverse, with audition capturing vision, if visual signals are degraded so that they become harder to localize (Alais and Burr, 2004). It seems, therefore, that the integration of different sensory cues in the brain is statistically optimal, in the sense that each cue is weighted in a task-specific way according to how reliable it is (Alais et al., 2010; Ernst and Banks, 2002).

These examples illustrate how interactions between the senses can have a considerable impact on how the world is perceived. Circuits within the brain must therefore be able to merge multisensory signals that are linked in space and time, as well as more complex cues, such as facial expressions and their associated vocalizations. Although certain brain regions such as the superior colliculus (SC) in the midbrain and the posterior parietal cortex, prefrontal cortex, and superior temporal sulcus have long been associated with specific multisensory functions, it is now clear that convergence of different modality inputs is much more widespread than previously realized. This is particularly the case in the cortex, where even those areas typically associated with modality-specific processing, such as the auditory or visual cortex, are now thought to be part of an interactive network of brain regions that are influenced by multiple sensory systems (reviewed by Alais et al., 2010; Ghazanfar and Schroeder, 2006). Inputs from other modalities to primary and secondary cortical areas may serve to amplify responses to related input from the dominant modality (Schroeder et al., 2008), but there is also evidence that they can alter the sensitivity of cortical neurons in more specific ways (e.g., Bizley and King, 2008; Ghazanfar et al., 2005). Moreover, the finding that early cortical sensory areas are engaged when crossmodal illusions, including the ventriloquism effect (Bonath et al., 2007) and the sound-induced perception of illusory light flashes (Mishra et al., 2007), are experienced indicates that these brain regions as well as the more traditional association areas are likely to contribute to perception in a multisensory world.

In spite of the widespread intermixing of sensory modalities in the cerebral cortex, surprisingly little is known about the development of those circuits. Instead, the SC has, for many years, served as a model system for investigating both the principles of multisensory integration by neurons in the adult brain and the developmental processes that allow different sensory inputs to be combined and coordinated in the first place. This chapter therefore focuses primarily on the developmental mechanisms involved in merging multisensory spatial information in this midbrain structure. Although relatively few attempts have been made to examine the maturation of multisensory processing in the cortex, valuable insights into how the different senses interact at this level during development have been obtained by investigating the crossmodal consequences of early sensory deprivation. These studies, which are based predominantly on humans and other species that have been deprived of their vision or hearing, are considered in the second part of the chapter.

4.2 MULTISENSORY PROCESSING IN THE SC

The mammalian SC receives visual, auditory, and somatosensory afferents from a large number of subcortical and cortical brain areas (e.g., Edwards et al., 1979; King et al., 1998a; Wallace et al., 1993). As far as we know, these inputs are all unisensory and converge, often on the same neurons, in the deeper layers of the SC. In contrast, the superficial layers contain only visually responsive neurons. Nevertheless, the sensory representations found in both the superficial and deeper layers are arranged topographically with respect to their receptive field locations (Cynader and Berman, 1972; King and Hutchings, 1987; King and Palmer, 1983; Middlebrooks and Knudsen, 1984; Stein et al., 1976; Wallace and Stein, 1996). Moreover, these maps lie in spatial register with one another so that different modality signals arising from a particular direction in space, and therefore, potentially from the same source, are represented in a corresponding region of the SC. For those deep-layer neurons that receive converging visual, auditory, and somatosensory afferents, this means that their unisensory receptive fields overlap and covary with the anatomical location of the neurons within the SC.

One of the most important and well-studied properties of SC neurons is that the number of spikes evoked by a combination of two or more stimulus modalities is often higher than that of the response to each stimulus presented by itself and may even exceed the sum of those responses. Multisensory enhancement is typically most pronounced when the individual stimuli are weakly effective in driving the neurons (Meredith and Stein, 1986) and is observed when those stimuli are presented in close temporal and spatial proximity (King and Palmer, 1985; Meredith and Stein, 1996; Meredith et al., 1987). In contrast, pairing multisensory signals that are widely separated in time or space does not enhance,

and may even depress, the response to unisensory stimulation. These interactions between the different sensory inputs reaching the SC should therefore serve to amplify the neuronal responses to a multisensory target, such as an object that can be seen and heard.

Neurons in the deeper layers also discharge prior to eye and head movements, and while the SC is implicated in different motor behaviors, its principal function is to shift an animal's gaze toward sensory stimuli located on the contralateral side of the body (reviewed by Gandhi and Katnani, 2011). Superimposing the different sensory representations in the SC therefore allows each of the spatial cues associated with a multisensory target to trigger, via a common motor output map, a gaze shift in that direction. The principles of multisensory integration exhibited by SC neurons suggest that spatiotemporally coincident stimuli will, by evoking stronger responses in SC neurons, promote more accurate orienting behavior, whereas pairing unisensory stimuli from different locations or at different times should have the opposite effect. Similarly, integration of inputs from different sensory modalities would be expected to have the greatest effect on orienting behavior when the individual cues are weak. Studies in cats (Stein et al., 1988) and humans (Corneil et al., 2002) have indeed confirmed that this is the case. Moreover, in cats, deactivation of descending projections from two association areas in the cortex, the anterior ectosylvian sulcus (AES) and the rostrolateral suprasylvian sulcus (rLS), eliminates both the multisensory integrative processes displayed by SC neurons (Jiang et al., 2001) and the behavioral benefits of synthesizing inputs from different sensory modalities (Jiang et al., 2002).

Because multisensory enhancement of the responses of SC neurons occurs only when each stimulus falls within its excitatory receptive field, the spatial registration of the sensory maps in the SC would appear to be essential if these interactions are to signal the different modality cues associated with a common source. However, maintaining map registration is problematic because spatial information is specified by each sensory modality using a different frame of reference. The visual map is coded in retinal coordinates, and so the receptive fields of SC neurons will shift relative to the head as the eyes move and therefore potentially become misaligned with the auditory receptive fields, which are centered on the head and ears, and the body-centered somatosensory receptive fields. However, electrophysiological recordings from SC neurons in awake animals have shown that somatosensory (Groh and Sparks, 1996) and auditory (Hartline et al., 1995; Jay and Sparks, 1984; Populin et al., 2004) responses are modified by changes in eye position, suggesting that these signals are partially transformed into a common eye-centered reference frame that matches the coordinates of the visual map.

Combining appropriate inputs from different sensory modalities during development is also challenging, particularly since the spatial relationship between the sense organs can change as the body grows. The following section examines the role of sensory experience in aligning the different modality maps and in the maturation of multisensory integration in the SC.

4.3 DEVELOPMENT OF MULTISENSORY RESPONSES IN THE SC

Each of the sensory systems appears to begin functioning at a different stage of development, with somatosensory sensitivity emerging first and visual last (Gottlieb, 1971) (see Chapter 3). This sequence has also been observed in the SC, where recordings from newborn kittens have shown that the earliest sensory responsive neurons are activated only by tactile stimuli, followed a few days later by the first acoustically responsive neurons and subsequently by responses to visual stimuli (Figure 4.1; Stein et al., 1973). The maturation of multisensory neurons follows the same order, with neurons sensitive to both tactile and auditory stimuli appearing during the second postnatal week, almost 2 weeks before the first visually responsive multisensory neurons (Figure 4.1; Wallace and Stein, 1997). However, in more precocial species, including humans and other primates, most sensory systems become functional before birth, and the SC of newborn monkeys has been shown to contain many multisensory neurons (Wallace and Stein, 2001).

Despite these differences in the postnatal age at which multisensory neurons develop, a common feature of all the species, both precocial and altricial, that have been studied is that the sensory response properties of deep SC neurons initially differ in a number of ways from those seen in older animals (Campbell et al., 2008; Stein et al., 1973; Wallace and Stein, 1997, 2001; Withington-Wray et al., 1990a). In common with other brain areas, sensory responses recorded from SC neurons in very young animals typically have longer latencies, are more sluggish, and show greater habituation to repeated stimulation than is the case in later life. They also lack at least some of the stimulus selectivity that is characteristic of the adult. The details of these age-dependent differences vary to some extent between species and stimulus modalities, but it has consistently been observed that the spatial receptive fields of SC neurons in infant animals are larger than those found in adults and that the earliest multisensory neurons lack the capacity to integrate different modality cues in ways that either enhance or depress their responses.

The key events in the maturation of the sensory representations in the SC therefore comprise a gradual contraction of receptive fields and the appearance of
FIGURE 4.1 Postnatal development of multisensory neurons in the deeper layers of the cat superior colliculus (SC). The percentage of sensory neurons responding to stimuli in two or more modalities is plotted as a function of age. The arrows indicate the ages at which the first unisensory responses have been recorded in the deep SC layers of this species. The pie charts show how the incidence of multisensory neurons increases as development proceeds. *Adapted from Wallace MT and Stein BE (1997) Development of multisensory neurons and multisensory integration in cat superior colliculus.* Journal of Neuroscience *17: 2429–2444, with permission.*

multisensory integration. Indeed, Wallace and Stein (1997) observed that there is a clear correlation between these developmental changes, with the size of the deep-layer receptive fields in cats being a good predictor of whether the neurons will display the capacity to synthesize multisensory inputs. Although this suggests that these events may be causally related, perhaps involving maturation of the same or closely related cellular mechanisms, other aspects of sensory processing also need to be considered.

Foremost among the other factors is the sometimes overlooked fact that the development of sensory representations in the brain depends on the maturation of the relevant sense organs as well as the neural circuits involved (See Rubenstein and Rakic, 2013. Readers are also encouraged to read Chapters 2, 3, 14 within this book). Determining the relative contributions of these factors is generally not straightforward, but studies of the developing auditory representation have provided unique insights into this. Because sound frequency is mapped along the length of the cochlea in the inner ear, sound source location has to be derived by comparing the amplitude and timing of sounds reaching each ear and by sensing the spectral-shape cues produced by the direction-dependent way in which the external ears filter the incoming sound (King et al., 2001). Individual variations in the size and shape of the head and external ears are matched by differences in the binaural and monaural localization cue values corresponding to each direction in space. Consequently, the localization cues available in infancy, when the auditory receptive fields are very large and lack topographic order, are different from those provided by adult ears. But, if virtual acoustic space stimuli are used to allow infant ferrets to hear through adult ears, the auditory receptive fields immediately shrink and are

no longer any different in size from those found in adult animals (Campbell et al., 2008).

This result would seem to indicate that growth-related changes in the physical dimensions of the head and external ears can account for the contraction of auditory spatial receptive fields that occurs during postnatal development. However, whether a similar process contributes to the maturation of spatial tuning in other modalities is less clear. In the visual system, for example, the maturation of receptive fields seems to be determined more by the specificity of the afferent connections than by the resolution of the optics or the photoreceptors (Jacobs and Blakemore, 1988; Kiorpes and Movshon, 1990; Tavazoie and Reid, 2000) (see Chapter 14). Moreover, even though providing infant ferrets with adult ears removes age-dependent differences in spatial tuning, no improvement is seen in the topography of the auditory representation in the SC, which gradually emerges over the course of several weeks following hearing onset (Figure 4.2; Campbell et al., 2008). Thus, central mechanisms must also be involved in auditory map development (see Chapter 2).

As noted in the previous section, descending signals from association areas of the cerebral cortex must be available if multisensory integration is to be observed in adult cats. Those inputs also appear to be critically involved in the maturation of the multisensory integrative properties of SC neurons. Evidence for this comes from the observation that the development in these neurons of a capacity to integrate their different sensory inputs coincides with the functional maturation of inputs from the AES (Wallace and Stein, 2002). Moreover, in cats in which the AES and rLS were lesioned in infancy, no difference is seen either physiologically (Jiang et al., 2006) or behaviorally (Jiang et al., 2007) between the
FIGURE 4.2 Maturation of auditory spatial topography in the ferret SC. (a–e) Each panel plots the auditory best azimuth of deep-layer SC neurons as a function of the visual best azimuth of neurons recorded in the overlying superficial layers. The data were obtained at the postnatal ages indicated at the top of each panel using free-field stimuli. Because adultlike visual topography is present in the superficial SC layers throughout this developmental period, the topographic order of the auditory map is reflected in the degree to which it is in register with the visual map. Auditory responses recorded at near-threshold sound levels (~10 dB > unit threshold) are shown in red; suprathreshold levels (~25 dB > unit threshold), in blue. A linear regression was fitted to the data from each sound level at each age group (red and blue lines; the black line is the 45° diagonal indicating perfect alignment of the visual and auditory data). The inset panel in (e) plots the correlation coefficient (R) of each regression slope as a function of age. At both sound levels, there is a steady increase in the R value during development, indicating an improvement in topographic order in the auditory representation. *Adapted from Campbell RA, King AJ, Nodal FR, Schnupp JWH, Carlile S, and Doubell TP (2008) Virtual adult ears reveal the roles of acoustical factors and experience in auditory space map development.* Journal of Neuroscience 28: 11557–11570, with permission.

responses to spatiotemporally matched visual and auditory stimuli and those made to the most effective unisensory stimuli. What signals the cortex provides that are apparently so critical for multisensory integration in the midbrain have yet to be identified.

Collectively, these studies suggest that infant animals should not be able to benefit from combining inputs across the different senses. Unfortunately, little is known about the multisensory perceptual abilities in developing animals because of the difficulty of conducting such experiments. In contrast, a great deal of research has been carried out on human infants. Although these studies have demonstrated that certain multisensory processing skills are present at birth, the ability to match or integrate particular combinations of sensory cues continues to mature over the following months and years. Of particular relevance to the maturation of multisensory spatial processing is the finding that infants only start to integrate auditory and visual localization cues toward the end of the first year of life (Neil et al., 2006), which is clearly consistent with the gradual appearance of the multisensory integrative properties of SC neurons. But while many studies point to a progressive expansion in multisensory abilities, such as the ability to perceive

more complex crossmodal relationships based on gender or affect, recent work suggests that a developmental narrowing also takes place, leading to infants losing their initial ability to match the visual and auditory attributes of nonnative social signals (reviewed by Lewkowicz and Ghazanfar, 2009). What appears to be critical for these changes in multisensory perception is exposure to appropriate sensory inputs during early life. How experience influences the maturation of multisensory circuits in the brain is considered in the following sections.

4.3.1 Role of Experience in Aligning the Sensory Maps in the SC

The importance of experience in merging the spatial cues provided by different sense systems has been demonstrated in a number of studies in which sensory inputs have been altered in particular ways. For example, if barn owls (Knudsen, 1985; Mogdans and Knudsen, 1992) or ferrets (King et al., 1988, 2000) are raised with one ear blocked, the auditory receptive fields in the SC (or its homolog in birds, the optic tectum) develop relatively normally and follow the topography of the visual

representation, even though the sound localization cues available are highly abnormal. A compensatory change in the developing auditory representation can also be induced by manipulating the visual inputs. This has been achieved in barn owls by mounting prisms in front of the animal's eyes, which, because these animals have very limited eye movements, results in a corresponding displacement of the visual map in the optic tectum. Prism rearing produces a corresponding shift in both the tectal map of auditory space (Figure 4.3(a) and 4.3(b); Knudsen and Brainard, 1991) and in the accuracy of sound-evoked head-orienting responses (Knudsen and Knudsen, 1990). A shift in the auditory map in the SC has also been observed in ferrets in which the orbital position of the contralateral eye was changed by removing the medial rectus muscle in infancy (King et al., 1988). As discussed,

auditory responses in the mammalian SC are modulated whenever an animal alters its direction of gaze. However, the shift in auditory spatial tuning observed in this study appeared to be caused by visual experience rather than the change in eye position itself (King and Carlile, 1995).

In barn owls, prism-induced plasticity of auditory spatial tuning has also been described in another midbrain nucleus, the external nucleus of the inferior colliculus (ICX), where a map of auditory space is first generated and then relayed to the optic tectum (Brainard and Knudsen, 1993; Figure 4.3(c) and 4.3(d)). The shift in the auditory map in the ICX is brought about by a rewiring of connections from the central nucleus of the inferior colliculus (ICC; DeBello et al., 2001) and appears to be triggered by visual signals that are transmitted from the upper layers of the optic tectum to the ICX (Hyde and

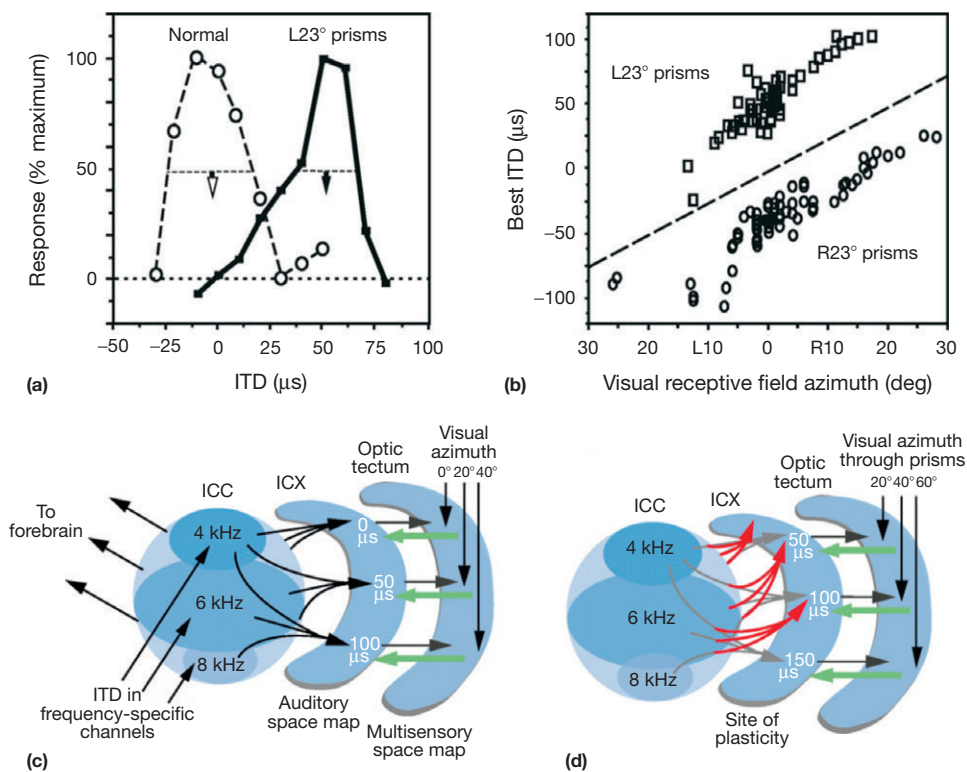

FIGURE 4.3   Prism adaptation in the barn owl. (a) The effects of prism experience on the spatial tuning of neurons in the optic tectum. These neurons derive their azimuth sensitivity through their tuning to interaural time differences (ITDs). Before prism experience (Normal), the neuron shown is tuned to about 0° μs ITD, matching its visual receptive field, which is centered at 0° azimuth. After a young owl has experienced prisms that displace the visual field to the left by 23° (L23°) for more than 8 weeks, the ITD tuning at this site has shifted toward the values produced by sounds at the locations of the neuron's optically displaced visual receptive field (in this case, 50 μs right-ear leading). Down arrows indicate the best ITD in each case. Negative ITD values indicate left-ear leading. (b) Best ITDs plotted as a function of visual receptive field azimuth for neurons recorded in the optic tecta of owls raised with either L23° prisms (boxes) or R23° prisms (circles). The expected relationship found in normal owls is indicated by the dashed line. (c) The midbrain pathway in a normal barn owl. ITDs are mapped in frequency-specific channels in the central nucleus of the inferior colliculus (ICC). Information across frequencies is then integrated by neurons in the external nucleus of the inferior colliculus (ICX) to create space-specific auditory neurons that are organized to form a map of contralateral space. The map is conveyed to the optic tectum, where it merges with a visual map of space from the retina and forebrain. Topographic projections back from the optic tectum to the ICX (green arrows) are thought to carry visual spatial information to instruct auditory plasticity in the ICX. (d) Following a period of several weeks of prism experience during early life, a systematic change occurs in the ICC-ICX projection (red arrows), which shifts the auditory maps in both the ICX and the OT, so that they realign with the shifted visual map. *Adapted from Keuroghlian AS and Knudsen EI (2007) Adaptive auditory plasticity in developing and adult animals.* Progress in Neurobiology *82: 109–121, with permission.*

Knudsen, 2002). A similar circuit is likely to exist in mammals, where the exclusively visual superficial layers of the SC project topographically both to the deeper multisensory layers and to the nucleus of the brachium of the inferior colliculus (IC; Doubell et al., 2000, 2003), which is the principal source of auditory input to the SC (Figure 4.4; King et al., 1998a). The finding that partial lesions of the superficial SC layers in neonatal ferrets disrupt the developing topography of the underlying auditory representation suggests that they might provide a template for guiding the development and plasticity of the auditory responses (King et al., 1998b).

Therefore, vision plays an instructive role in merging multisensory spatial information during development through its influence on the maturation of the auditory space map. This resembles the visual dominance seen in studies of stimulus localization by adult humans described in the first section of this chapter and is consistent with the fact that vision generally provides more precise and reliable spatial information. Moreover, as previously discussed, a map of auditory space has to be computed in the brain by tuning neurons to spatial cues whose values depend on the physical dimensions of the head and external ears, and those dimensions often change considerably during development. The retinotopic visual map most likely guides the emergence of auditory spatial selectivity by helping to overcome the uncertainty and variability in the relationship between auditory localization cues and directions in space and thus promotes the alignment of sensory maps that are constructed in different ways (Gutfreund and King, 2012).

Early loss of vision therefore results in a partial breakdown in visual–auditory map alignment (King and Carlile, 1993; Knudsen et al., 1991; Wallace et al., 2004). Some studies have also reported that auditory neurons in the SC of visually deprived animals can have abnormally large receptive fields (Knudsen et al., 1991; Wallace et al., 2004; Withington, 1992; Withington-Wray et al., 1990b) or are ambiguously tuned to multiple sound directions (King and Carlile, 1993). Although confirming that visual inputs play a pivotal role in guiding the formation of a normal map of auditory space in the brain, accurate sound localization can develop in the absence of vision. Indeed, as discussed in more detail later

FIGURE 4.4 Circuits underlying auditory map formation in the mammalian superior colliculus (SC). (a) The left panel shows in a camera lucida drawing of a coronal section through the ferret midbrain the distribution of retrograde and anterograde labeling following a single injection of biotinylated dextran amine conjugated with fluorescein in the nucleus of the brachium of the inferior colliculus (nBIC). Fibers and terminals are represented by lines and labeled somata by circles. The right panel shows a lateral view of the ferret midbrain, with the arrows illustrating the topographic organization of the projection from the nBIC to the deeper SC layers. (b) Series of sections from a ferret in which a single injection of biocytin had been made in the superficial visual layers of the SC. The light gray shading depicts areas containing boutons, and black stippling indicates axons. (c) Summary of visual and auditory inputs to the deeper layers of the SC. This part of the SC receives converging inputs from several auditory brainstem and cortical areas, including a spatially ordered projection from the nBIC. Neurons in the superficial layers of the SC project topographically both to the underlying deeper layers and also to the nBIC (not shown). The map of visual space in the superficial layers appears to provide an activity template that guides the development and plasticity of the auditory representation. Other abbreviations: IC, inferior colliculus; LGN, lateral geniculate nucleus; MGB, medial geniculate body; PAG, periaqueductal gray. Anatomical data from Doubell et al. (2003) and Nodal et al. (2005).

in this chapter, visually impaired or blind individuals can localize sound just as well as or even better than subjects with normal sight (Collignon et al., 2009; King and Parsons, 1999; Lessard et al., 1998; Rauschecker and Kniepert, 1994; Röder et al., 1999). Such improvements in perceptual abilities could, of course, be based on changes in other regions of the brain, particularly in the cortex. But, where multisensory spatial representations are brought together, as in the SC, concurrently available visual inputs are used to constrain the developing auditory map so that it matches the visual field representation.

Although these studies emphasize the importance of vision in coordinating multisensory inputs in the developing brain, it is not always vision that dominates intersensory spatial relations. If the somatosensory receptive fields of SC neurons are shifted by modifying the position of the vibrissae in newborn mice, a compensatory reorganization of the visual map takes place (Benedetti and Ferro, 1995). Indeed, while there is strong evidence that plastic auditory inputs are guided by a stable visual template, it has also been proposed that each of the senses is weighted during development according to the reliability of the spatial information they provide (Witten et al., 2008) in much the same way that visual and auditory spatial signals are now thought to interact when humans make localization judgments (Alais et al., 2010). In this scenario, auditory receptive fields are plastic simply because they are larger than the visual receptive fields and therefore convey less precise spatial information.

4.3.2 Role of Experience in the Development of Multisensory Integration in the SC

In addition to its importance in aligning the different maps in the SC, appropriate sensory experience is critical for the emergence of the multisensory integrative abilities of SC neurons. Thus, multisensory neurons in the SC of dark-reared cats have abnormally large spatial receptive fields and lack the capacity to integrate different modality cues (Wallace et al., 2004). In other words, combining spatiotemporally congruent visual and auditory stimuli did not produce the enhancement of unisensory responses that is characteristic of animals that have been raised normally.

However, while experience with objects that can be both seen and heard promotes intersensory map alignment, this is not a prerequisite for multisensory integration. Wallace and Stein (2007) showed this by raising cats in the dark and periodically presenting them with simultaneous light and sound at a fixed spatial disparity. Although most of the SC neurons recorded when the animals were fully grown again had receptive fields that had failed to contract and lacked multisensory

integration, a few had relatively small visual and auditory receptive fields whose relative locations matched the spatial configuration of the bisensory stimuli to which they had been exposed (Wallace and Stein, 2007). As in normally raised control cats, these neurons did exhibit multisensory enhancement when visual and auditory stimuli occurred together within their respective receptive fields, but this now meant presenting those stimuli from different locations in space. Provision of abnormal multisensory experience can therefore lead to neurons developing the capacity to integrate visual and auditory cues from seemingly unrelated sources. This illustrates the importance of aligning the different sensory maps in the SC, as it is presumably only then that behaviorally relevant crossmodal interactions can take place.

Behavioral observations in visually deprived humans also highlight the importance of experience in acquiring the ability to synthesize inputs from different modalities. Like the dark-reared cats, humans lacking early patterned visual experience as a result of congenital cataracts show reduced auditory–visual interactions, whereas their performance in unisensory tasks was normal (Putzar et al., 2007).

4.4 DEVELOPMENT OF MULTISENSORY CIRCUITS IN THE CORTEX

Early anatomical studies reported the presence in newborn animals of transient inputs from other sensory systems to areas of the cortex that are traditionally viewed as modality specific (Dehay et al., 1988; Innocenti and Clarke, 1984). However, since multisensory convergence is observed to a greater or lesser extent throughout the fully mature cerebral cortex, it is unlikely that such connections disappear altogether. Little is known about the maturation of the multisensory response properties of cortical neurons. However, Wallace et al. (2006) recorded in the AES of cats at different postnatal ages and found that responsiveness to somatosensory, auditory, and visual stimulation emerges in that order and that the capacity of the multisensory neurons to integrate crossmodal cues takes several months to mature. This sequence therefore parallels the ontogeny of sensory function in the SC.

By raising barn owls with prismatic spectacles, Miller and Knudsen (1999) found that, as in the space-mapped regions of the midbrain, visual experience shapes the developing auditory spatial receptive fields of neurons in the forebrain. However, the great majority of evidence for multisensory interactions in the cortex during development has come from studies in mammals in which experience of one modality has been restricted or eliminated altogether. In the cat AES, for example, early visual deprivation has been reported to cause an expansion

in the territory of auditory neurons (Rauschecker and Korte, 1993) and a sharpening of their spatial sensitivity (Korte and Rauschecker, 1993), as well as a change in multisensory integrative properties, which become dominated by response depression rather than enhancement (Carriere et al., 2007). These results therefore differ from those described previously for the SC, in which visual deprivation tends to either broaden or leave auditory spatial tuning unchanged and prevents the appearance of multisensory integration. Nevertheless, they show that, as in the midbrain, sensory experience plays a critical role in shaping the functional organization of cortical multisensory areas.

Many other studies have also examined the crossmodal consequences of temporary or permanent loss of one of the senses. The enhanced perceptual abilities that are often reported in those studies could result from altered processing within the neural pathways of the intact modalities (Elbert et al., 2002; Korte and Rauschecker, 1993), perhaps reflecting the greater attention paid to those modalities in the absence of the sense that has been lost. But the functional identity of an area of sensory cortex can also change if its primary input is removed, to be replaced by inputs from other modalities (Figure 4.5). Remarkably, this can happen even if existing multisensory inputs are temporarily unmasked in adulthood. Thus, wearing a blindfold for a few days leads to primary visual cortex becoming recruited for tactile processing (Merabet et al., 2008). However, the most dramatic examples of sensory substitution have been reported in humans who are congenitally deaf or blind. For example, the visual cortex appears to contribute to the superior auditory localization abilities of blind individuals (Collignon et al., 2007; Gougoux et al., 2005; Renier et al., 2010). This presumably results either from the formation of novel functional connections from auditory to visual brain areas or from the unmasking of connections that are now known to exist normally.

The capacity of a cortical area to take on the functions of a different sensory modality has been illustrated in a series of studies in animals in which visual inputs were surgically redirected into the auditory thalamus and cortex. Neonatal lesions of the midbrain (SC and IC) partially remove normal retinal targets and the main source of auditory input to the medial geniculate body. As a result, retinal afferents form connections that allow visual information to be conveyed to the auditory cortex (Kalil and Schneider, 1975; Sur et al., 1988). In 'rewired' ferrets, neurons in the auditory cortex have been shown to display receptive field properties, including orientation and direction selectivity, characteristic of the visual cortex (Roe et al., 1992), and even support limited visually guided behavior (von Melchner et al., 2000). Similar results have been obtained in hamsters in which visual afferents were redirected into either the auditory (Frost et al., 2000) or somatosensory cortex (Métin and Frost, 1989).

These studies show that the modality specificity of a given area of the cortex is determined by its inputs and can change in behaviorally relevant ways if normal inputs are replaced by those from another sense. Nevertheless, the functional specificity of different cortical areas seems to be retained following crossmodal reorganization. In early blind humans, part of the occipital cortex normally involved in visual spatial processing is more strongly activated when subjects perform auditory or tactile localization rather than identification tasks (Renier et al., 2010). Similarly, visual localization deficits are produced in deaf cats by deactivating auditory cortical areas that are known to be involved in sound localization in animals with normal hearing (Lomber et al., 2010; Meredith et al., 2011). Such crossmodal plasticity could potentially arise from an expansion or unmasking of connections that selectively link cortical areas sharing the same or related functions in different modalities. Alternatively, this reallocation of resources might be mediated via top–down pathways to different sensory areas involved in stimulus localization.

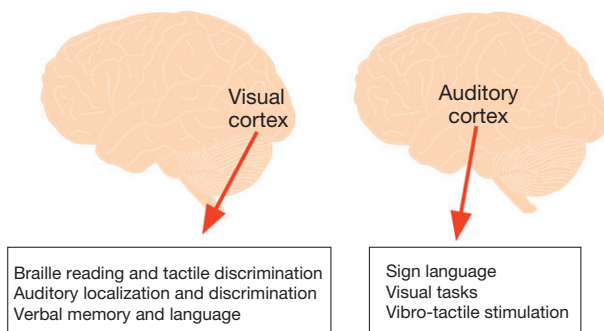

FIGURE 4.5 Crossmodal plasticity in the cortex following sensory deprivation. (a) Recruitment of visual cortex in the blind for tactile processing (e.g., Braille reading, sound localization, and verbal memory). (b) Recruitment of auditory and language-related areas in deaf people for viewing sign language, peripheral visual processing, and vibrotactile stimulation. *Reproduced from Merabet LB and Pascual-Leone A (2010) Neural reorganization following sensory loss: The opportunity of change.* Nature Reviews Neuroscience *11: 44–52.*

4.5 SENSITIVE PERIODS IN THE MATURATION OF MULTISENSORY PROCESSING

The finding that human multisensory perceptual abilities narrow during infancy (Lewkowicz and Ghazanfar, 2009) suggests that a sensitive period of development may exist during which experience is particularly effective in shaping the functional architecture of the brain. Several studies have indicated that the guiding influence of vision on the maturation of auditory space maps in the midbrain is

developmentally regulated (King et al., 1998b; Knudsen and Brainard, 1991), and similar findings have been obtained from behavioral studies (Knudsen and Knudsen, 1990). However, more recent experiments have shown that adaptive crossmodal plasticity is possible throughout life. To some extent, plasticity in later life is constrained by changes in neural circuitry that take place during the sensitive period. For example, visual experience can adjust auditory spatial tuning in the midbrain of adult barn owls if the animals were previously exposed to the same prismatic displacement, but not if adult birds are fitted with prisms that displace the visual field in the opposite direction (Knudsen, 1998). This experience-specific plasticity in adulthood can be accounted for by changes in midbrain connectivity induced by prism rearing (Figure 4.3), which leave a 'trace' that can be reactivated by appropriate experience in later life. A similar explanation likely applies to other forms of sensory plasticity that were previously thought to be restricted to a sensitive period of development (Hofer et al., 2009).

The question of whether sensitive periods exist can also be addressed in deprivation studies either by determining whether the age at which the sensory loss occurs influences the nature and extent of the changes that take place in the brain or by examining the potential for recovery if the missing function is restored. That a sensitive period is present for the acquisition of multisensory integration is suggested by studies of patients who have had congenital cataracts removed. Even after several years of multisensory experience, they lack the ability to synthesize different modality cues normally (Putzar et al., 2007). Integration of auditory and visual cues is possible, however, if sensory function is restored early enough. Congenitally deaf children fitted with cochlear implants within the first 2 ½ years of life exhibit the McGurk effect, whereas, after this age, auditory and visual speech cues can no longer be fused (Schorr et al., 2005). In contrast, recent animal studies suggest that sensitivity to crossmodal experience might be maintained in later life. Following repeated presentation of spatiotemporally congruent visual and auditory cues to anesthetized adult cats that had been reared in the dark, SC neurons start to acquire their characteristic multisensory integrative properties (Yu et al., 2010).

Most of the evidence for compensatory crossmodal changes in neural processing and behavior following sensory deprivation has come from subjects who have been blind or deaf from birth or early in life. But while functional and anatomical differences do exist between early- and late-onset blind individuals (e.g., Cohen et al., 1999; Jiang et al., 2009; Stevens and Weaver, 2009), enhanced nonvisual abilities have also been reported following late-onset blindness (Fieger et al., 2006; King and Parsons, 1999; Occelli et al., 2008; Voss et al., 2004).

Together, these studies show that the mature brain retains some capacity for crossmodal plasticity, although

to a lesser extent than that seen during development. As with other aspects of sensory processing (e.g., Kacelnik et al., 2006), behavioral training is likely to be an important factor in determining the extent to which the mature brain can adapt to changes in input. Similarly, adult barn owls exhibit much greater visually induced auditory plasticity if the stimuli acquire behavioral significance for the animals (Bergan et al., 2005). This suggests that top–down regulation of sensory responses is part of the circuitry involved in integrating multisensory information in the brain.

4.6 CONCLUDING REMARKS

The studies reviewed in this article show that sensory experience plays a vital role during development in establishing and maintaining the neural circuits responsible for synthesizing information across different sensory modalities. Much of this evidence has come from research in animals, which provide an opportunity both to alter sensory inputs in a controlled and reproducible manner in ways that are not possible in humans and to investigate how different senses interact at the level of individual neurons. Nevertheless, many of the animal studies have examined the crossmodal consequences of depriving inputs in one sensory modality and therefore offer valuable insights into the changes that likely take place in the human brain following blindness or deafness.

The emphasis in most of the animal work has been on the development of multisensory spatial interactions, particularly at the level of the SC, where vision has been shown to play a pivotal role in aligning the different modality maps and in the maturation of multisensory integration. The SC has provided a model system for research in this area, leading to the formulation of a number of general principles that also apply to other aspects of multisensory processing. Nevertheless, most multisensory functions, at least in primates, rely on cortical activity, and it will clearly be important to extend the range of developmental studies to include other processes, such as the integration of faces and voices during infancy.

The considerable crossmodal plasticity that takes place during development, and to some extent in later life too, has clear adaptive value. This enables information from different sensory modalities to be merged in behaviorally relevant ways and allows for crossmodal compensatory changes to take place following sensory deprivation. However, these changes can potentially be maladaptive in that they may limit the capacity of the brain to utilize sensory inputs that are restored as a result, for example, of cataract surgery or cochlear implantation. The growing evidence for adult crossmodal

plasticity nevertheless holds out the promise of developing effective rehabilitation strategies in such cases for patients who are recovering from early sensory loss.

5.1 OVERVIEW OF THE MICROCIRCUIT IN THE CEREBELLAR CORTEX

5.1.1 Cell Types and Afferent Fibers

The cerebellum consists of the cortex and the centrally located deep cerebellar nuclei (DCN). The cerebellar cortex exhibits a characteristic trilaminar structure composed of the molecular layer, Purkinje cell (PC) layer, and granular layer. In its mediolateral extent, the cerebellar cortex is divided into three longitudinal regions: vermis (medial cerebellum), paravermis (intermediate cerebellum or pars intermedia), and hemisphere (lateral cerebellum). Each of these regions is folded into lobules. The DCN also have three divisions: the medial (fastigial), interpositus (globose and emboliform), and lateral (dentate) nuclei, each of which is connected topographically with the vermis, paravermis, and hemisphere, respectively. Cerebellar neurons with distinct cytological and neurochemical properties reside in specific layers and sites of the cerebellum. They are connected with each other and also with specific brain regions outside the cerebellum (Figure 5.1).

PCs are the sole output neurons of the cerebellar cortex. The somata of PCs are aligned in the PC layer. PCs extend well-arborized dendrites in the molecular layer and project γ-aminobutyric acid (GABA)ergic axons to DCN and vestibular nuclei. There are two distinct excitatory afferents to the cerebellum, that is, climbing fibers (CFs) and mossy fibers (MFs; Palay and Chan-Palay, 1974). In adulthood, each PC is innervated by a single
FIGURE 5.1　Neuronal component and synaptic wiring diagram of the cerebellum. Neurons painted with warm colors (yellow, orange, and pink) represent excitatory neurons, while those with cold colors (blue, light blue, and green) indicate inhibitory neurons. DCN, deep cerebellar nuclei; GL, granular layer; ION, inferior olivary nucleus; ML, molecular layer; PCL, Purkinje cell layer; UB, unipolar brush cell. PN, pontine nuclei; RF, reticular formation; RN, red nucleus; SC, spinal cord; VL/VA, ventral lateral/anterior thalamic nucleus.

CF originating from the inferior olive of the contralateral medulla oblongata (Eccles et al., 1966). Each CF forms hundreds of synapses by twisting around the proximal dendritic compartment. Therefore, activation of CFs causes strong depolarization of PC dendrites, triggers regenerative 'Ca^{2+} spikes' due to activation of voltage-gated Ca^{2+} channels (VDCCs) in PC dendrites (Miyakawa et al., 1992), and generates characteristic 'complex spikes' in the PC soma (Eccles et al., 1966) that are composed of a fast somatic Na$^+$ action potential followed by slow dendritic Ca^{2+} spikes. In contrast, MFs originating from various extracerebellar regions, such as the spinal cord, pontine nuclei, and reticular formation, convey motor and sensory information to the distal dendritic compartment of PCs through parallel fibers (PFs), the axons of granule cells (GCs; Ito, 1984). Approximately, 10^5–10^6 PFs innervate a given PC, while each PF forms only one or two synapses onto individual PCs (Napper and Harvey, 1988). Thus, excitation of a single PF only weakly depolarizes PC dendrites, and about 50 GCs should fire synchronously to generate a single Na$^+$ action potential (called 'simple spike') in the PC soma

(Barbour, 1993). PFs also excite two types of GABAergic interneurons in the molecular layer, basket cells, and stellate cells. Although these two types of interneuron share similar features (Sultan and Bower, 1998), they differ in short-term plasticity (Bao et al., 2010), gene expression (Schilling and Oberdick, 2009), and most importantly, the target of projection. Basket cell axons innervate the soma and surround the axon initial segment (AIS) of PCs, while stellate cells innervate dendrites of PCs (Palay and Chan-Palay, 1974). The specialized conical structure formed by basket cell axons around the AIS is called the pinceau formation (Ango et al., 2004).

In the granular layer, there are several types of interneurons, which do not project to PCs directly. Golgi cells, Lugaro cells, and globular cells are inhibitory interneurons with a dual glycinergic/GABAergic phenotype (Ottersen et al., 1988). Golgi cells extend dendritic trees radiating through the cerebellar cortex. They receive excitatory inputs from PFs in the molecular layer and from MFs and presumably also from CFs in the granular layer. Golgi cells, in turn, innervate GC dendrites in the cerebellar glomeruli, thus providing both feedforward and feedback inhibition to GCs. Golgi cells also receive inhibitory inputs presumably from other Golgi cells, basket cells, stellate cells, and Lugaro cells. Lugaro cells are fusiform inhibitory interneurons lying just beneath the PC layer. They receive GABAergic inputs from axon collaterals of PCs and project axons to the molecular layer to innervate basket and stellate cells, thus providing feedback inhibition to PCs through these molecular layer interneurons (Laine and Axelrad, 2002). Globular cells have globular somata at variable depths in the granular layer and are thought to be a subtype of Lugaro cells (Laine and Axelrad, 2002). Lugaro cells and globular cells are neurochemically distinguished from Golgi cells; the former express calretinin, while most of the latter express mGluR2 and neurogranin (Simat et al., 2007). Unipolar brush cells are excitatory interneurons enriched in the granular layer of the vestibulocerebellum. They are characterized by single short dendrites terminating with a brush of dendrites, which engulf one or two rosettes of glutamatergic and cholinergic MFs. They innervate dendrites of other unipolar brush cells and GCs, thus regarded as an intermediate component that amplify excitatory drives of MFs on to GCs (Mugnaini and Floris, 1994).

DCN neurons receive excitatory inputs from collaterals of MFs and CFs, and inhibitory inputs from PC axons. Thus, information from the cerebellar cortex is integrated with direct inputs from MFs and CFs in DCN neurons. In the DCN, GABAergic neurons are either local interneurons or projection neurons targeting their axons to the inferior olive (De Zeeuw et al., 1988), while non-GABAergic neurons (presumably glutamatergic) project to the rest of the brain, including the red nucleus

and the thalamus. Thus, the DCN is in the key position of the cerebellar system and the source of cerebellar output.

5.1.2 Generation of Neurons that Constitute Microcircuits Related to PCs

All GABAergic neurons in the cerebellum originate from Ptf1a-expressing cells in the ventricular zone (Hoshino et al., 2005). Of these, projection neurons, that is, PCs and DCN neurons projecting to the inferior olive, are specified within the ventricular zone at the onset of cerebellar neurogenesis in early prenatal life (Altman and Bayer, 1997; Miale and Sidman, 1961). GABAergic interneurons also derive from the ventricular zone, but the progenitors continue to proliferate in the prospective white matter up to postnatal development (Zhang and Goldman, 1996). Phenotypic specification and diversity of GABAergic interneurons appear to be created by instructive cues provided by the microenvironment of the prospective white matter (Leto et al., 2009). On the other hand, the rhombic lip generates all progenitors of glutamatergic cerebellar neurons which then migrate via different pathways. Glutamatergic neurons in the DCN migrate to the nuclear transitory zone before descending to the prospective DCN (Fink et al., 2006). GC precursors first migrate to the cerebellar surface and form the external granular layer. There, they continue to proliferate during the postnatal period, and then descend to the internal granular layer (Rakic, 1971). Unipolar brush cells migrate to their destination through developing white matter (Englund et al., 2006).

5.1.3 Compartmentalization of the Cerebellum

Although the basic cellular composition and wiring diagram are uniform across the cerebellum, longitudinal organization of the cerebellar cortex has been demonstrated using anatomical, physiological, and molecular mapping techniques (Apps and Hawkes, 2009). Longitudinal cerebellar zones have been defined anatomically by cholinesterase labeling in the white matter and topographic projection of CFs and PC axons (Voogd and Ruigrok, 2004). Longitudinal zones are further divided into smaller units called microzones, based on high synchrony of complex spike activity (Llinas and Sasaki, 1989; Sugihara et al., 1993) and Ca^{2+} spikes (Mukamel et al., 2009; Schultz et al., 2009). Each microzone is $\sim$500 μm in width, stable across behavioral states, and has a sharp boundary with the neighboring microzones (Mukamel et al., 2009). This synchrony is based on electrical coupling of nearby olivary neurons through dendrodendritic gap junctions (Llinas et al., 1974; Sotelo

et al., 1974) and topographical olivocerebellar projections, that is, from given subregions of the inferior olive to specific longitudinal cortical zones (Sugihara et al., 2001).

Elaborate and fine compartmentalization can be recognized as cerebellar stripes by histochemistry for various molecules expressed in PCs. The best example of 'late' markers, which reveal the adult topography (postnatal day 15 onward), is aldolase C or zebrin II antigen (Hawkes and Leclerc, 1987), while 'early' markers of topography, such as calbindin and L7, typically reveal zones and stripes during perinatal development (embryonic day 13 (E13) to postnatal day 5(P5); Wassef et al., 1985)). These stripes are reproducible between individuals and conserved across species. Using a novel molecular marker, phospholipase Cβ4 (PLCβ4), which is continuously expressed in zebrin II-negative PCs from embryonic stage to adulthood (Nakamura et al., 2004; Watanabe et al., 1998), some stripes in the adult cerebellum have been shown to derive from two or more distinct embryonic clusters (Marzban et al., 2007). Importantly, studies with small tracer injections have shown that the topography of zebrin II expression pattern corresponds to that of the olivary projection to the cerebellar cortex and further to that of the olivary projection to the DCN and cerebellar cortical projection to DCN (Pijpers et al., 2005; Sugihara and Shinoda, 2004, 2007). These lines of evidence support the idea that the entire cerebellar system is formed by parallel assembly of an olivo–cortico–nuclear microcomplex (Ito, 1984).

5.2 DEVELOPMENT OF CF–PC SYNAPSES

5.2.1 Multiple Innervation of PCs by CFs in Early Postnatal Period

PCs undergo drastic changes in their morphology from late embryonic to early postnatal days (Armengol and Sotelo, 1991). PCs are born at the cerebellar ventricular zone at E10–E13 and migrate to form a multilayer below the molecular layer. At the end of radial migration, PCs exhibit bipolar shapes at E19–P0 ('simple and fusiform cell' by Armengol and Sotelo, 1991). Then, at P1–P3, new stem dendrites emerge from all aspects of the cell bodies, which confer the complex shapes of PCs ('complex-fusiform cell' by Armengol and Sotelo, 1991). From P3 to P6, such stem dendrites disappear by retraction of the long dendritic branches ('regressive–atrophic dendrites' by Armengol and Sotelo, 1991). In the meantime, PCs line up in a monolayer, which is completed by P5. PCs undergo explosive outgrowth of perisomatic protrusions that emerge in all directions from the cell bodies (the stage of 'stellate cells' by

Armengol and Sotelo, 1991). Upto P10, PCs extend single or double stem dendrites into the molecular layer, which grow and split into many dendritic branches, with simultaneous withdrawal of long somatic processes. The polarity of PCs is determined during this developmental period. From P10 to P15, the growth of the dendritic arbor occurs mainly in its lateral domain, whereas from P15 on, the dendritic growth occurs in the vertical plane and the height of the dendritic field reaches the adult level at P30.

After reaching the primitive cerebellum around E18, axons of inferior olivary neurons give rise to thick and thin collaterals (Wassef et al., 1992). This stage is called the 'creeper stage' (Chedotal and Sotelo, 1993) at which the 'CFs,' the thick collaterals of olivary axons, creep between immature PCs. At this stage, PCs have just completed their migration and are organized in a multilayer of 'simple and complex-fusiform cells'. Initially, each olivocerebellar axon forms about 100 'creeper' CFs (Sugihara, 2005). Then, the CF to PC synapse undergoes three distinct phases of postnatal development, which are described by Ramón y Cajal in his pioneering studies (Cajal, 1911): the 'pericellular nest' stage, the 'capuchon' stage, and the 'dendritic' stage. At the 'pericellular nest' stage, CFs surround the cell bodies of PCs and establish contacts with the abundant pseudopodia stemming from the soma and form a plexus on the lower part of the PC soma. At this stage, PCs have many perisomatic protrusions that emerge in all directions from the cell bodies, and therefore, this stage is called the phase of 'stellate cells' (Armengol and Sotelo, 1991). Among the 100 'creeper' CFs of each olivocerebellar axon, only around 10 can develop 'pericellular nests.' The 'capuchon' stage is characterized by the displacement of the plexus of CF collaterals to the apical portion of PC somata and main dendrites. Finally, at the 'dendritic' stage, CFs undergo translocation to growing PC dendrites and expanding their innervation territories.

Earlier electrophysiological studies on juvenile rats *in vivo* showed that stimulation to the inferior olive after P3 elicits CF-mediated responses in PCs (Crepel, 1971). However, in contrast to the all-or-none nature of CF responses in the adult animals, the responses of juvenile PCs are graded in parallel with the increase in the stimulus strength (Crepel et al., 1976). This was the first evidence that PCs are innervated by multiple CFs in early postnatal development. Later extensive studies *in vivo* revealed that both the percentage of PCs innervated by multiple CFs and the average number of CFs innervating individual PCs decrease with postnatal development and that most PCs become singly innervated by CFs (Crepel et al., 1981; Mariani and Changeux, 1981). These results clearly indicate that developmental elimination of redundant CF inputs occurs during postnatal development.

5.2.2 Functional Differentiation of Multiple CFs

Multiple CFs initially form functional synapses on the PC soma at around P3 (Chedotal and Sotelo, 1993; Morando et al., 2001). When recorded from PCs in cerebellar slices at this developmental stage, excitatory postsynaptic currents (EPSCs) elicited by stimulating multiply-innervating CFs are much smaller than those of mature CFs (Bosman et al., 2008; Hashimoto and Kano, 2003, 2005; Ohtsuki and Hirano, 2008; Scelfo and Strata, 2005). Therefore, CF inputs become stronger, while redundant CFs are eliminated during postnatal development.

Changes in the relative synaptic strengths of multiple CFs innervating the same PC have been systematically studied during postnatal development (Hashimoto and Kano, 2003) by recording CF-mediated EPSCs in PCs from cerebellar slices of mice aged P2–P21. This systematic study showed that more than five discrete CF-EPSCs with similar amplitudes are recorded in PCs from neonatal mice around P3 (Figure 5.2(a), ~P3). In contrast, in the second postnatal week, PCs with multiple CF-EPSCs have one large CF-EPSC and a few small CF-EPSCs (Figure 5.2(a), ~P7 and ~P12). These results indicate that synaptic strengths of multiply-innervating CFs are relatively uniform in neonatal mice, and one CF is selectively strengthened during postnatal development (Bosman et al., 2008; Hashimoto and Kano, 2003, 2005). Quantitative assessments of the disparity among the amplitudes of multiple CF-EPSCs in individual PCs demonstrate that one CF is selectively strengthened among multiple CFs innervating the same PC from P3 to P7 (Figure 5.2(b); Hashimoto and Kano, 2003). These electrophysiological data are consistent with the morphological observation that the innervation pattern of CFs over PCs drastically changes during this postnatal period in rats (Sugihara, 2005). At P4, CFs have many creeping terminals in the PC layer and their swellings do not aggregate at particular PC somata (creeper type). Then, from P4 to P7, CFs surround several specific PC somata and form aggregated terminals on them (nest type; Sugihara, 2005).

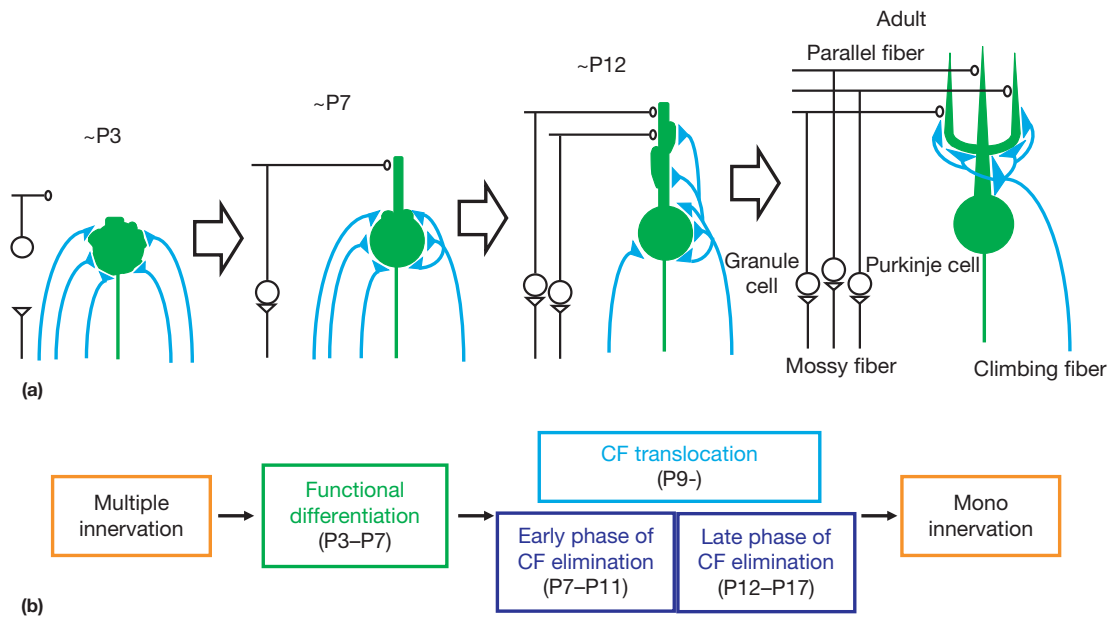
There are clear differences in electrophysiological properties between EPSCs elicited by the strongest CF input and those by other weaker inputs. Transient rises of glutamate concentration in the synaptic cleft are significantly higher after stimulation of the strongest CF than the weaker CFs (Hashimoto and Kano, 2003). This is thought to result from the fact that the probability of multivesicular release (i.e., more than one synaptic vesicle released simultaneously to a given postsynaptic site from the corresponding presynaptic release site) is higher for the strongest CF than for the weaker CFs. Further electrophysiological examination suggested that


FIGURE 5.2 Postnatal development of CF–PC synapses. (a) Diagrams of CF–PC synapses at four representative stages of postnatal development in mice. (b) Four distinct phases in postnatal development of CF–PC synapses. *Reproduced with permission from* European Journal of Neuroscience *34, 1697–1710, with permission.*

the number of release sites facing a narrow postsynaptic PC region is larger in the strongest CF than in weaker CFs (Hashimoto and Kano, 2003).

5.2.3 Dendritic Translocation of Single CFs

Morphological evidence indicates that the site of CF innervation of PC changes from soma to dendrite during early postnatal development, a phenomenon known as 'CF translocation' (Altman and Bayer, 1997). The relationship between the selective strengthening of single CFs and CF translocation was investigated by using both electrophysiological and morphological techniques (Hashimoto et al., 2009a). The location of synapses along the somatodendritic domains of PCs can be estimated by analyzing the kinetics of quantal EPSCs (qEPSCs) arising from single synaptic vesicles in CF terminals.

At P7–P8 when the selective strengthening of single CFs on each PC has just been completed, there is no significant difference in the distribution of the rise times (i.e., time from the onset to the peak) of qEPSCs for the strongest compared with the weaker CFs. Since the rise time of qEPSCs is proportional to the distance from the synaptic sites to the somatic recording site (Roth and Hausser, 2001), synapses of the strongest and weaker CFs are thought to be located on the soma at around P7 (Figure 5.2(a), ~P7). At P9–P10, the incidence of qEPSCs with slow rise times was more frequent for the strongest than for the weaker CFs, suggesting the initiation of CF translocation (Figure 5.2(b)). The difference in the distribution of qEPSC rise times for the strongest

compared with the weaker CFs becomes larger from P11 to P14. While the incidence of qEPSCs with slow rise times becomes more frequent for the strongest CFs with age, the qEPSC rise times for weaker CFs remain almost unchanged from P9 to P14. These electrophysiological data collectively indicate that (1) synaptic competition among multiple CFs occurs on the soma before P7 (Figure 5.2(a), ~P3 and ~P7, Figure 5.2(b)), (2) only the strongest CF ('winner' CF) starts to translocate to dendrites at P9 and the translocation continues thereafter (Figure 5.2(a), ~P12, Figure 5.2(b)), and (3) synapses of the weaker CFs ('loser' CFs) remain around the soma (Figure 5.2(a), ~P12).

Morphological data are consistent with these electrophysiological observations. When subsets of CFs are labeled by an anterograde tracer, biotinylated dextran amine (BDA), injected into the inferior olive, pericellular nests with extensive branching of CFs are observed at P7, P9, and P12. At P7, in spite of the presence of immature stem dendrites in PCs, CFs innervate the soma and spare the dendrites (Figure 5.3(a)). Dendritic innervation of CFs starts at P9 (Figure 5.3(b)) and at P12, and thereafter, the territory of innervation extends progressively along the PC dendrites (Figure 5.3(c) and 5.3(d)).

5.2.4 Early Phase of CF Synapse Elimination

Detailed assessment of the postnatal development of CF innervations in mouse cerebellar slices demonstrates that there is no significant reduction in the average number of CFs per PC from P3 to P6 when functional
FIGURE 5.3   Developmental profile of CF innervations from perisomatic nest stage to peridendritic stage. (a–e) Fluorescent labeling of CFs with BDA (red) and PCs with calbindin antibody (green) at respective postnatal days. *Reproduced from Hashimoto K, Ichikawa R, Kitamura K, Watanabe M, and Kano M (2009) Translocation of a 'winner' climbing fiber to the Purkinje cell dendrite and subsequent elimination of 'losers' from the soma in developing cerebellum.* Neuron *63: 106–118, with permission.*

differentiation of multiple CFs occurs (Hashimoto et al., 2009b). The value then decreases progressively from P6 to around P15 (Hashimoto et al., 2009b; Scelfo and Strata, 2005). CF synapse elimination therefore does not proceed in parallel with functional differentiation of multiple CFs but starts after the strengthening of single CFs to individual PCs. Crepel et al. (1981) showed that elimination of surplus CFs consisted of two distinct phases, the early phase up to around P8 and the late phase from around P9 to P17 (Crepel et al., 1981). The early phase occurs normally in animals with mild X-irradiation to the cerebellum during the early postnatal period, which causes selective loss of GCs and PFs while leaving PCs intact. In marked contrast, the late phase is severely impaired by inhibiting GC production by X-irradiation. This study indicates that the early phase of CF synapse elimination is independent of PF–PC synapse formation, whereas the late phase is critically dependent on it. However, since the animal models with 'hypogranular' or 'agranular' cerebella often have abnormalities of cerebellar development other than GC genesis and PF–PC synapse formation, there remains a possibility that CF synapse elimination might be influenced by such developmental defects.

The analysis of mutant mice deficient in the glutamate receptor δ2 subunit (GluRδ2 or GluD2) demonstrates that there are two distinct phases of CF synapse elimination. GluRδ2 is richly expressed in PCs and its deletion causes impairment of PF–PC synapse formation leading to reduction of PF–PC synapse number to about half of that in wild-type mice. In spite of the severe impairment of PF synapse formation, GluRδ2 deletion does not significantly affect the laminar structure of the cerebellum and morphology of the PC and its dendritic tree (Kashiwabuchi et al., 1995; Kurihara et al., 1997). In GluRδ2 knockout mice, the average number of CFs innervating each PC is similar to that of control mice from P5 to P11. However, the value is significantly larger than that of control mice from P12 to P14. Thus, CF synapse elimination in mice can be classified into two distinct phases, namely, the 'early phase' from P6 to around P11 which is independent of PF–PC synapse formation and the 'late phase' from around P12 and thereafter which requires normal PF–PC synapse formation (Figure 5.2(b); Hashimoto et al., 2009b).

Molecular mechanisms of the early phase of CF synapse elimination remain largely unknown. However, patterns of CF activity have been reported to influence the early phase of CF synapse elimination. Andjus et al. disrupted the normal activity pattern of CFs in rat at P9–P12 by administration of harmaline, which induced synchronous activation of inferior olive neurons (Andjus et al., 2003). This treatment caused persistent multiple CF innervations of PCs in rats at P15–P87. Furthermore, a recent report strongly suggests that PC activity is crucial for CF synapse elimination. Lorenzetto et al. (2009) generated transgenic mice that expressed a chloride channel-YFP fusion protein specifically in PCs to suppress their excitabilities. In these mice, the expression of chloride channel was observed in PCs during the 'early phase' at P9, and multiple CF innervations persisted up to P90. Therefore, perturbation of PC activity is considered to cause impairment of the 'early phase' of CF synapse elimination. In addition, insulin-like growth factor I (IGF-1) is reported to be involved in CF synapse elimination from P8 to P12 (Kakizawa et al., 2003). IGF-1 is thought to enhance the strengths of CF synapses and promote their survival, whereas the shortage of IGF-1 appears to impair the development of CF synapses (Kakizawa et al., 2003). In addition, Sherrard et al. reported recently that the active, phosphorylated form of full-length TrkB, a receptor for

brain-derived neurotrophic factor (BDNF), fell around the onset of the early phase of CF synapse elimination. In contrast, the expression of the truncated form, which acts as a negative regulator of TrkB signaling, rose at the same developmental stage (Sherrard et al., 2009). This finding suggests that decrease in TrkB signaling might permit the elimination of surplus CF synapses, although TrkB signaling appears to be involved in the 'late phase' of CF synapse elimination presumably through the maturation of GABAergic inhibitory synapses (see Section 5.2.5).

Morphological data indicate that CFs that undergo dendritic translocation keep their synapses on the PC soma during the second postnatal week. In contrast, synaptic terminals of the weaker CFs are confined to the soma and the basal part of the primary dendrite. The characteristic pericellular nest consists of somatic synapses originating from collaterals of a single predominant CF and from weaker CFs and thus represents multiple CF innervation of PCs (Hashimoto et al., 2009a). Therefore, CF synapse elimination is thought to be a process of nonselective pruning of perisomatic synapses, which spares dendritic synapses of a single predominant CF and leads to monoinnervations of that CF (Hashimoto et al., 2009a).

Hashimoto et al. (2011) have recently reported that the P/Q-type VDCC expressed in PCs drives the early phase of CF synapse elimination (Hashimoto et al., 2011). They generated mice with PC-selective deletion of Ca$_V$2.1, a pore-forming subunit of the P/Q-type VDCC that constitutes the major Ca^{2+} current component in PCs (PC-Ca$_V$2.1 KO mice; Mintz et al., 1992; Stea et al., 1994). Although initial CF to PC synapse formation appears

normal at around P4 in PC-Ca$_V$2.1 KO mice, subsequent CF synapse development and elimination are severely impaired. First, biased strengthening of a single CF input in each PC from P5 to P7 is absent in PC-Ca$_V$2.1 KO mice, and multiple CF inputs equally become larger by about fourfold. Second, more than one CF undergoes translocation to dendrites in PC-Ca$_V$2.1 KO mice. Third, CF synapse elimination is severely impaired in PC-Ca$_V$2.1 KO mice until around P12 (Hashimoto et al., 2011). Global Ca$_V$2.1 KO mice have essentially the same defects in CF synapse development and elimination as PC-Ca$_V$2.1 KO mice (Hashimoto et al., 2011; Miyazaki et al., 2004). These results indicate that Ca^{2+} influx through P/Q-type VDCC into PCs is essential for selective strengthening of a single CF input in each PC, dendritic translocation of the strengthened CF, and the early phase of CF synapse elimination.

5.2.5 Late Phase of CF Synapse Elimination

In GluRδ2 knockout mice, CFs invade into the distal dendrites and form ectopic synapses there (Hashimoto et al., 2001; Ichikawa et al., 2002). These ectopic CF synapses appear around P10 when PF synapse formation and PC dendritic arborization occur most vigorously. The similar type of multiple CF innervation is also found in a mutant mouse deficient in cbln1 in which PF to PC synapse formation is severely impaired (Hirai et al., 2005). These results indicate that PFs compete for the innervation territory with CFs during development and play a role in restricting CF innervation to proximal dendrites (Figure 5.4). The details of this phenomenon will be described in Section 5.3.3.

FIGURE 5.4 Mechanisms underlying the late phase of CF synapse elimination. PF–PC synapses play two distinct roles in the late phase. PF synapses are formed and maintained on distal dendrites of PCs through the interaction of Cbln1 and GluRδ2. First, PF synapses occupy the postsynaptic sites on the distal dendrites and confine the CF innervation sites to the proximal dendrites (restriction to proximal dendrites). Second, neural activity along the pathway of mossy fiber, GC, and PF involving N-methyl-D-aspartate (NMDA) receptor at MF to GC synapses drives mGluR1 to PKCγ signaling cascades in PCs (activation of mGluR1 signaling cascade). The signaling molecules downstream of PKCγ are currently unknown, but this eventually leads to elimination of somatic CF synapses including those of weak CFs and of somatic collaterals of strong CF (elimination of somatic synapses). TrkB, myosin Va, brain-specific receptor-like protein (BSRP), and glutamate-aspartate transporter (GLAST) are also involved in the late phase of CF synapse elimination, but details of the mechanisms of their actions in CF synapse elimination are unknown. *Modified from Kano, M., Hashimoto, K., Tabata, T., 2008. Type-1 metabotropic glutamate receptor in cerebellar Purkinje cells: a key molecule responsible for long-term depression, endocannabinoid signalling and synapse elimination. Philosophical Transactions of the Royal Society B 363, 2173–2186.*

Another role of PF synapses is to activate type 1 metabotropic glutamate receptor (mGluR1) and its downstream signaling cascades in PCs to drive the process of CF synapse elimination. It is shown that the mutant mouse deficient in mGluR1 is impaired in CF synapse elimination (Kano et al., 1997; Levenes et al., 1997). Mice deficient in signaling molecules downstream of mGluR1, that is, $G_{\alpha q}$, PLCβ4, and PKCγ, are also impaired in CF synapse elimination (Hashimoto et al., 2000; Kano et al., 1995, 1998; Offermanns et al., 1997). Electrophysiological examination of CF innervation following postnatal development demonstrates that the regression of CF synapse normally occurs during the first and second postnatal weeks in all of the four mouse strains. However, these mice display abnormality in CF synapse elimination during the third postnatal week. These results suggest that the signaling cascade from mGluR1 to protein kinase C (PKC)γ is essential for the late phase of CF synapse elimination, but it is dispensable for the early phase of CF synapse elimination (Figure 5.2(b)). Importantly, the formation and function of PF to PC synapses are normal in these mutant mice. Therefore, the impaired CF synapse elimination is not caused secondarily by the defect in PF synaptogenesis.

The defect in the CF synapse elimination in the mGluR1-deficient mouse is restored in the mGluR1-rescue mice in which mGluR1a has been introduced specifically into PCs (Ichise et al., 2000). Regression of CF synapses is impaired in mice by PC-specific expression of a PKC inhibitor peptide (De Zeeuw et al., 1998). Furthermore, the distribution of multiply-innervated PCs in the cerebellum of PLCβ4 knockout mice exactly matches that of the PCs with predominant expression of PLCβ4 in the wild-type mouse cerebellum (Kano et al., 1998). These lines of evidence clearly indicate that the signaling from mGluR1 to PKCγ in PCs but not other cell types plays a central role in CF synapse elimination.

The mGluR1 signaling required for the late phase of synapse elimination is thought to be driven by PF activity, since mGluR1 can readily be activated by PF inputs (Batchelor et al., 1994; Finch and Augustine, 1998; Takechi et al., 1998). Furthermore, chronic blockade of N-methyl-D-aspartate (NMDA) receptors within the cerebellum results in the impairment of CF synapse elimination (Rabacchi et al., 1992) specifically in its later phase (Kakizawa et al., 2000). NMDA receptors are not present at either PF or CF synapses onto PCs during second and third postnatal weeks, but they are abundantly expressed at MF to GC synapses (Kakizawa et al., 2000). Therefore, the chronic blockade of NMDA receptors within the cerebellum should affect MF to GC transmission. These results suggest that neural activity along MF–GC–PF–PC pathway and subsequent activation of mGluR1 are prerequisite for the late phase of CF synapse elimination (Figure 5.4; Kakizawa et al., 2000).

Besides the mGluR1 signaling in PCs, a neurotrophin receptor, TrkB (Bosman et al., 2006; Johnson et al., 2007), a motor protein, myosin, Va (Takagishi et al., 2007), a glutamate transporter, glutamate-aspartate transporter (GLAST) (Watase et al., 1998), and a novel brain-specific receptor-like protein family, brain-specific receptor-like protein (Miyazaki et al., 2006), are also involved in CF synapse elimination. Since genetic or pharmacological deletion of these molecules in mice impairs CF synapse elimination in the second postnatal week, these signaling cascades are thought to be involved in the 'late phase' of CF synapse elimination. The involvement of a neurotrophin receptor, TrkB, is especially interesting, because TrkB signaling is required for normal development of GABAergic innervations of PCs. In TrkB knockout mice, the number of GABAergic synapses is reduced and the inhibitory postsynaptic currents are prolonged (Bosman et al., 2006), which suggest the GABA$_A$ receptors do not undergo the normal α3 to α1 subunit switching (Takayama and Inoue, 2004). It is therefore possible that normal development of GABAergic inhibitory synapses onto PCs is prerequisite for the late phase of CF synapse elimination (Nakayama et al., 2012). As for other molecules potentially involved in the late phase of CF synapse elimination, null mutant mice deficient in Ca^{2+}/calmodulin-dependent protein kinase IV (CaMKIV) are reported to have persistent multiple CF innervations, but it is unclear at what stage of postnatal development the impairment occurs (Ribar et al., 2000). It is also reported that null mutant mice deficient in α-calcium/calmodulin-dependent protein kinase II (CaMKIIα) display multiple CF innervations at P21–P28, but this phenotype disappears in adulthood (Hansel et al., 2006), suggesting that CaMKIIα deficiency delays but does not prevent CF synapse elimination.

During synapse elimination in the neuromuscular junction, bulb-shaped tips of retreating motor axons and the axon fragments ('axozomes') are engulfed by Schwann cells (Bishop et al., 2004). These axon bulbs, axozomes, and Schwann cell cytoplasm are often positively stained with Lysotracker Red, a marker for the lysosomes and late endosomes of living cells, suggesting axonal digestion through autophagy and subsequent heterophagy by Schwann cells (Song et al., 2008). It is also reported that Lysotracker-positive structures surrounding PCs, which are presumed to be within Bergmann glia, are abundant during the second and third postnatal weeks (Song et al., 2008). This result suggests that retreating CF axons might be digested in a manner similar to the retreating motor axons at neuromuscular junction.

The current model for the mechanisms underlying the late phase of CF synapse elimination is illustrated in Figure 5.4. First, PF synapses confine the CF innervation territories to proximal dendrites of PCs (Figure 5.4). Second, PF activity involving NMDA receptor at MF to

GC synapses drives mGluR1 to PKCγ signaling cascades in PCs (Figure 5.4), which leads to nonselective elimination of somatic CF synapses (Figure 5.4). The signaling molecules downstream of PKCγ are currently unknown. The molecular mechanisms underlying morphological elimination of the weaker CFs are also unknown. Some mechanisms must convey transsynaptic retrograde signaling from PCs to weaker CFs.

A recent study using organotypic slice culture shows that CF synapse elimination occurs only during the critical period that depends on the maturation stage of postsynaptic PCs but not on presynaptic olivary neurons (Letellier et al., 2009). The authors cocultured immature or mature medulla containing the inferior olive with naïve or non-naïve PCs (i.e., PCs that have not undergone synapse elimination or those that have experienced synapse elimination, respectively). They found that multiple CF innervation was observed when either the PCs were naïve or CFs were immature. Interestingly, non-naïve PCs could not eliminate multiple CFs. These results suggest that CF synapse elimination during the critical period leaves indelible trace in PCs that prevents the elimination process from occurring in the later stage (Letellier et al., 2009).

5.3 DEVELOPMENT OF PF–PC SYNAPSES

5.3.1 Formation of PF–PC Synapses

PF–PC synapses increase in number and mature in the early postnatal period, concomitant with differentiation of GCs and growth of PC dendrites. During the first 10 days of a rodent's life, production and migration of GCs as well as growth of PC dendrites are slow (Altman and Bayer, 1997). In this period, the proliferative or outer zone of the external granular layer has constant thickness of four to five cells, while the depth of the premigratory or inner zone increases progressively (Altman and Bayer, 1997). In the premigratory zone, postmitotic GCs extend future PFs in the transverse plane, and then migrate downward along Bergmann fibers in the molecular layer (Altman and Bayer, 1997; Rakic, 1971). As a consequence, T-shaped axon of GCs differentiates, and horizontal beams of PFs become a part of the upper zone of the molecular layer. PC dendrites are immature, particularly in the upper zone of the molecular layer, where dendrites extend filopodium-like protrusions, PF–PC synapses are few in number, spines are often free of innervation, and coverage by Bergmann glia is incomplete (Kurihara et al., 1997; Yamada et al., 2000).

In the next ten postnatal days, PC dendrites grow dynamically, the bulk of GCs come into existence, and PF–PC synapses explosively increase in number (Takacs and Hamori, 1994). Moreover, almost all spines form synaptic contact with PF terminals, and PF–PC synapses are equipped with well-developed postsynaptic density and complete astroglial coverage (Kurihara et al., 1997; Spacek, 1985; Yamada et al., 2000). Analyses using agranular and hypogranular animal models, where PF–PC synaptogenesis is hindered by spontaneous gene mutation or postnatal X-ray irradiation, have demonstrated that PF synapse formation in PCs plays a critical role in the elongation, branching, and planar development of dendritic trees (Sotelo, 2004).

5.3.2 Stabilization and Maintenance of PF–PC Synapses

Our understanding of the molecular mechanism of PF synapse formation in PCs has been greatly advanced by molecular identification of GluRδ2 (Araki et al., 1993; Lomeli et al., 1993) and analyses of mutant mice defective in this gene *grid2* (GluRδ2-knockout mice and spontaneous *hotfoot* mutant mice; Guastavino et al., 1990; Kashiwabuchi et al., 1995). Like other ionotropic GluR subunits, GluRδ2 preserves three transmembrane domains (TM1, TM3, and TM4), reentrant hairpin loop (TM2) surrounding a channel pore, ligand-binding domains in the *N*-terminal region, and protein–protein interaction sites in the *C*-terminal region (Uemura et al., 2004; Yuzaki, 2004). However, GluRδ2 does not function as a glutamate-gated ion channel (Kakegawa et al., 2007a,b).

In the brain, GluRδ2 is expressed almost exclusively in PCs (Araki et al., 1993; Lomeli et al., 1993) and selectively localized at PF but not CF synapses (Landsend et al., 1997; Takayama et al., 1995). PCs in GluRδ2-defective mice display characteristic phenotypes mostly related to PF synapse structure and function, including reduction in the number of PF synapses per PC to about half of the wild-type mice (54% in control PCs; Kurihara et al., 1997), emergence of free spines lacking synaptic contact in the distal dendritic domain (37% of the total spines; (Ichikawa et al., 2002; Kurihara et al., 1997)), mismatching of pre- and postsynaptic specialization at PF synapses (Guastavino et al., 1990; Takeuchi et al., 2005), impaired long-term depression (LTD) at PF synapses (Kakegawa et al., 2008; Kashiwabuchi et al., 1995; Uemura et al., 2007), impaired motor learning (Kakegawa et al., 2008; Kishimoto et al., 2001), and severe ataxia (Guastavino et al., 1990; Kashiwabuchi et al., 1995). In a drug-inducible, PC-specific GluRδ2-knockout mouse strain, mismatched PF–PC synapses, free spines, and motor discoordination are induced and exacerbated in the adult cerebellum, concomitant with a decrease in GluRδ2 protein (Takeuchi et al., 2005). Furthermore, expression of the *N*-terminal domain of GluRδ2 in human embryonic kidney cells induces presynaptic differentiation (Uemura

and Mishina, 2008) and its viral transfer to adult GluRδ2-knockout mice rapidly restores PF synapse formation and motor discoordination (Kakegawa et al., 2009). Thus, GluRδ2 strengthens and regulates the connectivity of PF–PC synapses in both the developing and adult cerebella. On the other hand, the last seven amino acids known as the T-site, which binds to various PDZ domain-containing proteins including postsynaptic density (PSD)-93, PTPMEG, delphilin, nPIST, and synaptic scaffolding molecule are essential for cerebellar LTD and motor learning (Kakegawa et al., 2008; Uemura et al., 2007).

Cbln1 or precerebellin was originally identified as a precursor of PC-specific peptide cerebellin (Slemmon et al., 1984). However, C-terminal two-thirds of Cbln1 shares significant structural similarity with the globular domain of complement C1q chain (Urade et al., 1991), and the full-length Cbln1 is released into the culture medium as a hexameric complex (Bao et al., 2005). Thus, Cbln1 now belongs to the C1q/tumor necrosis factor superfamily. Of four members (Cbln1–4), Cbln1 is highly expressed in cerebellar GCs together with Cbln3 (Hirai et al., 2005; Miura et al., 2006), exists as Cbln1 homomeric and Cbln1/3 heteromeric complexes (Iijima et al., 2007; Pang et al., 2000), and selectively accumulates in the synaptic cleft facing PF terminals, but not CF terminals, in PCs (Iijima et al., 2007; Miura et al., 2009). Cbln1-knockout mice show characteristic phenotypes similar to, or even severer than, GluRδ2-knockout mice (Hirai

et al., 2005). In PCs of Cbln1-knockout mice, 78% of the spines are free of innervation and 14% have mismatching in pre- and postsynaptic differentiation (Figure 5.5). Hence, only 8% of spines in Cbln1-knockout mice establish normal matched synapses with PF terminals. LTD at PF–PC synapses and motor coordination is also impaired. When recombinant Cbln1 is applied to the subarachnoid space of adult Cbln1-knockout mice, only a single injection can rapidly restore PF–PC synapse structure and function, and cerebellar ataxia (Ito-Ishida et al., 2008). These common phenotypes in GluRδ2- and Cbln1-knockout mice and their rapid rescue by genetic or molecular supplementation are explained by the fact that transsynaptic interaction of postsynaptic GluRδ2 and presynaptic neurexins is mediated by Cbln1. Thus, through this unique interaction, Cbln1 acts as a bidirectional synaptic organizer for both pre- and postsynaptic components at PF–PC synapses (Matsuda et al., 2010; Uemura et al., 2010).

The strengths of PF synapses, but not CF synapses, in PCs are selectively decreased when postsynaptic mGluR1 or inositol 1,4,5-trisphosphate (IP_3) signaling is chronically inhibited, when PF activity is inhibited by suppressing NMDA receptor-mediated inputs to GCs or when antibody against BDNF is applied *in vivo* (Furutani et al., 2006). The weakening is due to reduction of glutamate release probability from PFs. The weakening of PF–PC synaptic strength is reversed by
FIGURE 5.5   Electron micrographs of free spines (f) and mismatched synapses (m) in Cbln1-knockout mice. Free spines are thoroughly enwrapped by the lamellate processes of Bergmann glia. *Arrowheads* indicate the portion of the PSD that is not opposed by the presynaptic active zone. Normal matched synapses (n) are very rare in this mutant. In (d), the presence of postsynaptic density with no presyanptic terminal differentiation suggests that the spine with such postsynaptic density is either free or mismatched spine (hence labeled "f/m(?)." Scale bar = 0.2 μm. *Reproduced from Watanabe, M., Molecular mechanisms governing competitive synaptic wiring in cerebellar Purkinje cells.* Tohoku Journal of Experimental Medicine *214, 2008:175–190, with permission.*

Scale bar, 200 nm.

in vivo application of BDNF. These results suggest that postsynaptic mGluR1 activation and the following IP$_3$ signaling maintain presynaptic function through BDNF at PF–PC synapses (Furutani et al., 2006). In this regard, it is interesting to note that free spines on PC dendrites emerge in the spontaneous ataxic mutant rigoletto (*rig*) (also known as waddles; *wdl*), which is caused by a 19-bp deletion in the exon 8 of carbonic anhydrase-related protein *Car8* (Hirasawa et al., 2007). Car8 is known to bind to IP$_3$ receptor and reduce its affinity for IP$_3$ (Hirota et al., 2003). In future studies, it is important to investigate how Car8 modulates the mGluR1-IP$_3$ signaling and whether Car8 is involved in the GluRδ2–Cbln1–neurexin interaction, both of which regulate the connectivity of PF–PC synapses.

5.3.3 Heterosynaptic Competition Between PF and CF Inputs

The proximal compartment of PC dendrite appears smooth in contour due to low spine density and is innervated by single CFs. On the other hand, the distal compartment is made up of spiny branchlets studded with numerous spines and innervated by PFs (Figure 5.6, middle). Accumulated experimental evidence indicates that the construction of such excitatory synaptic organization stands on competitive equilibrium between CFs and PFs whose expansions are promoted by distinct mechanisms. Surgical, pharmacological, and genetic manipulations that shift this equilibrium can alter the organized innervations pattern.

Disruption of GluRδ2 gene in mice not only causes abnormal structure and function of PF synapses but also affects the mode of CF innervations (Ichikawa et al., 2002). In the molecular layer, CF branches are distributed in the inner four-fifths (84% of the molecular layer thickness) in control mice, whereas their distribution almost reaches the pial surface (95%) in GluRδ2-knockout mice. When the tracer-labeled CFs were followed from the soma to the tips of PC dendrites by serial electron microscopy, CF branches in GluRδ2-knockout mice extend distally and take over the free spines on the distal dendrites. Such aberrant extension occurs toward not only distal dendrites of the same PCs but also those of the neighboring PCs. The latter type of spine takeover results in multiple innervation of a PC by CFs of different neuronal origins. This anatomical evidence for multiple CF innervation is consistent with electrophysiological recording combined with Ca^{2+} imaging. In GluRδ2-knockout mice, a single strong CF elicits large EPSCs with a fast rise time and large Ca^{2+} transients over the entire dendritic tree, whereas weak CFs elicit small EPSCs with a slow rise time and small Ca^{2+} elevation that is confined to distal dendrites (Hashimoto et al., 2001). These findings indicate that GluRδ2 is essential for restricting CF innervation to the proximal dendritic compartment and thereby preventing multiple CF innervation at the distal dendritic compartment (Figures 5.4 and 5.6, right).

This mechanism is also active in the adult cerebellum. The ablation of GluRδ2 in adulthood also leads to progressive distal extension of ascending branches of CFs, and they aberrantly innervate distal dendrites of the target and neighboring PCs (Miyazaki et al., 2010). Furthermore, transverse branches of CFs, which are short motile collaterals forming no synapses in wild-type animals (Nishiyama et al., 2007), display aberrant mediolateral extension and innervate distal dendrites of neighboring and remote PCs. Consequently, many PCs are connected by single main CFs and surplus CFs that innervate small parts of the distal dendrites. Surplus CF-EPSCs with slow rise time and small amplitude also emerge progressively after GluRδ2 ablation. Therefore,

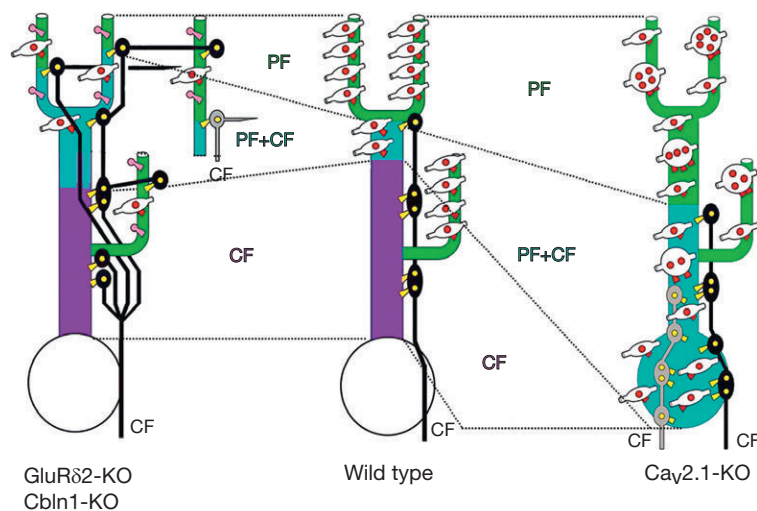

FIGURE 5.6 Summary diagram of molecular mechanisms for competitive synaptic wiring in PCs. Note that the climbing fiber (CF) and parallel fiber (PF) territories are reversed in mutant mice defective in GluRδ2/Cbln1 (left) and Ca$_V$2.1 (right). With both mechanisms, CF and PF territories are sharply segregated, and CF mono-innervation is established in wild-type animals (middle). *Reproduced from Watanabe, M., 2008. Molecular mechanisms governing competitive synaptic wiring in cerebellar Purkinje cells.* Tohoku Journal of Experimental Medicine 214, 2008:175–190, with permission.

GluRδ2 is essential to keep CF mono-innervation in the adult cerebellum by suppressing aberrant invasion of CF branches to the territory of PF innervation.

In contrast, CF innervation is regressed but PF innervation expands to the proximal compartment, when surgical lesion to olivocerebellar projections is made in adult animals or activities in the cerebellar cortical neurons are blocked with the sodium channel blocker tetrodotoxin or with the synaptic scaffolding molecule AMPA) receptor antagonist 2,3-Dioxo-6-nitro-1,2,3,4-tetrahydrobenzo [f]quinoxaline-7-sulfonamide (Bravin et al., 1995; Cesa et al., 2007; Kakizawa et al., 2005). The latter change often accompanies hyperspiny transformation at the proximal dendritic compartment (Bravin et al., 1995; Cesa et al., 2007). Similar changes are reproduced in global knockout mice of $Ca_V2.1$, a pore-forming subunit of the P/Q-type VDCC (Miyazaki et al., 2004). In $Ca_V2.1$-knockout mice, hyperspiny transformation is induced at proximal dendrites and somata of PCs, and many of these ectopic spines are innervated by PF terminals. Conversely, the distribution of CFs is regressed to lower portions of the molecular layer, and they innervate spines from somata and basal dendrites. Furthermore, in more than 90% of $Ca_V2.1$-knockout PCs, their basal dendrites and somata are innervated by CFs of different neuronal origins. As a result, the proximal somatodendritic compartment in $Ca_V2.1$-lacking PCs receives chaotic innervation by numerous PFs and multiple CFs (Figure 5.6, right). Thus, CF activities leading to AMPA receptor activation and subsequent Ca^{2+} influx through P/Q-type Ca^{2+} channels are essential for monopolizing the proximal dendritic compartment by a single main CF and for expelling other excitatory inputs from that compartment.

Taken altogether, excitatory synaptic wiring in PCs is formed and maintained through homosynaptic competition among CFs and heterosynaptic competition between PFs and CFs. GluRδ2 and Cbln1 fuel heterosynaptic competition in favor of PF innervation, whereas P/Q-type VDCCs facilitate both heterosynaptic and homosynaptic competitions in favor of single main CFs. Based on these molecular mechanisms, PCs establish territorial innervations by PF and CF and mono-innervation by CF.

5.4 DEVELOPMENT OF INHIBITORY SYNAPSES FROM STELLATE CELLS AND BASKET CELLS TO PCS

5.4.1 Formation of Basket Cell–PC Synapses

Basket cells innervate the AIS of PC and constrict characteristic pinceau formation in the mature cerebellum (Ito, 1984; Palay and Chan-Palay, 1974). The innervation by basket cell axons of PCs seems to begin when basket cells migrate across the PC layer at the end of the first postnatal week (Ango et al., 2004). The basket cell axons initially form synaptic contacts on the somata of PCs. Then, they appear to move directly to AIS without searching for other possible targets. Upon reaching the AIS, basket cell axons extend multiple terminal branches and eatablish pinceau formation. This behavior strongly suggests that there are guidance cues for basket cell axons along the surface of the PC with gradient from soma to AIS.

Several molecules have been identified that accumulate at AISs of PCs. These include membrane-associated adaptor protein ankyrin-G and one of its binding partner, neurofascin 186 (NF186), a splice variant of neurofascin which belongs to the L1 subgroup of the Ig superfamily (Brummendorf et al., 1998). It is thought that ankyrin-G is stabilized at the AIS partly through its interaction with β4-spectrin tetramers which bind to actin network (Davis et al., 1996). Ankyrins and β-spectrins are known as intracellular adaptor proteins that recruit ion channels, transporters, and cell adhesion molecules to subcellular domains. They are thought to constitute microdomains for intercellular contact and signaling (Bennett and Baines, 2001; Bennett and Chen, 2001). On the other hand, neurofascin is known as a cell-surface glycoprotein that is shown to mediate axon–axon interactions *in vitro* (Rathjen et al., 1987). The distribution of NF186 on PC surface is particularly intriguing. NF186 exhibits subcellular concentration gradient in PCs from AIS toward the soma and dendrites, being highest at AIS and very low at the top of the soma and in the dendrites (Figure 5.7(a); Ango et al., 2004). This gradient is already formed at the end of the first postnatal week when the basket cell axons first contact the somata of PCs. Therefore, it is highly likely that the gradient of NF186 plays an important role in guiding basket cell axons to AIS (Figure 5.7(a)). Since ankyrin-G is expressed exclusively at AISs in PCs, there may be two forms of NF186, the ankyrin-G bound form that is restricted to AIS and the ankyrin-G free form that is distributed to the surface of the PC soma.

Evidence for the requirement of ankyrin-G and NF186 in basket cell axon targeting and pinceau synapse formation at AIS of PC has been presented by the analysis of ankyrin-G knockout mice in which the NF186 gradient in PCs is abolished (Figure 5.7(b); Ango et al., 2004). In these mice, basket cell axons are not restricted to AIS but instead are present on the soma and slightly more distal portion of PC axons (Figure 5.7(b)). Although some basket cell axon bundles successfully reach the AIS, they are very thin, extend along PC axons abnormally, and followed the ectopic localization of NF186. The synaptic contacts visualized by a GABA synthesizing enzyme, GAD65, were greatly reduced at pinceau synapses. These results strongly suggest that NF186 is a substrate for the growth of basket cell axons and its gradient functions as a guidance cue. The results
FIGURE 5.7 Subcellular specificity of basket cell and stellate cell inhibitory connections to PCs. Schematics showing the inhibitory synaptic connectivity patterns of the wild-type (a), ankyrin-G-deficient (b), and CHL1-deficient (c) mice. In wild-type mice, a sharp gradient of neurofascin is present from AIS toward the soma. In ankyrin-G-deficient mice, this gradient is no longer restricted to the AIS, which causes mistargeting of basket cell axons and reduced synapse formation. In CHL1-deficient mice, stellate cell axons are not properly guided by Bergmann glia fibers, and synapse formation is decreased. SC, stellate cell; BC, basket cell; PC, Purkinje cell; BG, Bergmann glia. *Reproduced from Williams ME, de Wit J, and Ghosh A (2010) Molecular mechanisms of synaptic specificity in developing neural circuits.* Neuron 68: 9–18, with permission.

also suggest that NF186 bound to ankyrin-G at AIS is required for the stabilization of pinceau synapses. Further supporting evidence of this notion has been obtained from the experiments to disrupt NF186 function directly in PCs (Ango et al., 2004). Expression of the dominant-negative form of NF186 into PCs during the process of establishing pinceau does not affect AIS-restricted ankyrin-G distribution or guidance of basket cell axons to AIS. However, GAD65-labeled pinceau formation is decreased in the infected PCs to the same extent as in ankyrin-G-deficient PCs. Therefore, either remaining endogenous NF186 can guide the basket cell axons to AIS or NF186 is required specifically for pinceau synapse stabilization while other molecules interacting with ankyrin-G guide the basket cell axons to AIS (Huang et al., 2007; Williams et al., 2010).

5.4.2 Formation of Stellate Cell–PC Synapses

Stellate cells are GABAergic inhibitory interneurons whose somata are located in the molecular layer. In the mature cerebellum, their axons innervate dendrites of PCs with ascending and descending collaterals, and with a plexus of finer branches and terminals. Similarly to basket cells, stellate cells are derived from dividing progenitors in the white matter of postnatal cerebellum (Zhang and Goldman, 1996). The stellate cell precursors migrate into the molecular layer a few days later than the basket cell precursors, with a peak between P8 and P11 but continuing till P14 (Yamanaka et al., 2004). By using a

green fluorescent protein- bacterial artificial chromosome transgenic reporter mouse line in which GFP was mainly expressed in stellate cells and basket cells, Huang and colleagues demonstrated how stellate cell axons establish their innervations of PC dendrites after they reach the molecular layer (Ango et al., 2008). Between P12 and P16, stellate cells become bipolar and extend neuritis in horizontal orientation. Then, at P16–P18, stellate cell axons send ascending and descending collaterals, which are further elaborated with appearance of plexus of finer branches up to P40. Importantly, both ascending and descending collaterals of stellate cell axons are strictly associated with the fibers of Bergmann glia that are visualized by the staining of the glia-specific cytoskeleton protein glial fibrillary acidic protein (GFAP). During the third and fourth postnatal weeks, Bergmann glia fibers are known to extend lateral varicoses and fine processes and form an extensive reticular meshwork. Radial fibers from neighboring Bergmann glia are aligned to form palisades in parlobular plane, which are perpendicular to PC dendrites (Altman and Bayer, 1997). In contrast to the close association to Bergmann glia fibers, stellate cell axons do not follow PC dendrites. Bergmann glia fibers enwrap segments of PC dendrites in a patchy, en passant pattern, which is in contrast to the close association to stellate cell axons. Triple immunolabeling of stellate cell axon terminals, Bergmann glia fibers and PC dendrites indicates that stellate cell boutons are formed at the intersection between Bergmann glia fibers and PC dendrites. Thus, Bergmann glia fibers may function as an intermediate scaffold to guide

stellate cell axons along the characteristic trajectories toward multiple PC dendrites and to form synaptic contacts (Figure 5.7(a); Ango et al., 2008).

Since neurofascin, a member of the L1 cell adhesion molecule (L1CAM) subfamily, is crucial for targeting of basket cell axons to the AIS of PC, it is possible that other members of L1CAM might be important for the targeting of stellate cell axons to PC dendrites. A systematic survey of the expression patterns of L1CAMs during postnatal cerebellar development revealed that close homologue of L1 (CHL1) is distributed in a radial stripe pattern that exactly matches the expression of the Bergmann glia marker GFAP, but not the PC marker calbindin (Ango et al., 2008). CHL1 expression in Bergmann glia fibers is prominent as early as P8, reaching higher levels around P18, and then declining in adulthood. CHL1 is also expressed in stellate cells, but the expression is delayed, being undetectable at P8, becoming obvious around P14, and remaining in adulthood (Ango et al., 2008). These expression patterns suggest the involvement of CHL1 in the stellate cell axon targeting to PC dendrites.

A series of experiments using CHL1-deficient mice have clarified the importance of Bergmann glia fibers and CHL1 in organizing stellate cell innervations of PC dendrites (Figure 5.7(c); Ango et al., 2008). In CHL1 knockout mice, stellate cell axons exhibit abnormal trajectories and orientation, and aberrant innervations of PC dendrites (Figure 5.7(c)). In addition, there is a clear reduction in the staining of GAD65, a marker for GABAergic inhibitory synaptic terminal, and the density of stellate cell synapses along PC dendrites. Such aberrant stellate cell axons can form morphologically normal synapses onto PC dendrites albeit with reduced efficacy and density, but many of them are not maintained and the stellate cell axon terminals become atrophic with age. In contrast, there is no change in the GAD65 staining in the AIS of PC (Figure 5.7(c)). Furthermore, there is no change in excitatory synapses from PFs and CFs in CHL1-deficient mice. Importantly, the selective defect in stellate cell innervations and synapse formation on PC dendrites is observed in mice with conditional deletion of CHL1 in Bergmann glia. These results demonstrate that Bergmann glia fibers function as guiding scaffolds, and CHL1 is a molecular signal for organization of stellate cell axon arbors and directing their innervations of PC dendrites (Huang et al., 2007; Williams et al., 2010).

5.4.3 Activity-Dependent Remodeling of Inhibitory Synapses

Several lines of evidence indicate that $GABA_A$ receptor-mediated signaling coordinates pre- and postsynaptic maturation during activity-dependent development of inhibitory synapses (Huang, 2009; Huang and Scheiffele, 2008; Huang et al., 2007). For example, altering GABA synthesis by manipulating the expression of GAD67 greatly influences inhibitory synaptic innervation in the visual cortex (Chattopadhyaya et al., 2007). Acute suppression of the γ2 subunit of $GABA_A$ receptor not only disrupts $GABA_A$ receptor clustering but also reduces innervations of the γ2-deficient neurons by GABAergic terminals (Li et al., 2005). In cerebellar PCs, genetic deletion of the α1 subunit of $GABA_A$ receptor in mice causes complete loss of functional $GABA_A$ receptors and synaptic inhibition in PCs by P18 (Fritschy et al., 2006). Morphologically, GABAergic synaptic terminals from stellate cells are reduced by 75%, whereas basket cell synapses on PC soma are not affected. During postnatal development, GABAergic terminals from stellate cells are initially formed normally onto PC dendritic shafts. PCs of the α1 knockout mice transiently express α3 subunit and have functional $GABA_A$ receptors during early postnatal development (Patrizi et al., 2008). However, subsequent down-regulation of α3 results in complete loss of GABAergic currents and a decreased rate of GABAergic synaptogenesis (Patrizi et al., 2008). Simultaneously, ectopic mismatched synapses begin to be formed between GABAergic terminals and PC dendritic spines (Fritschy et al., 2006; Patrizi et al., 2008) on which normally glutamatergic excitatory terminals make synaptic contacts. Interestingly, the postsynaptic adhesion molecule neuroligin-2 is correctly targeted to inhibitory synapses lacking $GABA_A$ receptors, whereas neuroligin-2 is absent from the mismatched synapses albeit the presence of GABAergic terminals (Patrizi et al., 2008). These results indicate that $GABA_A$ receptors are not required for the formation of synapses, but they appear to be crucial for activity-dependent regulation of synaptic density, presumably through promoting the stabilization of transient axodendritic contact into mature inhibitory synapses.

5.5 SUMMARY AND CONCLUSIONS

The cerebellum provides a good system to study how microcircuits are formed during peri- and postnatal development. The cerebellar cortex consists of only seven types of neurons, that is, PC, GC, basket cell, stellate cell, Golgi cell, Lugaro cell, and unipolar brush cell, and there are two glutamatergic excitatory afferents. The PC is the sole output neuron of the cerebellar cortex and inhibits neurons in the DCN. Bergmann glia, the characteristic astrocyte in the cerebellar cortex, plays multiple roles in neural circuit formation and synaptic transmission such as migration of GCs and guidance of stellate cell axons. The neural circuits made by these cell types and afferents are basically the same throughout the cerebellum.

In the first section of this chapter, we briefly described the cell types and the synaptic organization of the cerebellum and how these cells are generated and migrate to their final positions. We also mentioned the mediolateral compartmentalization based on olivocerebellar projection and some molecular background of the compartmentalization.

In the second section, we made an overview of postnatal development of CF–PC synapses, which is one of the best-studied examples of synapse elimination in the brain. Shortly after birth, each PC is innervated by multiple CFs with similar synaptic strengths on the soma. Subsequently, a single CF is selectively strengthened during the first postnatal week. Then, at around P9, only the strongest CF ('winner' CF) starts to extend its innervation to PC dendrites. In contrast, synapses of the weaker CFs ('loser' CFs) remain on the soma and the most proximal portion of the dendrite, and they are eliminated progressively during the second and third postnatal weeks. From P6 to P11, the elimination proceeds independently of PF–PC synapse formation. From P12 and thereafter, the elimination of weaker CFs requires normal PF–PC synapse formation and is dependent on the PF synaptic inputs that activate mGluR1 and its downstream signaling in PCs.

In the third section, we described how PF synapses are formed and maintained on dendritic spines of PCs. We introduced a recent hot topic that Cbln1 interacts with GluRδ2 on PC dendritic spines and neurexin on PF terminals and that the GluRδ2–Cbln1–neurexin system stabilizes and maintains PF–PC synapses. We also mentioned that mGluR1-mediated calcium signaling in PC dendrites causes release of BDNF and maintains presynaptic function of PFs. Furthermore, we showed that innervation territories of PFs and CFs on PC dendrites stand on the equilibrium caused by heterosynaptic competition between PFs and CFs and homosynaptic competition between multiple CFs.

In the fourth section, we summarized how GABAergic inhibitory synapses from basket and stellate cells are targeted to the PC's AIS and dendrites, respectively. Basket cell axons seem to be guided to PC's AIS following the gradient of neurofascin, a member of L1CAM. This gradient is caused by cross-linking of neurofascin to ankyrin-G that is localized to AISs. On the other hand, stellate cells direct their axons along Bergmann glia fibers to PC dendrites. The association of stellate cell axons to Bergmann glia fibers is mediated by CHL1, another member of L1CAM. We also mentioned that GABA$_A$ receptors appear to be crucial for activity-dependent regulation of the density of inhibitory synapses on PCs.

The cerebellum has been attracting many neuroscientists who pursue the mechanisms of synapse formation, synapse elimination, and synapse remodeling. The small number of cell types and little regional variation in the layer structure and synaptic organization in the cerebellum enable us to perform quantitative and detailed morphological and electrophysiological analyses, when compared to other brain areas. An example is the study of developmental synapse elimination. While this process is intensively studied in peripheral synapses such as neuromuscular junction and autonomic ganglia, it is generally very difficult to do detailed analyses of synapse elimination in the CNS because of small synapse size, heterogeneity and abundance of synaptic inputs to each neuron, and the complexity of synaptic organization. The CF to PC synapse is one of a few examples in the CNS in which developmental synapse elimination can be studied quantitatively by electrophysiological and morphological techniques. Synapses from retinal ganglion cells to the lateral geniculate nucleus and those from the lateral lemniscus to the ventral basal thalamus are also known to undergo massive elimination during postnatal development and have been studied intensively. Formation of inhibitory topographic map in the auditory brainstem is another example in which developmental refinement occurs through synapse elimination. As for the molecular and cellular mechanisms, developmental synapse elimination at CF to PC connection is best characterized among the four types of synapses, as detailed in this review. Thus, CF synapse elimination is an excellent model system for the study of developmental synapse refinement, which is comparable to that of the visual cortex.

The topics introduced in this chapter, that is, CF synapse elimination, maintenance of PF synapses through GluD2-cbln1-neurexin interaction, and targeting of basket cell and stellate cell axons to PCs, are breakthroughs in this field of neuroscience. Continuing researches on cerebellar microcircuits will elucidate fundamental mechanisms of the formation, elimination, maturation, and maintenance of neural circuits in developing CNS.

6.1 INTRODUCTION

Dendritic spines are the principal site for excitatory transmission in the brain. Since their description by Ramon y Cajal and Tanzi at the end of the nineteenth century, dendritic spines have been at the focus of intense research aimed at understanding their function in the processing of neuronal activity. The initial belief that they could play a role in learning and memory processes actually has received strong support from numerous studies that have analyzed their morphological and functional properties. First, dendritic spines exhibit important activity-dependent forms of plasticity that affect both their strength and structural organization, contributing in this way to information processing. Second, recent developments in confocal imaging techniques have provided evidence that spines are dynamic structures that can grow and be eliminated throughout life and thus make possible a continuous adaptation of brain circuits to experience. Third, at the molecular level, dendritic spines, and particularly their postsynaptic density, the region where receptors are located, form a highly complex structure in terms of protein composition, diversity, and implicated signaling mechanisms, illustrating the key role played by dendritic spines in signal integration. Finally, progress in the genetic identification of molecular defects underlying human diseases has provided strong evidence that alterations of a wide array of synaptic proteins lead to important

cognitive and behavioral disorders, establishing a direct link between dendritic spine synapses and higher brain functions.

6.2 GENERAL MORPHOLOGICAL CHARACTERISTICS OF DENDRITIC SPINES

Dendritic spines are mostly found on cortical excitatory neurons. They can however also be found on inhibitory interneurons such as cerebellar Purkinje cells, spiny stellate cells of basal ganglia or olfactory granule cells. Spines are also found in invertebrates, for example in mushroom bodies in flies or arthropods, and many of the properties described here also apply to these other types of spines.

A major characteristic of dendritic spines is their high level of morphological variability (Figure 6.1(a)). To make sense of the functional implications of this variability, researchers have tried to classify them according to various morphological criteria, including size, shape, organization of the spine and/or postsynaptic density (PSD), or presence of specific organelles revealed in electron microscopic (EM) studies. In the rat hippocampus, where most studies of dendritic spines have been performed, the size of the spine head determined by the length of the largest diameter varies between 0.2 and 1.3 μm, which roughly corresponds to volumes of 0.004–1.2 μm^3; thus, corresponding to variations differed by a factor of about 300. These variations in spine volume usually also are correlated with variations in the size of the PSD, size of the presynaptic terminal, and presence of various organelles in the spine: large spines are more likely to contain a spine apparatus or ribosomes.

Dendritic spine synapses are composed of several different elements. The PSD is a highly organized structure characterized by a high density of receptors and channels, associated signaling proteins, adhesion molecules, and cytoskeletal elements assembled together by a variety of scaffold proteins. It represents the contact zone, where synaptic transmission occurs. PSD size, measured with three-dimensional (3D) EM reconstruction, can vary widely, between 0.008 and 0.54 μm^2 at hippocampal CA1 excitatory synapses (Harris and Stevens, 1989). The shape of the PSD is also quite variable and in most cases, it appears on 3D EM reconstruction as a single, macular area, but more complex shapes are not uncommon and particularly have been associated with increased synaptic remodeling and possibly receptor content and turnover (Ganeshina et al., 2004; Geinisman et al., 1993; Toni et al., 1999, 2001). These include PSDs interrupted in the middle, often referred to as perforated PSDs, or PSDs composed of two or multiple individual parts that may correspond to separate transmission zones, referred to as segmented PSDs (Figure 6.1(b)). Synapses with complex PSDs are mostly present on large mushroom-type spines and may represent, depending on conditions, between 5% and 25% of all PSDs.

The postsynaptic membrane of dendritic spines is separated from the presynaptic terminal by a synaptic cleft (Figure 6.1(a)) that is usually 10–20 nm wide and contains dense material binding the two membranes together. The exact content of the synaptic cleft material is not known, but it likely consists of transsynaptic fibrils that often are regularly spaced (Zuber et al., 2005).
FIGURE 6.1 EM illustrations of the variability of spine and PSD size and shape. (a) Spine heads of different sizes and shapes (nos 1–5). Spine no. 1 is of a thin type, spine nos. 2–5 are of mushroom type. PSDs in spines 2 and 4 are of a complex shape. Arrow points at spine apparatus in spine no. 4. Spine nos. 1, 4, and 5 contact the same presynaptic bouton (multi-synaptic bouton). Arrows in spine no. 2 point at a complex PSD. Astrocytic processes surrounding this synapse are marked with asterisks. Scale bar 0.5 μm. (b) 3D reconstructions of different types of PSDs (macular, U-shaped, perforated, segmented, and multi-innervated spine with two separate PSDs, shown with contacting presynaptic boutons).

Dendritic spines are almost always in contact with a presynaptic bouton formed by an enlargement of the axonal shaft and filled with synaptic vesicles containing neurotransmitter that is released at the presynaptic active zone facing a PSD (Figure 6.1(a)). In addition, spine synapses are often surrounded by fine astrocytic processes (Figure 6.1(a)) that may contribute to synaptic network functions by controlling the local synaptic environment and coordinating synaptic activity and plasticity (Genoud et al., 2006; Haydon, 2001; Lushnikova et al., 2009; Volterra and Meldolesi, 2005; Witcher et al., 2007).

Dendritic spines may also contain several intracellular organelles. About half of them have what is referred to as the spine apparatus composed of smooth endoplasmic reticulum (ER) (Spacek and Harris, 1997). Smooth ER forms a continuous network throughout dendritic segments and spines (Cooney et al., 2002) and is likely to be important for regulating calcium content, local protein synthesis, or both. Confocal imaging has shown a continuity of spine ER with dendritic ER and a surprisingly high degree of turnover in individual spines (Toresson and Grant, 2005). Ribosomes are often found at the base of dendritic spines. They are either associated with ER or free in the cytoplasm and serve local protein synthesis. Free polyribosomes showed redistribution from dendritic shafts into enlarged spines after induction of long-term potentiation (LTP), pointing at the importance of local synthesis for synaptic plasticity (Bourne et al., 2007; Ostroff et al., 2002). Spines may contain endosomal systems consisting of clathrin-coated vesicles and pits, large uncoated vesicles, tubular compartments, multivesicular bodies, and multivesicular bodies–tubule complexes. The recycling endosomes, the part of the system that transports membrane-bound proteins onto and off the cell surface, is of particular importance for activity-related delivery of glutamate receptors to the synapse, as well as for activity-induced structural plasticity of spines (Park et al., 2006; Racz et al., 2004). Another important component of dendritic spines is actin filaments (F-actin). They constitute a major element of dendritic spine cytoskeleton and as such play an essential role in many aspects of spine formation, plasticity and dynamics (Hotulainen and Hoogenraad, 2010). Finally, microtubules, a major cytoskeletal element of dendrites and small unmyelinated axons, are generally absent from dendritic spines. However, recent studies have provided evidence for the presence of microtubules in a small portion of dendritic spines. Notably, growing microtubule ends can transiently enter dendritic spines, interact with F-actin binding protein cortactin, and presumably modulate actin dynamics in the spine in an activity-dependent fashion (Hu et al., 2011; Jaworski et al., 2009). A recent EM study, using a special microtubule-stabilizing fixative, demonstrated the presence of microtubules in CA1 dendritic spines after strong LTP induction and suggested that they could be implicated in AMPA receptors (AMPAR) trafficking to stimulated PSDs (Mitsuyama et al., 2008).

6.3 VARIATIONS IN SPINE SYNAPSE ORGANIZATION

Although the significance of the variability in spine size and shape is still largely unclear, one distinction that has emerged as potentially meaningful is between spines with a large head, a constricted neck and a large PSD (usually referred to as mushroom type spines: Figures 6.1(a) and 6.2(e)), and long and thin spines, with a small head and a filopodia-like shape (often referred to as thin spines: Figures 6.1(a) and 6.2(d)). There is now evidence that these two classes of spines may have different functional properties and could correspond to different phases of the life of a spine: thin spines representing immature, newly formed protrusions that are less likely to remain stable, while mushroom type spines would represent mature, stable spines that have undergone a process of activity- or plasticity-mediated enlargement and remodeling (Bourne and Harris, 2007). Along with mushroom spines and thin spines, which represent more than 80% of all excitatory spines in mature tissue, several other protrusion morphologies or spine structures have been reported under particular developmental or activity conditions.

A first type of protrusion, mainly seen during the early phases of synaptic network development, is comprised by filopodia (Figure 6.2(c)). Filopodia are typically referred to as long, very motile protrusions devoid of an enlargement at the tip. They can grow and retract within minutes and have been shown to be able to transform into dendritic spines. They are therefore believed to represent precursors of dendritic spines (Ziv and Smith, 1996). Filopodia are mainly seen during early stages of development, where they can represent up to 20% of all protrusions, but their proportion then decreases with maturation, so that in mature tissue they constitute only a few percent depending upon criteria used to identify them. A clear distinction between filopodia and thin spines is indeed often difficult. At the EM level, filopodia are often defined by the absence of a PSD at the tip, while with confocal imaging it is the absence of enlargement at the tip and their motility that best characterize them. Filopodia may sometimes express a PSD, which is then usually located at the base or along the length of the protrusion. Formation and stability of filopodia appears to be controlled by calcium transients present in the developing dendrite (Lohmann et al., 2005) and their growth seems to be targeted, as they are able to form transient contacts specifically with excitatory axons and not with inhibitory ones (Lohmann and Bonhoeffer, 2008).
FIGURE 6.2   EM illustrations of different types of excitatory synapses. (a) Two presynaptic terminals (magenta) making shaft synapses (red) on the dendritic shaft (blue), cut transversally, with a mitochondria in the center surrounded with endoplasmic reticulum. (b) Stubby spine on a dendritic segment (blue) with a macular PSD (red). (c) Filopodia. (d) Thin spine with a macular PSD. (e) Mushroom spine with a complex PSD and spine apparatus (arrow). (f) Two spines (s) sharing a common presynaptic bouton (multi-synaptic bouton). (g) Multi-innervated spine (s) with two different PSDs (arrows) contacting two different presynaptic boutons. (h) Cortical spine (s) with excitatory (top) and inhibitory (bottom) synaptic contacts. Scale bars for the top and bottom rows: 0.5 Mm.

While filopodia grow directly from dendrites, thin and motile protrusions extending from dendritic spines can also be observed. These have been referred to as spinules, and they are usually associated with spines having large heads and complex PSDs. Their occurrence appears to be promoted by glutamate application and seems to require AMPAR transmission (Richards et al., 2005). They could therefore result from a reorganization of the spine actin cytoskeleton mediated by synaptic activity and thus be associated with activity- or plasticity-mediated spine remodeling.

Other particular categories of synaptic contacts are made up of shaft and sessile synapses. Shaft synapses are contacts made by an axonal bouton directly on a dendritic shaft (Figure 6.2(a)). In adults, most shaft synapses seen on major apical dendrites are actually formed by inhibitory contacts, but a fraction of them may also be excitatory. Overall, excitatory shaft synapses represent less than 10% of all excitatory synapses in mature tissue. This proportion, however, is higher during development and may also vary as a function of neuronal type and brain region. It has been shown that shaft synapses can give rise to dendritic spine synapses through the extension of a protrusion (Marrs et al., 2001). Alternatively, shaft synapses could also result from the retraction of dendritic spines. Finally, they might have specific functions, as their contribution to signal integration in dendrites is more important than for spine synapses. Consistent with this interpretation, their formation and number appear to be specifically regulated by a signaling system implicating ephrin B3 (Aoto et al., 2007).

Synaptic contacts can also be made on short dendritic protrusions devoid of a neck; these are referred to as stubby or sessile spines (Figure 6.2(b)). They probably represent an intermediate stage between excitatory shaft synapses and spine synapses with a neck. At the EM level, they usually constitute only a very small proportion (in the range of a few percent) of all protrusions in mature tissue. Reportedly, their number is modulated by activity and induction of LTP (Chang and Greenough, 1984).

While most spine synapses are formed between individual axonal boutons and dendritic spines, there are examples where a single axonal bouton contacts multiple dendritic spines (also referred to as multiple spine bouton, Figure 6.2(f)) and cases where a single spine is contacted by multiple axonal boutons (forming multi-innervated spines, Figures 6.1(b) and 6.2(g)). These cases are usually quite rare, representing only a few percent of all synaptic contacts in mature tissue, but their occurrence has been shown to increase under developmental or plasticity conditions. Notably, an increase in multiple spine boutons has been reported following induction of LTP, with the additional interesting feature that in many cases the two spines contacted by the same axonal boutons arose from the same dendrite (Toni et al., 1999). This observation was therefore interpreted as indicating a process of new spine growth and synapse formation triggered by induction of plasticity. Similar images of multiple spine boutons have also been reported when analyzing the development and integration of new neurons in the hippocampal dentate gyrus (Toni et al., 2007) or under conditions of spine growth promoted by whisker trimming in the somatosensory cortex (Knott et al., 2006). These results therefore suggest that images of multiple spine boutons could reflect a transient competition for the same presynaptic boutons between a pre-existing spine and a newly formed one, and thus translate an ongoing process of synaptogenesis.

Multi-innervated spines are similarly rather infrequent in mature tissue, reaching 2–3% of all protrusions. Recent analysis of the mechanisms underlying this particular synaptic configuration has revealed the role played by the transsynaptic release of nitric oxide (NO) by the growing spine. Under conditions where this release is enhanced, it promotes the differentiation of nearby axonal shafts into presynaptic boutons and the formation of additional synaptic contacts on the same spine. Conversely, blockade of NO production during development is associated with a reduction in the formation of spines and synapses (Nikonenko et al., 2008). As the production of NO at synapses is linked to the level of expression of scaffold proteins such as PSD-95 or SAP97 (Poglia et al., 2010), one might consider the possibility that the formation of a multi-innervated spine occurs as a result of enhanced growth of the PSD. Also, as the strength of a synapse correlates with the size of the PSD, multi-innervated spines could reflect the existence of highly potent synaptic contacts.

Finally, there are also cases of excitatory dendritic spines that bear at the same time an inhibitory synaptic contact (Figure 6.2(h)). This situation is not seen in all tissues and has been mainly reported at spine synapses in different cortical areas. In the somatosensory cortex for example, the proportion of these spines with excitatory/inhibitory synapses is low under control situations, but can markedly increase as a result of strong, lasting sensory stimulation (Knott et al., 2002). The mechanisms underlying the formation of these particular spine synapses are currently unknown, but could represent a means for controlling the level and specificity of excitation in cortical regions.

6.4 MOLECULAR COMPOSITION AND SIGNALING MECHANISMS

Excitatory dendritic spine synapses represent one of the most complex biological structures in terms of their molecular composition and diversity. Despite their small size, dendritic spines contain and express more than 1000 different proteins often organized in multi-protein signaling complexes (Emes et al., 2008). Additionally, synaptic proteins very often exist in different subtypes that confer subtle functional properties.

A central mechanism targeted by many synaptic regulators appears to involve the control of the trafficking of synaptic proteins, among which are receptors and PSD-associated proteins. At excitatory synapses, multiple neurotransmitter receptor subtypes (NMDA, AMPA and metabotropic receptors) are usually expressed and further characterized by various subunit compositions and distinct biophysical properties. These receptors are embedded in a matrix of scaffolding proteins, which together with adhesion and signaling molecules constitute the PSD. Structurally, the PSD is a large network of interconnected protein assemblies, one important function of which might be to regulate the number and subunit composition of the receptors present at the synapse.

Regulation of these mechanisms likely occurs in a number of different ways, but a key role therein is certainly played by synaptic activity. At many excitatory synapses, high-frequency trains of stimulation are able to trigger specific signal transduction pathways that serve as important mechanisms for the regulation of synaptic strength. Changes in synaptic efficacy are currently viewed as the most prevalent molecular model for mechanisms of information processing, learning and memory (Cooke and Bliss, 2006). Numerous forms of synaptic plasticity and changes in synaptic strength have been reported at central synapses depending on brain region, cell type, and age. Some of these are short-lasting such as facilitation or post-tetanic potentiation, but the most interesting forms result in long-lasting changes in synaptic efficacy (Bliss and Collingridge, 1993). These may lead either to increases or to decreases in synaptic strength (Dudek and Bear, 1993) and involve pre- or postsynaptic mechanisms

(Nicoll and Malenka, 1995). The best-known example of synaptic plasticity is probably the form of LTP that is expressed at CA1 hippocampal synapses. In this type of plasticity, the change in synaptic strength is triggered by an activation of postsynaptic NMDA type of glutamate receptors (NMDAR) leading to calcium fluxes in dendritic spines. This in turn activates signal transduction pathways, among which protein kinases – calcium/calmodulin-dependent protein kinase II (CaMKII) in particular – play an important role (Lisman et al., 2002). While the specific sequence of molecular events involved in the lasting increase in synaptic strength is still a matter of debate, much recent evidence suggests that synaptic potentiation depends heavily upon the number of receptors expressed at synapses and thus upon local trafficking of receptors within individual dendritic spines (Malenka and Nicoll, 1999; Malinow and Malenka, 2002).

One interesting hypothesis to account for the lasting changes in synaptic strength is the idea that receptors and scaffolding proteins interact to form receptor-binding slots controlling synaptic strength (Bats et al., 2007; Lisman et al., 2002). Biochemical and imaging studies indicate that the main scaffold proteins (e.g. PSD-95, SAP97, GKAP, Shank or Homer) are more densely expressed at synapses (60–400 molecules of each per synapse) than receptors and thus outnumber glutamate receptors (0–200 receptors per synapse). They have therefore been proposed to provide a structural basis for the formation of a pool of receptor-confining domains likely to account for modifications of synaptic strength. Glutamate receptors, especially AMPARs, exhibit a high level of lateral mobility within membranes and can exchange rapidly at synapses in a way that is highly sensitive to activity (Triller and Choquet, 2008). Synaptic stimulation or calcium uncaging reduce AMPAR diffusion, so that active synapses tend to trap AMPARs more efficiently than inactive synapses (Borgdorff and Choquet, 2002). Additionally, large PSDs capture and retain more PSD-95 than smaller PSDs and thus may favor trapping of AMPARs (Gray et al., 2006). Synaptic activity is therefore able to regulate glutamate receptor and scaffold protein dynamics at synapses, thereby providing a mechanism for activity-dependent targeting and retention of receptors at individual synapses.

Numerous proteins participate to the regulation of receptor expression at synapses. In addition to the major scaffold proteins, auxiliary transmembrane regulatory proteins (TARPs), PDZ proteins and protein kinases also play an important role (Nicoll et al., 2006). These proteins may affect not only the lateral mobility of receptors at synapses (Opazo et al., 2010) but also their intracellular trafficking, which is crucial for controlling the abundance of glutamate receptors at synapses. Within dendritic spines, AMPAR internalization is thought to occur at endocytotic zones, defined as clathrin-coated membrane domains located adjacent to the PSD (Racz et al., 2004). These internalized receptors are then transferred to recycling endosomes, which may function as a supply mechanism for providing AMPARs to synapses. Upon induction of plasticity, AMPARs are rapidly inserted at synapses, although the precise location at which this exocytotic process might take place remains unclear. Evidence suggests that AMPAR incorporation at synapses following LTP induction could occur through lateral diffusion from a pool driven to the surface primarily on dendrites (Makino and Malinow, 2009).

In addition to activity, several other signaling pathways also contribute to regulate receptor trafficking. Among these, small GTPases play a particularly important role. GTPases form a large family of proteins characterized by their ability to bind and hydrolyze GTP. They generally act as molecular switches affecting various biological activities regulating growth and migration of many cell types. Their action is therefore not restricted to neurons and synapses. GTPases cycle between an active GTP-bound and inactive GDP-bound state and are tightly regulated by a variety of modulators, many of which are either activity-dependent or linked to signaling from synaptic adhesion molecules. At synapses, GTPases appear to control receptor trafficking in different ways, either directly or through their action on the actin cytoskeleton or the local translation machinery (Boda et al., 2010). Ras and Rap, for example, are two GTPases that exert opposing effects on the regulation of AMPAR delivery to synapses. Ras activation promotes the trafficking of GluA1-containing AMPARs from a deliverable pool located near the PSD to the synapse, while stimulation of Rap signaling promotes spine shrinkage, removal of GluA2/3 containing AMPARs and depression of synaptic transmission (Kielland et al., 2009).

It is interesting that changes in synaptic strength are also associated with a remodeling of potentiated synapses. Repetitive confocal imaging of identified synapses upon induction of plasticity has shown that the changes in synaptic strength are accompanied by an enlargement of the dendritic spine head which correlates with the increased sensitivity to glutamate (Matsuzaki et al., 2004). This effect is rapid and can be long-lasting. Although its significance is still unclear, these results indicate that remodeling of the spine architecture through modifications of the actin cytoskeleton is part of the processes that underlie plasticity. Regulation of the actin cytoskeleton is a complex process that involves different signaling pathways, among which are the small GTPases Rac and Cdc42. Much recent evidence suggests that this cascade could participate in the regulation of spine size. By integrating activity and transsynaptic signals through adhesion molecules such as N-cadherin or EphrinB receptors, this pathway could tightly control

the function of the actin cytoskeleton through PAK, LIM kinase, or cofilin-dependent mechanisms and in this way regulate the growth, size, and morphology of spines (Penzes and Jones, 2008; Tolias et al., 2007). Another pathway implicated in the regulation of the spine actin cytoskeleton could integrate signals from the extracellular matrix (Gundelfinger et al., 2010). The importance of this signaling is particularly well illustrated by studies of matrix metalloproteases (MMPs), which degrade the extracellular matrix and markedly affect synaptic structure and function. One of them, MMP9, is associated with enhanced activity, is required for LTP at hippocampal synapses, and mediates through integrin signaling spine enlargement and synaptic potentiation (Wang et al., 2008). The extracellular matrix additionally plays an important role in controlling the lateral diffusion of membrane proteins at synapses by forming compartments that might affect plasticity properties (Frischknecht et al., 2009).

Another mechanism likely to play an important role in the functional maturation and plasticity properties of excitatory spine synapses is the local regulation of protein synthesis. Pharmacological inhibition of protein synthesis interferes with induction of plasticity and much recent evidence indicates that activity is able to promote a local translation of messenger RNAs in dendritic spines (Kelleher et al., 2004). This is associated with a redistribution of polyribosomes into large dendritic spines upon induction of LTP (Ostroff et al., 2002). At the molecular level, evidence points to an activity-mediated translation of proteins such as CaMKII or Arc (Bramham, 2008) that could play a role in mechanisms of synaptic plasticity by regulating actin dynamics, spine size, and the organization of the postsynaptic density.

6.5 MECHANISMS OF SPINE FORMATION

There appear to be at least two different processes through which new excitatory spine synapses can be formed. One includes as an initial step the growth of a very motile protrusion, the filopodium, which extends from the dendrite up to several microns and then makes contact with potential partners before eventually retracting into the form of a dendritic spine. Filopodia are mainly seen during early phases of synaptic development, when the distance to potential partners is greater (Ziv and Smith, 1996). Due to their high motility, they are ideally suited to explore the space around the dendrites searching for appropriate binding partners.

How exactly they contribute to synapse formation remains poorly understood. Filopodia have been shown to make repeated, transient contacts with axons, which in some cases can be stabilized, over a range of minutes, through the generation of calcium transients (Lohmann and Bonhoeffer, 2008). This implies a capacity of filopodia to sense their environment. It does not seem that this signaling is mediated through the neurotransmitter glutamate, since glutamate receptor antagonists do not affect contact formation by filopodia. However, specific recognition mechanisms likely play a role, since filopodia are able to discriminate between partners and never make stabilized contacts with inhibitory axons (Lohmann and Bonhoeffer, 2008). Once a contact has been made, filopodia may eventually be transformed into spines (De Roo et al., 2008a; Maletic-Savatic et al., 1999; Marrs et al., 2001; Trachtenberg et al., 2002; Zuo et al., 2005). The success rate of this process, however, seems to be variable. Imaging studies in young mice or in hippocampal slice cultures suggest that only 10–20% of filopodia may actually be transformed into spines and that most of these spines still disappear within subsequent days (De Roo et al., 2008a; Zuo et al., 2005). Filopodia might however play a more important role during early phases of development, when the probability to reach a partner is lower and the motility of the filopodium is an advantage. Recent work in fact showed that decreasing filopodia motility by interfering with EphrinB signaling reduced the rate of synaptogenesis. This effect was notably prominent in early, but not late, development (Kayser et al., 2008). This is consistent with the notion that the contribution of filopodia to synapse formation may be restricted to early development.

Several different molecules have been identified as regulating the motility and behavior of filopodia. These can be classified in two categories: "accelerators" and "brakes". The accelerators include calcium/calmodulin-dependent protein kinase II (CaMKII) (Jourdain et al., 2003), syndecan-2 (Ethell and Yamaguchi, 1999; Lin et al., 2007), and paralemmin-1 (Arstikaitis et al., 2008), which enhance filopodia formation and further accelerate spine maturation. In striking contrast, the brakes are molecules that not only induce but also maintain dendritic filopodia, thus slowing spine maturation and sometimes even causing spine-to-filopodia reversion (Furutani et al., 2007; Kumar et al., 2005; Matsuno et al., 2006; Pak and Sheng, 2003; Vazquez et al., 2004). A particularly good example of a brake molecule is telancephalin (Yoshihara et al., 2009).

In more mature tissue, time-lapse imaging has shown that new protrusions may also directly appear as spines (Engert and Bonhoeffer, 1999; Trachtenberg et al., 2002). This process, which occurs within minutes, probably accounts for about half of all protrusions formed in young hippocampal tissue (De Roo et al., 2008a; Engert and Bonhoeffer, 1999; Jourdain et al., 2003). Typically, these new spines have long necks and small heads, which sometimes makes them difficult to distinguish from filopodia, except that they are less motile. In young neurons, new spines and filopodia are produced at a high rate and seemingly in a random fashion (Lendvai et al., 2000).

Also, a significant proportion are essentially transient and tend to disappear within hours (Cruz-Martin et al., 2010; De Roo et al., 2008a; Holtmaat et al., 2005). The reasons for this are still unknown, but could be linked to a failure to find a proper partner, to establish a contact, or to sense or relay activity. There might also be specific conditions in very young tissue that do not favor the induction of plasticity and thus reduce the probability that these new spines will become stabilized (Ehrlich et al., 2007).

What are the different steps that lead to formation of a synaptic contact at nascent synapses? 3D EM reconstruction of newly formed spines *in vitro* and *in vivo* or following LTP-inducing protocols in slices has revealed that they do not seem initially to express a PSD (De Roo et al., 2008a; Knott et al., 2006; Nagerl et al., 2007). Consistent with this, EM analyses in the cortex or hippocampus have shown the existence of a small population of spine-like protrusions devoid of PSD or even without presynaptic partners, suggesting that spine growth could precede synapse formation (Arellano et al., 2007; De Roo et al., 2008a; Knott et al., 2006). The speed of this process appears to be quite variable. Based on morphological criteria (presence of a postsynaptic density on 3D EM reconstruction or expression of PSD-95-EGFP), the formation of mature synapses appears to require between 5 and 24 h. However, functional analyses of spine sensitivity to glutamate uncaging suggest that a new protrusion could respond to released transmitter much faster, within tens of minutes (Zito et al., 2009). This suggests that receptors may be present or sense transmitter before a morphologically mature PSD is apparent. One principal takeaway, however, is that formation of new, functional synapses can be a fast process, taking just minutes to hours.

Another interesting set of questions pertains to the respective roles of the pre- and postsynaptic partners in regulating the formation of the new synapse. The observation that new protrusions initially grow without expressing a PSD indicates that the growth of the protrusion is probably initiated postsynaptically. Similarly, recent evidence indicating that the control of the number of PSDs and contacts made on a spine is regulated by the postsynaptic release of nitric oxide (NO) further suggests a primary role for the postsynaptic side in the control of the formation of a contact with a given partner (Nikonenko et al., 2008). However, there is also evidence indicating a role for active axon terminals in the promotion of spine growth. Notably, presynaptic activity and glutamate have been shown to promote spine growth (Maletic-Savatic et al., 1999; Richards et al., 2005). In addition, new protrusions seem to prefer to grow towards axonal boutons with active synapses (Knott et al., 2006; Toni et al., 2007); conversely, activated presynaptic boutons may grow filopodia-like protrusions that establish synaptic contacts (Nikonenko et al., 2003). These observations therefore suggest that glutamate may also act as a trophic factor that could guide new protrusions to active boutons. Additionally, a great variety of adhesion and signaling molecules expressed either on pre- or postsynaptic structures have been shown to promote synapse formation even between non-neuronal partners (Dalva et al., 2007; Han and Kim, 2008). The process of synapse formation is therefore very likely to depend upon complex signaling mechanisms linked to numerous secreted or membrane-bound molecules present on both pre- and postsynaptic structures.

6.6 SPINE DYNAMICS AND DEVELOPMENT OF SYNAPTIC NETWORKS

In vivo analyses of spine behavior over periods ranging from minutes to days and months has revealed that spines are very dynamic structures that exhibit various forms of motility and morphological remodeling. A first type of motility initially reported in cultures, but also described *in vivo*, relates to fast (seconds to minutes) twitching of spine heads that has been linked to a continuous rearrangement of the actin cytoskeleton (Fischer et al., 1998; Majewska et al., 2006). Although this form of motility has been associated with activity and experience-dependent plasticity (Oray et al., 2004), its significance in terms of synapse function and properties remains unclear. One possibility is that this spine twitching relates to the mechanisms of protein turnover, which is particularly high in dendritic spines. Proteins such as PSD-95, Ras, or Shank3 have been shown to redistribute between synaptic and dendritic pools within a few minutes to a few hours (Gray et al., 2006; Tsuriel et al., 2006). These trafficking mechanisms might possibly require a continuous rearrangement of the actin cytoskeleton.

On a different timescale, spines have also been shown to undergo a continuous turnover through a process of formation and elimination (Figure 6.3(a)). The rate of spine growth and disappearance is particularly high during development and critical periods when the main organization of the cortical synaptic network is established (Cruz-Martin et al., 2010; Lendvai et al., 2000; Zuo et al., 2005). Spine turnover then decreases with brain maturation but remains effective at a low level even in adult mice (Grutzendler et al., 2002; Trachtenberg et al., 2002). Quantification of spine turnover in various brain regions has been difficult and shows great variability. In mice, turnover rate can affect as many as 5–20% of total spines per hour during the first weeks after birth, decreasing to about 5–10% per week at 1 month of age and 1–2% per month in adult
FIGURE 6.3 Confocal images illustrating spine dynamics in hippocampal slice cultures. (a) Dentritic segment of a CA1 pyramidal neuron expressing eGFP and imaged at 24 h interval. Plus and minus signs indicate newly formed and lost spines. Scale bar: 1 μm. (b) Enlargement and stabilization of a stimulated spine in a cell expressing mRFP and loaded with the calcium indicator Fluo4-AM. Line scan analysis of the spine observed at time 0 h showed an increased calcium transient upon electrical stimulation of a group of CA3 cells. Theta burst activation of this spine resulted in an enlargement of the spine head 5 h later and promoted the persistence of the spine over the next 48 h. Scale bar: 1 μm. (c) Line scan analyses through the spine illustrated in (b) and showing the red (mRFP) and green (Fluo4-AM) signals. Scale bars: 0.5 μm; 0.5 s. (d) Stimulated spines show a significantly increased stability over the next 48 h than non-stimulated spines (n=37 and 44 spines analyzed).

tissue (Cruz-Martin et al., 2010; Holtmaat and Svoboda, 2009); however, these values vary quite substantially depending on the cortical region or cell type analyzed, the criteria used for analysis, and the experimental approach. For example, the possible effects of anesthesia must be considered (De Roo et al., 2009). Despite this vartiability, the important message delivered by these studies is that remodeling of synaptic connections is very substantial during development and remains a significant phenomenon throughout life. Further interesting information provided by these experiments concerns the lifetime of a synapse. Analyses of spine stability over weeks or months have shown that not all spines have the same lifespan. While many new spines appear to be very transient, others may persist for prolonged periods of time, up to years under *in vivo* conditions (Grutzendler et al., 2002; Holtmaat et al., 2005). Consistent with the changes in spine dynamics, the fraction of persistent spines also increases as a function of development, with more than 95% of spines surviving months in adult tissue.

An important issue regarding the mechanisms of spine dynamics pertains to their contribution to the function and development of brain networks. Repetitive imaging approaches have shown that stimulation protocols that are used to induce LTP are associated with the growth of new protrusions (Engert and Bonhoeffer, 1999; Maletic-Savatic et al., 1999; Nagerl et al., 2007;

Toni et al., 1999). This growth process can, however, also be associated with an increased elimination of spines and thus involves a more subtle control of spine dynamics (De Roo et al., 2008b; Nagerl et al., 2004). Sensory stimulation and motor learning have both been reported to stimulate an increase in spine turnover, leading to modifications of network organization (Holtmaat et al., 2006; Wilbrecht et al., 2010; Xu et al., 2009; Yang et al., 2009). Similarly, in the visual cortex, monocular deprivation and restoration of binocular vision are associated with marked changes in spine dynamics and spine density (Hofer et al., 2009). All of these results suggest a strong link between functional plasticity and specific synaptic rearrangements.

The question, however, is to understand the specificity of these synaptic rearrangements and how they may affect brain networks at a functional level. An important hint is provided by studies of spine dynamics in relation to induction of synaptic plasticity. When LTP is induced at a group of synapses, several structural rearrangements can be observed (Figure 6.3(b–c)). First, stimulated synapses enlarge (De Roo et al., 2008b; Ehrlich et al., 2007; Harvey and Svoboda, 2007; Kopec et al., 2007; Matsuzaki et al., 2004), a process closely correlated with the accumulation of AMPAR at the synapse (Zito et al., 2009) and the reorganization of the actin cytoskeleton (Honkura et al., 2008). Spine size and synaptic efficacy are thus tightly linked.

A second important characteristic of potentiated synapses is that they are switched to a stable state (De Roo et al., 2008b). This effect is very specific for potentiated synapses since unstimulated synapses tend to undergo elimination (Figure 6.3(d)). How this activity-dependent structural remodeling of spines confers stability on them is still unclear. The close correlation existing between spine head size, PSD size, receptor number, and stability suggests that the phenomenon could be non-specifically related to the amount of receptors and proteins accumulated at the synapse: larger spines with larger PSDs express more adhesion and cross-linking molecules and are more stable. An important aspect to consider in this interpretation is that the size of spine heads shows continuous fluctuations over time (De Roo et al., 2008b; Holtmaat et al., 2005; Yasumatsu et al., 2008). Small spines can enlarge and retract over periods of days. This would suggest that stability, together with PSD size and strength, could continuously fluctuate according to the activity history of the synapse. Another interpretation, however, might be that there exist specific molecular events able to reinforce spine stability. For example, it has been suggested by ultrastructural analyses that stabilization could be provided through the acquisition by the potentiated spines of the machinery for mRNA translation. This would allow local regulation of protein synthesis and trafficking and thus confer independence and stability to the spine (Bramham, 2008; Ostroff et al., 2002; Steward and Falk, 1985). Additionally, this could be associated with the expression at the synapse of specific proteins able to stabilize the cytoskeleton or anchor pre- and postsynaptic structures. Recent evidence suggests that N-cadherin could play such a role (Mendez et al., 2010a). N-cadherin is expressed on both sides of the synaptic cleft and is involved in the formation of homophilic binding domains, which might account for the periodic protein complexes observed across the cleft (Zuber et al., 2005). Expression of dominant-negative mutant N-cadherin or knockdown of N-cadherin expression leads to the formation of unstable synapses. Conversely, expression of N-cadherin is associated with a synapse-specific increase in stability. Additionally, N-cadherin expression is regulated by synaptic activity, and it is selectively expressed in potentiated synapses upon induction of LTP, leading to a switch in stability of synapses. A main function of LTP during development might therefore be to promote stabilization through a change in the composition of the PSD and, importantly, an increase in the expression of the adhesion molecule N-cadherin.

The third important structural change induced by induction of LTP is an increase in spine dynamics. This process also shows specificity. Following induction of plasticity, growth predominantly takes place at the vicinity of stimulated synapses, promoting in this way the formation of clusters of activated synapses (De Roo et al., 2008b). This might have important consequences, particularly for spines on remote dendrites, where spatiotemporal clustering of synaptic activity may play an important role for information processing (Nevian et al., 2007). Additionally, spine elimination also occurs in a very selective manner, since the process concerns mainly unstimulated spines. Thus, the changes in spine dynamics triggered by patterns of activity will affect differentially synaptic connections by favoring clustered activity with new partners, while eliminating inactive synapses. Together, these studies indicate that during development, plasticity mechanisms not only change synaptic strength, but also act as a major process organizing the wiring of synaptic networks. By switching stimulated synapses to a persistent state and additionally promoting the replacement of unstimulated synapses by new ones, LTP operates as a selection mechanism that maintains connections mediating coherent, synchronized activity, while, at the same time, favoring adaptation of the network. This fine-tuning process could be particularly important during critical periods, ensuring the specificity of network development, and may serve as an efficient learning and memory system. In keeping with this interpretation, *in vivo* work analyzing spine dynamics associated with a learning task in motor cortex found that memory of the task was associated with an increase in spine turnover and a selective stabilization of newly formed spines over the course of months (Xu et al., 2009; Yang et al., 2009).

In addition to activity patterns inducing synaptic plasticity, spine growth or elimination appears to be also regulated by a number of other homeostatic processes. One factor that seems to be very important for the regulation of spine dynamics during critical periods of development is the balance between excitation and inhibition (Hensch et al., 1998; Morishita and Hensch, 2008). In the visual cortex, alteration of this balance markedly affects the onset, formation, and plasticity of ocular dominance columns. This process, which is directly related to mechanisms of spine formation and pruning (Hofer et al., 2009), is regulated by GABAergic inhibition. Recent work has identified an important functional, bidirectional recruitment of fast-spiking interneurons during experience-dependent plasticity (Yazaki-Sugiyama et al., 2009). Also, in a manner consistent with this, the application of anesthetics to developing cortical tissue promotes a rapid enhancement of spine and synapse formation leading to a marked increase in spine density on pyramidal neurons (De Roo et al., 2009). Interestingly, this control by the excitation/inhibition balance could still persist even in the adult visual cortex. Recent experiments show that the removal of a molecular brake responsible for the age-dependent loss of visual plasticity demonstrates

the persistence of a control by the excitation/inhibition balance and suggests that the mechanisms which reduce adult structural plasticity could work by adjusting this balance (Morishita et al., 2010).

In addition, growth factors and hormones are also very likely to participate in the regulation of spine dynamics. For example, there is strong evidence suggesting an important role for estrogens in the regulation of spine formation and density (McEwen, 2010). The effect is rapid and affects spine growth but not spine elimination (Mendez et al., 2010b); it may thus represent a homeostatic mechanism for adapting spine density and the complexity of synaptic networks through changes in spine dynamics.

6.7 SPINE ALTERATIONS AND BRAIN DISEASE

Alterations of dendritic spine morphology or function represent key features of various developmental psychiatric disorders and neurodegenerative diseases. In the last two decades, progress concerning the identification of genetic alterations associated with mental retardation and autism spectrum disorders has revealed that, in many instances, these defects concern genes coding for synaptic proteins or proteins involved in the regulation of synaptic properties (Bourgeron, 2009; Laumonnier et al., 2007; Ropers, 2006). Analyses of the underlying mechanisms using gain and loss of function approaches have revealed various kinds of alterations, especially defects affecting spine morphology, spine density, or synaptic plasticity. One of the best examples of intellectual disability is probably the fragile X syndrome linked to the silencing of the fmr1 gene (Bagni and Greenough, 2005). The protein coded by the fmr1 gene (FMRP) is associated with polyribosomes in dendrites and spines, and can be found in dendritic RNA granules that travel on microtubules in dendrites. FMRP is thus believed to play a role in the regulation of local translation at individual synapses, acting both as translational suppressor and/or activator. The main defects reported in Fmr1 knockout mice include an increased spine density with more long, thin, tortuous spines reminiscent of immature filopodia-like spines, as well as defects in synaptic plasticity characterized by impaired cortical LTP and enhanced metabotropic glutamate receptor (mGluR)-mediated long-term depression (LTD). This has led to the hypothesis that FMRP could function as a negative feedback mechanism to suppress mGluR-stimulated translation implicated in LTD and the endocytosis of AMPARs (Huber et al., 2002). As such, knockdown of FMRP is believed to result in an increased mGluR-dependent removal of surface AMPARs, and evidence suggests that this defect could be corrected by antagonists of metabotropic receptors (Dolen et al., 2007).

Several other mutations of synaptic proteins identified as associated with cognitive disabilities, autism spectrum disorders, or even schizophrenia also result in dendritic spine abnormalities. This is the case for oligophrenin, PAK3, ARGHEF6, SynGAP, Shank, and EPAC2, but defects have also been reported in a mouse model of the 22q11 syndrome, a condition at high risk for schizophrenia, or following interference with disrupted-in-schizophrenia 1 (DISC1) (Boda et al., 2004; Govek et al., 2004; Node-Langlois et al., 2006; Sala et al., 2001; Vazquez et al., 2004; Woolfrey et al., 2009). In many of these cases, the synaptic defects include an increase in the fraction of long, thin and immature spines, and this is also often associated with alteration of glutamate receptor recycling. These results have therefore led to the hypothesis that cognitive disability could primarily result from alterations of dendritic spine plasticity, either because of defects in receptor recycling mechanisms that affect synaptic strength or because of alterations in spine formation, maturation, or dynamics that could interfere with the development and specificity of synaptic networks (Boda et al., 2010).

In addition to these developmental psychiatric disorders, spine pathology has also been observed in association with degenerative diseases such as Alzheimer's disease (Selkoe, 2002; Spires et al., 2005), Parkinson's disease (Day et al., 2006), or prion disease (Fuhrmann et al., 2007). In mouse models of Alzheimer's disease, the vicinity of amyloid plaques is characterized by highly dismorphic neurites and spine loss, a phenotype that could be caused by the inhibition by amyloid oligomers of LTP mechanisms and the promotion of LTD (Wei et al., 2010). These results thus also suggest that changes in spine dynamics may provide an important contribution to the alterations and dysfunctions of neuronal networks in degenerative and memory disorders.

6.8 CONCLUSION

Dendritic spines are remarkable structures that exhibit a high degree of structural and functional specialization. They are tightly controlled by activity and signaling mechanisms that determine their properties of plasticity and their long-term maintenance in brain networks. The complexity of these regulations and their impact on the formation and function of brain circuits clearly highlight the key role played by dendritic spines in the processing of information by neuronal networks.

Cortical Columns

Z. Molnár

University of Oxford, Oxford, UK

7.1 INTRODUCTION

Modularity is a common organizational principle in all parts of the brain. The cerebral cortex exhibits a laminar and a radial organization. Cortical columns are sometimes regarded as the basic functional units in cerebral cortical processing, development, and evolution. *Cortical column* is a historic term that can refer to a vertically arranged cell constellation, a pattern of connectivity, myelin distribution, metabolic characteristics, staining property, vasculature, magnitude of specific gene expression, embryonic origin, or functional properties. The columnar organization reflects the intermittently recursive mapping of several variables under the two-dimensional surface of the neocortex in a variably independent or combined (e.g., hypercolumn) manner. The term *cortical column* is constantly evolving with the improved understanding of the organization and function of the various radially oriented groups of cells that share certain functional or anatomical properties.

Columns are ubiquitous in the brain but are in no way obligatory, and comprehensive descriptions of the various specific forms of "columns" in the brain are still evolving. To date, comparative studies have failed to identify a specific sensory, motor, or cognitive function that is specifically associated with the presence or absence of a particular form of cortical column. The developing cortex contains numerous radial determinants. Pyramidal neurons are generated in "ontogenic units" and subsequently disperse radially. It has been shown that sibling cells have a stronger tendency to establish synaptic connections with each other in the cortical plate. However, the link between the embryonic and adult columnar constellations is currently not known.

There are, therefore, several problems related to the term and concept of cortical column. (1) The often loose, general, and uncritical use of the term can be confusing. (2) Related to the lack of a universal presence of certain types of column within some cortical areas, brains, or species undermines the idea that similar building blocks comprise all cortical circuits. (3) The concept that the cortical column (or even just an arbitrary columnar unit along the depth of the cortex) has a universally constant number of neurons associated with it, with only the primate visual cortex showing a difference. (4) The lack of correlation between the absence or presence of particular types of column and specific mode of sensory or cognitive processing capacities (across the same brain or across close or more distant species). (5) Although there is evidence for the overall radial disposition of the pyramidal neuron clones and a higher probability of synapse formation between sibling cells, there is a lack of correlation between the columnar development of the brain and columns in the adult cortex.

Knowledge of the laminar and columnar organization of the cerebral cortex is continuously advancing, and with this the conceptual details of the columnar organization also is changing. The time may arrive when both the concept and the nomenclature will have to adapt to these changes.

The hypothesis of the column as the fundamental processing unit of the cerebral cortex was formulated by Mountcastle (1957) from studies of cells responding to a single modality of tactile stimuli (cutaneous or deep joint receptors) in the somatosensory cortex of cats. The concept emerged from Mountcastle's work and was developed further over five decades; he claimed that the cerebral cortex can be further subdivided into "complex processing and distributing units that link a number of inputs to a number of outputs via overlapping internal processing chains" (Mountcastle, 1957).

By exploring the physiological, anatomical, genetic, and developmental properties of the cerebral cortex, more details of its organization were revealed, and many of these new entities were referred to as 'columns.' The emerging concept in cerebellar circuits by Eccles et al. (1967) fueled the quest for a fundamental cortical processing unit, an archetypical cortical column, which was intensified in the hope of identifying modules that are general for all cortical areas. There are references to functional columns, minicolumns, hypercolumns, ontogenetic or embryonic columns, ocular dominance (OD) columns, orientation columns, and barrel columns. The only common theme linking these terms is that they refer to a structural, physiological, or developmental organization that transcends the laminar pattern and is perpendicular to it. None of these several types of columns are general to all cortical areas, and several are restricted to the primary sensory areas. Table 7.1 gives three definitions and Table 7.2 gives a list of some of the terms that refer to cortical columnar structures. There are so many varieties of cortical columns defined by different criteria and by different authors that it is difficult to define, relate, or compare these columns. The concept of an archetypical cortical column is no better defined now than when it was first introduced.

In this chapter, the following points are discussed and examined: (1) the problems associated with the current nomenclature; (2) the evidence for and against the idea that columns are the common building blocks of the cortex; (3) the question of how constant the cell numbers are within a column and how homogeneous is the structure of the various columns; (4) the possible functions of the columns; and (5) the current knowledge of the columnar development in the cortex.

TABLE 7.1 Examples for definitions of cortical columns

1. Mountcastle (1997) "The modular organization of nervous systems is a widely documented principle of design for both vertebrate and invertebrate brains of which the columnar organization of the neocortex is an example. The classical cytoarchitectural areas of the neocortex are composed of smaller units, local neural circuits repeated iteratively within each area. Modules may vary in cell type and number, in internal and external connectivity, and in mode of neuronal processing between different large entities; within any single large entity they have a basic similarity of internal design and operation. Modules are most commonly grouped into entities by sets of dominating external connections. This unifying factor is most obvious for the heterotypical sensory and motor areas of the neocortex. Columnar defining factors in homotypical areas are generated, in part, within the cortex itself. The set of all modules composing such an entity may be fractionated into different modular subsets by different extrinsic connections. Linkages between them and subsets in other large entities form distributed systems. The neighborhood relations between connected subsets of modules in different entities result in nested distributed systems that serve distributed functions. A cortical area defined in classical cytoarchitectural terms may belong to more than one and sometimes to several distributed systems. Columns in cytoarchitectural areas located at some distance from one another, but with some common properties, may be linked by long-range, intracortical connections."

2. http://en.wikipedia.org/wiki/Cortical_minicolumn
   "A cortical column, also called hypercolumn or sometimes cortical module, [1] is a group of neurons in the brain cortex, which can be successively penetrated by a probe inserted perpendicularly to the cortical surface and which have nearly identical receptive fields. Neurons within a minicolumn encode similar features, whereas a hypercolumn 'denotes a unit containing a full set of values for any given set of receptive field parameters.' [2] A cortical module is defined as either synonymous with a hypercolumn (Mountcastle) or as a tissue block of multiple overlapping hypercolumns (Hubel & Wiesel).

   Various estimates suggest there are 50–100 cortical minicolumns in a hypercolumn, each comprising around 80 neurons. An important distinction is that the columnar organization is functional by definition, and reflects the local connectivity of the cerebral cortex. Connections 'up' and 'down' within the thickness of the cortex are much denser than connections that spread from side to side."

3. Boucsein et al. (2011) http://www.ncbi.nlm.nih.gov/pmc/articles/PMC3072165/ "This slightly ambiguous term loosely describes the concept of vertically arranged groups of cells that share certain functional and/or anatomical properties and could represent a 'basic functional unit' in cortical processing. They are ubiquitous in the brain but in no way obligatory, and a comprehensive description of the various forms of 'columns' in the brain is still lacking."

7.2 THE CORTICAL COLUMN NOMENCLATURE REFLECTS THE HISTORY OF CHANGING CONCEPTS OF CORTICAL ANATOMY, FUNCTIONAL REPRESENTATION, AND DEVELOPMENT

7.2.1 Is the Isocortex Hexalaminar?

The cortex (hereafter referring to the forebrain 'neocortex' as distinct from the olfactory and hippocampal three-layered cortex) is organized horizontally into six laminae and vertically into groups of cells linked synaptically across and along the horizontal layers. The definitions of both laminae and radial modules are a historic convention rather than a biologically or functionally related demonstrable reality. All mammalian cerebral neocortices have a uniform laminar structure (therefore also called the isocortex) that has been historically and arbitrarily divided into six layers (Brodmann, 1909; Lorente de Nó, 1922, 1949; von Economo and Koskinas, 2008). This basic master plan is modified according to variations. These variations expose the problem of fitting the hexalaminar universal model to all mammalian cortices. Subdivisions of layers III, IV, V, and VI in some species, missing layers (IV) in some cortical areas, or fused layers (II/III) in other areas indicate that there is uncertainty and a random element to current laminar nomenclature (Molnár, 2011; Molnár and Belgard, 2012).

The radially oriented apical dendrites and processes and the general radial orientation within the cortex have been widely known since the cerebral cortex was first examined microscopically (see, e.g., Cajal, 1909). Also, the vertical connectivity linking neurons across cortical layers was described by Lorente de Nó (1938) in the primary somatosensory cortex of the mouse. The concept of a column emerged from the functional properties of the cortex and received attention after Vernon Mountcastle discovered that the neurons are arranged vertically (or radially in the convoluted cerebrum) in the form of columns spanning the width of the primate somatosensory cortex with cells in each column responding with distinct receptive field properties (superficial as compared to deep skin receptors) to a single receptive field at the periphery (Mountcastle et al., 1957). Although it is now known that these functionally distinct 'columns' were separate, distinct cortical areas and not functional units within a cortical area (Kaas et al., 2011), these observations drove further discoveries of an array of iterative neuronal groups (also called modules) that extend radially across cellular layers VI to II with layer I at the top. Subsequently, Hubel and Wiesel (1968) revealed the orientation and OD columns in the primary visual cortex, and this was followed by the observations of Abeles and Goldstein (1970) in the primary auditory cortex (Table 7.2). These physiological observations led to the

TABLE 7.2　Examples for terms that refer to columnar structures in the cortex

Module	Cortical area	Definition	Dimension	References
Cortical column/module	S1	Penetrations parallel to the pial surface and crossing the vertical axis of the cortex pass through 300–500-μm blocks of tissue in each of which neurons with identical properties are encountered. Sharp transitions are observed from a block with one set of properties to the adjacent block with different properties. The defining property for place is the peripheral receptive field, the zone on the body surface within which an adequate stimulus evokes a response of cortical cells	300–500-μm	Mountcastle (1957), Powell and Mountcastle (1959)
Ocular dominance column	V1	Ocular dominance (OD) columns or OD stripes are regions of neurons in the visual cortex that respond to the stimulation from either the left or right eye, and they can be defined both anatomically and physiologically	Variable	Hubel and Wiesel (1969)
Orientation columns	V1	Form orientation slabs that measure 0.5–1.0 mm in the iso-orientation direction and in which a full 180° rotation of orientation preference is repeated	560 μm	Hubel and Wiesel (1968)
Blobs	V1	Metabolic activity 2DG or cytochrome oxidase staining Blob cells respond differentially at low spatial frequencies (1.1 cycles per degree), interblob cells at higher frequencies (3.8 cycles per degree)	150-μm diameter, most prominent in layers II and III. Repeat intervals of 500–550 μm; the parallel rows are 350-μm apart	Hendrickson and Wilson (1979), Wong-Riley (1979), Livingstone and Hubel (1984)
Isofrequency bands	A1	Neurons of similar frequency preference are arranged in isofrequency bands (IFBs) across the primary auditory cortex (AI) of many mammals	No wider than 200 μm and 5–7 mm in length extending across the gyrus	Tunturi (1950), Brugge and Merzenich (1973)
Binaural summation columns	A1	Most neurons arrayed in a column perpendicular to the cortical surface display the same aural dominance and binaural interaction Summation columns occupy about two-thirds of the area sampled; suppression columns, about one-third. Within most suppression columns, the contralateral ear was dominant. Within summation columns, aural dominance varied. Summation columns appear to be composed of smaller columns differing in aural dominance	The sizes of binaural interaction columns vary considerably; some occupy several square millimeters of cortical surface. At least some binaural interaction columns occupy strips of cortex oriented orthogonal to isofrequency contours	Imig and Adrián (1977)
Motor columnar aggregates	Motor cortex	Pyramidal and nonpyramidal cells are clustered into columnar aggregates	300 μm wide, separated by 100-μm cell-sparse zones	Meyer (1987)
Motion columns	MT	Neurons in monkey MT with similar axes of motion preference are arranged in vertical columns, and these columns are themselves arranged in slabs in which a full rotation of 180° of axis of motion is represented	400–500 μm	Albright et al. (1984)

TABLE 7.2 Examples for terms that refer to columnar structures in the cortex—cont'd

Module	Cortical area	Definition	Dimension	References
Shape and face recognition columns	Homotypical inferotemporal cortex	Require moderately complex features (shapes and faces) for their activation		Gross et al. (1972), Perrett et al. (1992)
Microcolumns	All cortical areas	The dendrites of 3–20 large pyramidal cells of layer V form clusters that ascend together through layer IV	These modules are −30 µm in diameter and coccur with center-to-center spacing that varies from 20 to 80 µm; the wider spacing occurs in the larger brains of the macaque monkey and man	Fleischhauer et al. (1972), Peters and Walsh (1972)
Barrels	Some rodent S1	Cytoarchitectonic patterning of the layer IV neurons forming a ring-like structure on tangential sections	Variable 300 µm	Woolsey and van der Loos (1970)
Synaptic ZN	Monkey primary visual cortex	Synaptic Zn patches correspond to a subset of corticocortical terminations		Dyck et al. (2003)
VGLUT-2 columns	Rat and mouse barrel field	VGLUT-2 marker for thalamocortical termination	Variable 300 µm	Liguz-Lecznar and Skangiel-Kramska (2007)
Ontogenic units/columns	Monkey	The progenitor cells that generate the minicolumn	Each proliferative unit in the ventricular zone of the monkey consists of 3–5 stem cells, a number that gradually increases to 10–12 stem cells during development; the units are separated by glial septa (Rakic, 1988)	Rakic (1988)
Domains	Early postnatal rat cortex	Domains of spontaneously coactive neurons using optical recordings of brain slices labeled with the fluorescent calcium indicator fura-2 in early postnatal rat cortex	The functional domains were 50–120 µm in diameter on tangential slices; they spanned several cortical layers and resembled columns found in the adult cortex in coronal slices	Yuste et al. (1992)

concept that "neurons within a given column are stereotypically interconnected in the vertical dimension, share extrinsic connectivity, and hence act as basic functional units subserving a set of common static and dynamic cortical operations that include not only sensory and motor areas but also association areas subserving the highest cognitive functions" (Jones and Rakic, 2010). The inclusion of the highest cognitive functions was, of course, an extrapolation that lacked evidence. The concept that the cortex comprises similarly structured units is an attractive one, but it seems that there are far too many variations and individual units that can be highly specialized and vary within certain cortical areas, or sectors within areas.

7.2.2 The Loose and Uncritical Use of the Term in Ways That Are So Generalized as to Be Unhelpful and Even Confusing

Although the anatomical and functional columnarity of the neocortex has never been in doubt, over time and with more discoveries of radial arrangements in the cortex, the term 'cortical column' became looser as columns were defined by cell constellation, pattern of connectivity, myelin content, staining property, magnitude of gene expression, or functional properties (Rockland, 2010; Table 7.2). Although the term column is used by some to refer only to: 'interconnected neurons, with common input, common output, and common response properties extending through the thickness of the cortex,' others do not use these criteria, and the term 'column' evolved into a loose and somewhat ambiguous term referring to some aspect of the vertical organization of the cortex (Table 7.1, third definition).

Montcastle's definition of a column in 1997 is different from the one formulated in 1957, and it includes references to physiological, anatomical, and embryological aspects: "The basic unit of the mature neocortex is the *minicolumn*, a narrow chain of neurons extending vertically across the cellular layers II–VI, perpendicular to the pial surface. Each minicolumn in primates contains 80–100 neurons, except for the striate cortex where the number is 2.5 times larger. Minicolumns contain all the major cortical neural cell phenotypes, interconnected

in the vertical dimension. The minicolumn is produced by the iterative division of a small cluster of progenitor cells, a polyclone, in the neuroepithelium, via the intervening ontogenetic unit in the cortical plate of the developing neocortex" (Mountcastle, 1997).

This excerpt shows how, over the decades, the increasingly protean imagery evoked by the term 'column' now obliges investigators to acknowledge its conceptual and linguistic shortcomings (Rockland, 2010). Structural, functional, and embryological definitions are used loosely, and there is a lack of proper and unequivocal definitions. Therefore, it is difficult to define what constitutes a particular 'cortical column.' Moreover, the use of the terminology is not stringent. Most columns have no definable 'solid' borders; some of the structures referred to as a column do not extend across the entire thickness of the cortex from the pial surface to the white matter (e.g., barrels, microcolumns). The term 'column' has become too general. To convey the complex aspects of cortical organization adequately, additional adjectives are required to specify a particular entity. Mountcastle used the terms column and module interchangeably, but nowadays the term module is used more loosely. Other terms, such as 'patch' or 'domain,' suffer, to varying degrees, from the same problem (Rockland, 2010).

7.3 A LACK OF UNIVERSAL PRESENCE OF CERTAIN COLUMNS WITHIN CORTICAL AREAS, BRAINS, AND SPECIES IS UNDERMINING THE IDEA THAT SIMILAR BUILDING BLOCKS COMPRISE ALL CORTICAL CIRCUITS

7.3.1 The Use of Physiological Methods to Reveal Columns

Evidence for neocortical columnar organization was initially obtained in electrophysiological studies of single neurons in the somatic sensory cortex in anesthetized cats and monkeys (Mountcastle, 1957; Powell and Mountcastle, 1959). Microelectrode penetrations made normal to the pial surface encounter neurons in each cellular layer with similar properties of place and modality. Penetrations parallel to the pial surface and crossing the vertical axis of the cortex pass through 300–500-μm-sized blocks of tissue in each of which neurons with identical properties are encountered. Sharp transitions are observed from a block with one set of properties to the adjacent block with different properties. The defining property for place is the peripheral receptive field, the zone on the body surface within which an adequate stimulus evokes a response of cortical cells. To reveal the functional modularity in the cortex, 2-deoxyglucose,

optical recordings of intrinsic signals, voltage- and calcium-sensitive dyes, and expression of immediate early genes have also been used in both somatosensory and visual cortical areas (Horton and Adams, 2005).

7.3.2 Columnar Organization of Some Afferent and Efferent Projections

Both intrinsic and extrinsic cortical connections are often patchy and appear columnar in cross sections of the cerebral cortex. Various anterograde tracers injected *in vivo* are often dramatically patterned in cross section, especially in layer IV and adjacent layers. The problem here is that, very commonly, a patchy distribution of label that may involve only one or two laminae at most is interpreted as columnar, whereas the label can be a stripe, area, or spot, and the 'column' is projected to the structure because of the investigator's interpretation (Figure 7.1). By contrast, cortical or thalamic terminations in layer I are, in fact, transcolumnar, typically extending over several millimeters. "Bundles of axons from cells of thalamic modules project to columnar zones of termination in layers IV and IIb of the postcentral cortex, forming clusters separated by zones in which terminals are much less dense. Clustering obtains also for the ipsilateral corticocortical and transcallosal systems" (Mountcastle, 1997).

It is widely considered that the effective unit of operation in such a distributed system is not the single neuron and its axon, but groups of cells with similar functional properties and anatomical connections (Jones, 1999, 2010). This modular arrangement might allow a large number of neurons to be connected without a significant increase in cortical volume. Mitchison (1992) estimated that fusing 100 cortical columns would lead to a tenfold increase in cortical volume. The explanation for this surprising estimate is that within a column only restricted subsets of neurons are involved in long-distance connections, whereas the majority is only connected locally within the columns. Consequently, the length of axons that interconnect neurons is shortened, also reducing the cortical volume. The hypothesis requires that nerve cells in the middle layers of the cortex, in which most thalamic afferents terminate, should be joined by narrow vertical connections to cells in layers lying superficial and deep to them, so that all cells in the column are excited by incoming stimuli with only small latency differences. Experiments in the monkey, however, did not show such homogeneous arrangement and revealed that terminal arbors of individual thalamocortical axons are often smaller than the cross-sectional width of the region that showed a response revealed by optical recording in the so-called activity columns (Blasdel and Lund, 1983; Freund et al., 1989). Thus, 'activity columns' are
FIGURE 7.1 Examples of modular circuitry in the mammalian brain. (a) Ocular dominance columns in layer IV in primary visual cortex (V1) of a rhesus monkey (autoradiograph after injection of radioactive proline into one eye). (b) Blobs in layers II–III in V1 of a squirrel monkey (cytochrome oxidase (CO) histochemistry). (c) Stripes in layers II–III in V2 of a squirrel monkey (CO histochemistry). (d) Barrels in layer IV in the primary sensory cortex (S1) of a rat (succininc dehydrogenase histochemistry). (e) Barreloids in the ventrobasal nucleus of the thalamus in a rat (succinic dehydrogenase histochemistry). (f) Glomeruli in the olfactory bulb of a mouse (Sudan Black staining). *Reproduced from Purves D, Riddle DR, and LaMantia AS (1992) Iterated patterns of brain circuitry (or how the cortex gets its spots).* Trends in Neuroscience 15(10): 362–368.

assembled from the convergence of smaller units defined by arbors in a 300–500-μm wide space and not merely by activity-related or molecular factors (Inan and Crair, 2007). Moreover, analysis of a large data set of recordings has revealed that, within a cortical column, connectivity is highly nonuniform (Song et al., 2005).

7.3.3 Modules of the Visual Cortex

The visual *cortex* processes information concerning form, pattern, and motion within functional maps that reflect the layout of neuronal circuits. The columnar organization in the primate V-1 is defined by the neuronal properties of ocularity and place imposed by geniculate input and by orientation specificity generated by intracortical processing. The neurons studied in tangential penetrations vary systematically in ocularity (Figure 7.1(a)) and orientation selectivity (Hubel and Wiesel, 1969). As the primary visual cortex has been studied in great detail, this is the area where the cortical columns have been identified most methodically: OD columns, orientation columns, hypercolumns, and alternating callosal and ipsilateral columns (see Table 7.2).

7.3.3.1 OD Columns/Stripes

OD columns or OD stripes are regions of neurons in the visual cortex that respond to stimulation from either the left or right eye, and they can be defined both anatomically and physiologically (Hubel and Wiesel, 1969). Thalamocortical projections carrying signals from one eye or the other synapse mostly within layer IV. In a normally developed visual system, the area of dominance columns for each eye is the same, and each cortical cell responds to visual input predominantly according to its column. OD columns were revealed by single unit recording and transneuronal transport across the lateral geniculate synapse of radioactive amino acids (Hubel and Wiesel, 1969). OD columns are slab-like domains; columnar width is variable as a function of the visual field; that is, they are larger in the foveal representation (Hubel and Wiesel, 1977). In the peripheral visual field representation, the slab-like confirmation breaks up into patches (Adams et al., 2007). Monocular deprivation during early life prevents this balance from developing, and the nondeprived eye assumes control of nearly all cortical cells. These effects were largely identified by Wiesel and Hubel through studies on cats and monkeys (Hubel and Wiesel, 1969).

Similarly, for OD columns of the primate visual cortex, classical anatomical and physiological studies identified core and edge regions functionally distinguished by different degrees of monocular bias (LeVay et al., 1975). More recently, different conditions of visual deprivation have revealed functional subcompartments within OD columns, visualized by either changes in
FIGURE 7.2   Variable appearance of ocular dominance columns in normal squirrel monkeys (*reproduced from Adams DL and Horton JC (2003). Capricious expression of cortical columns in the primate brain.* Nature Neuroscience *6: 113–114*). Shown are photographic montages of layer 4 C from the left striate cortex of four squirrel monkeys with normal vision 10 days after left eye enucleation. Flatmounts were reacted for CO, and examples for the individual variations are presented: (a) Large, crisply segregated columns; (b) intermediate columns; (c) fine, indistinct columns; (d) rudimentary columns. The columns are essentially absent, although hints were visible in a few peripheral regions of cortex. Note thin profiles (arrows) radiating from the blind spot in (c) and (d), which represent shadows (angioscotomas) from retinal blood vessels. Columns were virtually absent in one-third of the animals (d). MC, monocular crescent; *, blind spot.

cytochrome oxidase (CO) activity (Horton and Hocking, 1998) or differential expression of immediate early genes (Takahata et al., 2009). Species variation in columnar structure is hard to reconcile with ideas about the fundamental importance of columns. Some members of single species, for example, squirrel monkeys, show enormous variability in the expression of OD columns (Adams and Horton, 2003). Some individuals have normal OD columns throughout the visual cortex; others have them only in parts of the visual cortex, while in some, they are nearly absent (Figure 7.2).

7.3.3.2 Orientation Columns

Within an orientation column, neurons throughout the vertical thickness of the cortex respond to stimuli oriented at the same angle (Hubel and Wiesel, 1968; Hubel et al., 1977, 1978). A neighboring column will then have neurons responding to a slightly different orientation from the one next to it. The functional maps of orientation preference in the ferret, tree shrew, and galago – three species separated since the basal radiation of placental mammals more than 65 Mya ago – share this common organizing principle (Kaschube et al., 2010). Maps of orientation tuning as viewed from the cortical surface (not in sections) contain singularities where orientation columns converge (Blasdel and Salama, 1986), also called pinwheels (Bonhoeffer and Grinvald, 1991).

7.3.3.3 Gene Expression in the Cortex in 'Columnar' Fashion

Zones of heightened CO levels can reveal metabolic zones arranged in a modular fashion across the cortex (Livingstone and Hubel, 1984; Figure 7.1(b)), but these do not extend through all cortical layers. In the monkey, primary visual cortex CO staining reveals metabolic activity in a nonuniform fashion (Wong-Riley, 1979). The patches of CO activity correspond to thalamocortical terminations (Livingstone and Hubel, 1982). Adjacent sections, reactive for synaptic zinc, show patches that correspond to another subset of corticocortical terminations (e.g., Ichinohe and Rockland, 2004). There are numerous other differences that distinguish cortical modules; some of these are associated with thalamic inputs (e.g., Vglut2; 5HTT).

7.3.4 Overlap Between Columnar Entities Within the Same Structures; Combining Physiological and Anatomical Definitions

Individual columns are embedded within distributed networks, and cortical modules are composed of groups of minicolumns. The same column can be part of different networks (e.g., OD and orientation columns or hypercolumns). Despite decades of work, the organization of these modules and their connections, singly or in relation to each other, is only poorly understood. Anatomical observations are often linked to modular patterns of increased metabolic activity, blood flow studies, 2DG uptake, or expression of immediate early genes depending on the stimulus, and may be limited to a single layer, a few layers, or a whole cortical thickness. However, some of these studies revealed no discrete anatomical arrangements that would explain modularity of function, or perceived anatomical arrangements were not in line with detected physiological changes, raising the question: how can an 'imperfect' anatomical

arrangement generate functionally distinct modules? At the cellular level, there is growing evidence that cortical columns contain multiple, highly specific, fine-scale sub-circuits (Otsuka and Kawaguchi, 2008; Yoshimura et al., 2005) and that within columns, there are locally hetero-geneous response properties (Sato et al., 2007).

7.4 NUMBER OF NEURONS IN A CORTICAL COLUMN

The various cortical columns that have been described by different anatomical or physiological methods have very different sizes, shapes, and diameters (examples shown in Figure 7.1). As discussed earlier, the term cor-tical 'column' is ambiguous – it can refer to small-scale minicolumns (diameter 50 μm), to larger scale macrocol-umns (diameter – 300–500 μm), or to multiple different structures within both categories (Jones, 2000; Rakic, 2007; Rockland, 2010).

7.4.1 General Concept that the Cortical Column (Even Just an Arbitrary Unit Column that Includes the Full Depth of the Cortex) Has a Universal Constant Number of Neurons Associated with It

Although there is very little quantitative work on the number of neurons in anatomically or physiologically identified cortical columns, it is expected that they are different. It is also generally accepted that the cortical surface areas vary much more than the radial thickness of the cortex. Powell, after returning to Oxford from Mountcastle's laboratory, was influenced by the concept of the column and set out to quantify parameters within a cortical segment that had roughly the same dimensions as the physiological columns that were estimated (Jones, 1999). After quantification in selected species, it has been proposed that regardless of the thickness of the cortex within an arbitrary (30-μm-wide, 25-μm-deep) vertical 'column' between the pial surface and the white matter of the cortex, the number of neurons is 110 in all cytoarchitectonic areas (Rockel et al., 1974, 1980). Under such conditions, the neuronal number was claimed con-stant in all mammalian species (mouse, rat, cat, Old World monkey, and human) and for all cortical thick-nesses, the numbers of cells in these arbitrary columns in prefrontal, primary motor, somatosensory, (posterior) parietal, and temporal neocortex (except the primary vi-sual cortex in primates) all being the same. There was only one area in the cortex that showed a difference from this constant number; in all primates studied (galago, marmoset, squirrel monkey, macaque monkey, baboon, and human), the number per 30-μm-wide, 25-μm-deep column of the visual cortex was increased to about

260–270. This increase is a reflection of the much higher packing density of cells in the true striate cortex. In a later study with Anita Hendrickson, Powell found that the neuronal number remained constant across both the monocular and binocular segments of the macaque visual cortex (Powell and Hendrickson, 1981). The changes in packing density of neurons in the arbitrary unit columns were inversely related to the volume of neuropil.

Using similar methods in marsupials, it has been established that the neuronal numbers are half the ones observed in the mouse in a similar arbitrary unit column (Cheung et al., 2007, 2010; Figure 7.3). Using a more recent 'unbiased' stereology method, Herculano-Houzel and her colleagues showed that the density of neurons in the neocortex varies as much as three times even among the highly related primate species (Collins et al., 2010; Herculano-Houzel et al., 2008; Lent et al., 2012). In spite of these observations, it is still true that cortical expansion in evolution is achieved by expanding the cortical surface area, with relatively little change in the thickness. The ratio for the cerebral cortical surface areas in the mouse, macaque, and human is 1:100:1000, whereas for cortical thickness, it is more like 1:1:1 as it is in the range of 2–4 mm in all three species (Rakic, 2009). However, the idea that all mammalian cortices in most areas have a very similar numerical constancy has to be abandoned. In fact, the differences noted earlier might hold a key to understanding cortical specializa-tions for specific functions.

7.5 LACK OF CORRELATION BETWEEN THE ABSENCE OR PRESENCE OF PARTICULAR COLUMNS AND A SPECIFIC SENSORY OR COGNITIVE PROCESSING NETWORK (COMPARISONS ACROSS THE SAME BRAIN AND ACROSS CLOSE AND MORE DISTANT SPECIES)

7.5.1 Microscopic and Macroscopic Cell Patterning Defining Cortical Modules

Most cortical columns can be related to some forms of cellular patterning in the cortex. These can be from subtle microscopic patterns to macroscopically identifiable features. Some distinctive body attachments with charac-teristic shapes are even recognizable in the somato-sensory cortex. Examples include the barrel cortex of the mouse (Woolsey and Van der Loos, 1970), representation of the nasal probosci of the star-faced mole (Catania and Kaas, 1995), and representation of the raccoon hand (Welker et al., 1964) or primate hand (Jain et al., 1998). These visible columns received special status in neuro-biology because they helped investigators to understand questions related to synaptic plasticity and map

formation. The barrel field is one of the best studied model systems in the mouse cortex; yet, its functional significance has still not been comprehended. Are they structures without any particular function (Horton and Adams, 2005)?

7.5.2 Are Barrels Cortical Columns?

It is puzzling that barrel fields are present in rats, mice, squirrels, rabbits, possums, and porcupines, but not in raccoons, beavers, or cats (Woolsey et al., 1975). The presence or absence of barrels is not related to the presence of actively mobile whiskers (whisking behavior), as guinea pigs do not whisk but nonetheless have a barrel field. The peripheral somatic sensory input is relayed through the brainstem and the ventrobasal complex of the thalamus before it is transmitted to layer IV,

the gateway of the sensory cortical circuitry. Thalamic axons form arbors and establish synapses in a periphery-related pattern in layer IV. This pattern formed by thalamocortical axons can be present in the absence of the cytoarchitectonic pattern that was originally termed barrels by Woolsey and Van der Loos (1970) (see López-Bendito and Molnár, 2003). The individual thalamocortical axon clusters that form periphery-related patterns are first surrounded by densely packed layer IV cells that form the walls of the actual cytoarchitectural 'barrels.' In the middle of each barrel is a plexus of thalamic fibers carrying signals from one corresponding whisker (Figure 7.4). In the barrel field of the rodent somatosensory cortex, dendritic bundles are mostly located in the barrel walls and septa, avoiding the hollows (mouse, Escobar et al., 1986).

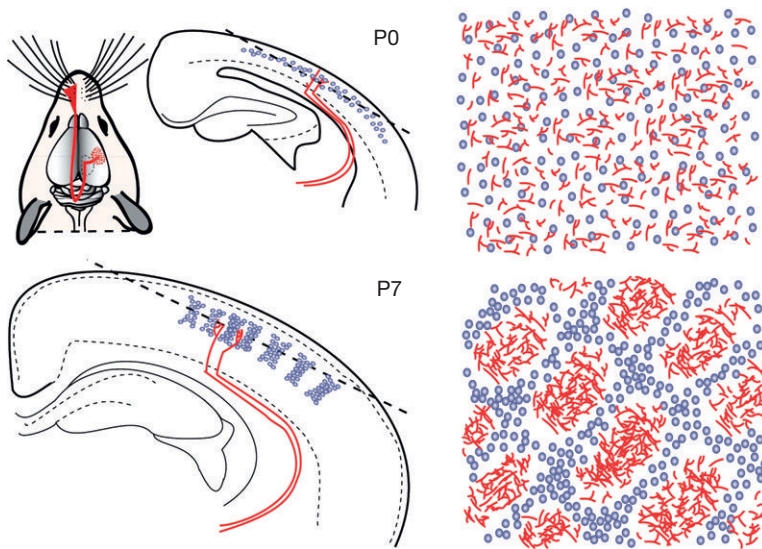
In the rodent barrel cortex, dendrites of neurons in layer IV conform to barrel limits (Harris and Woolsey,


FIGURE 7.4 Schematic overview of the development of the periphery-related thalamocortical patterning and the cytoarchitectonic barrel formation in the mouse. Thalamocortical fiber clusters arise from an initially uniform distribution of thalamocortical arbors (red), and they impose the characteristic patterning of layer IV neurons (blue). Left column represents coronal, right column tangential sections. *Reproduced from Molnár Z and Molnár E (2006) Calcium and NeuroD2 control the development of thalamocortical communication.* Neuron *49(5): 639–642.*

1979), but this seems to be an exceptional case. The best documented example of two thalamic systems in the same layer is from rodent barrel cortex (Alloway, 2008). In layer IV, thalamocortical projections from the ventral posterior medial (VPM) and the posterior nuclei target the barrels (lemniscal pathway) and their intervening septa (paralemniscal pathway), respectively. A similar segregation occurs more generally, but with segregation in different layers. The functional significance of the thalamocortical–corticocortical patterning is unknown, but could be related to differential processing by distinct postsynaptic populations. Barrels show variation in size and shape across S1. There have been few quantitative studies of the differences and their relevance.

Sakmann's group has presented a set of papers in which they define a 'standard' column in the rat somatosensory cortex as based on the topographically specific input from the large bundle of thalamocortical axons emanating from a single 'barreloid' in the VPM nucleus of the thalamus and terminating in one of the 'barrels' in the layer IV aggregations of neurons (Helmstaedter et al., 2007; Meyer et al., 2010; Wimmer et al., 2010). In this case, then, their column is of the kind defined originally by Mountcastle and not a minicolumn, although it may contain minicolumns as defined above. On the basis of measurements of concentrations of thalamocortical axon terminals labeled by green fluorescent protein expressed in their parent cells and extending the width of the periodic densities of terminations (which in layer IV are ∼300 μm wide) across the depth of the cortex, this column has a cross-sectional area of about 121 000 square microns and a depth of ∼1840 μm from the pia to white matter. A second kind of column defined by the authors has its basis in the terminations of axons arriving from

the posterior medial (Pom) nucleus of the thalamus and ending deep and superficial to the barrels and especially in the zones of reduced cell density or 'septa' lying between them. This column, as measured from septum to septum and across the intervening barrel, is thus a little wider than the column defined by inputs to the barrels; it has a cross-sectional area of approximately 124 000 square microns, but when projected across the depth of the cortex, it has the same length as the VPM-based column. The measurement of the Pom-based barrel might be rather arbitrary, as the authors describe the axons of Pom neurons as spreading horizontally for seemingly wider extents than those from VPM (Jones and Rakic, 2010).

The barrels in the rodent somatosensory cortex are not stereotyped. Hollow barrels, with cell-sparse cores, are typical of mice, young rats, and the anterolateral subfield of mature rats, but solid columns, with cell-dense cores, are typical of the main posteromedial field in rats (Rice, 1995). Variability is not reported for other columnar systems of connections, but this is likely because many of the systems are harder to visualize globally or require specialized tissue processing.

The function of the barrels in the rodent primary somatosensory cortex is not known. The cortical architecture can be missing or significantly disrupted and yet apparently remain functionally intact. For example, the disrupted barrel cortex in the reeler and in other mutant or transgenic mice is not associated with marked somatosensory deficits (López-Bendito and Molnár, 2003; Rakic and Caviness, 1995).

The degree to which the cortex is modifiable, and by what mechanisms, has been extensively investigated under various environmental manipulations. Although it is not known what the functional relevance (if any) of the

barrel arrangements may be, this system helped the understanding of various aspects of cortical circuit formation and plasticity. Study of the barrel field in various mouse mutants proved to be instrumental in the understanding of the molecular mechanisms of these interactions (Erzurumlu and Kind, 2001). The development of the periphery-related patterning of the thalamocortical projections and the induction of the cytoarchitectonic barrels require both pre- and postsynaptic interactions. During the first days of postnatal development, thalamic projections assume a periphery-related pattern within layer IV precisely mirroring the arrangements of the whiskers. Thalamocortical axon segregation is soon followed by the relocation of layer IV cells from an initially homogeneous distribution to the walls of the barrels surrounding the clustered thalamic projections (Molnár and Molnár, 2006; Figure 7.4).

Van der Loos and Woolsey (1973) provided evidence for the environmental influence on cortical cytoarchitectonic differentiation by demonstrating that changing or blocking the flow of sensory input from specific whiskers during the early stages of development results in a cascade of events that will change the arrangements and somatodendritic morphology of layer IV cells. With the development of finer techniques of clonal analysis and neuronal cell-type specification, one can anticipate a new generation of genetic and molecular manipulations that will help us elucidate the underlying mechanisms of barrel formation. Overexpression of NT3 is reported to result in an enhanced expression of dendritic bundles ('minicolumns') in the rat barrel cortex (Miyashita et al., 2010). However, it is not clear to what extent the barrels represent a general and valid model for cortical columns.

7.5.3 Microcolumns and Apical Dendritic Bundles

There are a number of examples of repeating microarrays of intracortical elements that are interpreted as conforming to a microcolumnar pattern of vertical connections. The observations on patterning of apical dendrites of pyramidal cells with somata located in layers II, III, and V have led, as noted above, to the introduction of the term minicolumns or microcolumns (Fleischhauer et al., 1972; Peters and Walsh, 1972). Innocenti and Vercelli (2010) distinguished minicolumns and bundles, whereas some investigators have used these terms interchangeably. Minicolumns of radially aligned cell bodies can be demonstrated by regular Nissl preparations or other histological methods that reveal cell bodies. Bundles are composed of the apical dendrites of pyramidal neurons whose cell bodies are in different layers and can be seen in material prepared by the Golgi

technique, stained with osmium for electron microscopical analysis, or with markers of somatodendritic morphology (e.g., microtubule-associated protein 2 or SMI32) (Peters and Walsh, 1972; Figure 7.5). Innocenti and Vercelli demonstrated bundles using retrograde transport of lipophilic tracers or intracellular injection of neurons in slice preparations (Innocenti and Vercelli, 2010). Myelinated axons are also organized in bundles; these bundles course close to those of the dendrites, and at least some of them originate from neurons whose apical dendrites are in a bundle (Peters and Sethares, 1996). Depending also on tangential location and depth, the minicolumns and bundles can be more or less sharp.

An average bundle is composed of the dendrites of 3–20 large pyramidal cells of layer V that form clusters that ascend together through layer IV. They are joined in the supragranular layers by the successive addition of the apical dendrites of pyramidal cells of layers II and III, and all ascend further, many sending their terminal arrays to layer I (Figure 7.5). Reconstructions have revealed that individual dendrites change their neighborhood relations along a bundle, superficial dendrites can be added between the dendrites from deeper layers, and individual dendrites can bifurcate to sending branches to neighboring bundles (Massing and Fleischhauer, 1973). In the monkey visual cortex, the microcolumns are estimated to consist of the dendrites of ≈142 pyramidal neurons. These modules are 30 μm in diameter and occur with center-to-center spacing that varies from 20 to 80 μm, the wider spacing occurring in the larger brains of the macaque monkey and man. Their estimated density is ≈1270 per mm^2 in the monkey visual cortex. In the visual cortex, the mean spacing between modules was found to be 60 μm in the rat, 56 μm in the cat, and 23 μm in the rhesus monkey (Peters, 1997). Not all apical dendrites from layer V enter into the composition of dendritic bundles (Rockland and Ichinohe, 2004). The presence of layer V is not considered the prerequisite to consider a bundle (Innocenti and Vercelli, 2010); however, this issue has not been investigated in mutant mouse cortex that lacks a particular subtype of layer V.

7.5.4 Complex Relationship Relations Between Minicolumns and Dendritic Bundles

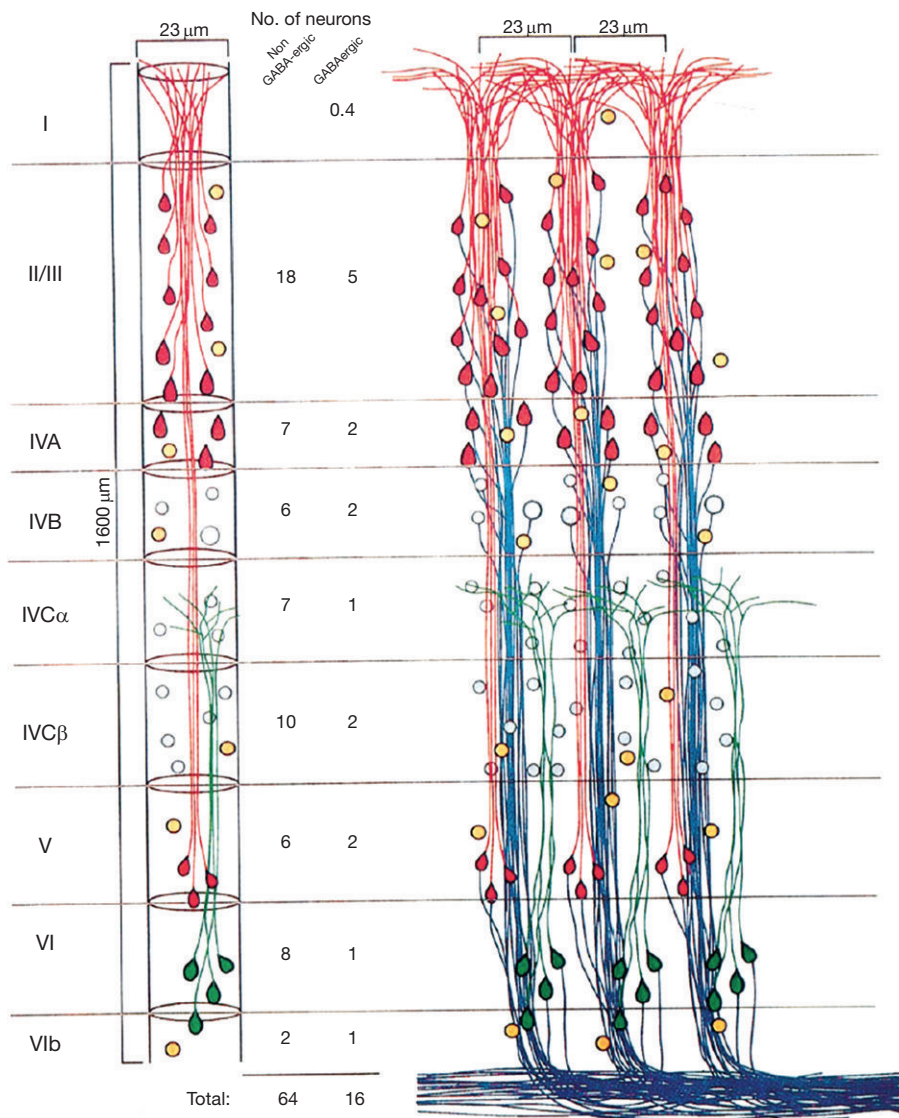
Cell bodies of neurons in a minicolumn can be seen to orient obliquely to engage their apical dendrite into the neighboring dendritic bundles already in layer V and more so in layer III (Gabbott, 2003; Peters and Kara, 1987; Peters and Walsh, 1972; Figure 7.5). The progressive addition of dendrites to the bundle from depth to surface in the cortex ('like onions held by their stem';


FIGURE 7.5 Bundles and microcolumns in the primary visual cortex of the macaque monkey. (*Reproduced from Peters A and Sethares C (1996) Myelinated axons and the pyramidal cell modules in monkey primary visual cortex.* Journal of Comparative Neurology *365: 232–255*). Left panel: Schematic representation of the arrangements of the apical dendrites of pyramidal cells. Layer II/III, IVA, and V pyramidal cells are shown in red, layer VI in green. Gray represents neurons of IVB and IVC without dendrites; azure represents GABAergic neurons. Right panel: Pyramidal minicolumns are represented adjacent to the dendritic bundles. Axons of pyramidal cells are depicted in blue.

Peters and Kara, 1987) also indicates that the bundles collect dendrites from more than one minicolumn of cell bodies (Massing and Fleischhauer, 1973; Peters and Kara, 1987; Vercelli et al., 2004).

Peters and Sethares (1996) observed that those neurons with apical dendrites in the same bundle also bundle their myelinated axons, indicating that neurons in a dendritic bundle might send their axons to the same target. Subsequently, Lev and White (1997) showed that, in the mouse area MsI, following injection of horseradish peroxidase in the contralateral hemisphere, all dendrites in a labeled bundle belonged to callosally projecting neurons, thus suggesting that dendritic bundles are target specific. This issue has been further investigated by Vercelli et al. (2004) in the visual cortex of the rat for different targets (ipsilateral cortex, superior colliculus (SC), pons, lateral geniculate nucleus, and striatum). This study strongly supports the concept that dendritic bundles are target specific. Moreover, the composition of dendritic bundles does not seem to depend on the age of the animal and is already established at P3. It is an interesting possibility that some transient elements join the bundles at early developmental stages from the early-generated neurons of the subplate. Thus, it has recently been demonstrated that subplate apical dendrites have a close association with layer V apical dendrites, having the same targets in the early postnatal barrel cortex (Hoerder-Suabedissen and Molnár, 2012). However, it is not known whether dendro-dendritic synapses occur in particular dendritic bundles or not.

Unlike what might have been expected, neurons of the same bundle are not more interconnected than neurons of different bundles (Krieger et al., 2007). There

are preferential connections between certain output neurons, interestingly between corticocortical and corticotectal neurons, whose apical dendrites lie in separate dendritic bundles in mouse (Brown and Hestrin, 2009).

Innocenti and Vercelli (2010) proposed that neurons in the different layers of one minicolumn, projecting to different targets, send their apical dendrites to separate dendritic bundles, where they join apical dendrites of neurons from neighboring minicolumns projecting to the same target or combination of targets. They propose that, in a given cortical locale (area or part of an area), an assembly of apical dendritic bundles, which includes each of the outputs to distant cortical or subcortical structures, their parent somata and basal dendrites, and the portion of the neuropil that pertains to them, constitutes a cortical output unit.

Dendritic bundles and microcolumns can be identified in all cortical areas in the cerebral cortex of different mammalian species, such as rodents, carnivores, and primates including humans. The dendritic bundling seems to offer two important advantages. It might minimize the length of the axonal arbors that contact specific neuronal classes, and in development it might simplify the axonal search and recognition of targets. The link, if any, between the minicolumn and apical dendritic bundles and functional cortical units is not yet established. The link between the anatomical organization and the physiological units is not clear.

7.5.5 Columns Outside the Mammalian Isocortex

Columnar arrangements are present in numerous structures in mammals. Iterated circuitry is present in the olfactory bulb glomeruli (Figure 7.1(f)), and in the barreloids (Figure 7.1(e)) and barrelettes in the ventrobasal thalamic nucleus and brainstem, respectively. Columnar structures are also present in the laminated structure of the SC (Harting et al., 1992; Illing and Graybiel, 1986). These are revealed by acetylcholinesterase reactivity as 200–600-μm-wide patches (Harting et al., 1992; Mana and Chevalier, 2001).

Rockland (2010) gives an overview of these patterns: "The periaqueductal gray contains longitudinal columns of afferent inputs, output neurons, and intrinsic interneurons thought to coordinate different strategies for coping with different types of aversive stimuli' (Bandler and Shipley, 1994; Keay and Bandler, 2001). The lateral septal nucleus is reported to have a complex system of chemically and connectionally distinct zones of transverse sheets (Risold and Swanson, 1998). Some thalamic nuclei have distinct domains, which are neurochemically and connectionally distinguishable (Rausell and Jones, 1991). The basal ganglia are organized into neurochemically and connectionally distinct striosomes and matrix (Graybiel and Ragsdale, 1978)."

In the cerebellar cortex, an elaborate array of modular subdivisions is revealed by histochemical markers, the topography of afferent projections and some efferent projections, and gene expression in subpopulations of Purkinje cells (PCs) (Sillitoe and Joyner, 2007; Voogd and Glickstein, 1998). Zebrin II expression in PC reveals a parasagittal stripe pattern, each stripe consisting of a few hundred to a few thousand PCs, that is highly reproducible, activity independent, and conserved across species. Other molecular and connectivity markers have an orderly relation to zebrin+ or zebrin− stripes (Larouche and Hawkes, 2006). The functional importance of this striking organization remains to be elucidated, but, as compared to the mosaicism of the SC, it has been suggested to subserve a massively parallel architecture with a high number of processing channels (Larouche and Hawkes, 2006). Minicolumn-like dendritic bundles can also be found in numerous noncortical structures (e.g., Roney et al., 1979).

7.5.6 Columns in Nonmammals

The columnar organization of the cerebral cortex is a broadly documented principle of design preserved throughout mammalian evolution (Mountcastle, 1997), and it is often considered unique to mammals. Karten has questioned the assumption of the uniqueness of the neocortical cells and circuits in mammals and has argued for a similar laminar and columnar organization in the avian brain (Wang et al., 2010). Using contemporary methods, Karten and colleagues demonstrated the existence of comparable columnar functional modules in the laminated auditory telencephalon of an avian species (*Gallus gallus*). Tracer placed into individual layers of the telencephalon within the cortical region, which is considered similar to the mammalian auditory cortex by Karten and colleagues, revealed extensive interconnections across layers and between neurons within narrow radial columns perpendicular to the laminae (Wang et al., 2010). This columnar organization was further confirmed by visualization of radially oriented axonal collaterals of individual intracellularly filled neurons. These findings indicate that laminar and columnar properties of the neocortex are not unique to mammals and may have evolved from cells and circuits found in more ancient vertebrates (Shepherd and Grillner, 2010; Montiel et al., 2012).

7.5.7 What Is the Function of a Cortical Column?

The functional rationales for the columnar organization of the cerebral cortex include arguments for 'augmenting of cortical surface area during speciation;

modular segregation of inputs; and facilitation of computation by enhancing information processing' (Purves et al., 1992). Modular clustering is believed to be important to allow a large number of neurons to be connected without a significant increase in cortical volume (Mitchison, 1992).

However, if modules are essential for information processing, why is it that they are present in some species but not in others without any noticeable perceptual differences (Horton and Adams, 2005; Purves et al., 1992)? Or, if they are essential in enhanced computation, why are they not present in higher motor and association areas (Purves et al., 1992)? The criteria for the identification for modules/columns are so diverse that it is possible that some variables that might define patchy or modular arrangements might be identified in the future.

The experimental paradigms provided by the barrel and the OD column tend to influence the way the cerebral cortex is looked at as a whole, but neither is clearly built up from microcolumnar units of cells or connections. None of these cortical arrangements is associated to a particular cognitive or perceptual ability in species where they are present or absent. Horton and Adams argue that the lack of correlation across species with or without OD columns and vision, and with or without cortical barrel field and whisker function, strongly argues for the 'lack of particular function of these striking but inconstantly expressed anatomical features' (Horton and Adams, 2005).

Dendritic bundles have been found throughout the mammalian brain and are believed to serve fundamental roles in the brain's functioning. However, no physiological experiments to determine their function have been performed on these well-established anatomical units. The function of the anatomical microcolumns as fundamental units of organization is also not clear. Much more comprehensive analysis of the intricacies of intracortical connectivity and the anatomy and physiology of microcolumns in all cortical areas of several species is needed. Combining these approaches could clarify several issues (see Bock et al., 2011). Microcolumns might represent fine-grain functional modularity of the cortex. The radial dispersion of these clusters in some columns is about 400 µm in all species, similar to the spread of some dendritic arbors.

7.5.8 Columns in Neuropathology

Cortical modules have drawn the attention of neuropathologists not because their function is known, but because they can be visualized, quantified, and compared between subjects. They might be epiphenomena, but they are detectable entities and therefore can be used as diagnostic signs for abnormal cortical organization.

The periodicities of microcolumnar structures (that contain about 11 neurons and have a periodicity of about 80 µm) were disrupted in two examples of neurodegenerative disease in human (Jones, 2000). Some alterations of the microcolumnar structures have been described in the brains of the more elderly (Peters, 1997).

Currently, it is not known what degree of radial allocation and lateral neuronal dispersion is essential for the proper radial delivery and intermixing of neuronal types in cortical columns. Alterations in the clonal dispersion of neurons have been linked to neuropsychiatric disorders associated with abnormal columnar organization (Torii et al., 2009).

7.6 WHAT IS THE CORRELATION BETWEEN THE COLUMNAR DEVELOPMENT OF THE BRAIN AND FUTURE COLUMNS?

7.6.1 Cortical Columns During Development

Mountcastle emphasized that the mode of generation of the cortex already reflects its basic columnar organization (Mountcastle, 1997). From Golgi preparations and from Nissl-stained material, the radial orientation of neurons within the developing cerebral cortex is apparent from the very beginning (Cajal, 1909). Neurons assume a radial orientation and dendritic polarity shortly after their generation. These observations triggered theories that much of the anatomical substrate for a columnar organization would already be specified at early developmental stages before activity-dependent mechanisms could be activated (Rakic, 1988).

7.6.2 Ontogenic Units/Columns – The Fundamental Building Blocks in the Developing Neocortex

There is strong evidence for the overall radial migration of pyramidal neurons in all mammalian cortices (Rakic, 2009). Clonally related postmitotic pyramidal neurons are initially deployed in a geometrically columnar pattern in the embryonic primate cerebrum. Rakic proposed that the location of the cohorts of cortical neurons from a single neuronal progenitor is not random but is largely predictable (Rakic, 1988). Each neuron in mature cortical 'minicolumns' is derived from one of a small group of progenitors forming a polyclonal group in the ventricular zone (VZ) (Kornack and Rakic, 1995).

The progenitor cells that generate the minicolumn were termed ontogenic columns (Rakic, 1988). Rakic estimated that "each proliferative unit in the ventricular zone of the monkey consists of 3–5 stem cells, a number that gradually increases to 10–12 stem cells during

development; the units are separated by glial septa" (Rakic, 1988). According to this theory the surface area, and thus the size of the neocortex, is determined by the number of ontogenetic units set by the number of symmetric divisions of progenitor cells in the neural epithelium before migration begins (Rakic, 1988, 2009). It has been suggested that one important phenomenon for the increased cerebral complexity during evolution may be the multiplication of neuronal columns throughout the cerebral cortex (Rakic and Caviness, 1995).

According to this theory, functional columns in the adult cerebral cortex must consist of several ontogenic columns (polyclones). The visual display of these ontogenetic units has not been achieved, and it is still unclear to what extent and how gene expression in the VZ could play a role in the development of discrete functional units, such as minicolumns or columns. Cell lineage experiments using replication-incompetent retroviral vectors have shown that the pyramidal neuronal progeny of a single neuroepithelial/radial glial cell in the dorsal telencephalon is organized into discrete radial clusters of sibling excitatory neurons (Kornack and Rakic, 1995; Noctor et al., 2001). Costa et al. (2009) noted that most neuronal clones derived from E13 progenitors span 150–250 μm in the horizontal axis and contribute to all cortical layers generated after that embryonic stage. The same authors performed mathematical extrapolations for injections at the onset of neurogenesis in the cerebral cortex (E10–11) and suggested that neuronal siblings would not disperse by more than 400–500 μm. Thus, both the radial and horizontal dispersions of excitatory neuronal clones fit well with the possibility that they could help to create a structural basis for the future specification of columns.

How these developmental neural clusters relate to adult anatomical and physiological columns has not been addressed. Neurons from different clones intermix with the adjacent columns as they migrate across the intermediate zone. In addition to the radial allocation of clonally related neurons, short lateral shifts and transfers from their parental to the neighboring radial glial fibers have been described (Kornack and Rakic, 1995; Noctor et al., 2001; Tan and Breen, 1993). These dispersed neurons intermix with neurons originating from neighboring proliferative units. The molecular mechanisms, their role, and the significance of this lateral dispersion for cortical development are not understood. A recent study revealed that the lateral dispersion depends on the expression levels of Eph receptor As (EphAs) and ephrin-As during neuronal migration. Torii et al. (2009) demonstrated that an EphA and ephrin-A (Efna) signaling-dependent shift in the allocation of clonally related neurons is essential for the proper assembly of cortical columns in the mouse cerebral cortex (Figure 7.6). Currently, it is not known what degree of radial allocation and lateral neuronal dispersion seems to be essential or optimal for the proper radial delivery and intermixing of neuronal types in the cortical columns. The degrees of mixing of derivatives of different progenitors have not been estimated in different species.

7.6.3 Sibling-Neuron Circuits in the Developing Columns

Thus, both the developing cortex and the adult cortical columns have overwhelmingly radial arrangements. In the developing brain, the clonally related neurons have higher chances of being situated within the same radial volume of cortical tissue (Tan and Breen, 1993). It has been proposed that the initial columnar organization may act as a seed to establish the primary information-processing unit in the cortex.

This raises the question as to whether neurons from the same clone develop connectivity preferentially. Are
FIGURE 7.6 Eph receptor A (EphA) and ephrin-A (Efna) signaling-dependent shift in the allocation of clonally related neurons changes the level of lateral dispersion in the embryonic brain. Torii and colleagues demonstrated that lateral dispersion depends on the expression levels of EphAs and ephrin-As. Increased EphAs and ephrins during neuronal migration leads to increased tangential sorting of cortical neurons. The figure represents the distribution of EYFP-labeled neurons (green or black) during development in the cortex in which control or EphA7 expression plasmid was delivered using electroporation (EP) with EYFP plasmid. Scale bars, 600 mm (for E18.8), 50 mm (for E15.5), and 200 mm (for P4). *Reproduced from Torii M, Hashimoto-Torii K, Levitt P and Rakic P (2009) Integration of neuronal clones in the radial cortical columns by EphA and ephrin-A signalling.* Nature 461(7263): 524–528.

they more likely to develop chemical synapses with each other rather than with neighboring nonsiblings? Cell lineage or clonal analysis studies have been combined with recording experiments to study the possibility that the cell lineage of single neuroepithelial/radial glia cells could form radial columns of sibling, interconnected neurons. Yu and colleagues (2009) identified individual clones of cortical pyramidal neurons by injecting enhanced green fluorescent protein (EGFP)-expressing retroviruses into the lateral ventricle of mouse embryos at early stages of neurogenesis. They made simultaneous whole-cell recordings on two EGFP-expressing sister neurons and observed that these cells displayed unidirectional synaptic connections in 35% of pairs. In contrast, less than 7% of radially situated nonsister excitatory neurons were connected (Yu et al., 2009). This experiment provides strong support for the idea that excitatory neurons generated from the same progenitor keep spatial relationships and display (mutual) connectional preferences, but it stops short of relating the clones to adult cortical columns. There is a distinction between the idea that sibling neurons have predictable arrangements and connectivity and the idea that adult columns are 'preformed' and prespecified in ontogenic units in the VZ. More work is needed to clarify these issues.

The potential molecular mechanisms involved in the establishment of sibling-neuron circuits are not known. It has been hypothesized that neurons derived from the same progenitor are more likely to display similar chemical and physical properties because of their genetic inheritance (Costa and Hedin-Pereira, 2010). Sister neurons might share more of the combinatorial transcription code that has been present in the common cortical progenitors, and therefore the sister neurons might share a similar set of surface molecules that are important for cell–cell recognition or for molecular guidance cues. The molecular determinants of the cell-intrinsic properties for cell–cell recognition between sibling neurons in the cortex remain a largely uncharted territory.

7.6.4 Transient Columnar Domains During Development

The coordinated calcium fluctuation patterns underlying gap junction-mediated communication were suggested as a possible basis for the formation of initial functional cell assemblies in the postnatal cerebral cortex. Yuste et al. (1992) observed distinct domains of spontaneously coactive neurons using optical recordings of brain slices labeled with the fluorescent calcium indicator fura-2 in early postnatal rat cortex. Their observations emphasized the discrete multicellular patterns that are mediated through communication via gap junctions. The functional domains were 50–120 μm in diameter on tangential slices; they spanned several cortical layers and resembled columns found in the adult cortex in coronal slices. In the developing somatosensory cortex, domains were smaller than, and distinct from, the barrels. Gap junctions coupled the neurons within each domain. Gap junction domains persisted after blockade of sodium- and calcium-dependent action potentials, suggesting that they may promote metabolic rather than activity-related assemblies (Kandler and Katz, 1998).

There are modules and columns within the developing cortex that are present only transiently during development, but not in the adult. Numerous stains are transient during barrel development (Erzurumlu et al., 1990; Mitrovic and Schachner, 1996). OD columns are more apparent during development or upon visual deprivation than in normal adults in the marmoset, and the presence or absence of OD columns has been debated in the adult marmoset (Chappert-Piquemal et al., 2001; Spatz, 1989). There are transient circuits that show a pattern that is transiently related to the (sensory) periphery of the vibrissae in the barrel cortex in the mouse, and this involves the neurites of the early generated and largely transient subplate neurons (Piñon et al., 2009; Hoerder-Suabedissen and Molnár, 2012). These changes in cortical patterning may reflect the development of synaptic integration that will provide coherent activity among groups of target cells, but it has been questioned whether the observed patterns themselves have any functional relevance (Purves et al., 1992). Induction of visible and distinguishable barrel patterns or of OD columns has not been linked to a particular sensory or motor capacity (Horton and Adams, 2005; Purves et al., 1992).

Prior to birth, monocular transduction pathways are already established through a process known as Hebbian learning. Spontaneous retinal activity in one eye of the developing fetus leads to neuronal depolarization (Galli and Maffei, 1988) that can propagate through the thalamus (Mooney et al., 1996). Synapses that receive multiple inputs are more likely to propagate the signal, whereas errant connections will not be sufficient to trigger another action potential. If glutamate has been released by the presynaptic axon terminal, postsynaptic neurons that depolarize become permeable to calcium ions. Calcium entry leads to a chemical process that strengthens the synapse, making it more likely to survive than other connections.

Although orientation columns can develop without any externally elicited sensory visual input (before birth), their maintenance relies on postnatal sensory-driven visual activity (Crair et al., 1998).

7.7 SUMMARY AND THE WAY FORWARD

1. There are several problems associated with the current nomenclature of columns. The concept of a

'universal cortical column' is very captivating in anatomical, physiological, and developmental models of the cerebral cortex, and this is reflected in the current terminology that aims to gloss over differences rather than expose them. There is overwhelming evidence for various forms of radial organization, and some of the modular (columnar) organizations are striking (Douglas and Martin, 2004). However, there are various types of cortical columns, and there is a need to define them more clearly as a better understanding of their properties is gained. The term 'column' might be modified or abandoned altogether when there is more information about the types of cortical circuits and the range of their operations. The term column is still used because of its captivating concept. For the time being, there is no easy alternative to 'column.' It is necessary to establish more specific terminology that will allow specific reference to particular entities. As the cell types of the cerebral cortex become better characterized morphologically, chemically, and physiologically, the details of the types of connections and circuits that they establish with one another within the cortex are becoming understood.

2. It is now known that columns/modules are characteristic of the neocortex, but there is no single structure or function that is *the* common building block of all cortical areas in all mammals. The observations made on the barrels in S1 and the OD columns in V1 have had an enormous influence on the way the cerebral cortex is looked at as a whole; however, it is increasingly apparent that this cannot be generalized to all regions. Horton and Adams write: "At some point, one must abandon the idea that columns are the basic functional entity of the cortex. It now seems doubtful that any single, transcendent principle endows the cerebral cortex with a modular structure. Each individual area is constructed differently, and each will need to be taken apart cell by cell, layer by layer, circuit by circuit, and projection by projection to describe fully the architecture of the cortex" (Horton and Adams, 2005). Under the influence of the new data, the concept will also gradually change and the elusive idea of a 'universal cortical unit' that extends radially as a homogeneous building block in all areas in all mammals may finally have to be rejected.

3. The previous finding of constant cell numbers within an arbitrary unit column and the homogeneous structure of the column is not supported by recent observations. On the contrary, it is apparent that cortical areas exhibit huge differences in cell composition, cell numbers, and connectivity (Lent et al., 2012).

4. The possible functions specifically associated with the presence or absence of a particular column (e.g., OD columns, barrels) is not clear. Comparative studies have yet to identify a specific sensory, motor, or cognitive function that is specifically associated with a particular form of cortical column. Purves and colleagues postulated that the columnar patterns arise because they are an "incidental consequence of the rules of synapse formation" (Purves et al., 1992).

5. There is overwhelming evidence for early columnar allocation of the developing pyramidal neurons. It is also evident that at early developmental stages an early organization has already been specified before activity-dependent mechanisms could take place. The link between the clonally related neuronal assemblies and future modules of the cortex is not yet clear, but with the current repertoire of methodologies, these issues can now be addressed.

8.1 INTRODUCTION

The fetal period in humans is characterized by a number of fundamental events in the construction of the nervous system, such that at birth, many of the primary circuits already have been formed and display remarkable functional performance, although development evidently continues after birth until full maturity is reached at around age 30. Considerable evidence indicates that electrical activity expressed in the human fetal brain – and in lower mammals at corresponding developmental stages – controls a number of developmental processes, including neuronal differentiation, migration, synaptogenesis, and synaptic plasticity (for review, see Ben-Ari et al., 1997; Blankenship and Feller, 2010; Feldman et al., 1999; Feller and Scanziani, 2005; Fox, 2002; Henley and Poo, 2004; Katz and Crowley, 2002; Katz and Shatz, 1996; Rakic and Komuro, 1995; and Zhou and Poo, 2004a). Probably the most thoroughly elaborated evidence has been generated by studying sensory cortices, in which development of sensory maps is critically influenced by activity from the sensory periphery. However, the physiology of the fetal central nervous system, and notably the electrical patterns of organized neuronal activity that underlie map formation, has remained obscure for a long time. This is mainly a result of technical limitations in recording electrical activity from the fetal brain in utero. An important and almost paradoxical aspect of the problem is that the fetus develops

in utero under conditions of virtually complete sensory deprivation. Knowing the importance of input from the sensory periphery for development of the nervous system raises an important question: What are the mechanisms that provide sensory stimulation to the developing sensory systems *in utero*? This question is accompanied by a number of related issues. For example, how are the early sensory inputs processed in developing circuits, and what are the specific activity patterns associated with the activity-dependent formation of the cortical maps? How are these early activity patterns generated, and how are they transformed to the mature mode of sensory processing necessary to support behavioral function?

In this chapter, we attempt to answer these questions by reviewing experimental evidence obtained in the premature human neonate and in the postnatal rodent, which seems to be an excellent model for studying the processes that occur during the human fetal development. In both systems, endogenous mechanisms for the activation of sensory pathways exist in two developing sensory systems: the somatosensory and the visual. In the somatosensory system, sensory input is generated by sensory feedback resulting from spontaneous movements. In the visual system, it is provided by spontaneous retinal waves generated in the initially light-insensitive retina. In both systems, this endogenously activated "sensory" input drives oscillatory bursts in thalamocortical networks. These central oscillations occur in a topographic manner and thus provide binding between the aligned elements of sensory circuits to create conditions for the activity-dependent formation of cortical maps. The generation of the early oscillatory patterns, which primarily include oscillations in alpha–beta and gamma frequency ranges, involves glutamatergic synapses including an input from the thalamus. The fast rhythmic components of early activities are generated primarily by α-amino-3-hydroxyl-5-methyl-4-isoxazole-propionate (AMPA) receptors at glutamatergic synapses, whereas *N*-methyl-D-aspartic acid (NMDA) receptors, also activated during the early oscillatory bursts due to summation of rhythmic input, provide conditions for NMDA-R-dependent synaptic plasticity. The local nature of early activity is generated as a result of the topographic organization of the thalamic input. Spread of early activity is limited by the delayed maturation of the long-range horizontal connections in the cortex and by surround inhibition provided by GABAergic interneurons even at a very early age. We propose a model in which the early oscillatory patterns shape early circuits according to spike-time-dependent plasticity (STDP) in localized regions.

We will finally discuss how early cortical activity patterns are related to the development of sensory signal processing and explorative functions. The main function of our brain consists of the online processing of the input from the external world and the body and the generation of an output according to previous experience and prediction. Although the early oscillatory bursts are reliably activated by endogenous mechanisms, these activity patterns are poorly suited for the exploration of the environment. Early in development, external sensory stimuli evoke all-or-none oscillatory bursts similar to those triggered by endogenously activated sensory input; however, this paradigm enables only a primitive form of sensation, not the high-frequency graded sensory processing required for explorative functions. With maturation, early oscillatory bursts disappear in association with a rapid developmental switch in the mode of sensory processing from bursting to "acuity." In the visual system, this switch occurs shortly before the onset of patterned sensory input – birth in the human and eye opening in the rat – in association with an emergence of the active cortical state. A similar switch also occurs in the somatosensory whisker-related rat barrel cortex just before the onset of active whisking. Thus, the early bursting mode of sensory signal processing is related to the development of the sensory cortex, but not to the exploration of the external world. This suggests an inside-out development of the sensory cortex, which initially is tuned to the internally generated activity at the sensory interface and serves to embed it into topographically organized sensory cortical maps and, once this is achieved and the maps are well tuned, switches to the exploration mode, enabling reliable high-frequency processing of sensory signals from the environment.

8.2 NEOCORTICAL PATTERNS IN PREMATURE HUMAN NEONATES

Determining the patterns of activity expressed in the fetal brain is a challenging task. While the standard way to characterize electrical brain activity is to record the electrical signals from the head surface using scalp electroencephalography (EEG), such recordings cannot be performed in the fetus (although some attempts have been made to record the EEG and the magnetoencephalograph (MEG) through the mother's abdomen). At present, the main approach to fetal brain activity consists of scalp EEG recordings from premature neonates. In this group of patients surveyed in specialized intensive care units, neurophysiological monitoring is a part of the standard patient examination. Evidently, as the environment is very different and the functions of many systems (cardiovascular, respiratory, and digestive) undergo significant development after birth, a question could be raised as to whether cortical activity in premature neonates is the same as in the fetus. For the most part, the answer is 'yes,' because EEG development is largely age-dependent, and the EEG patterns expressed in premature neonates match the gestational age, but not the

actual postnatal age. Moreover, studies using magneto-encephalography in the fetus *in utero* document a remarkable similarity with the temporal organization of activity and electrographic patterns observed in the gestational age-matching premature neonates. Therefore, scalp EEG from premature neonates is today considered a reliable approach to measuring fetal brain function.

Characteristic adult EEG patterns emerge essentially during the postnatal period and undergo pronounced changes in the amplitude and distribution of oscillations in different frequency bands until age 30 (Niedermeyer and Da Silva, 2005; Uhlhaas et al., 2010). Thus, the premature infant EEG displays a number of unique activity patterns. These include a number of distinct transient periods of rhythmic activity and intermittent sharp events that are expressed during certain periods of development (Anderson et al., 1985; Lamblin et al., 1999; Scher, 2006; Stockard-Pope et al., 1992). At mid-gestation, activity is dominated by intermittent delta waves from 0.3 to 2 Hz. By the 7th month, slow oscillations become intermixed with rapid rhythms. During the second half of gestation, the dominant EEG pattern in central, temporal, and rostral regions is the delta-brush (Anderson et al., 1985; Lamblin et al., 1999; Scher, 2006; Stockard-Pope et al., 1992) (Figure 8.1). Different terms have also been used in the literature to describe this pattern including spindle-shaped bursts of fast activity (Ellingson, 1958), rapid rhythm (Dreyfus-Brisac, 1962; Nolte et al., 1969; Parmelee et al., 1969), rapid bursts (Dreyfus-Brisac, 1962), spindle-like fast (Watanabe and Iwase, 1972), fast activity at 14–24 Hz (Goldie et al., 1971), and ripples of prematurity (Engel, 1975). A delta-brush consists of 8–25 Hz spindle-like, rhythmic activity superimposed on a delta wave. Often, delta-brushes occur in a sequence, and these grouped delta-brush activities may stay for up to 10 s, giving rise to so-called slow activity transients, or SATs, that, in direct coupled (DC) recordings, attain unusually large amplitudes of up to 800 μV (Vanhatalo et al., 2002, 2005). Such DC shifts are filtered and therefore not observed using conventional high-pass (>0.5–1 Hz) EEG recordings. Delta brushes are expressed in all cortical areas and fade near term. While resembling sleep spindles in some ways, delta brushes and sleep spindles appear to be distinct patterns. Sleep spindles emerge only during the second postnatal month.

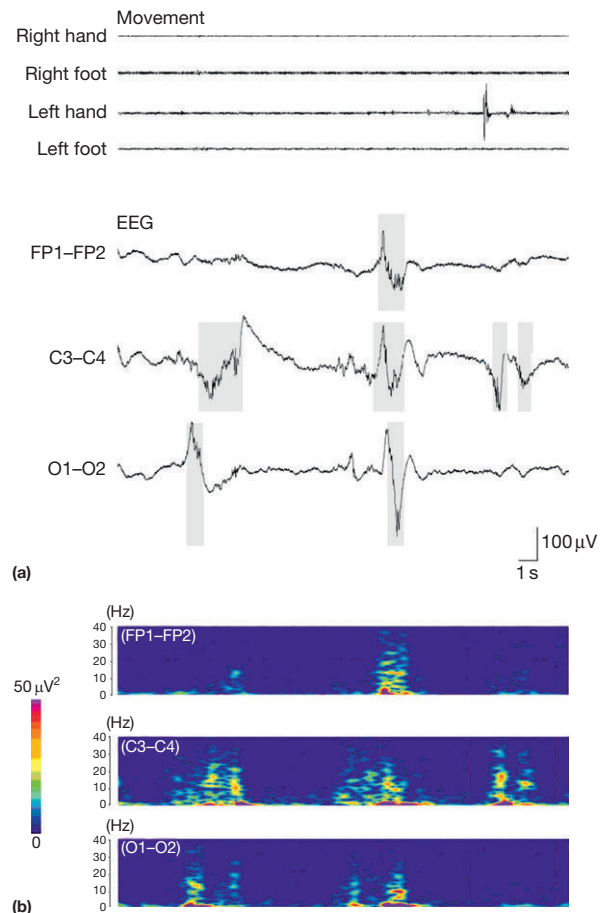
Besides delta-brushes, other patterns expressed in the premature brain include the neonatal 'delta crest' (isolated frontopolar delta waves with superimposed fast activity), midline frontal theta–alpha burst, EEG spikes and sharp transients, anterior slow dysrhythmia, and temporal sawtooth or temporal theta bursts (Anderson et al., 1985; Lamblin et al., 1999; Scher, 2006; Stockard-Pope et al., 1992). Because nearly all information about the earliest cortical patterns in humans derives from scalp-recorded EEGs of premature infants, these


FIGURE 8.1 Delta-brushes in the human preterm neonate. (a) Representative example of three simultaneous EEG traces recorded in bipolar transversal montage (frontal FP1–FP2, central C3–C4, and occipital O1–O2) during quiet sleep in a 30-week, postconceptional-age neonate. Bursts of delta waves alternate with periods of hypoactivity. Delta-brushes are characterized by alpha–beta oscillations superimposed on delta waves (gray squares). Traces above show concomitant hand- and foot-movement recordings. (b) Wavelet analysis of bipolar EEG recordings shown in (a). *Adapted with permission from Milh M, Kaminska A, Huon C, Lapillonne A, Ben Ari Y, Khazipov R (2007) Rapid cortical oscillations and early motor activity in premature human neonate.* Cerebral Cortex 17: 1582–1594.

observations alone do not inform us whether they represent pathological activity of the immature brain or the normal physiological patterns of developing neuronal networks. Addressing these issues requires simultaneous recording of neuronal spiking and EEG activity in intact developing tissue.

8.3 THE FIRST ORGANIZED CORTICAL NETWORK PATTERNS IN THE NEONATAL RODENT

Offspring of rats and mice are altricial, that is, they are born in an immature state (Clancy et al., 2001). Although it is difficult to provide exact comparisons between

humans and rodents, the level of rat brain development at the day of birth (P0) can be roughly compared to the state of human cortex at mid-gestation, and term in humans roughly corresponds to the postnatal day P12 in the rat or mouse. Therefore, postnatal rodents could be an excellent model to study the developmental events that occur during the human fetal period. However, despite a rich repertoire of activity patterns observed in preterm human neonates during the second half of gestational age, until recently no organized brain activity had been reported during the first ten postnatal days in rodents. Based on EEG recordings, organized cortical activity in infant rodents was thought to commence with the emergence of delta waves, starting from P11 (Frank and Heller, 1997; Gramsbergen, 1976; Jouvet-Mounier et al., 1970). This stands in contrast with a number of patterns of correlated activity found in the neonatal cortical slices *in vitro* (for review, see Allene and Cossart, 2010). It should be noted that recording activity in neonatal rats is technically difficult because the skull is cartilaginous, making mechanically stable, movement-artifact-free recordings difficult to perform. This problem has been solved through the development of the technique of recordings from head-restrained animals with a dental cement-enforced head cup, first under anesthesia (Leinekugel et al., 2002) and later in the nonanesthetized (Khazipov et al., 2004b) and decerebrated rat pups (Karlsson and Blumberg, 2005). At present, this technique is widely used in neonatal rats to perform intracortical recordings of the local field potential and multiple units using electrode arrays, patch-clamp recordings from individual neurons, and imaging (Colonnese et al., 2010; Mohns and Blumberg, 2008; Sipila et al., 2006; Yang et al., 2009). Using this technique, several activity patterns had been described in neonatal rodents, revealing a remarkable similarity to the activities seen in human premature neonates and enabling investigation of their underlying mechanisms. These patterns so far have been thoroughly investigated in only the sensory cortices (notably somatosensory and visual areas) and the hippocampus.

8.3.1 Spindle- and Gamma-Bursts in Somatosensory Cortex

In the neonatal rat somatosensory cortex, formation of the body map representation occurs during the first postnatal week. Because modulation of sensory-driven experience strongly influences this process during this time, this period is also known as the critical period of the somatosensory map development. During this period, thalamocortical axons grow into the neocortex and form input-specific patterns of synapses with neocortical neurons (e.g., the whisker-specific-barrel pattern

in the barrel cortex) (Erzurumlu and Jhaveri, 1990; Higashi et al., 2002; Molnar et al., 2003; Petersen, 2007; Price et al., 2006; Woolsey and Van Der Loos, 1970). Manipulations of the peripheral receptors, or of cortical activity, during this critical period can disrupt the formation of thalamocortical synapses (Cases et al., 1996; Catalano and Shatz, 1998; Feldman et al., 1999; Foeller and Feldman, 2004; Fox, 1992, 2002; Fox and Wong, 2005; Lu et al., 2006; O'Leary et al., 1994; Persico et al., 2001; Van der Loos and Woolsey, 1973; Woolsey and Wann, 1976). Pharmacological or genetic manipulations associated with a loss of function of NMDA-Rs result in malformations of barrel cortex development and functional deficits (Dagnew et al., 2003; Fox, 2002; Fox et al., 1996; Iwasato et al., 2000; Lee et al., 2005a,b; Schlaggar et al., 1993). During the critical period, thalamocortical synapses display an enhanced NMDA-R contribution and increased NMDA-R-dependent synaptic plasticity, including the conversion of 'silent' pure NMDA-R-based synapses to fully functional mixed AMPA/NMDA-R synapses, as well as switching to fast AMPA-receptor-mediated synaptic transmission from slow kainate-mediated transmission (Bannister et al., 2005; Barth and Malenka, 2001; Carmignoto and Vicini, 1992; Crair and Malenka, 1995; Daw et al., 2006; Feldman et al., 1998, 1999; Hestrin, 1992; Isaac et al., 1995, 1997; LoTurco et al., 1991; Monyer et al., 1994).

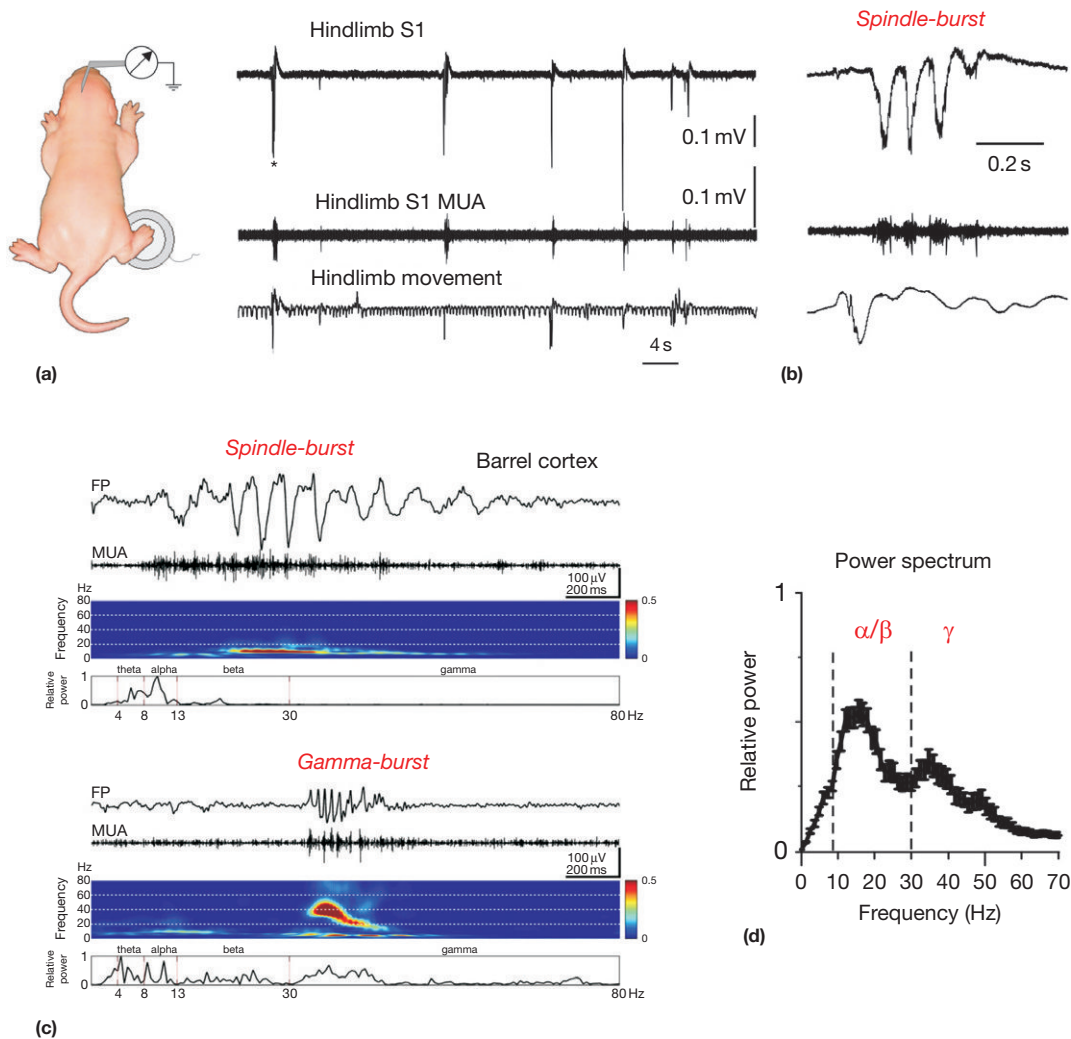
What are the patterns of cortical activity that underlie this activity-dependent plasticity during this critical period? Extracellular and patch-clamp recordings from rats during the first postnatal week revealed two predominant organized patterns of activity in the somatosensory neocortex: so-called spindle-bursts and gamma-bursts (Khazipov et al., 2004b; Marcano-Reik and Blumberg, 2008; Marcano-Reik et al., 2010; Minlebaev et al., 2007, 2009; Seelke and Blumberg, 2010; Yang et al., 2009) (Figure 8.2). Both are transient local oscillatory events, with a difference in the dominant frequency of oscillation and in the size of the recruited network. A spindle-burst is a transient burst of rhythmic, 5–25 Hz activity with a duration of approximately 1 s and a recruiting cortical zone of approximately a half millimeter. Gamma-bursts (40–50 Hz) are typically shorter in duration (150–300 ms) and are more local ($\sim$200 μm) events. Spindle bursts and gamma bursts may also intermingle. Recordings in the DC mode, without high-pass filtering of the signal, revealed that spindle bursts are associated with relatively large (up to hundreds of μV) negative delta waves. A tight temporal and quantitative correlation between the power of the alpha–beta oscillations and the time course and amplitude of the delta wave, a similar depth profile and location of the major current sinks in the dense cortical plate, and involvement (though differential, see below) of ionotropic glutamate receptors in the generation of


FIGURE 8.2 Spindle- and gamma-bursts in primary somatosensory cortex (S1) of the newborn rat. (a) Wide-band recordings of extracellular activity and filtered (0.3–5 kHz) MUA in S1 hindlimb area of a P2 rat. Positivity is up. Bottom, movement of the contralateral hindlimb. Continuous rhythm reflects respiration. Note that field events and synchronized unit bursts are associated with movements. The event marked by * is shown at an expanded time scale in (b). (c) Examples of spindle-bursts (top panel, P1) and gamma-bursts (bottom panel, P3) in the neonatal rat barrel cortex. Below the traces are shown color-coded wavelet spectra and relative powers in different frequency domains. (d) Average power spectrum of the bursts recorded in neonatal rat barrel cortex (pooled data from 14 P2–7 rates, total 499 bursts). Note two peaks at alpha–beta (8–30 Hz; spindle-bursts) and gamma (30–80 Hz, gamma-bursts) frequency ranges. *Adapted with permission from (a, b): Khazipov R, Sirota A, Leinekugel X, Holmes GL, Ben-Ari Y, Buzsaki G (2004b) Early motor activity drives spindle bursts in the developing somatosensory cortex.* Nature *432: 758–761; (c) Yang JW, Hanganu-Opatz IL, Sun JJ, Luhmann HJ (2009) Three patterns of oscillatory activity differentially synchronize developing neocortical networks* in vivo. Journal of Neurophysiology *97: 692–700.*

both components, indicate that the high-frequency oscillations and the delta waves are two components of a single activity (Minlebaev et al., 2009). The identification of the slow component of spindle-bursts supports their homology with the human electrographic pattern of delta brushes, which are also expressed in somatosensory cortical areas of human premature neonates during the second half of gestation. The remarkable similarities between these two patterns indicate that they are the same physiological phenomenon (Khazipov and Luhmann, 2006). This also confirms that

the neonatal rodent can be a useful model for studying the mechanism and physiological roles of this activity pattern in cortical development.

Spindle bursts share some similar electrographic characteristics with adult sleep spindles (Steriade, 2001). However, in contrast to sleep spindles, neonatal spindle bursts are local events with a limited tendency to spread. Furthermore, spindle bursts are present in the waking pup even during walking and feeding and are typically triggered by myoclonic twitches of isolated muscles or whole-body startles. Myoclonic twitches are one of the

most remarkable developmental motor phenomena in the neonatal rat (Blumberg and Lucas, 1994; O'Donovan, 1999; Petersson et al., 2003), human fetus, and premature neonate (Cioni and Prechtl, 1990; de Vries et al., 1982; Hamburger, 1975; Prechtl, 1997; and is discussed extensively in Rubenstein and Rakic, 2013.). This particular type of motor activity results from the stochastic bursts of activity generated in the spinal cord under brainstem control (Blumberg and Lucas, 1994; Karlsson et al., 2005; Kreider and Blumberg, 2000). Delay between the movements and cortical spindle bursts, and the observation that spindle bursts can also be induced by direct sensory stimulation, indicated that spindle bursts are triggered by sensory feedback initiated by spontaneous movements (Figure 8.2(a)). At present, whether gamma bursts are initiated by sensory feedback is unknown, but both spindle bursts and gamma bursts are efficiently triggered by external stimulation (Khazipov et al., 2004b; Marcano-Reik and Blumberg, 2008; Marcano-Reik et al., 2010; Minlebaev et al., 2007; Yang et al., 2009). Importantly, spindle bursts and gamma bursts persist after sensory deafferentation (e.g., spinal cord transection or application of local anesthetics), although at a reduced frequency (Khazipov et al., 2004b; Yang et al., 2009). These results suggest that spindle bursts and gamma bursts are endogenous – probably thalamocortical or intracortical – oscillations. However, external stimuli brought about by the thalamocortical afferents can trigger these oscillations in the somatosensory cortex in a somatotopic manner.

In addition to gamma and spindle bursts, the somatosensory cortex of rodents during the first postnatal week also displays sharp wave transients (Khazipov et al., 2004b; Seelke and Blumberg, 2010) that may reflect sensory feedback events resulting from brief movements that failed to initiate oscillatory bursts. Long oscillations lasting for >40 s and reminiscent of SATs have also been described, although these events are rare in the somatosensory cortex (Yang et al., 2009).

8.3.2 Spindle Bursts and SATs in Visual Cortex

Despite the similarities between the functional organization of somatosensory and visual systems during the first postnatal week, there is an important difference. In the somatosensory system, sensory stimulation reliably evokes cortical responses starting from near birth – as soon as thalamic axons enter the cortex; in the visual system, however, the retina is insensitive to light during the first postnatal week. During this developmental period, when the visual cortical map is formed, the retina generates spontaneous waves of activity (see Rubenstein and Rakic, 2013). These waves are generated in the network of retinal ganglion and amacrine cells, and locally synchronize retinal activity local domains (Galli

and Maffei, 1988; Meister et al., 1991; Torborg and Feller, 2005; Wong et al., 1993). Using an original *in vitro* preparation of the neonatal mouse intact retina – lateral geniculate nucleus (LGN) thalamic nucleus, it was demonstrated that spontaneous retinal activity is transmitted via the optic nerve to the LGN, where it drives bursts of activity (Mooney et al., 1996). Modulation of retinal waves during the first postnatal week results in alteration of retinal projections to their subcortical targets, suggesting an instructive role for retinal waves in the development of retinogeniculate connectivity (Chandrasekaran et al., 2005; Grubb et al., 2003; McLaughlin et al., 2003; Mrsic-Flogel et al., 2005; Muir-Robinson et al., 2002; Nicol et al., 2007; Penn et al., 1998; Shatz and Stryker, 1988; Stellwagen and Shatz, 2002). Evidence also exists for the contribution of retinal waves to cortical development. In monkeys, ocular dominance columns (ODCs) are formed already *in utero* before visual experience (Rakic, 1976). Although enucleation experiments suggest that retinal input may not be required for the formation of ODCs (Crowley and Katz, 1999), complete blockade of retinal activity can disturb segregation of thalamocortical connections in ODCs (Stryker and Harris, 1986). In neonatal mice, suppression of retinal waves during the first postnatal week also results in imprecise geniculocortical mapping (Cang et al., 2005). Furthermore, blockade of retinal waves in ferrets disrupts formation of ODCs. Together, these data show that spontaneous retinal waves are also involved in the development of thalamic connections to the visual cortex (Cang et al., 2005).

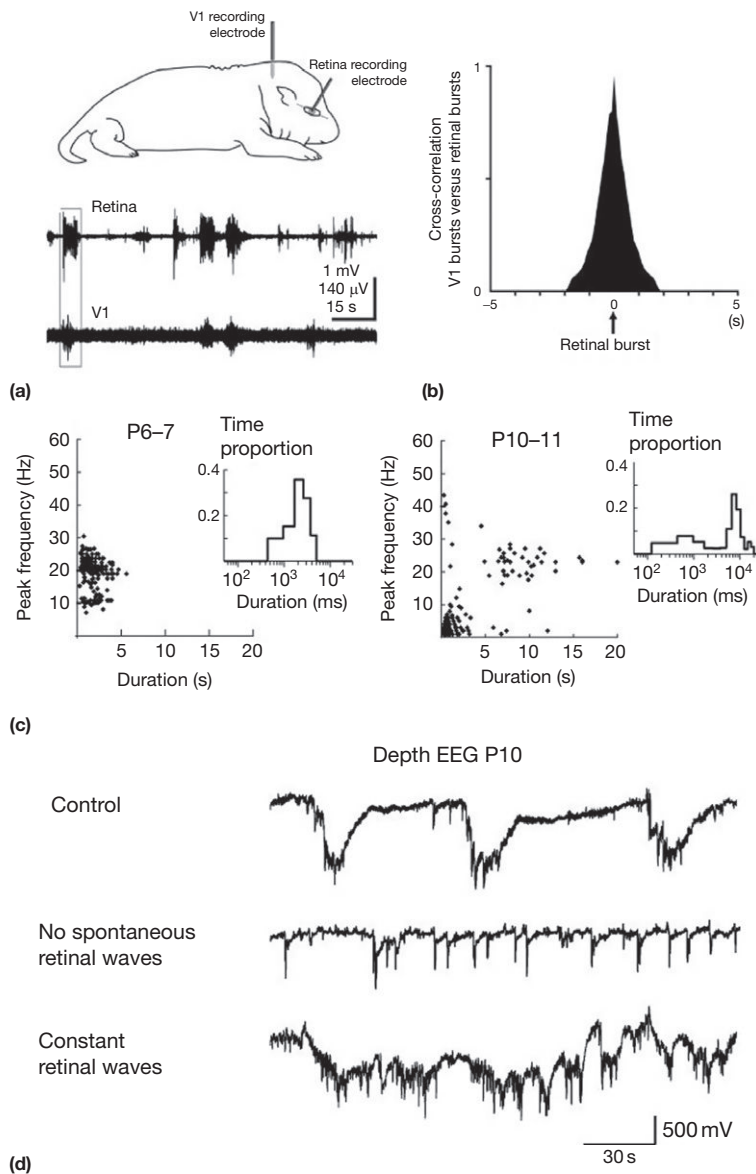
These findings suggested the hypothesis that retinal waves are transmitted to and trigger activity in the developing visual cortex. This hypothesis has been tested in neonatal rats (Colonnese and Khazipov, 2010; Hanganu et al., 2006). Using extracellular and whole-cell recordings from the visual cortex of neonatal rats *in vivo*, it was shown that, as in the somatosensory cortex, the dominant pattern of activity in the visual cortex during the first postnatal week is a spindle burst (Figure 8.3). Simultaneous recordings from the retina and the primary visual (V1) cortex revealed a strong correlation between spindle bursts in the visual cortex and spontaneous retinal waves. In addition, V1 spindle bursts could be reliably evoked by direct stimulation of the optic nerve. Pharmacological modulation of retinal activity affected the rate of occurrence of V1 spindle bursts; for instance, intraocular forskolin injection, known to increase the frequency and amplitude of retinal waves (Tsai et al., 1987), greatly increased the rate of occurrence of cortical spindle bursts in the contralateral V1 cortex. On the other hand, blocking the propagation of retinal activity with local application of tetrodotoxin or removing the retina resulted in a twofold reduction of V1 spindle-burst frequency, analogous to the reduction of somatosensory spindles after spinal cord transections.


FIGURE 8.3 Retinal drive of visual cortex activity in neonatal rats. (a) Simultaneous recordings of retinal and cortical activity during the first postnatal week reveal synchrony of retinal bursts and cortical spindle-bursts. (b) Cross-correlation of cortical and retinal activity bursts. (c) Diversification of activity patterns during the second postnatal week. Spontaneous activity P6–7 forms a single distribution of duration and presence of rapid oscillations (spindles). By P10–11, elongation of bursts containing rapid oscillations (SATs) and the emergence of short-activity bursts with no oscillatory component lead to two clearly separable activity patterns. (d) Manipulation of spontaneous retinal waves specifically affects SATs, either eliminating them when retinal waves are blocked (enucleation or intra-ocular urethane injection) or increasing their occurrence when retinal activity is increased (retinal inhibition blockade). *Adapted with permission from Hanganu IL, Ben Ari Y, Khazipov R (2006) Retinal waves trigger spindle bursts in the neonatal rat visual cortex.* Journal of Neuroscience *26: 6728–6736 (a, b) and Colonnese MT and Khazipov R (2010) "Slow activity transients" in infant rat visual cortex: A spreading synchronous oscillation patterned by retinal waves.* Journal of Neuroscience *30: 4325–4337 (c, d).*

During the second postnatal week, when the retina becomes responsive to light, spontaneous activity in the visual cortex starts to diversify. Spindle bursts start to group in long-lasting events associated with large amplitude, slow (5–10 s long) DC shifts that are highly reminiscent of SATs in the human premature neonate (Figures 8.3 and 8.4). SATs in the rat are completely eliminated by enucleation. In addition, their main characteristics (duration, interevent intervals, and subburst structure) exactly match those of phase III retinal waves recorded *in vitro*. This indicates that SATs are also driven by retinal waves, as are spindle bursts during the first postnatal week. In parallel, starting from postnatal day P9 a separate class of events of short duration (200 ms) emerges, reminiscent of cortical up-states, which also start to be seen at around the same age in cortical slices

in vitro (Allene et al., 2008; Rheims et al., 2008). Similarly, in postnatal day P22–39 ferrets, V1 multiple unit activity is organized in bursts with about 10-Hz intraburst multi-unit activity (MUA). Studied with multielectrode arrays, this bursting activity exhibited a patchy structure that reflects ODCs in the visual cortex (Chiu and Weliky, 2001, 2002).

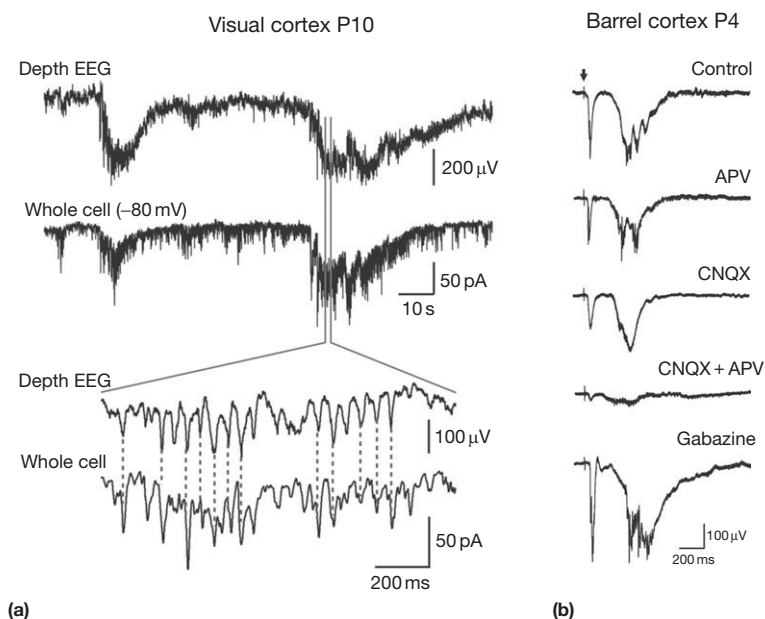
In parallel with the electrophysiological discovery of the early oscillatory patterns, a related pattern, termed early network oscillations (ENOs), has been described using calcium imaging of large neuronal populations *in vivo* (Adelsberger et al., 2005). ENOs are characterized by synchronous intracellular calcium increases that last for about 1 s and recur at about 10-s intervals in P3–4 rats, similar to spindle-bursts. Recorded in the temporal cortex, ENOs mainly occurred during movement-free


FIGURE 8.4   The mechanisms of the early oscillatory bursts. (a) Simultaneous depth EEG (field-potential, top trace) and whole-cell (400 μm depth, bottom trace) recordings from P10 rat visual cortex show that the infra-slow wave of SATs is composed of a similar long-duration depolarizing current. At expanded time base, rapid oscillations in the field potential are closely correlated with excitatory synaptic currents. (b) Pharmacological analysis of spindle-bursts evoked by electrical whisker pad stimulation in the P4 rat barrel cortex. Note that rapid oscillatory component (brush) is suppressed by the cortical application of the AMPA/kainate receptors (CNQX), whereas the delta-component is blockaded by combined application of AMPA/kainate and NMDA-receptor antagonists (CNQX and APV). Blockade of GABA(A) receptors with gabazine enhances the response. *Adapted with permission from: (a) Colonnese MT and Khazipov R (2010) "Slow activity transients" in infant rat visual cortex: A spreading synchronous oscillation patterned by retinal waves.* Journal of Neuroscience 30: 4325–4337; (b) Minlebaev M, Ben Ari Y, Khazipov R (2009) NMDA receptors pattern early activity in the developing barrel cortex *in vivo.* Cerebral Cortex *19: 688–696.*

resting periods, and it remains unknown whether ENOs in the somatosensory cortex are associated with movements. Nevertheless, optical ENOs appear similar to the electrographically defined spindle-bursts, including duration of events and inter-event intervals. Although the dynamics of intracellular calcium increases during ENOs were rather smooth and no high-frequency component characteristic oscillation was evident, this may be due to slow dynamics of intracellular calcium and the limited temporal resolution of calcium imaging methods compared to electrophysiological recordings. Further experiments using simultaneous electrophysiological and imaging approaches are needed to determine whether or not spindle bursts and ENOs reflect the same fundamental physiological patterns. Before speculation about the functional role of the early spontaneous patterns, we discuss the available observations that provide insights into their physiological mechanisms.

8.4 MECHANISMS OF EARLY NETWORK PATTERNS

The synaptic basis of the generation of the early activity patterns was explored using whole-cell patch-clamp recordings from neonatal rat somatosensory (Khazipov et al., 2004b; Minlebaev et al., 2007, 2009) and visual (Colonnese and Khazipov, 2010; Colonnese et al., 2010; Hanganu et al., 2006) cortex. These studies have revealed a pivotal role for glutamatergic and GABAergic synapses in the generation of the early activity patterns.

The mechanisms of spindle-bursts were investigated in detail in the neonatal rat barrel cortex (Minlebaev et al., 2007, 2009) using a superfused cortex preparation *in vivo*, enabling the application of drugs directly to the cortex. Pharmacological analysis revealed that generation of spindle-bursts in the neonatal barrel cortex primarily involves glutamatergic mechanisms (Figure 8.4). Interestingly, the relative contribution of AMPA/kainate and NMDA-Rs to the generation of the delta and alpha–beta components is different. Rapid alpha–beta oscillations mainly require AMPA/kainate receptors, and blockade of NMDA-Rs has no significant effect on this rapid oscillatory component. On the other hand, delta waves are generated by both types of glutamate receptors acting in concert, though with a primary contribution of NMDA-Rs. The differential contribution of the AMPA/kainate and the NMDA-Rs to the two components of the spindle-burst probably reflects a difference in the kinetics of the synaptic currents mediated by these receptors. AMPA-R-mediated synaptic currents have fast rise and decay times in the millisecond range (see, e.g., Crair and Malenka, 1995; Kidd and Isaac, 1999; Khazipov et al., 2004b) and therefore are ideally suited for synchronization of the rapid activities, such as alpha–beta oscillations. NMDA-R-mediated synaptic currents have rise times in the range of tens of milliseconds and decay times of hundreds of milliseconds; they are particularly slow at the immature synapse (Carmignoto and Vicini, 1992; Chittajallu and Isaac, 2010; Hestrin, 1992; Khazipov et al., 1995; Monyer et al., 1994). The slow kinetics of NMDA-R-mediated synaptic currents enables their powerful summation during rhythmic activation of synaptic inputs during spindle-bursts. The high NMDA/AMPA ratio at the immature synapses is another important factor contributing to the

increased contribution of NMDA-Rs to the delta wave (Chittajallu and Isaac, 2010; Crair and Malenka, 1995; Durand et al., 1996; Gasparini et al., 2000; Isaac et al., 1997; Voronin et al., 2004).

NMDA-R-dependent patterns of activity in developing cortical networks have also been described in cortical tissue *in vitro*, including hippocampal giant depolarizing potentials (GDPs) (Ben-Ari et al., 1989) and associated calcium oscillations (Allene and Cossart, 2010; Allene et al., 2008; Crepel et al., 2007; Leinekugel et al., 1997) and neocortical bursting and oscillatory activity (Arumugam et al., 2005; Dupont et al., 2006; Garaschuk et al., 2000; Kandler and Thiels, 2005; LoTurco et al., 1991). Interestingly, in the case of hippocampal GDPs, depolarizing γ-aminobutyric acid (GABA) may facilitate activity of NMDA-Rs by attenuation of their voltage-dependent magnesium block (Khazipov et al., 1997; Leinekugel et al., 1997). Activation of NMDA-Rs during spindle-bursts may be directly linked to the plasticity mediated by these receptors in the developing cortex. Indeed, pharmacological or genetic manipulations associated with a loss of function in NMDA-Rs results in malformations of barrel cortex development and functional deficits (Dagnew et al., 2003; Fox, 2002; Fox et al., 1996; Iwasato et al., 2000; Lee et al., 2005a,b; Schlaggar et al., 1993). During the critical period, thalamocortical synapses display an enhanced NMDA-R contribution and increased NMDA-R-dependent synaptic plasticity, including the conversion of 'silent' pure NMDA-R-based synapses to fully functional mixed AMPA/NMDA-R synapses, as well as a switch to fast AMPA-receptor-mediated synaptic transmission from slow kainate-mediated transmission (Bannister et al., 2005; Barth and Malenka, 2001; Carmignoto and Vicini, 1992; Crair and Malenka, 1995; Daw et al., 2006; Feldman et al., 1998, Hestrin, 1999, 1992; Isaac et al., 1995, LoTurco et al., 1997, 1991; Monyer et al., 1994). Activation of NMDA-Rs achieved by massive summation of thalamocortical input during spindle bursts provides a long time window for coincident activation of cortical neurons by the thalamocortical cells. This physiological paradigm may underlie the NMDA-R-dependent plasticity in developing thalamocortical synapses, including both potentiation/maintenance of the activity during spindle-burst synapses and depression/elimination of those synapses that are less recruited by spindle-bursts. Plasticity in developing synapses is spike-time-dependent, and the synaptic strength can be bi-directionally modified by correlated pre-/postsynaptic spiking within a narrow time window on the order of 10 ms (Mu and Poo, 2006; Chapter 9). While recent findings indicated that the early oscillatory patterns may induce bi-directional plasticity at thalamocortical synapses (Minlebaev et al., 2011), whether STDP occurs during early oscillatory patterns is an important question for the further research.

While a considerable amount of data has now accumulated about network mechanisms of spindle-bursts, the generation of gamma-bursts is less well understood. In the adult brain, neuronal synchronization by gamma oscillations is a fundamental process in cortical computation (Buzsaki, 2006; Fries, 2009). Synchronized by inhibition (Bartos et al., 2007), gamma oscillations subserve perceptual binding (Gray and Singer, 1989) and support synaptic plasticity (Wespatat et al., 2004). The ontogeny and role of gamma oscillations in developing networks, however, remain controversial. It was generally accepted that gamma oscillations emerge relatively late in development (Uhlhaas et al., 2010) as associative cortical layers and large-scale connections (Bureau et al., 2004; Luhmann et al., 1986), which are required for perceptual binding, and GABAergic inhibition (Daw et al., 2007; Doischer et al., 2008; Luhmann and Prince, 1991), which is pivotal for gamma rhythmogenesis, both develop on a delayed timescale. Yet, several studies have now indicated the existence of transient, local, gamma-burst oscillations in the neonatal rat somatosensory (Yang et al., 2009) and visual (Colonnese et al., 2010) cortices. Moreover, studies in the neonatal rat barrel cortex revealed that the early gamma oscillations (EGOs) are specifically evoked in a single cortical barrel by stimulation of the corresponding (principal) whisker (Minlebaev et al., 2011). Simultaneous recordings from the ventro-posterior-medial (VPM) barreloids and cortical barrels have shown that the EGOs are primarily driven by a thalamic oscillator and synchronize neurons in a single thalamic barreloid and the corresponding cortical barrel. Basing on these findings and the results of whole-cell recordings from L4 neurons, the following network EGOs model has been suggested: (1) Sensory input from a whisker activates the gamma oscillator in the thalamic barreloid, which provides topographic feedforward synchronization in the corresponding cortical barrel; (2) cortical interneurons become involved in EGOs in an age-dependent manner: until ~P5, EGOs are independent of cortical inhibition, but starting from P5, along with the development of feedforward inhibition, interneurons are recruited and support EGOs by controlling runaway recurrent cortical excitation. Thus, during the first postnatal week, EGOs undergo evolution from a primitive form of cortical activity passively following a thalamic oscillator to a more complex interactive model in which an active cortical oscillator, by virtue of emerging inhibition, starts to support gamma oscillations. Interestingly, artificial EGOs mimicked by pairing subthreshold gamma-rhythmic thalamic input with action potentials in L4 neurons in thalamocortical slices resulted in long-lasting potentiation of thalamocortical EPSPs. It has been suggested that in contrast to the inhibition-based "adult" gamma oscillations, which emerge at the end of the second postnatal week and

enable horizontal synchronization, EGOs are primarily driven by gamma-rhythmic excitatory thalamic inputs and provide vertical synchronization between topographically aligned thalamic and cortical neurons. Multiple replay of the sensory input in the thalamocortical synapses during EGOs ("repetitio est mater studiorum!") may allow thalamic and cortical neurons to be woven into vertical topographic functional units prior to the development of horizontal binding and other integrative cortical functions subserved by "adult" gamma oscillations in the mature brain.

Another intriguing question concerns the contributions of depolarizing and excitatory GABA actions to the early cortical-activity patterns. GABA is the main inhibitory neurotransmitter in the adult brain. Synchronous inhibition by hyperpolarization and a shunt provided by GABAergic interneurons are instrumental for the generation of various activity patterns in the adult brain (Bartos et al., 2007; Buzsaki, 2006; Freund and Buzsaki, 1996; Wang, 2010). However, slice preparations suggest that early in development – including the embryonic period and the first postnatal week in rodents – GABA, acting via chloride-permeable GABA(A) receptors, exerts a depolarizing and excitatory action on immature neurons as a result of their elevated intracellular chloride concentration (LoTurco et al., 1995; Luhmann and Prince, 1991; Owens et al., 1996; Tyzio et al., 2006; Yamada et al., 2004; Yuste and Katz, 1991; reviewed in Ben Ari et al., 2007; and is discussed extensively in Rubenstein and Rakic, 2013). Elevated intracellular chloride in the immature neurons is a result of high activity of the chloride-loading co-transporter NKCC1 and delayed expression of the chloride extruder KCC2 (Rivera et al., 1999; Yamada et al., 2004). Depolarizing GABA is involved in the generation of the primitive pattern of neuronal network activity in the immature hippocampus and cortex – so-called GDPs (Allene et al., 2008; Ben-Ari et al., 1989; Dzhala et al., 2005; Khazipov et al., 2004a; Rheims et al., 2008; Sipila et al., 2005). During GDPs, both pyramidal cells and interneurons fire randomly within a very large time window of few hundreds of milliseconds. Excitation of pyramidal cells and interneurons during GDPs is brought about by synergistic excitatory actions of GABA and glutamate (Bolea et al., 1999; De la Prida et al., 1998; Khazipov et al., 1997; Lamsa et al., 2000; Leinekugel et al., 1997; Menendez et al., 1996; Valeeva et al., 2010).

Does GABA play a similar excitatory action in the generation of the early oscillatory patterns of cortical activity *in vivo*? Unfortunately, at present there is surprisingly little experimental evidence that GABA exerts excitatory actions on immature cortical neurons *in vivo*, as it does *in vitro*. At present, the only information available about the roles of GABAergic interneurons *in vivo* is based on the effects of pharmacological manipulations of GABAergic synaptic transmission on network-driven activities.

In the neonatal rat hippocampus, the dominant neuronal network patterns of activity (GDPs *in vitro* and sharp waves *in vivo*) are blocked by the NKCC1 antagonist, bumetanide, which shifts the reversal potential of the GABA(A)-receptor-mediated responses toward negative values (Dzhala et al., 2005; Sipila et al., 2006; Tyzio et al., 2006). Although a similar effect of bumetanide on the GABA(A) reversal potential was found in neocortical neonatal neurons (Tyzio et al., 2006; Yamada et al., 2004), bumetanide did not significantly affect spindle-bursts in the barrel cortex *in vivo* (Minlebaev et al., 2007). Therefore, it appears that early hippocampal patterns of sharp waves *in vivo* and GDPs *in vitro* are more dependent on the depolarizing actions of GABA than the neocortical pattern of spindle-bursts, consistent with observations *in vitro* (Garaschuk et al., 2000; Rheims et al., 2008).

However, GABAergic interneurons do clearly participate in the generation of spindle-bursts and gamma-bursts in an age-dependent manner, as evidenced by the effects of the GABA(A)-receptor antagonists and positive allosteric GABA(A)-receptor modulators. Although blockade of GABA(A) receptors does not significantly affect the frequency of oscillations in the alpha–beta frequency domain, it does increase the power of these oscillations, as well as increase the amplitude of the delta component and the occurrence of spindle-bursts. Gamma oscillations are little affected by blockade of cortical inhibition until P5, but they are suppressed in older animals. The opposite manipulation, enhancement of GABA(A)-receptor-mediated currents by diazepam, reduces by twofold the occurrence of spindle-bursts. These results suggest that GABAergic interneurons play an inhibitory role in spindle-burst generation. In keeping with these findings, blockade of GABA(A) receptors strongly increases the size of cortical areas activated during spindle-bursts. Spindle-bursts are local events, and the diameter of the cortical zones activated during spindle-bursts usually does not exceed 0.5 mm. After blockade of GABA(A) receptors, spindle-bursts can be recorded at distances up to 1–2 mm. Thus, the spread of spindle-bursts is determined not only by the topographic thalamocortical excitatory input (Agmon et al., 1996; Bureau et al., 2004; Ferezou et al., 2006; Higashi et al., 2002; Khazipov et al., 2004b; Kidd and Isaac, 1999; Petersen and Sakmann, 2001), but also by surround GABAergic inhibition that prevents horizontal spread of the activity via long-range glutamatergic cortical connections, a pattern also observed in the adult neocortex (Chagnac-Amitai and Connors, 1989; Fox et al., 2003; Sun et al., 2006). The inhibitory action of GABA at the network level does not necessarily imply a hyperpolarizing action, as even depolarizing GABA may produce strong inhibition via shunting mechanisms amplified by activation of the voltage-gated potassium channels and inactivation of sodium channels (Borg-Graham

et al., 1998; Gao et al., 1998; Gulledge and Stuart, 2003; Lu and Trussell, 2001). These results, which suggest an inhibitory role of GABA during generation of spindle-bursts, are in general agreement with the finding that GABA(A) antagonists induce hypersynchronous seizure-like activity in the neocortex *in vivo* by P3 (Baram and Snead, 1990) and *in vitro* by P2 (Wells et al., 2000). These results are also in keeping with the plasticity changes induced in the developing barrel cortex by chronic treatment with the GABA(A)-receptor agonist, muscimol (Wallace et al., 2001).

8.5 DISCONTINUOUS TEMPORAL ORGANIZATION OF THE EARLY ACTIVITY

The uniqueness of immature cortical activity consists not only of developmentally restricted patterns of activity, but also stems from its *discontinuous temporal organization* (Figures 8.5 and 8.6). The first reports of the discontinuous nature of early cortical activity were made in human preterm neonates using scalp electrographic recordings by Dreyfus-Brisac, Monod, and their colleagues. Analyzing EEGs from preterm neonates during the second half of gestation (Dreyfus-Brisac, 1962; Dreyfus-Brisac and Larroche, 1971; Dreyfus-Brisac et al., 1956), they noted that the cortical EEG was organized in intermittent bursts separated by periods of isoelectric EEG that could last for tens of seconds. This temporal organization was named *tracé discontinu*. With maturation, flat periods between the bursts became shortened, and starting from about 30 weeks of postconceptional age, *tracé discontinu* evolves to *tracé alternant* with low-voltage activity between the bursts, though

even at term, some discontinuity is still evident (Lamblin et al., 1999; Stockard-Pope et al., 1992).

Such extreme discontinuity of cortical activity is striking. Indeed, showing EEG recordings obtained from a healthy premature neonate to an "adult" neurophysiologist without revealing the age of the patient would result in a diagnosis such as severe posthypoxic encephalopathy or barbiturate coma. Yet, this discontinuity is a normal feature of the immature cortex, and this raises several questions: Does discontinuity simply reflect immaturity of the nervous system, which is incapable of maintaining continuous activity, or, in keeping with Mozart's claim that the most meaningful element of a musical masterpiece is a pause, has it physiological roles for development?

The first question about human discontinuity is whether it results from true network silence as observed during slow-wave sleep in adults, or is it the result of temporally uncoordinated activity of neurons? This question has been examined in neonatal rats. Extracellular recordings of multiple unit activity showed that neurons fire virtually no action potentials during isoelectric EEG epochs. In agreement with this result, patch-clamp recordings revealed that neurons stay relaxed at their resting membrane potential ~ 80 mV and receive very little synaptic input during isoelectric EEG periods. This means that isoelectric EEG epochs reflect synchronous neuronal silence. Such a state of collective silence, called the down-state, also exists in the adult EEG. Considerable evidence suggests that isoelectric epochs are by nature the same phenomenon as down-states of long duration. In adults, down-states with durations from tens of milliseconds to a few hundred milliseconds occur during deep sleep in alternation with up-states (Buzsaki, 2006; Steriade, 2001; Steriade et al., 1993). Oscillation
FIGURE 8.5   Developmental changes in continuity of human cortical activity. (a) EEG of preterm infants at 25, 29, and 37 gestational weeks. The duration of silent periods decreases, while the length of periods of continuous activity increases with age. (b) Quantification of the proportion of EEG containing continuous activity (continuity defined as >80% continuous activity in 5-min epochs with attenuated activity 10–20 μV lasting no longer than 5 s). *Adapted with permission from Connell JA, Oozeer R, Dubowitz V (1987) Continuous 4-channel EEG monitoring: A guide to interpretation, with normal values, in preterm infants.* Neuropediatrics *18: 138–145.*

between up- and down-states generates slow waves in the EEG, and therefore these deep stages of sleep are also called slow-wave sleep oscillations. Intracellular studies indicate that when the level of mutual excitation in the cortical network falls below the critical level maintaining the up-state, which is partly due to the activity-dependent depression in glutamatergic synapses, neurons return to their resting membrane potential during down-states (Contreras et al., 1996; Sanchez-Vives and McCormick, 2000; Shu et al., 2003).

Immature neurons do just the same, but for much longer periods of time; however, one important difference between immature cortical activity and adult sleep is that the immature cortex maintains these long-duration down-states even when the animal is awake. In adults, the awake state is characterized by a continuous (a.k.a. activated or desynchronized) mode of cortical function.

Intracellular recordings show little difference between continuous cortical activity during awake, REM sleep, and up-states during slow-wave sleep. The activated cortical state is not present in neonatal rats or young premature neonates and starts to emerge in the rat during the second postnatal week and a month before term in humans, coinciding with the emergence of clearly differentiable sleep states in both species (Jouvet-Mounier et al., 1970; Lamblin et al., 1999). Interestingly, the active state does not emerge simultaneously in the entire cortex. Increase in the amount and continuity of spontaneous activity occurs first in the somatosensory and then in the visual cortex, both in the rat and humans, which also coincides with elimination of delta-brushes and spindle-bursts in these areas (Colonnese et al., 2010; Curzi-Dascalova et al., 1993; Dreyfus-Brisac and Larroche, 1971; Lamblin et al., 1999).

At least two developmental factors are likely involved in the emergence of the activated cortical state: development of arousal systems and intracortical connections. In the rat, maturation of sleep/wake transitions depends on noradrenergic development (Gall et al., 2009) and maturation of cholinergic (Mechawar and Descarries, 2001) and noradrenergic afferents and receptor distributions (Latsari et al., 2002; Venkatesan et al., 1996) around this time. Isolating the forebrain from ascending neuromodulatory arousal inputs in P13–15 rats reverses the developmental increase in spontaneous cortical activity, reinstating an immature mode of discontinuity (Figure 8.6). Continuity can then be reinstated by cortical application of norepinephrine (Colonnese et al., 2010), a key initiator of the activated cortical state (Berridge and Waterhouse, 2003; Foote and Morrison, 1987a,b). However, this is not to say that arousal systems are not functional before this time. Actually, many aspects of brainstem and forebrain arousal systems operate well before the emergence of the active cortical state; for example, infant rats and humans give evidence of behavioral sleep–wake cycles, state-dependent firing of hindbrain sleep control neurons (Karlsson et al., 2005), and modulation of cortical EEG patterns by the sleep state (Seelke and Blumberg, 2010). Furthermore, functional monaminergic and cholinergic connections are in place quite early (Hanganu et al., 2007; Johnston and Coyle, 1981). Yet, arousal systems appear incapable of inducing a continuous active state in the immature cortex. Thus, the acquisition of brainstem control of cortical states likely requires more than a simple engagement of neuromodulatory systems, and also thalamocortical changes. A prominent candidate is the strengthening of long- and short-range intracortical connectivity, required for maintenance of the activated cortical state (Sanchez-Vives and McCormick, 2000; Shu et al., 2003).

A number of observations are consistent with an increase in functional cortical connectivity over this time period. First, while k-complexes and sleep-spindles, stimulated by light in adults, are synchronized throughout the cortex (Amzica et al., 1998) via horizontal cortical and corticothalamic connections (Contreras et al., 1996, 1997), delta-brushes are local events (Khazipov et al., 2004b; Yang et al., 2009). Second, as noted earlier, in adults, episodes of network silence (down-states) during sleep do not exceed 500 ms (Steriade, 2001), whereas the silent periods in the young rat pups or preterm infants can run to tens of seconds. Such long silent periods are observed in cortical slabs and slices, that is, under conditions of markedly reduced cortical connectivity (Sanchez-Vives et al., 2000; Steriade et al., 2005; Timofeev et al., 2000). Finally, the network of horizontal connections between pyramidal neurons emerges shortly before eye opening in cats (Callaway and Katz, 1990; Galuske and Singer, 1996) and ferrets

(Durack and Katz, 1996; Ruthazer and Stryker, 1996), independently of visual input. In humans, dense horizontal connections are also first observed at GW37 (Burkhalter et al., 1993). Therefore, emergence of the continuous mode of cortical activity likely results from a coincidence of two developmentally regulated factors: (1) maturation of the brainstem arousal input to the cortex, which provides tonic neuronal depolarization, and (2) formation of excitatory synaptic connections between cortical neurons, which are needed for maintenance of the activated cortical state.

In conclusion, it is tempting to propose a hypothesis whereby discontinuity and long silent periods are important for circuit development. Growing evidence indicates that developing synapses display very high levels of plasticity, as governed by the Hebbian principle "neurons that fire together wire together" (Hebb, 1949), which in a more elaborated way is formulated as STDP (Dan and Poo, 2006; Mu and Poo, 2006). STDP implies that the strength of synaptic connections can be bi-directionally modified – either potentiated or depressed – depending on spike timing in pre- and postsynaptic neurons. If the spike in a presynaptic neuron precedes the spike in the postsynaptic neuron (as in the case the postsynaptic neuron was driven by the presynaptic neuron), the synapse will be potentiated; if the opposite occurs, the synapse is depressed. The most efficient changes in both directions occur when correlated spiking occurs within a time window of ten of milliseconds. These functional changes in the strength of synaptic connections were proposed as precursors of further anatomic changes – synapse stabilization and elimination in the cases of potentiation and depression, respectively.

Let us put STDP into the context of temporal organization, that is continuity/discontinuity, and examine how this is expected to impact plasticity in a thalamocortical synapse. We know that a sensory input triggers topographic delta-brushes, providing pre-before-post firing in the appropriate thalamocortical synapse and thus conditions for potentiation/stabilization. From the plasticity standpoint, the ideal case for potentiation would be if two conditions are met: (1) each pre-spike is followed by a post-spike, and (2) each post-spike is preceded by a pre-spike. These conditions will be achieved if topographic thalamocortical synapses provide a necessary and sufficient excitatory drive to cortical cells. Excitation of cortical neurons by intracortical synapses during intracortically generated spontaneous activity would introduce noise to the system, as random – in relation to thalamic input – firing of cortical neurons will create variable conditions for STDP in the thalamocortical synapse. In the developing cortex, this noise is eliminated by delayed introduction of horizontal connections, which strongly increases the plasticity impact of sensory-driven thalamocortical bursts. This hypothesis is supported by

studies in the developing *Xenopus* retinotectal system, in which it was shown that activity-induced synaptic modifications are quickly reversed either by subsequent spontaneous activity in the tectum or by exposure to random visual inputs (Zhou and Poo, 2004b; Zhou et al., 2003). This reversal depended on the burst spiking and activation of the *N*-methyl-D-aspartate subtype of glutamate receptors. Stabilization of synaptic modifications could be achieved by an appropriately spaced pattern of induction stimuli. These findings underscore the vulnerable nature of activity-induced synaptic modifications *in vivo* and suggest a temporal constraint on the pattern of visual inputs for effective induction of stable synaptic modifications. These findings are also linked to the developmental changes in the sensory-evoked activity patterns that will be discussed in the next section.

8.6 EARLY ACTIVITY PATTERNS AND THE DEVELOPMENT OF PERCEPTION

In this chapter, we have identified two characteristics of neocortical activity during the time of cortical layer formation and thalamic in-growth and map formation: the presence of "slow-activity transients" containing rapid oscillations (including spindle-bursts and delta-brushes) and a discontinuous pattern of activity, that is, the presence of long periods of neuronal silence. We argue that these features are the result of a unique network state specific to early development that is optimized to drive synaptic plasticity in thalamocortical networks in response to spontaneous activity generated in the sense organs. Because early spontaneous activity at the sensory periphery is infrequent, the early cortex must remain mostly quiet. Secondly, because cortical circuits are concerned primarily with the presence and absence of activity within topographic space, they produce bursts of highly correlated firing containing little additional information.

The final question that concerns us is the transition to mature patterns of cortical activity: when do they occur and what are their behavioral correlates and mechanisms? This issue has been studied most extensively in the visual system. Here the activity patterns in the sense organ are best understood, and relative roles of neuronal activity and the environment in maturation can be examined. Cortical visual development can be roughly divided up into four periods: (1) the completely pre-visual period, when phase 2 retinal waves are transmitted to the cortex; (2) an obscured visual phase, when phase 3 (glutamatergic) retinal waves are prominent but coexist with initial photo-receptor-driven light responses (Huberman et al., 2008) that allow cortical visual responses to be driven through the closed eye-lids

(Akerman et al., 2004; Chapman and Stryker, 1993; Ohshiro and Weliky, 2006); (3) a pre-critical period (Feller and Scanziani, 2005) that follows eye-opening, during which new visual experience drives development of binocularity, orientation, and direction selectivity (Smith and Trachtenberg, 2007; White et al., 2001); and (4) the classical critical period for monocular deprivation plasticity (Hubel and Wiesel, 1970).

As reviewed above, the early period of spontaneous cortical activity, consisting of delta-brushes, SATs, and discontinuity occurs throughout the first and second visual development periods, rapidly maturing around the time of eye-opening and the transition to the third period. Colonnese et al. (2010) examined the role of this transition of thalamocortical networks in determining visual-response properties in rats and human preterm infants. In the somatosensory system, both spontaneous muscular twitches and direct touch are effective in eliciting cortical delta-brushes. Perhaps this is not surprising, given that the ultimate effect on the sense organ was similar. However, the activation of retinal ganglion cells by light is weaker and patterned differently than during retinal waves (Blankenship et al., 2009; Kerschensteiner and Wong, 2008; Tian and Copenhagen, 2003). This casts doubt on a possible interaction between these transmission systems for spontaneous and evoked visual activity. Furthermore, primate retinas have weaker and less-organized spontaneous activity during the later gestational period (Warland et al., 2006), further questioning a potential interaction between spontaneous and evoked activity patterns in humans.

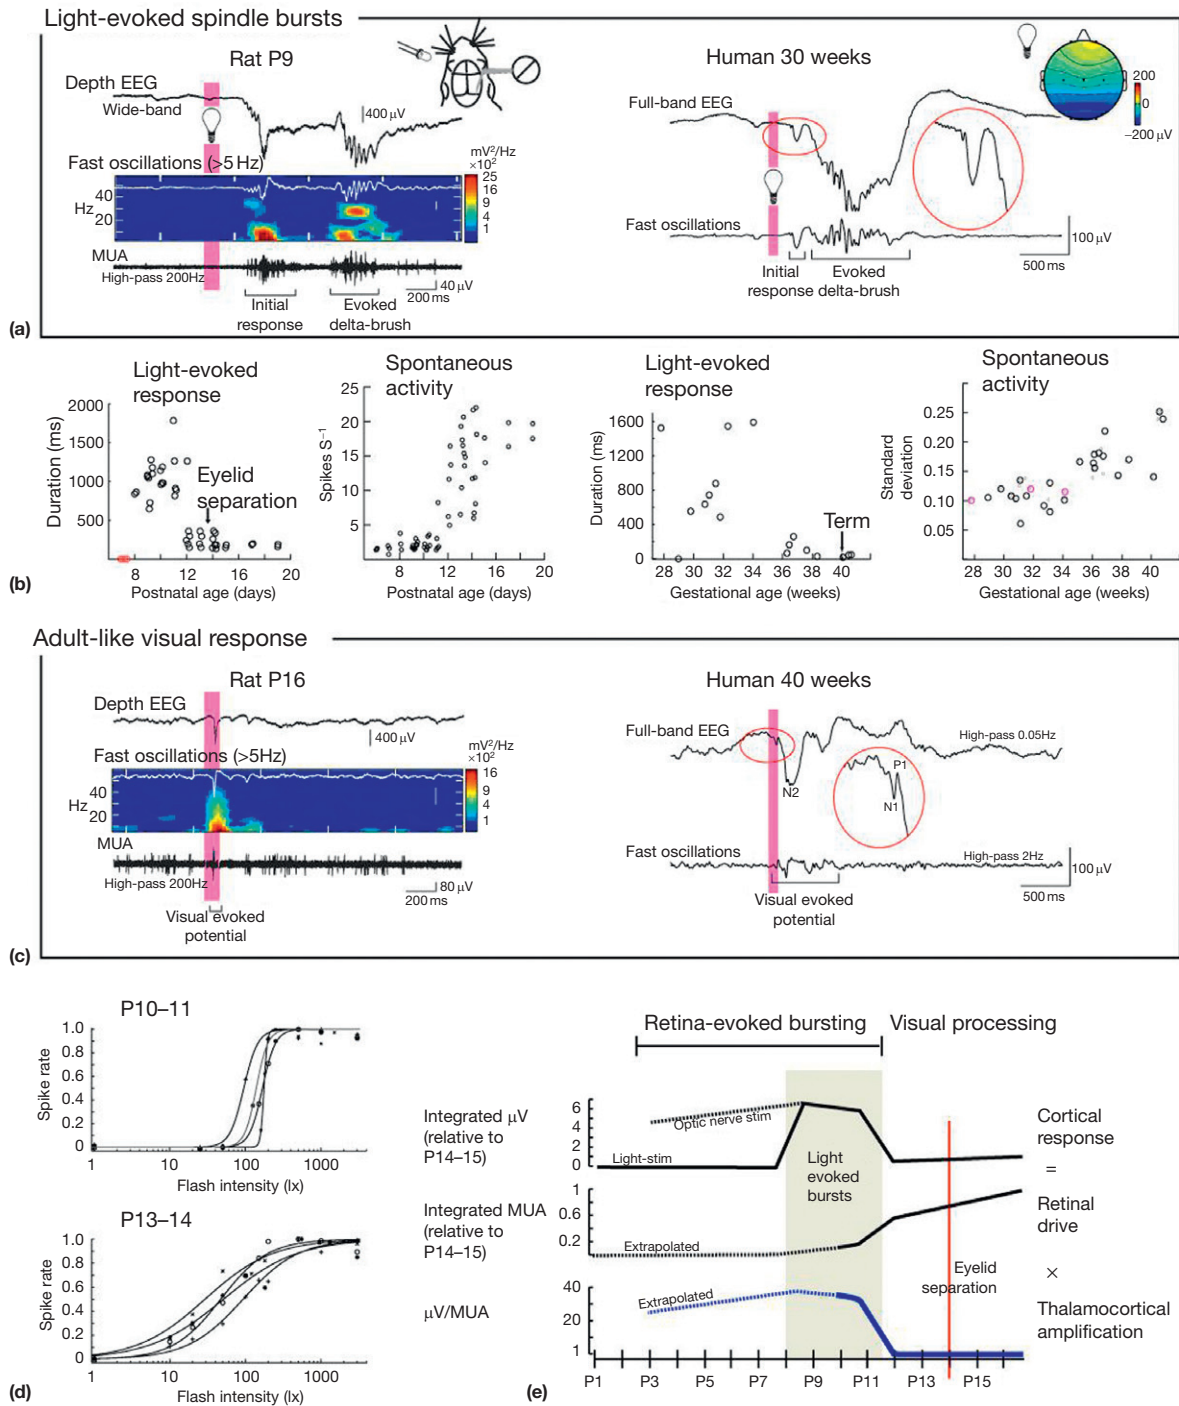
Despite these facts, whole-field light flashes directed to the closed eyelids of rats evoked a complex of oscillatory patterns in the cortex typical of the spontaneous activity patterns observed at this age (Figure 8.7(a)). Despite weak or absent retinal visual responses *in vitro*, robust light responses could be evoked as early as P8. Cortical light responses consisted of a complex of described activity patterns, including an initial response that included a gamma-burst and a GDP, followed by an evoked delta-brush. Electrical stimulation of the retina showed that these patterns did not result from simply the triggering of retinal waves by light, but emerged in the thalamocortical circuit following even brief inputs. Similar visual stimuli evoked a similar complex of activity patterns, including delta-brushes, in the occipital EEGs of sleeping preterm infants from as early as they could be recorded (27 gestational weeks). Thus, the network properties dedicated to transmitting retinal waves are also recruited during visual stimulation, even though the importance of such stimuli to thalamocortical activity at these ages is questionable. Together, these data show that the early activity bursts are a fundamental response to thalamic input, regardless of source, that shapes sensory processing.


FIGURE 8.7 Role of thalamocortical-network changes in the development of visual processing. (a) Cortical visual responses during early development in rats (left) and preterm infants (right). During the period of discontinuous cortical activity, full-field light flashes trigger bursts of endogenous delta-brush oscillations resulting in a large amplitude potential and long-lasting response. Example wide-band traces from depth EEG (rat) or surface EEG (human) are shown along with a time-series spectrogram and MUA for the rat and a high-pass filtered trace to show rapid oscillations for the human. Electrode map in the top-right corner shows localization of the negative slow wave to occipital electrodes. (b) Linked development of the mature pattern of visual processing and continuous cortical activity. In both species, short visual responses and continuous cortical activity rapidly emerged just before active visual exploratory behavior at eye-opening (rats) or birth (humans). (c) Example traces of visual-evoked responses after eye-opening (rats) or birth (humans). (d) Bursting behavior of early cortical circuits prevents graded visual responses. Spike rates in layer 4 of the rat visual cortex during the initial response show all-or-nothing bursting to graded light intensities during the period of discontinuity. Graded visual responses are observed rapidly following the switch in cortical activities. (e) Early cortical oscillations amplify thalamic input during the early period. This amplification is downregulated to allow for graded visual processing just before pattern vision. Thalamocortical amplification was estimated by dividing the evoked cortical potential by the *in vitro* retinal spiking response in age-matched rats. *Adapted with permission from Colonnese MT, Kaminska A, Minlebaev M, Milh M, Bloem B, Lescure S, Moriette G, Chiron C, Ben-Ari Y, Khazipov R (2010) A conserved switch in sensory processing prepares developing neocortex for vision.* Neuron *67: 480–498.*

Using this controlled stimulation to assay the development of the thalamocortical response properties revealed that the developmental transition to mature patterns of visual response occurs as a rapid switch 1–2 days before eye-opening in rats (Figure 8.7(b) and 8.7(c)). In addition to this switch in visual-response patterns, the amount and continuity of spontaneous activity began to increase (and would continue to do so over the next weeks) on the same day. A similar switch in evoked and spontaneous activity occurred in the occipital cortex of human infants between 34 and 36 gestational weeks, that is, just before natural term (human fetuses open their eyes at the end of the second trimester). In both species, this switch consisted of a loss of the early cortical burst oscillations and their replacement by the visual evoked potential (VEP). As such, it results in a surprising decrease in the size and duration of visual responses.

Functionally, why would visual responses need to become reduced in size just before the onset of visual processing? One clue comes from examining the response curves to varying light intensities before and after the switch (Figure 8.7(d)). Before the switch, visual responses were 'all-or-none' bursts, effectively registering the presence of a minimal stimulation, but not its intensity. Only after the reduction of visual response with the switch could graded responses be attained. Measurement of the spiking responses of retinal ganglion cells in acutely excised retina allowed further quantification of the input–output relationships before and after the switch (Figure 8.7(e)). These revealed an inverse relationship between retinal and cortical light responses, with the reliability of retinal spiking to light flashes rapidly increasing just as the amplitude of the cortical response decreased. This had the effect of massively decreasing the amplification in thalamocortical circuits. Thus, we suggest that the primary role of early activity patterns, in addition to precisely synchronizing activity, is to amplify weak, young inputs. Such an amplification is incompatible with visual processing and thus is downregulated before vision is initiated at eye-opening or birth.

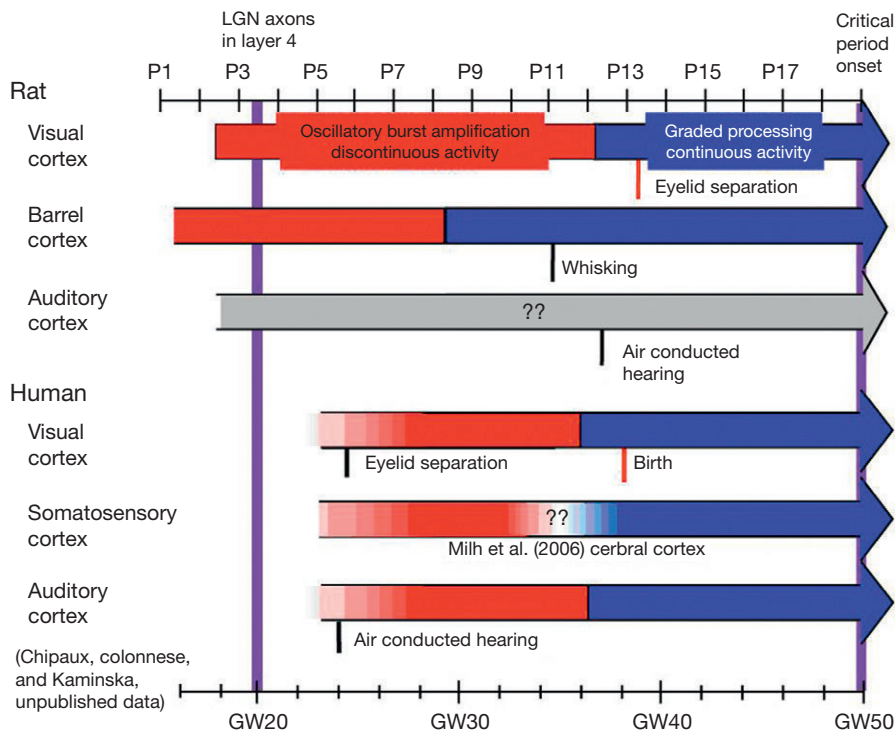
This switch in cortical-activity patterns, from a discontinuous mode with early bursting oscillations to continuous baseline activity with more restricted, graded response, appears to be universal for all sensory systems studied so far (Figure 8.8). Intriguingly, while the developmental template remains the same, the timing of the switch appears to differ between sensation and species, with the common feature being that it occurs shortly before the onset of active sensation for that system. This is best illustrated in the somatosensory whisker system, where passive activation (i.e., external touch of the whisker) is distinguished from active touch, or whisking. Rats begin active whisking 2–3 days before eye-opening (Landers and Philip, 2006). Similarly, they experience the same switch in cortical activity before the visual cortex (Figure 8.8, top). The issue has not been examined in depth in human infants, but the available data suggest less heterogeneity in the timing of the switch between


FIGURE 8.8   Two-state model of cortical-activity development. Known transition times from early bursting responses (evoked delta-brushes) to mature responses for multiple sensory systems in the human and the rat. Developmental timelines are aligned to the independent time points shown by purple lines. The timing of the switch in cortical circuits is correlated to the onset of exploratory sensation (e.g., whisking or eye-opening), which occurs at different times for the rat, but simultaneously at birth for humans, and this heterochrony is matched in the cortical-activity pattern development. ?? signifies unexplored time points. *Adapted with permission from Colonnese MT, Kaminska A, Minlebaev M, Milh M, Bloem B, Lescure S, Moriette G, Chiron C, Ben-Ari Y, Khazipov R (2010) A conserved switch in sensory processing prepares developing neocortex for vision.* Neuron 67: 480–498.

sensory systems. This is consistent with our notion that timing is tied to active exploration, which in humans occurs for all systems around the same time, namely birth.

The mechanisms responsible for the timing of this switch are poorly understood. The close correlation with the acquisition of continuous activity implicates the regulation of spontaneous activity in the switch. This is confirmed by observations that surgical isolation of mid/hindbrain ascending neuromodulatory systems from the neocortex reinstates early bursting as well as increases the discontinuity of activity (Figure 8.6). Such a regulation of sensory processing by the level of synaptic background activity is consistent with observations in adult animals (Destexhe et al., 2003). Neocortical neurons, during waking or 'up-states' observed during slow-wave sleep, receive constant synaptic activity, which is maintained through local network dynamics (Haider and McCormick, 2009) that can modulate gain (Chance et al., 2002) and adjust the sensitivity to inputs (Arieli et al., 1996; Borg-Graham et al., 1998). The timing of this switch is closely linked to the surge in synaptic density observed in the cerebral cortex that begins just before birth in monkeys and humans (Bourgeois and Rakic, 1996; Huttenlocher and Dabholkar, 1997) and before nest-exit/eye-opening in rats (Blue and Parnavelas, 1983). Interestingly, this is one of the sole features of neocortical development that violates the conserved timing of neurogenic events across mammalian species (Clancy et al., 2001), suggesting it is independently regulated to support the active exploration of the sensory world that will follow. Despite this violation of neurogenic timing and heterogeneity between sensory systems, the timing of the switch does not appear to be experience-dependent, as neither dark rearing nor early eye-opening could modify its timing in rats (Colonnese et al., 2010).

The evidence reviewed so far in this chapter is consistent with the hypothesis that early circuit development is characterized by a unique state of cortical-network dynamics in which spontaneous activity is maintained in a discontinuous mode and inputs are amplified by cortical-burst oscillations. This period appears tightly regulated to coincide with the sensory isolation experienced in the womb (or maintained by eye- or ear-canal closure in rodents), and to end when sensory processing is initiated. From this point on, many of the gross characteristics of adult cortical activity can be discerned, including clear regulation of cortical EEG by sleep state (Jouvet-Mounier et al., 1970), increased frequency of delta-waves in slow-wave sleep (Seelke and Blumberg, 2008, 2010), and the reduction and eventual elimination of SATs in counterpoint to continuous activity (Vanhatalo and Kaila, 2006). However, the development of cortical activity is by no means complete by this point. Again, this has been examined most deeply in the visual

system. Immediately following the change from immature patterns in the visual cortex, the pre-critical period is initiated and appears to exist in a transitional time, after the elimination of early activity patterns but before the acquisition of completely adult patterns. For example, cortical activity in ferrets freely viewing natural scenes just after eye-opening was dominated by highly correlated spontaneous activity bursts, an effect that was reduced by the time of the critical period (Fiser et al., 2004). These continuing changes are likely driven by many of the same developmental processes underlying the early switch in cortical activities such as increasing synaptic density and changes in neuromodulatory systems. However, several unique processes are also occurring over this time to mature cortical dynamics, including but not limited to the increasing sparcification of cortical circuits (Rochefort et al., 2009) driven by changes in intrinsic excitability (Golshani et al., 2009), increased reliability of the synaptic drive of layer 2/3 cells (Stern et al., 2001), the development of perisomatic inhibition (Hensch et al., 1998; Huang et al., 1999), and the final acquisition of strong sleep-associated rhythms (Miyamoto et al., 2003) that are necessary for the opening of the critical period for ocular-dominance plasticity.

Thus, throughout the development of the sensory systems, the changing network dynamics of the thalamocortical circuits are closely tied to the changing processes of synaptic plasticity and circuit formation that depend on them.

Spike Timing-Dependent Plasticity

D.E. Shulz[1], D.E. Feldman[2]

[1]Centre National de la Recherche Scientifique, Gif sur Yvette, France; [2]University of California Berkeley, Berkeley, CA, USA

9.1 INTRODUCTION

Since its discovery 15 years ago, spike timing-dependent plasticity (STDP) has emerged as a leading candidate mechanism for activity-dependent synaptic plasticity during neural circuit development and for driving neural plasticity and learning in adults. This is due to its physiologically realistic induction requirements, powerful Hebbian properties, and prevalence across many cell types and synapses from insects to mammals. However, STDP is a more complex and less understood phenomenon than apparent from initial studies in *in vitro* brain slices. Though STDP is widely observed *in vitro*, whether STDP is a plausible learning mechanism under natural conditions *in vivo* has been questioned. A substantial number of studies have now characterized STDP from the molecular to the circuit and systems levels. The purpose of this review is to critically analyze the data on diversity of STDP, predicted functional properties, cellular mechanisms, and its role in circuit development and adult plasticity *in vivo*. Several excellent reviews of specific aspects of STDP

have been published (Abbott and Nelson, 2000; Caporale and Dan, 2008; Dan and Poo, 2006; Fino and Venance, 2011; Letzkus et al., 2007; Lisman and Spruston, 2005; Paulsen and Sejnowski, 2000). We conclude that STDP occurs broadly and with diverse cellular mechanisms; that it is powerfully modulated by dendritic excitability, network activity, and neuromodulation, which both enriches its computational role and will constrain its relevance *in vivo*; that STDP does occur *in vivo* at least under controlled experimental conditions; and that STDP may contribute to several basic features of neural circuit development and to several forms of adult learning.

9.2 DISCOVERY OF STDP

Activity-dependent long-term modification of synapse strength is critical for the development of neural circuits and underlies learning and memory in young and adult brains. The seminal theoretical description of activity-dependent plasticity was by Donald Hebb, who proposed that when cell A reliably contributes to spiking of postsynaptic cell B, synapse strength from A to B is functionally enhanced (Hebb, 1949). This rule was later amended to include weakening of ineffective synapses (Bienenstock et al., 1982; Sejnowski, 1977; Stent, 1973; von der Malsburg, 1973). In the period between the 1970s and 1990s, long-term synaptic potentiation and depression (LTP and LTD) were discovered and shown to implement Hebbian synaptic plasticity. These forms of synaptic plasticity have since been observed in almost every area of the brain. In classical LTP and LTD, the change in synaptic weight depends on temporally correlated pre- and postsynaptic activity (reviewed in Fregnac and Shulz, 1999). This is termed correlation-dependent plasticity (CDP). The temporal requirement for pre- and postsynaptic coactivation in CDP was not considered to be very stringent (±50 ms or more), and plasticity was thought to be largely independent of the precise timing and order of action potentials.

Some studies, however, noted that the order of activation of the presynaptic and postsynaptic neurons was crucial in determining the sign of plasticity (LTP or LTD) (Levy and Steward, 1983). Gustafsson et al. (1987) showed that LTP was induced if an excitatory postsynaptic potential (EPSP) preceded a postsynaptic spike burst by <100 ms and was not induced if the EPSP immediately followed the burst. This order of pre- and postsynaptic activity was later shown to induce LTD (Debanne et al., 1994, 1996). In 1997, several groups discovered that induction of LTP and LTD by pairing pre- and postsynaptic action potentials was critically dependent on the order and relative timing of single spikes, down to the millisecond scale (Bell et al., 1997; Bi and Poo, 1998; Debanne et al., 1994, 1997; Markram et al., 1997; Figure 9.1). Confirmation at many other synapses followed. This form of temporally precise bidirectional Hebbian plasticity was termed STDP (Abbott and Nelson, 2000). STDP has been proposed on theoretical grounds to be a major mechanism for the induction of *in vivo* synaptic plasticity (Abbott and Nelson, 2000; Gerstner et al., 1996; Song et al., 2000; van Rossum et al., 2000). In the canonical form of STDP, as occurs in cortical pyramidal cells, when a presynaptic spike (and the resulting EPSP) leads a postsynaptic spike by up to 10–20 ms, an increase in synapse strength (LTP) is induced. Conversely, LTD is observed when a postsynaptic spike precedes a presynaptic spike and EPSP by short (0–20 ms) or long (0–100 ms) intervals, depending on the synapse being studied (Feldman, 2000; Froemke and Dan, 2002; Markram et al., 1997; Nishiyama et al., 2000; Sjostrom and Nelson, 2002; Sjostrom et al., 2001). Functionally, this rule causes synaptic inputs that contribute to postsynaptic firing being potentiated, while uncorrelated inputs onto otherwise active postsynaptic cells are depressed. This implements Hebb's learning rule (Abbott and Nelson, 2000; Paulsen and Sejnowski, 2000).

STDP has been extensively studied both experimentally and computationally. The mechanisms and functional consequences of STDP have been characterized in many different systems both *in vivo* and *in vitro*. Here, recent progress in the relevance of STDP in the intact brain is reviewed, with a particular emphasis on its functional properties, its multiple cellular mechanisms, and its implication in development, adult plasticity, and learning.

9.3 PREVALENCE AND DIVERSITY OF STDP

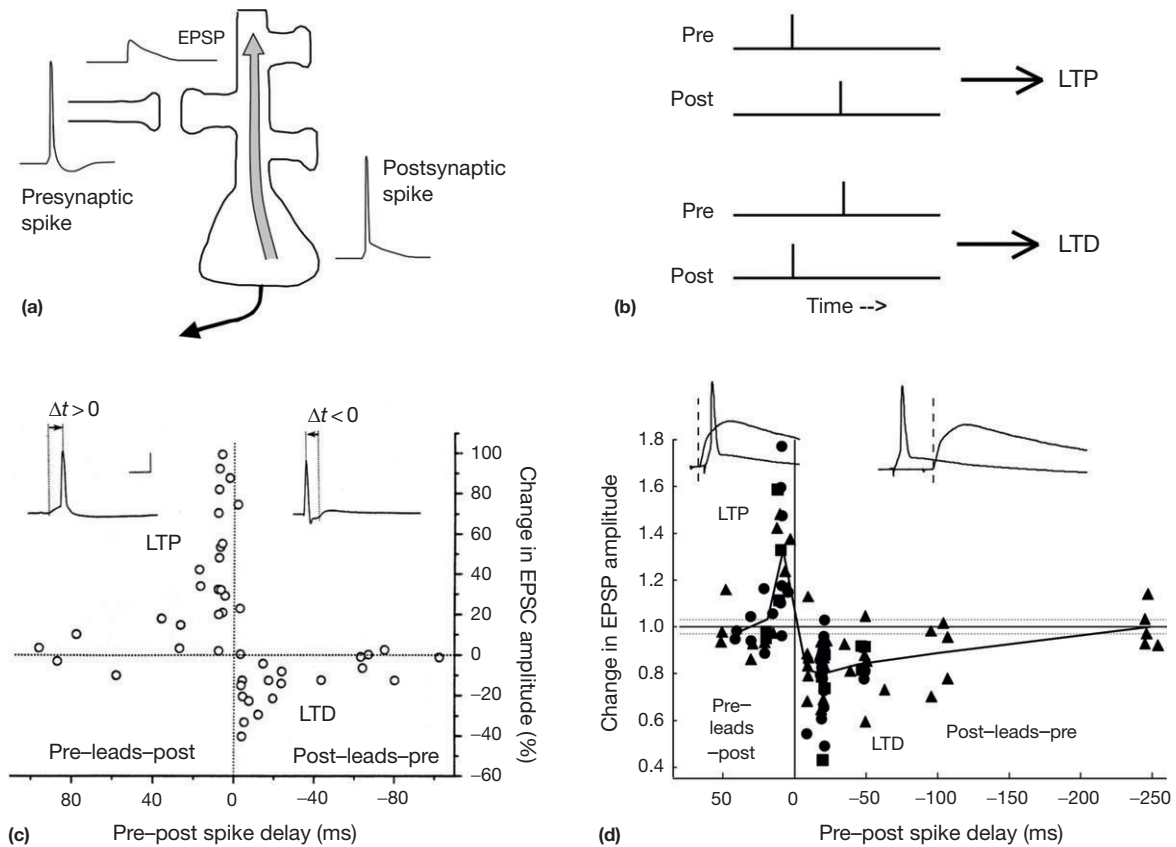
STDP is highly prevalent in the nervous system, from insects to mammals. It has been observed at a wide variety of excitatory and inhibitory synapses in many brain areas and in multiple cell types and preparations, including neuronal cell cultures, *in vitro* brain slices, and *in vivo*. While all STDP depends on precise timing and order of pre- and postsynaptic spikes, the precise temporal windows, magnitude, and sign of plasticity are remarkably diverse across synapses (Figure 9.2) (reviewed in Caporale and Dan, 2008; Shulz and Jacob, 2010). This diversity of STDP rules reflects both the existence of distinct cell type-specific forms of STDP, and the fact that nonassociative factors (i.e., factors besides pre–post spike timing) strongly modulate STDP induction. These factors include the number and frequency of postsynaptic spikes during induction (Froemke and Dan, 2002; Froemke et al., 2005; Sjostrom et al., 2001), the level


FIGURE 9.1 Spike timing-dependent plasticity. (a) Induction of STDP by pairing presynaptic spikes, which evoke EPSPs in dendrites, with postsynaptic spikes that backpropagate from the soma through the dendritic tree. (b) Temporal order dependence of STDP. (c) STDP learning rule reported by Bi and Poo (1998) for synapses in hippocampal cell culture. Each symbol is one neuron, which was presented with pre–post spike pairing at one delay. (d) STDP learning rule reported by Feldman (2000) for putative L4 synapses onto L2/3 pyramidal cells in acute slices of somatosensory cortex.

of postsynaptic depolarization evoked by presynaptic spikes (Sjostrom and Hausser, 2006; Sjostrom et al., 2001, 2004, 2008), synapse location in the dendritic tree (Froemke et al., 2005; Letzkus et al., 2006; Sjostrom and Hausser, 2006), and regulation by neuromodulators (Pawlak and Kerr, 2008; Reynolds and Wickens, 2002; Seol et al., 2007).

Three major classes of STDP can be distinguished within the substantial diversity of STDP forms. These are (a) canonical Hebbian STDP in which pre-leading-post and post-leading-pre spike pairings lead to LTP and LTD, respectively; (b) anti-Hebbian STDP in which both LTP and LTD occur but with an inverse relationship to spike timing compared to Hebbian STDP; and (c) all-LTD STDP in which LTD of synaptic transmission occurs irrespective of pre–post temporal order but only for pre–post intervals within a defined time window. This latter case is correlation-dependent, but with the opposite sign to that predicted by Hebb, and is often termed anti-Hebbian LTD. Variation within these classes is substantial and may reflect the existence of cell type-

specific subforms of STDP or the effects of nonassociative factors that vary across experiments.

In canonical Hebbian STDP (e.g., Bi and Poo, 1998; Feldman, 2000; Markram et al., 1997), induction of LTP occurs when presynaptic spikes occur up to ~10–20 ms before postsynaptic spikes. LTD is induced by the reverse order, when postsynaptic spikes lead presynaptic spikes by up to 20–100 ms, depending on the synapse. This form of STDP is prevalent at excitatory synapses onto cortical pyramidal neurons (Figure 9.2(j); Bi and Poo, 1998; Feldman, 2000; Markram et al., 1997; Nevian and Sakmann, 2006; Nishiyama et al., 2000; Sjostrom et al., 2001; Wittenberg and Wang, 2006) and nonpyramidal excitatory neurons in the auditory brainstem (Figure 9.2(g)) (Tzounopoulos et al., 2004). It also occurs at excitatory synapses onto some striatal interneurons (Figure 9.2(a) and 9.2(d); Fino et al., 2008, 2009). In anti-Hebbian STDP, spike order and timing trigger LTP versus LTD induction but with a time dependence opposite to canonical Hebbian STDP: post-leading-pre spiking drives LTP, while pre-leading-post spike order drives LTD. This

has been observed at parallel fiber synapses onto GABAergic Purkinje-like neurons in the electrosensory lobe of the electric fish (a structure analogous to the mammalian cerebellum) (Bell et al., 1997; Figure 9.2(h)) and at excitatory synapses onto medium-sized spiny neurons of the striatum, which are GABAergic output neurons (Fino et al., 2005; Figure 9.2(b)), as well as excitatory inputs onto cholinergic striatal interneurons (Fino et al., 2008; Figure 9.2(e)). In all-LTD STDP, synapses undergo LTD irrespective of the temporal order, as long as the pre–post interval is less than ∼20–50 ms, depending on cell type. All-LTD STDP occurs at excitatory inputs onto several excitatory and inhibitory neurons (Figure 9.2(c), 9.2(i), and 9.2(l); Birtoli and Ulrich, 2004; Egger et al., 1999; Tzounopoulos et al., 2004), including fast-spiking inhibitory neurons in neocortex (Birtoli and Ulrich, 2004; Egger et al., 1999; Lu et al., 2007; Tzounopoulos et al., 2004). Classical cerebellar LTD at parallel fiber inputs onto Purkinje neurons is also a form of all-LTD STDP (Wang et al., 2000).

These distinct STDP forms occur in the same brain structure and even at synapses made by single axons on two distinct target cell types. For example, parallel fiber excitatory input onto fusiform principal neurons of the dorsal cochlear nucleus shows classical Hebbian STDP, while parallel fiber input onto glycinergic cartwheel neurons shows an all-LTD form of STDP triggered by pre–post spike intervals (Tzounopoulos et al., 2004; Figure 9.2(g) and 9.2(i)). This difference is likely to result from the interaction of different transmitter systems. An even stronger example is the excitatory cortical input to the striatum (Fino and Venance, 2011). Excitatory synapses from cortical pyramidal cells onto striatal parvalbumin-positive fast-spiking neurons show Hebbian STDP (Fino et al., 2008; Figure 9.2(a)). Cortical inputs onto neuronal nitric oxide synthase (nNOS)-expressing interneurons also show Hebbian STDP but with a peculiar time course in which the LTD window extends to pre-leading-post intervals up to +20 ms (Fino et al., 2009; Figure 9.2(d)). Excitatory inputs onto cholinergic interneurons show either anti-Hebbian STDP (Figure 9.2(e)) or LTD-only STDP (Figure 9.2(f)), depending on the excitability state of the postsynaptic neuron. Thus, multiple postsynaptic cell type-specific forms of STDP coexist in the striatum. This diversity of STDP forms may affect striatal output in ways that are not yet fully explored (Fino and Venance, 2011).

STDP of inhibitory synapses onto excitatory neurons has been much less studied but seems distinct from excitatory synapses. In the entorhinal cortex, inhibitory inputs from layer two onto stellate cells exhibit a modified Hebbian STDP with a temporal range between −5 and +5 ms in which no plasticity is induced (Haas et al., 2006; Figure 9.2(m)). In the hippocampus, inhibitory inputs to CA1 pyramids exhibit a symmetrical curve, with potentiation induced by both pre–post and post–pre pairings within ±20 ms and depression induced by longer negative or positive intervals (Woodin et al., 2003; Figure 9.2(k)).

In conclusion, STDP has diverse forms, though three main classes can be distinguished. The wide variety of cell type-specific STDP rules may extend the computational power of neuronal circuits and enable differential control of processing and storage of information by subpopulations of neurons. Despite this diversity, most of our understanding of STDP in neural development and learning focuses on canonical Hebbian STDP. Additional regional variation in STDP may result from neuromodulatory gradients (see Reynolds and Wickens, 2002 for dopamine).

9.4 FUNCTIONAL PROPERTIES OF STDP

STDP differs from classical CDP in its requirement for postsynaptic somatic action potentials, its dependence on pre- versus postsynaptic spike order, and its 10-ms-scale spike timing dependence. Historically, correlation-dependent LTP and LTD were first discovered in response to sustained high-frequency or low-frequency presynaptic spiking, which drive strong postsynaptic depolarization and LTP or weak postsynaptic depolarization and LTD, respectively (Bliss and Lomo, 1973; Dudek and Bear, 1992; Mulkey and Malenka, 1992). The critical induction requirement at most synapses is temporally correlated presynaptic spiking and postsynaptic depolarization, as shown by pairing presynaptic activation with direct intracellular depolarization of the postsynaptic neuron (Wigstrom et al., 1986). The molecular coincidence detector is the postsynaptic N-methyl-D-aspartate (NMDA) receptor, which fluxes calcium in response to simultaneous glutamate and postsynaptic depolarization (Wigstrom and Gustafsson, 1986). Correlation-dependent, NMDA receptor (NMDAR)-dependent LTP and LTD became regarded as the canonical form of LTP and LTD at excitatory synapses onto excitatory neurons, though other, distinct forms of LTP and LTD are plentiful (e.g., Chevaleyre et al., 2006; Nicoll and Malenka, 1995).

In CDP, postsynaptic depolarization can arise from any source including subthreshold dendritic depolarization, local dendritic spiking, or somatic action potentials, and the sign of plasticity is determined by the magnitude of postsynaptic depolarization, not the precise order or timing of pre- and postsynaptic spikes (Lisman and Spruston, 2005; Paulsen and Sejnowski, 2000). In contrast, STDP explicitly depends on postsynaptic somatic action potentials, which backpropagate through the dendrites to synapses, and the sign and magnitude of plasticity depend on the sequential order and precise

(10-ms scale) timing of pre- versus postsynaptic spikes (Bi and Poo, 1998; Magee and Johnston, 1997; Markram et al., 1997). The existence of STDP therefore reveals the critical importance of precise spike timing for LTP and LTD.

A common function of Hebbian STDP and CDP is that they both implement bidirectional Hebbian synaptic plasticity at excitatory synapses, which is the basis for most modern theories of activity-dependent synapse development and associative learning (Miller, 1994). In bidirectional Hebbian plasticity, when neuron A consistently participates in driving spikes in neuron B, the A→B synapse is strengthened (Hebb, 1949), while ineffective inputs that do not drive postsynaptic spikes are weakened (Bienenstock et al., 1982; Sejnowski, 1977; Stent, 1973; von der Malsburg, 1973). CDP approximates this rule by assuming that when pre- and postsynaptic activities are strongly correlated, effective synapses exist that causally drive postsynaptic spikes and therefore should be potentiated. In contrast, synapses with weak firing correlations are assumed to be ineffective and should be depressed. Hebbian STDP implements this rule by virtue of precise spike timing: synapses at which presynaptic spikes lead postsynaptic spikes by a brief 10–20 ms interval must help drive postsynaptic spikes and are potentiated, while synapses at which postsynaptic spikes lead presynaptic spikes are ineffective synapses onto otherwise active neurons and are depressed (Song and Abbott, 2001; Song et al., 2000; van Rossum et al., 2000). Moreover, Hebbian STDP at many synapses is biased toward LTD (Figures 9.1(d) and 9.2(j)) (e.g., Debanne et al., 1998; Feldman, 2000; Froemke et al., 2005; Sjostrom et al., 2001). This LTD-biased STDP drives depression of presynaptic inputs that are uncorrelated with postsynaptic spiking, thus providing an additional means of weakening ineffective inputs (Feldman, 2000). Thus, Hebbian STDP implements bidirectional Hebbian plasticity (Abbott and Nelson, 2000; Paulsen and Sejnowski, 2000). Because STDP drives Hebbian potentiation at low, physiologically realistic firing rates, STDP may be the natural means of LTP induction in low firing rate brain regions, neuron classes, or brain states (Paulsen and Sejnowski, 2000).

Hebbian STDP has other functional properties that are distinct from CDP, and arise from the spike order dependence and overall shape of the STDP learning rule. (1) LTD-biased STDP promotes stable firing rates in neuronal networks because LTP at effective synapses (which promotes higher firing rates) is counterbalanced by synapse weakening by spontaneous uncorrelated spiking (which reduces firing rates). This results in a stable state in which postsynaptic spikes occur relatively rarely and spike trains are irregular and physiologically realistic (Song et al., 2000; van Rossum et al., 2000). In contrast, CDP is unstable due to positive feedback between firing rate, firing correlation, and synapse strengthening (unless negative correlation is taken into account or a homeostatic form of metaplasticity is added). (2) STDP prevents formation of strong bidirectional recurrent excitation, which forms with correlation-based learning rules and helps drive runaway network activity (Abbott and Nelson, 2000; Clopath et al., 2010). (3) STDP implements competition between convergent inputs to a postsynaptic cell, which is a key feature of developmental plasticity (Katz and Shatz, 1996). Competition arises because synapses that fire first tend to generate pre-leading-post spike order and are strengthened, while later inputs exhibit post-leading-pre spike order and are weakened. As a result, strong early inputs competitively weaken other synapses with later or less effective input (Abbott and Nelson, 2000; Kempter et al., 1999; Song et al., 2000; Zhang et al., 1998). Correlation-based learning rules do not generate competition between inputs without constraints on total synapse strength or other normalization rules like history-dependent metaplasticity (Bienenstock et al., 1982). (4) STDP helps maintain synchronous spiking during signal propagation in feedforward networks, which is critical for network function (Bruno and Sakmann, 2006; Swadlow and Gusev, 2000; Usrey and Reid, 1999). Consider a feedforward network in which neurons exhibit a wide range of spike latency to a synchronous network input. With STDP, feedforward synapses onto postsynaptic cells that spike earliest will be weakened, thereby increasing spike latency, while synapses onto those cells that spike later will be strengthened, reducing their spike latency (Cassenaer and Laurent, 2007; Suri and Sejnowski, 2002; Zhigulin et al., 2003). (5) STDP is a powerful mechanism for learning temporal sequence information because sequential activation of connected neurons drives LTP at synapses from the first to the second neuron, but drives LTD at synapses in the reverse direction. The result is emergence of directional connectivity, tuning for learned sequences, and the ability to predict future events from past stimuli (Blum and Abbott, 1996; Engert et al., 2002; Fiete et al., 2010; Rao and Sejnowski, 2001). In contrast, CDP cannot, on its own, learn rapid sequence information.

Because of these theoretical properties, Hebbian STDP is widely proposed to store learned associations and temporal sequence information in excitatory networks and to contribute to use-dependent developmental maturation of excitatory synapses. In contrast, anti-Hebbian STDP is appropriate to reduce the representation of inputs that are temporally associated with a strong, spike-eliciting input (e.g., as occurs in cerebellum during storage of negative images of predicted sensory input) (Abbott and Nelson, 2000; Bell, 2001).

A major, unresolved debate is the relationship between Hebbian STDP and CDP. Section 9.5 discusses

whether these are mechanistically distinct forms of plasticity versus different operating regimes of the same fundamental plasticity mechanism. Here, functional evidence that STDP and CDP are strongly interrelated is reviewed. Despite the widespread notion that STDP depends only on spike timing, and not on firing rate, substantial evidence shows that STDP depends on pre- and postsynaptic firing rate and burst structure (Froemke and Dan, 2002; Markram et al., 1997; Nevian and Sakmann, 2006; Pfister and Gerstner, 2006; Sjostrom et al., 2001; Tzounopoulos et al., 2004; Wang et al., 2005; Wittenberg and Wang, 2006; Zilberter et al., 2009). For example, neocortical L5 and CA1 pyramidal cell synapses exhibit Hebbian STDP at moderate firing rates, but high pre- and postsynaptic firing rates (>10–50 Hz) induce LTP independent of spike timing, and low firing rates generate LTD with post-leading-pre firing order and no plasticity with pre-leading-post order (Markram et al., 1997; Sjostrom et al., 2001; Wittenberg and Wang, 2006). Unitary L2/3–L2/3 synapses similarly exhibit only LTD at low postsynaptic firing rates but exhibit Hebbian STDP during high-frequency postsynaptic bursts (Zilberter et al., 2009). These observations suggest that STDP operates primarily in a permissive middle range of firing frequency, while high firing rates drive correlation-dependent LTP and low firing rates produce a strong bias toward LTD (Figure 9.3(a)). STDP also requires a critical level of

subthreshold dendritic depolarization prior to spiking, which is generated by summation of EPSPs across multiple synaptic inputs and is necessary to allow effective backpropagation of spikes (Delgado et al., 2010; Sjostrom and Hausser, 2006; Sjostrom et al., 2001; Stuart and Hausser, 2001). Thus, STDP is interdependent on spike timing, firing rate, and subthreshold dendritic depolarization.

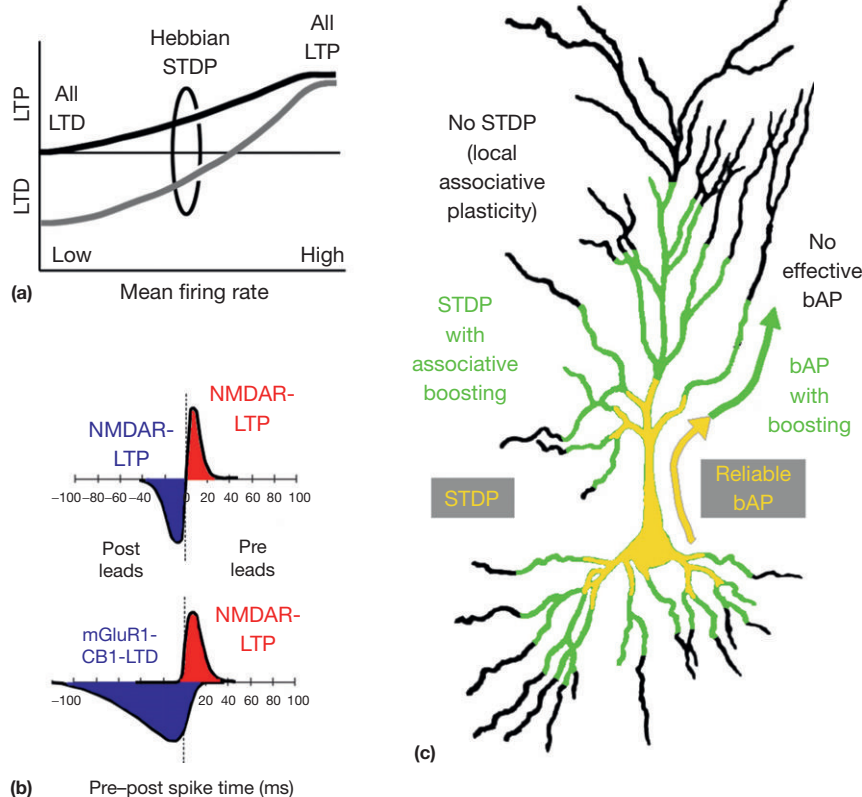
These experimental data suggest that STDP and CDP represent two functional modes of a single, more general plasticity mechanism. Some groups have argued that STDP is the fundamental 'kernel' of long-term plasticity – that STDP is driven by individual pairs of pre- and postsynaptic spikes and that nonlinear summation of STDP across spike pairs explains firing rate-dependent plasticity driven by sustained or complex spike trains (Froemke and Dan, 2002; Froemke et al., 2006; Pfister and Gerstner, 2006; Wang et al., 2005; Wittenberg and Wang, 2006). Other groups have argued that STDP and CDP represent distinct fundamental modes of a single, unified plasticity process that is sensitive to spike timing, firing rate, and postsynaptic voltage. Indeed, a unified biochemical model based solely on calcium and NMDA receptor dynamics successfully explains major properties of both STDP and firing rate-dependent LTP and LTD (Badoual et al., 2006; Shouval et al., 2002, 2010). Similarly, a phenomenological plasticity model based on interaction of presynaptic spikes with time-filtered postsynaptic membrane potential predicts all


FIGURE 9.3 Cellular mechanisms for STDP. (a) Firing rate dependence of STDP. Curves show magnitude of LTP or LTD that results from pre-leading-post (black) or post-leading-pre (gray) spike pairings, as a function of mean pre- or postsynaptic firing rate. Bidirectional Hebbian STDP occurs with moderate firing rates. (b) Hebbian STDP can be composed of NMDAR-LTP and NMDAR-LTD (top) or NMDAR-LTP and mGluR1–CB1-LTD (bottom). (c) Proposed dendritic zones for STDP, based on efficiency of action potential backpropagation through the dendrites.

major features of Hebbian STDP (Clopath et al., 2010; Pfister and Gerstner, 2006). If this unified view is correct, the term 'STDP' should be taken to describe the spike time dependence of the general hybrid time- and rate-dependent plasticity process, rather than a biochemically distinct form of plasticity.

The hybrid time- and rate-dependent model of plasticity powerfully predicts major features of circuit development in a cortical column-like network containing feedforward and recurrent synapses (Clopath et al., 2010). When input to the model consists of long-duration spike trains mimicking rate coding of sensory stimuli, feedforward synapses modify to generate small receptive fields, and recurrent synapses develop strong bidirectional connections between neurons with similar receptive fields (due to timing-independent LTP driven by high firing rates of coactive neurons). This behavior is classically expected from correlation-dependent Hebbian plasticity. In contrast, when model input consists of spatiotemporal sequences of brief spiking responses, feedforward synapses still undergo Hebbian plasticity to generate receptive fields, but recurrent synapses develop strong unidirectional connections that reflect the temporal sequence in the learned pattern, as predicted by STDP. Thus, the hybrid time- and rate-dependent model can explain activity-dependent development of key circuit features according to input statistics to different brain regions (Clopath et al., 2010).

In summary, Hebbian STDP has robust Hebbian properties and appears well suited to drive realistic circuit development for neurons, brain regions, and activity states with low firing rates. Despite its name, STDP depends not only on spike timing but also on firing rate and postsynaptic voltage, suggesting a close relationship to CDP. One view, supported by recent modeling studies, suggests that STDP and CDP are different operating regimes of a hybrid spike timing-, rate-, and depolarization-dependent plasticity mechanism. Because neuromodulation can also powerfully regulate STDP (see Section 9.5), three-factor plasticity rules that include presynaptic spiking, postsynaptic activity, and neuromodulatory signals are capturing increasing interest computationally (e.g., Fremaux et al., 2010) and experimentally.

9.5 CELLULAR MECHANISMS OF STDP

The distinct forms of STDP (Section 9.3) are mediated by distinct biochemical and molecular plasticity mechanisms. In addition, even nominally identical forms of STDP (e.g., Hebbian STDP at excitatory synapses) can be mediated by different biochemical pathways in different neurons or synapses. Thus, STDP is mechanistically heterogeneous across synapses. Here, a discussion is presented on STDP mechanisms in comparison with

mechanisms for classical correlation-dependent LTP and LTD, which are triggered by joint activation of glutamate receptors (NMDA receptors or metabotropic glutamate receptor – mGluRs) and postsynaptic depolarization. STDP appears to involve identical biochemical pathways, but the primary source of postsynaptic depolarization is somatic action potentials that backpropagate through the dendrites to active synapses (backpropagating APs, bAPs).

Three major, biochemically distinct forms of LTP and LTD have been shown to underlie both CDP and STDP: (1) NMDAR-dependent LTP, in which NMDARs detect correlated presynaptic glutamate release and postsynaptic depolarization by their dual requirement for glutamate binding and voltage-dependent relief of Mg^{2+} blockade. NMDARs flux calcium, which is the postsynaptic second messenger for plasticity. Strong correlated activity generates strong NMDA currents and high postsynaptic calcium, which activates protein kinases including CaMKII. CaMKII phosphorylates AMPA receptors (AMPARs), increasing single-channel conductance and triggering AMPAR delivery to the postsynaptic membrane, which is the primary expression mechanism for LTP (Malinow and Malenka, 2002). Presynaptic components of expression can also occur but are less understood (Enoki et al., 2009). (2) NMDAR-dependent LTD, in which weaker pre- and postsynaptic activity correlations evoke less NMDAR current than for LTP, leading to lower dendritic calcium. This activates protein phosphatases including PP1 and calcineurin, which trigger LTD by trafficking of AMPARs away from the postsynaptic membrane (Malinow and Malenka, 2002). In NMDAR-dependent LTP and LTD, the NMDAR is the sole coincidence detector for plasticity, and the sign of plasticity is determined by the magnitude and time course of NMDAR-mediated calcium flux, with high calcium generating LTP, moderate calcium LTD, and low calcium no plasticity (Artola and Singer, 1993; Lisman, 1989; Yang et al., 1999). (3) mGluR-dependent and/or cannabinoid type 1 (CB1) receptor-dependent LTD, which usually leads to LTD via a decrease in presynaptic transmitter release probability. Postsynaptic NMDARs are not required for this LTD. In CB1-dependent LTD, the retrograde signal is an endocannabinoid (eCB), a phospholipid transmitter synthesized by postsynaptic dendrites in response to calcium and/or mGluR activation, which diffuses retrogradely to activate CB1 receptors on the presynaptic terminal. CB1 receptors are G protein-coupled receptors that drive a long-lasting decrease in release probability via mechanisms that are still not completely understood (Chevaleyre et al., 2006; Wilson and Nicoll, 2002). While mGluR-dependent LTD typically involves CB1 signaling, some mGluR-dependent, CB1-independent forms of LTD also exist; however, they are not discussed separately here.

The large majority of STDP is composed of combinations of these three forms of LTP and LTD. Other forms of LTP and LTD exist but are less studied or not yet linked to STDP and are generally not considered here (Malenka and Bear, 2004).

9.5.1 Biochemical Signaling Pathways for Hebbian STDP

At least two mechanistically distinct forms of Hebbian STDP exist. The first form is composed of NMDA-dependent LTP and NMDA-dependent LTD and occurs at CA3–CA1 hippocampal synapses and some synapses on neocortical L2/3 pyramidal cells (Figure 9.3(b)). In this form of STDP, the NMDAR is the sole coincidence detector for appropriate pre- and postsynaptic spike timing. Thus, both LTP and LTD components of STDP require NMDARs (Froemke et al., 2005; Nishiyama et al., 2000). When a presynaptic spike occurs just before a postsynaptic spike (pre-leads-post), a strong supralinear calcium signal is produced via dendritic NMDARs, while post-leading-pre spike order triggers a weaker, sublinear calcium signal (Koester and Sakmann, 1998; Magee and Johnston, 1997). The magnitude of calcium signal is thought to be the sole trigger for plasticity, with high calcium driving LTP and low calcium driving LTD (Lisman, 1989). Spike timing is thought to control NMDAR-mediated calcium signals by several mechanisms. Brief pre-leading-post spike intervals drive maximal calcium signals because (i) the noninstantaneous kinetics of Mg^{2+} unblock of NMDA receptors causes maximal NMDA current to occur when glutamate release leads postsynaptic depolarization by a short interval (Kampa et al., 2004) and (ii) presynaptically evoked EPSPs inactivate A-type K^+ channels and activate voltage-gated sodium channels, generating a brief temporal window in which bAPs are boosted. This boosting of the bAP promotes greater NMDA current (Hoffman et al., 1997; Holbro et al., 2010; Stuart and Hausser, 2001). Post-leading-pre spike order generates weaker calcium signals because (i) glutamate release coincides with the modest depolarization following the bAP, generating NMDA currents only modestly greater than would occur at V_{rest} (Karmarkar and Buonomano, 2002; Shouval et al., 2002), and (ii) at some synapses, calcium influx during the bAP causes calcium-dependent inactivation of NMDA receptors so that presynaptic release evokes even less NMDA current (Froemke et al., 2005; Rosenmund et al., 1995; Tong et al., 1995).

This single coincidence detector model for STDP predicts that as pre-leading-post spike interval increases beyond the brief window for LTP, a second temporal window for LTD will occur because calcium will be reduced compared to its high value at short pre-leading-post intervals (Abarbanel et al., 2003; Karmarkar and Buonomano, 2002; Shouval et al., 2002). This second LTD window has been observed at CA3–CA1 synapses (Wittenberg and Wang, 2006) but, surprisingly, not at L2/3 synapses that are proposed to also use the single coincidence detector mechanism (Froemke and Dan, 2002).

The second major form of Hebbian STDP involves a combination of NMDA-dependent LTP and mGluR- and/or CB1-dependent LTD (Figure 9.3(b)). This form occurs at several synapses in L2/3 and L5 of the somatosensory and visual cortex and at cortical synapses onto striatal medium spiny neurons under conditions of GABAergic blockade. Here, postsynaptic NMDA receptors are required for spike timing-dependent LTP, but not LTD (Bender et al., 2006b; Corlew et al., 2007; Fino et al., 2010; Nevian and Sakmann, 2006; Rodriguez-Moreno and Paulsen, 2008; Sjostrom et al., 2003). LTD instead requires postsynaptic group I mGluRs; its effector phospholipase C; low-threshold T-, R-, or L-type voltage-sensitive calcium channels (VSCCs); and calcium release from inositol trisphosphate (IP3) receptor-gated internal stores (Bender et al., 2006b; Bi and Poo, 1998; Fino et al., 2010; Nevian and Sakmann, 2006; Nishiyama et al., 2000; Seol et al., 2007). These are components of a major NMDAR-independent pathway for synaptically evoked postsynaptic calcium release (Berridge, 1993). In addition, mGluRs and postsynaptic calcium synergistically drive eCB synthesis and release (Nakamura et al., 1999), leading to activation of presynaptic CB1 receptors and a reduction in release probability (Chevaleyre et al., 2006; Wilson and Nicoll, 2002). Thus, this form of LTD requires retrograde eCB signaling to CB1 receptors, and expression occurs by a decrease in presynaptic transmitter release probability (Bender et al., 2006b; Fino et al., 2010; Nevian and Sakmann, 2006; Rodriguez-Moreno and Paulsen, 2008; Sjostrom et al., 2003). This STDP involves two separate coincidence detectors: NMDA receptors detect pre-leading-post spike intervals and exclusively trigger LTP, whereas a separate mechanism within the mGluR–VSCC–PLC–IP3R–CB1 pathway detects post-leading-pre spike intervals and exclusively triggers LTD (Bender et al., 2006b; Fino et al., 2010; Nevian and Sakmann, 2006). As a result, dendritic calcium concentration is not strictly correlated with the sign of plasticity (Nevian and Sakmann, 2006), and unlike for the single coincidence detector form of STDP, no second LTD window exists (Bender et al., 2006b; Feldman, 2000; Froemke and Dan, 2002; Sjostrom et al., 2001). Remarkably similar mechanisms have been observed during non-Hebbian STDP LTD at the parallel fiber–cartwheel cell synapse in the dorsal cochlear nucleus (Tzounopoulos et al., 2007).

Though independent of postsynaptic NMDARs, the mGluR–CB1-dependent form of LTD often depends on

presynaptic NMDARs (preNMDARs) (Bender et al., 2006b; Casado et al., 2002; Corlew et al., 2007; Rodriguez-Moreno and Paulsen, 2008; Sjostrom et al., 2003). Extensive anatomical and physiological evidence supports the existence of preNMDARs at some synapses, which act as autoreceptors to boost release probability during baseline synaptic transmission (Berretta and Jones, 1996; Brasier and Feldman, 2008; Corlew et al., 2008; McGuinness et al., 2010). At synapses with this form of STDP, intracellularly loading the NMDAR blocker MK-801 into the presynaptic neuron blocks only LTD, while loading MK-801 into the postsynaptic neuron blocks only LTP (Rodriguez-Moreno and Paulsen, 2008). PreNMDARs contain NR2B, NR2C/D, and/or NR3A subunits, and STDP LTD is selectively blocked by NR2B and NR2C/D antagonists and in NR3 knockouts (Banerjee et al., 2009; Bender et al., 2006b; Corlew et al., 2008; Larsen et al., 2011; McGuinness et al., 2010; Sjostrom et al., 2003; Woodhall et al., 2001). PreNMDAR function is most prominent in early postnatal development, and spike timing-dependent LTD that is presynaptic and requires preNMDARs in juvenile cortex can become postsynaptic and independent of preNMDARs in older animals (Corlew et al., 2007) or can disappear altogether (Banerjee et al., 2009).

How the mGluR–VSCC–CB1–preNMDA signaling pathway detects appropriate post-leading-pre spike intervals for LTD is not known. In one model, each postsynaptic spike releases eCB to activate presynaptic CB1Rs, each presynaptic spike provides depolarization (and likely glutamate) to activate preNMDARs, and coincident CB1 and preNMDAR activation is required to drive LTD (Duguid and Sjostrom, 2006; Sjostrom et al., 2003). In this model, the post-leading-pre window for LTD reflects the delay and duration of CB1 activation following each postsynaptic spike, and preNMDAR activation restricts LTD to temporally coactive synapses. Consistent with this model, increasing eCB signal duration by inhibiting eCB catalysis broadens the LTD window, and pairing presynaptic spikes with exogenous CB1 agonists drives LTD (Sjostrom et al., 2003). In a second model, the spike order and timing detector for LTD is either phospholipase C (PLC), which is a known molecular coincidence detector that detects joint mGluR activation and VSCC-derived cytosolic calcium, or the IP3 receptor, which is activated by synergism between PLC-produced IP3 and cytosolic calcium (Berridge et al., 2003; Manita and Ross, 2009; Nakamura et al., 1999; Sarkisov and Wang, 2008). Acting through these or other mechanisms, mGluRs and calcium synergistically facilitate eCB synthesis, release, and synaptic plasticity (Chevaleyre et al., 2006; Hashimotodani et al., 2005, 2007). In this model, presynaptic spikes activate mGluRs, postsynaptic spikes drive VSCC calcium entry, and appropriately timed activation of both pathways is required for sufficient eCB release. This eCB signal then instructs LTD

at presynaptic terminals at which preNMDARs have been recently active (Bender et al., 2006b).

Recent evidence suggests that Hebbian STDP can also involve two other forms of LTP. Retinotectal synapses in *Xenopus laevis* and immature hippocampal mossy fibers exhibit spike timing-dependent LTD that is presynaptically expressed and is thought to use brain-derived neurotrophic factor (BDNF) as a retrograde signal (Mu and Poo, 2006; Sivakumaran et al., 2009; Zhou et al., 2003). BDNF has also been implicated in postsynaptic structural changes associated with STDP LTP (Tanaka et al., 2008). STDP LTP at L4–L2/3 synapses in the mature somatosensory cortex appears to require retrograde signaling by nitric oxide (Hardingham and Fox, 2006).

9.5.2 Biochemical Signaling Pathways for Anti-Hebbian and All-LTD STDP

Excitatory synapses onto inhibitory cartwheel cells in dorsal cochlear nucleus exhibit STDP that consists only of presynaptic CB1-mediated LTD at pre-leading-post time intervals (Figure 9.2(i)). Strikingly, at higher stimulation frequencies, these cells express postsynaptic NMDAR-dependent LTP, echoing the coexistence of these mechanisms in Hebbian STDP (Tzounopoulos et al., 2007). All-LTD STDP at parallel fiber–Purkinje cell synapses also involves postsynaptic mGluRs, VSCCs, IP3Rs, and presynaptic CB1 receptor activation but is expressed postsynaptically by AMPAR internalization (Safo and Regehr, 2005; Steinberg et al., 2006). Strong evidence suggests that the IP3 receptor is the order-dependent coincidence detector for this form of STDP (Berridge, 1993; Sarkisov and Wang, 2008; Wang et al., 2000). At other synapses, all-LTD STDP involves postsynaptic mGluR signaling (Birtoli and Ulrich, 2004; Egger et al., 1999; Lu et al., 2007) and sometimes IP3R signaling (Lu et al., 2007).

Overall, no unique cellular mechanisms have been discovered that differentiate STDP from previously known, non-spike timing-dependent forms of LTP and LTD. Instead, STDP at a given synapse seems to be a combination of a classical LTP mechanism (primarily NMDA-dependent, postsynaptic LTP) plus a known LTD mechanism (either postsynaptic NMDA-dependent LTD or mGluR/CB1-dependent presynaptic LTD). Therefore, the time-dependent features of STDP must result from previously unknown, short-timescale temporal dependence of these signaling pathways.

9.5.3 Dendritic Excitability and STDP

For postsynaptic somatic spikes to control STDP, they must backpropagate from the axonal initiation site to the synapse, where they relieve Mg^{2+} blockade of

glutamate-bound NMDA receptors at active synapses or open nearby VSCCs. Backpropagation is governed by voltage-dependent sodium, potassium, and hyperpolarization-activated cyclic nucleotide-gated (HCN) channels in dendrites (Spruston, 2008). Dendritic excitability therefore critically governs STDP. A major feature is that bAPs backpropagate decrementally so that in distal dendrites, they do not provide sufficient depolarization, when paired with a small EPSP for STDP. In the most distal branches, bAPs fail completely (Spruston, 2008). As a result, STDP in distal dendrites requires additional dendritic depolarization in addition to the bAP: either summated EPSPs from nearby convergent inputs (Sjostrom and Hausser, 2006; Sjostrom et al., 2001) or a brief burst of postsynaptic spikes at sufficiently high frequency (Froemke and Dan, 2002; Markram et al., 1997; Nevian and Sakmann, 2006; Sjostrom et al., 2001; Tzounopoulos et al., 2004; Wittenberg and Wang, 2006). These supralinearly boost the level of depolarization at the synapse and can activate dendritic sodium channels to allow bAPs to propagate more effectively to the synapse (Sjostrom and Hausser, 2006; Stuart and Hausser, 2001). This additional depolarization can also evoke local sodium or calcium spikes in the dendrite, which strongly promote STDP and other forms of plasticity (Golding et al., 2002; Kampa et al., 2006; Zhou et al., 2005). The dependence of STDP at many synapses on postsynaptic firing rate and postsynaptic bursts likely reflects this requirement for additional dendritic depolarization in addition to the bAP.

Dendritic filtering of bAPs appears to establish dendritic zones for STDP in pyramidal neurons (Kampa et al., 2007; Spruston, 2008; Figure 9.3(c)). Synapses on proximal dendrites, which experience strong bAPs, may exhibit STDP in response to single presynaptic and postsynaptic spikes. Somewhat more distal synapses require bAPs plus large EPSPs from multiple nearby synapses, or postsynaptic spike bursts, to drive STDP, perhaps with local dendritic spikes as intermediaries. Synapses on the most distal dendrites are likely to be outside the influence of bAPs so that STDP governed by somatic spikes is absent. These synapses instead exhibit plasticity based on strong local EPSPs that elicit dendritic sodium or calcium spikes or regenerative NMDA spikes (Golding et al., 2002; Gordon et al., 2006). The different magnitude and kinetics of depolarization in proximal versus distal dendrites can result in dramatically different STDP rules (Froemke et al., 2005; Letzkus et al., 2006). Thus, dendritic filtering of bAPs, plus other specializations (e.g., gradients of voltage-activated K^+ channels), leads to distinct dendritic 'plasticity zones' in which different rules for synapse modification exist. These may contribute to activity-dependent stabilization of different functional classes of synapses within these regions (Froemke et al., 2005).

As a result, dynamic modulation of dendritic excitability is predicted to strongly influence the magnitude and spatial extent of STDP. Local network states (e.g., UP states) and recent somatic depolarization can increase bAP amplitude (Tsubokawa et al., 2000; Waters and Helmchen, 2004), which may enhance STDP. Neuromodulators that alter bAP propagation (e.g., muscarinic acetylcholine receptors) could similarly increase or decrease the power of somatic spikes in controlling synaptic plasticity (Sourdet and Debanne, 1999; Tsubokawa and Ross, 1997). GABAergic inhibition increases the threshold for bAP backpropagation, which may suppress STDP (van den Burg et al., 2007), although STDP clearly occurs in networks with inhibition intact (Jacob et al., 2007; Meliza and Dan, 2006). Background activity, neuromodulation, and inhibition represent global factors that when added to mathematical STDP rules are likely to generate new adaptive capabilities in large recurrent networks of neurons (Clopath et al., 2010; Legenstein et al., 2008; Pfister and Gerstner, 2006).

9.5.4 Neuromodulatory Control of STDP

Many forms of plasticity are strongly regulated by behavioral state, including attention, vigilance, and reinforcement (e.g., Ahissar et al., 1992; Bao et al., 2001). These behavioral variables are mediated in the brain by acetylcholine, dopamine, noradrenaline, and other neuromodulators (Aston-Jones et al., 1991; Devauges and Sara, 1990; Sarter and Bruno, 2000; Sarter et al., 2005; Schultz, 2002). Substantial evidence shows that neuromodulation (particularly by acetylcholine) is required for use-dependent sensory plasticity in primary sensory cortex *in vivo*, both in juveniles (Bear and Singer, 1986; Kasamatsu and Pettigrew, 1976; Weinberger, 2003) and adults (Bakin and Weinberger, 1996; Delacour et al., 1990; Edeline et al., 1994a,b; Hars et al., 1993; Juliano et al., 1991; Metherate et al., 1988; Molina-Luna et al., 2009; Rasmusson and Dykes, 1988; Webster et al., 1991). Correspondingly, pairing sensory stimulation with microstimulation of cholinergic or dopaminergic afferents or focal application of acetylcholine induces robust long-term plasticity of sensory responses (Ego-Stengel et al., 2001; Kilgard and Merzenich, 1998; Shulz et al., 2000, 2003). These pairing effects can be temporally asymmetric: during pairing of auditory stimuli with microstimulation of the dopaminergic ventral tegmental area (VTA), responses to auditory stimuli that preceded VTA activity are enhanced in auditory cortex, while responses to stimuli that followed VTA activity are reduced (Bao et al., 2001). Thus, neuromodulators powerfully regulate cortical plasticity and can selectively reinforce sensory responses depending on their timing relative to neuromodulatory supervising signals. This

suggests that neuromodulation may be a third parameter (besides pre- and postsynaptic spiking) that governs the outcome of synaptic plasticity, including STDP (Ahissar et al., 1996; Crow, 1968; Kety, 1970; Pawlak et al., 2010; Reynolds and Wickens, 2002).

Neuromodulatory signals may affect STDP induction via a number of cellular and network parameters. On the network level, attention-related modulatory signals alter the sparseness of cortical activity (Vinje and Gallant, 2002) potentially rendering the system more sensitive to STDP induction. For instance, noradrenaline release in the visual cortex produces a reduction in the level of spontaneous and evoked activity (Ego-Stengel et al., 2002) which may lead the system into an optimized range of activity for STDP induction. However, no direct experimental evidence for this hypothesis is available yet.

On the cellular level, acetylcholine could dynamically regulate STDP by modifying the biophysical properties of dendrites and the amplitude and extent of bAPs (Sandler and Ross, 1999; Tsubokawa and Ross, 1997), whose backpropagation into the dendritic tree is required for STDP (Engelmann et al., 2008; Sjostrom et al., 2008). bAP backpropagation is well known to be modulated by the network state (Waters and Helmchen, 2004) and dendritic depolarization (Sjostrom and Hausser, 2006), both of which are modulated by ascending cholinergic signals (Colbert and Johnston, 1998; Hoffman and Johnston, 1998). Direct evidence for neuromodulatory control of STDP was shown by Seol et al. (2007), who discovered that acetylcholine and noradrenaline synergistically regulate STDP in the visual cortex *in vitro*: combined application of a muscarinic M1 agonist and a beta-adrenergic agonist enabled bidirectional STDP, while separate application of these agonists enabled spike timing-dependent LTD only and LTP only. Strong evidence also shows that dopamine (DA) modulates STDP in several brain structures (Bissiere et al., 2003; Couey et al., 2007; Lin et al., 2008; Pawlak and Kerr, 2008; Seol et al., 2007; Shen et al., 2008; Zhang et al., 2009; reviewed in Pawlak et al., 2010). Dramatic changes in the shape of the STDP curve were observed, for example, in CA1 hippocampal neurons in the presence of DA (Zhang et al., 2009) with a widening of the LTP side of the rule for pre–post pairings and an inversion of plasticity for the post–pre pairings.

Most, if not all, of the studies exploring the effect of neuromodulatory agents on STDP have been done *in vitro* (but see Cassenaer and Laurent, 2012 for an *in vivo* example of neuromodulation of the STDP rule by octopamine in the olfactory system of the locust). One cannot exclude that the timing of drug application relative to the conditioning stimuli and/or the local concentration of the neuromodulator at relevant synapses, both parameters not under control in the *in vitro* studies, are of

particular importance *in vivo* (Ahissar et al., 1996). Further *in vivo* experiments combining STDP induction protocols and selective activation of neuromodulatory ascending systems are needed to explore how local rules of synaptic plasticity are regulated by global factors acting on several spatial and temporal scales.

9.6 IS STDP RELEVANT *IN VIVO*?

Neuronal networks in the intact brain show an activity regime radically different from that in the *in vitro* quiescent slice or cell culture. This includes differences in the levels of neuromodulation and inhibition and the presence of spontaneous network activity that generates strong ongoing synaptic bombardment *in vivo*. Because all these factors powerfully regulate STDP induction, the relevance of STDP *in vivo* has been questioned. Of particular importance is whether backpropagating somatic action potentials are the major source of dendritic depolarization for plasticity *in vivo* (Lisman and Spruston, 2005). Strong inhibition and intense background synaptic activity reduce the ability of backpropagating action potentials to invade the dendritic tree (Sjostrom and Hausser, 2006), possibly preventing STDP induction (van den Burg et al., 2007). Instead, it has been proposed that the primary drivers of synaptic plasticity *in vivo* are locally generated dendritic spikes, which implement local associative plasticity within each dendritic branch or compartment (Golding et al., 2002; Gordon et al., 2006). Such plasticity would be computationally distinct from STDP because it is driven purely by local synaptic associations, rather than associations between synaptic input and somatic spiking.

To evaluate whether STDP is relevant *in vivo*, the evidence that STDP is induced *in vivo* under experimental conditions tailored to elicit it is discussed first and, second, whether STDP is likely to be a prominent learning rule during natural (nonexperimental) conditions. The current evidence is suggestive, but not yet compelling, that STDP does occur *in vivo* under experimental conditions tailored to elicit STDP. This section summarizes this evidence, which is discussed in more detail in Sections 9.7 and 9.8.

The strongest evidence comes from studies in which sensory stimuli are carefully timed with respect to evoked spikes in single recorded neurons, and STDP is assessed at the level of subthreshold synaptic responses (Bell et al., 1997; Cassenaer and Laurent, 2007; Engert et al., 2002; Jacob et al., 2007; Levy and Steward, 1983; Meliza and Dan, 2006; Mu and Poo, 2006; Zhang et al., 1998). The first evidence was from Levy and Steward (Levy and Steward, 1983), who electrically stimulated pre- and postsynaptic neurons in the hippocampus in the anesthetized rat and showed that associative

induction of potentiation and depression depended on the temporal order of stimulation. A series of studies in the retinotectal system of *X. laevis* tadpoles showed that natural visual motion stimuli elicit STDP at tectal synapses, measured from changes in visually evoked synaptic currents in tectal neurons (Engert et al., 2002; Mu and Poo, 2006; Zhang et al., 1998). In visual and somatosensory cortex of anesthetized rats, pairing sensory stimuli with postsynaptic spiking induced by intracellular current injection causes STDP of sensory-evoked postsynaptic potentials (Jacob et al., 2007; Meliza and Dan, 2006), although this plasticity is of substantially lower amplitude and more variable than in cortical slices (Feldman, 2000; Froemke and Dan, 2002).

Additional evidence comes from studies that infer STDP indirectly from changes in extracellularly recorded spiking and sensory perception following precisely timed presentation of sensory stimuli. In visual cortex of young and adult cats, pairing visual and/or electrical stimulation at precise time intervals induces changes in neural tuning (e.g., in orientation selectivity and receptive field location) that are compatible with STDP at horizontal, cross-columnar synapses (Fu et al., 2002; Yao and Dan, 2001; Yao et al., 2004) and the corresponding reorganization of cortical maps (Schuett et al., 2001). These same sensory stimulation protocols drive shifts in perception of orientation and position in humans with order and interval dependence consistent with STDP. This strongly suggests that STDP or STDP-like plasticity occurs in the intact brain under attentive conditions (Fu et al., 2002; Yao and Dan, 2001). Similar neurophysiological results were observed in primary auditory cortex of adult ferrets (Dahmen et al., 2008). However, these effects are much smaller and variable than STDP in brain slices, despite large numbers of pairings (Fu et al., 2002; Jacob et al., 2007; Meliza and Dan, 2006; Yao and Dan, 2001). In somatosensory cortex of adult rats, pairing spontaneous action potentials with subsequent whisker deflection drives selective depression of neural responses to the paired whisker consistent with STDP (Jacob et al., 2007). The magnitude of plasticity is again rather small, which may reflect the complex neural network activity that occurs in response to sensory stimuli and which may affect the probability of STDP induction (see Frégnac et al., 2010 for a critical review of these data). Nevertheless, the temporal specificity and the sign of plasticity observed in these studies are in agreement with STDP.

Some properties of plasticity induced *in vivo* are not identical to STDP *in vitro*. For example, STDP *in vivo*, in addition to being smaller and more variable than in brain slices, persists for just 10–15 min before being reversed by ongoing spontaneous activity (Yao and Dan, 2001; Zhou et al., 2003). In addition, the range of synaptic delays that drives synaptic depression *in vivo* is often narrower than *in vitro* (e.g., Cassenaer and Laurent, 2007; Dahmen et al., 2008; Fu et al., 2002; Jacob et al., 2007; Yao and Dan, 2001). Importantly, evidence for spike timing-dependent potentiation in mammalian cortex is weaker than for depression. Only a few studies have attempted to measure potentiation separately from depression in mammalian cortex, but these have found depression to be consistently induced, while potentiation is rarer and may be absent on average (Jacob et al., 2007; Meliza and Dan, 2006). In contrast, spike timing-dependent potentiation does clearly occur at developing retinotectal synapses (Engert et al., 2002). Thus, spike timing-dependent depression may be more robust in the cortex *in vivo* than potentiation, although more studies are needed to evaluate this. One difficulty in comparing STDP between *in vivo* and *in vitro* models is the heterogeneity in experimental protocols applied to induce STDP (Shulz, 2010; Shulz and Jacob, 2010). These include pairing sensory or synaptic stimulation with intracellular current injection to elicit one postsynaptic spike, pairing stimulation with a vigorous postsynaptic spike burst, pairing sensory–sensory stimulation, and differences in the number of pairings and anesthetic state. Neural networks react radically differently under these conditions, making comparisons of plasticity difficult.

While these studies suggest that STDP or STDP-like plasticity can occur *in vivo*, the functional importance of STDP relative to other synaptic learning rules during natural sensory input is unclear (reviewed in Caporale and Dan, 2008; Dan and Poo, 2006; Shulz and Jacob, 2010). That is, is STDP a major learning rule under natural conditions *in vivo*? This question is almost entirely untested and depends critically on both the availability of STDP mechanisms at the cellular level *in vivo* and the temporal patterns of spiking induced by natural sensory stimulation. In the primary visual cortex of the anesthetized adult cat, imposed covariance of pre- and postsynaptic spiking drives plasticity more robustly than presynaptic theta burst stimulation, which is thought to evoke postsynaptic spikes with a pre-leading-post spike order. This has been interpreted to suggest that firing correlations drive plasticity more efficiently than STDP (Frégnac et al., 2010). In contrast, evidence strongly suggests that spike order drives STDP during natural visual stimulation in the developing *Xenopus* optic tectum (Section 9.7.3). A major complication in all *in vivo* tests of STDP is the use of anesthesia, except for demonstration of small STDP-like effects on visual perception in humans (Fu et al., 2002; Yao and Dan, 2001). Additional work in awake animals will be required to assess the prominence of STDP under natural conditions.

9.7 FUNCTIONS OF STDP IN DEVELOPMENT

STDP is an increasingly prominent candidate mechanism to mediate activity- and experience-dependent components of neural circuit development. However, proof that it plays a causal role in circuit development is limited to a few brain regions. Here, evidence for this developmental role for STDP is summarized. The focus is on three questions: (1) Are developing synapses capable of STDP? (2) What are the predicted functions of STDP in development, based on theory and simulation? (3) What developmental functions have been empirically demonstrated to result from STDP *in vivo*?

9.7.1 Are Developing Synapses Capable of STDP?

Most studies of STDP at the synaptic and mechanistic levels have been performed in brain slices from juvenile, 2–3-week-old rats and mice or from developing *Xenopus* or chicks (Egger et al., 1999; Feldman, 2000; Froemke and Dan, 2002; Lu et al., 2007; Markram et al., 1997; Nevian and Sakmann, 2006; Sjostrom et al., 2001; Tzounopoulos et al., 2004; Wittenberg and Wang, 2006; Zhang et al., 1998). This is a period of robust circuit development and activity- and experience-dependent synapse refinement. Thus, STDP operates during activity-dependent development. Indeed, Hebbian STDP has been demonstrated *in vivo* at these ages, by pairing sensory stimulation with postsynaptic spikes evoked by extracellular or intracellular current injection or by sensory stimulation (discussed in detail below) (Engert et al., 2002; Jacob et al., 2007; Meliza and Dan, 2006; Mu and Poo, 2006; Schuett et al., 2001; Vislay-Meltzer et al., 2006; Zhang et al., 2000).

At older ages, STDP rules may change, though the evidence is somewhat conflicting. In brain slice experiments in L2/3 pyramidal cells in mouse S1, STDP LTD cannot be induced after P25, while STDP LTP persists into adulthood (Banerjee et al., 2009; Hardingham and Fox, 2006). In L2/3 of V1, STDP LTD similarly becomes more difficult to elicit after P23 but can be rescued if gamma-aminobutyric acid receptor type A (GABA-A) receptors are blocked during LTD induction (Corlew et al., 2007). These findings support a prevalent view that LTD is primarily a developmental phenomenon, but LTP is robust throughout life (Bear and Abraham, 1996). At odds with this view, STDP LTD can occur in L2/3 and L5 of adult S1 *in vivo* by pairing spontaneous postsynaptic spikes with whisker stimulation (Jacob et al., 2007), though this effect is weaker than in juveniles. It remains possible that LTD is robust in adults with appropriate neuromodulation (Seol et al., 2007).

Despite its prevalence in developing circuits, STDP is not universal, and is confined to specific synapses and dendritic locations, and requires specific spike train patterns to be activated (as reviewed in Sections 9.3 and 9.4). As a result, it is an empirical question whether STDP is a dominant force shaping neural circuit development, relative to other activity-dependent forms of synaptic plasticity.

9.7.2 What Are the Predicted Functions of STDP in Development, Based on Theory and Simulation?

In the activity-dependent phase of neural circuit development, coarse initial circuits that were specified by innate molecular cues are refined and optimized by sensory-driven and spontaneous neural activity. This occurs prominently during early postnatal life. It has been studied extensively in developing sensory maps, where early sensory experience shapes neuronal sensory responses, stimulus selectivity (sensory tuning), and microcircuit topography (Feldman and Brecht, 2005; Hensch, 2005; Ruthazer, 2005; White and Fitzpatrick, 2007). Computational studies over the past 25 years have shown that key features of activity-dependent development and plasticity can be explained by classical CDP, working together with additional mechanisms that implement activity-dependent competition between inputs (Miller, 1994). More recent computational studies show that Hebbian STDP drives realistic circuit development and plasticity, including features not predicted by CDP.

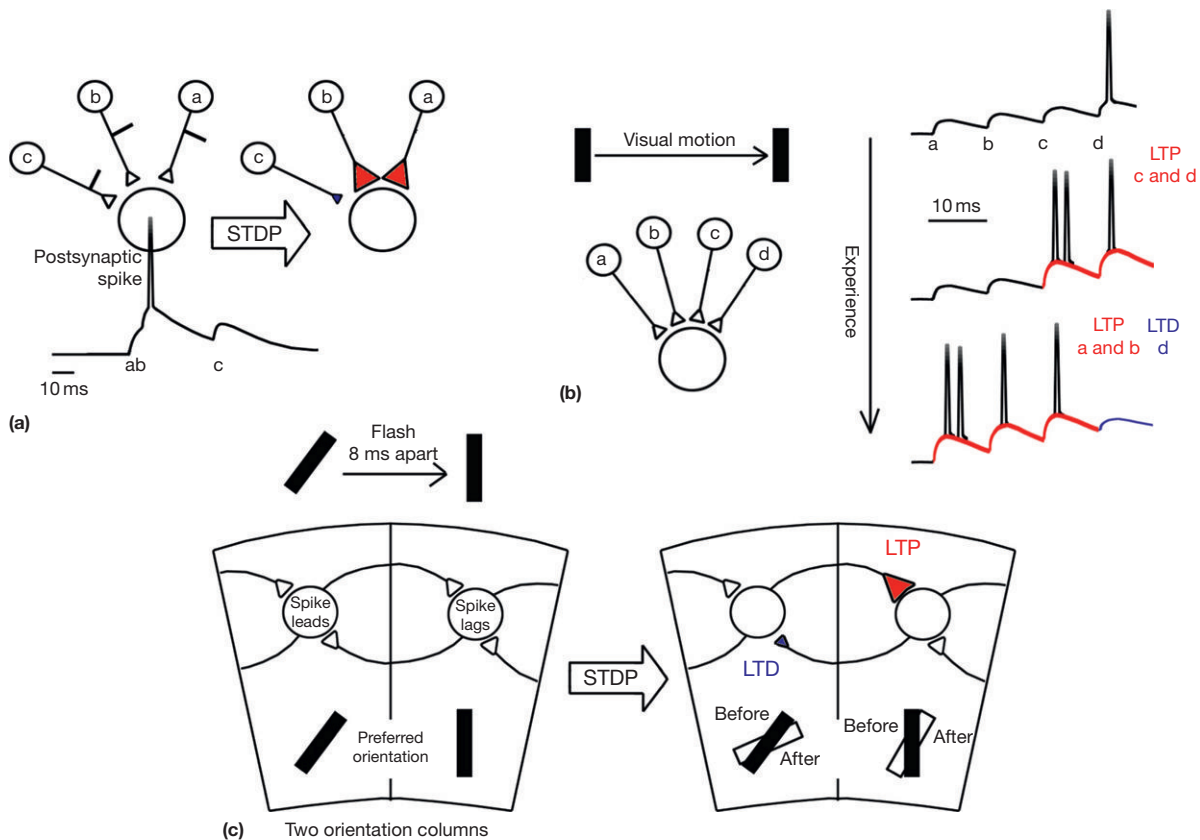
STDP has been shown in computational models to drive six common features of network development and experience-dependent plasticity (reviewed in detail in Abbott and Nelson, 2000; Gilson et al., 2010a). These include: (1) Basic Hebbian strengthening of coactive inputs that associatively evoke postsynaptic spikes and weakening of inputs with later or uncorrelated firing that fails to evoke postsynaptic spikes. This is illustrated in Figure 9.4(A). (2) Segregation of inputs onto target neurons based on temporal correlations of input spiking (Clopath et al., 2010; Gilson et al., 2010b; Gutig et al., 2003; Song and Abbott, 2001; Song et al., 2000). This property can explain both experience-dependent development of sensory receptive fields and gross segregation of inputs into distinct zones within a target region. Correlation-driven input segregation occurs in both networks with initially random connection strength and networks with coarse preexisting structure, corresponding to *de novo* emergence of circuit structure and plasticity of early innate circuits (Song and Abbott, 2001). (3) Selectivity for experienced spatiotemporal patterns (sequences) of input, including direction-selective responses in vision and spatial trajectories in the


FIGURE 9.4 Some roles of STDP in synapse development and adult plasticity. (A) STDP strengthens initially weak synapses that show correlated firing (a, b) and weakens synapses with later or uncorrelated firing (c). Trace shows EPSPs mediated by each synapse and an evoked postsynaptic spike, prior to STDP. LTP is in red; LTD is in blue. (B) Development of motion direction-selective responses by STDP. Four presynaptic cells (a–d) are imagined to be driven sequentially by a rightward moving visual stimulus. Traces show visual motion-evoked EPSPs and spikes in the postsynaptic cell prior to visual experience (top) and with increasing experience. Synapses are initially weak (black EPSPs). Visual experience causes synapses active before postsynaptic spikes to strengthen (red) and synapses active after postsynaptic spikes to weaken (blue). This increases responses to motion stimuli and shifts the receptive field to 'upstream' locations. (C) Hypothesis for plasticity of orientation tuning induced by flashing two oriented bars at a precise time delay. When an oblique bar is flashed before a vertical bar, cells in the oblique orientation column spike before the vertical column. This induces STDP at intracolumnar synapses between columns. These changes in intracolumnar projection efficacy cause orientation tuning to shift toward the first orientation and away from the second.

hippocampal place system (Blum and Abbott, 1996; Buchs and Senn, 2002; Mehta et al., 2000; Rao and Sejnowski, 2001). This reflects emergence of directional connections within recurrent networks, which does not occur by CDP (Clopath et al., 2010). In motor networks, this sequence learning mechanism causes the emergence of spontaneous repeated spike train sequences, which are useful in motor patterning (Fiete et al., 2010). (4) Competition between inputs, in which strong correlated activity in one set of inputs weakens other inputs (Kempter et al., 1999; Song et al., 2000; van Rossum et al., 2000; Zhang et al., 1998). Competition is a common feature of developmental plasticity but is not inherent in CDP (Miller, 1994). Competition emerges in STDP because correlated inputs summate to drive short-latency postsynaptic spikes, which in turn weaken subsequent, noncorrelated inputs. (5) Emergence of stable, physiologically realistic firing rates and naturalistic irregular spike trains (Kempter et al., 2001; Song et al., 2000). See Section 9.3 for explanation. (6) Establishment of coincidence detection by neurons (Fontaine and Peremans, 2007; Gerstner et al., 1996) and enhancement of temporal synchrony across neurons (Masuda and Kori, 2007). While submillisecond coincidence detection is a unique property of some auditory neurons, ~10-ms timescale coincidence detection is a basic feature of sensory neocortex and could be tuned, in part, by STDP (Azouz and Gray, 2003; Roy and Alloway, 2001).

Because of these findings, Hebbian STDP has emerged as a strong candidate mechanism for activity-dependent development of neural circuits. A detailed comparison between STDP and specific CDP models is beyond the scope of this review, but one major competing model is the Bienenstock, Cooper, and Munro (BCM) model that incorporates firing rate-dependent LTP and LTD with activity-dependent metaplasticity (Bienenstock et al.,

1982). This model explains many features of activity-dependent development and plasticity in sensory cortex (Smith et al., 2009). Remarkably, several implementations of STDP have been shown to be functionally equivalent to BCM, suggesting that they may reflect equivalent cellular processes (Clopath et al., 2010; Izhikevich and Desai, 2003; Senn et al., 2001).

While STDP may play a significant role in development, it cannot be universal. In some early developing networks, postsynaptic neurons are too immature to generate somatic sodium spikes (e.g., in L2/3 of S1 cortex in the first few days of whisker use) (Stern et al., 2001). STDP cannot guide development of synapses onto these neurons, but may function a few days later, as sensory-evoked spikes increase (Bureau et al., 2004). Likewise, brain regions that generate relatively few, precisely timed spikes in response to sensory input may be most likely to utilize STDP, whereas regions with high sensory-driven or spontaneous firing rates that are modulated at slow timescales are likely to use other forms of plasticity. For example, ON and OFF retinal ganglion cells exhibit prolonged spontaneous spike bursts (retinal waves) with ~1 s temporal offset between these cell populations. Development of segregated ON and OFF input zones in the lateral geniculate nucleus requires a burst-dependent learning rule that is sensitive to longer timescale correlations, rather than STDP, which is sensitive to ms-scale correlations (Gjorgjieva et al., 2009).

9.7.3 What Developmental Functions Have Been Empirically Demonstrated to Result from STDP *In Vivo*?

Experimental studies testing how STDP contributes to circuit development have focused primarily on three areas: use-dependent development of visual response properties in the optic tectum of *X. laevis*, use-dependent development of visual response properties in the mammalian visual cortex (V1), and deprivation-induced plasticity in the mammalian sensory cortex, primarily the rodent somatosensory cortex (S1). These are reviewed here.

9.7.3.1 STDP in Emergence of Direction Selectivity in *Xenopus* tectum

STDP can store information about spatiotemporal patterns of input activity (Blum and Abbott, 1996; Clopath et al., 2010; Mehta et al., 2000; Rao and Sejnowski, 2001). In vision, a highly relevant spatiotemporal pattern is visual motion, and many neurons in adults are selective (tuned) for visual motion direction. In the retinotectal system of *X. laevis*, strong evidence indicates that early visual experience with moving stimuli causes neurons to develop motion direction tuning via STDP.

In young *Xenopus* tadpoles, tectal neurons initially lack selectivity for visual motion direction. When a bar is repeatedly moved in a consistent direction across a young neuron's receptive field, excitatory synaptic responses evoked by the trained movement direction are selectively increased, causing tectal neurons to become tuned for the trained direction (Engert et al., 2002). Several lines of evidence show that this is due to STDP at retinotectal synapses. First, retinotectal synapses exhibit robust Hebbian STDP *in vivo*, by pairing either electrically or visually evoked presynaptic spikes with postsynaptic spikes (Zhang et al., 1998, 2000). Second, successful motion training occurs only when visual motion stimuli elicit postsynaptic spikes, and training causes retinal inputs active before evoked tectal spikes to be potentiated, while inputs active after tectal spikes are depressed. This is the hallmark of Hebbian STDP (Engert et al., 2002; Mu and Poo, 2006). The mechanics of this process have been determined using three sequentially flashed bars at different spatial positions to simulate visual motion. When sequentially flashed bars are paired with postsynaptic spikes that occur just after the center bar stimulus (either evoked by this stimulus or by current injection), responses to the first and second bars are increased, while responses to the third bar are decreased, as predicted by Hebbian STDP. Moreover, training with both real and simulated motion increases visual responses to flashed stimuli at spatial locations that are active prior to the receptive field center (i.e., locations that are 'upstream' in the trained movement direction). This asymmetrically expands the receptive field toward earlier-activated spatial locations (Engert et al., 2002), as predicted by computational models of Hebbian STDP driven by moving stimuli (Blum and Abbott, 1996; Mehta et al., 2000). In a recent computational model, STDP at retinotectal synapses was shown to explain all these findings (Honda et al., 2011). These results strongly suggest that natural motion stimuli drive emergence of motion direction tuning via STDP. This phenomenon is illustrated in Figure 9.4(B).

Several studies show that nonmoving visual stimuli also shape tectal visual receptive field properties via STDP. Pairing a small flashed bar or spot with a postsynaptic spike evoked by intracellular current injection induces LTP or LTD of visually evoked synaptic currents according to Hebbian STDP rules (Mu and Poo, 2006; Vislay-Meltzer et al., 2006). This increases or decreases visual responses to stimuli within the trained subregion of the tectal cell's visual receptive field, causing a systematic shift in receptive field location (Vislay-Meltzer et al., 2006). When repetitively flashed stationary stimuli are strong enough to evoke tectal spikes on their own, visual responses are enhanced. This is likely to reflect STDP LTP because strengthening occurs only when stimuli successfully evoke postsynaptic spikes, which imposes the pre-leading-post spiking order within the

20-ms temporal window for STDP LTP at this synapse (Zhang et al., 2000). This suggests that visually driven STDP mediates the activity-dependent increase in visual response strength during normal tectal development and may also contribute to the normal developmental decrease in receptive field size (Tao and Poo, 2005).

A final feature of tectal development that may be driven by STDP is the development of synchronous spiking mediated by recurrent excitation between tectal neurons. Visual stimulation elicits rapid, direct retinotectal excitation of tectal neurons, plus slower, longer-lasting excitation via recurrent synapses, which mediate sustained spiking to visual stimuli. Recurrent excitation is long lasting and temporally variable early in development and becomes rapid and synchronous with experience (Pratt and Aizenman, 2007). Sensory training with optic nerve stimulation or visual flashes strengthens recurrent inputs that are active prior to the mean spike time of tectal cells and weakens recurrent inputs active after this time. As a result, recurrent inputs become more rapid and temporally precise (Pratt and Aizenman, 2007), as predicted by Hebbian STDP (Cassenaer and Laurent, 2007; Suri and Sejnowski, 2002; Zhigulin et al., 2003). However, this behavior has not been proven to reflect STDP directly.

9.7.3.2 STDP in Experience-Dependent Development of Sensory Tuning in V1 Cortex

In mammalian V1, retinotopic and ocular dominance maps are already well developed at eye opening but are strongly modified by visual experience in the first weeks of life. In contrast, tuning for orientation and motion direction are weak or absent at eye opening and are induced by early visual experience (White and Fitzpatrick, 2007). Some evidence suggests that STDP contributes to each of these aspects of development. Arguably, the weakest evidence is for retinotopy. In developing kitten V1, pairing a focal visual stimulus with postsynaptic spiking elicited by current injection during whole-cell recording strengthens or weakens visually evoked responses, with temporal dependence consistent with Hebbian STDP. While this 'stimulus timing-dependent plasticity' modulates response strength, it does not shift receptive field location (Meliza and Dan, 2006). Stimulus timing-dependent plasticity of retinotopy has been observed in adult cats, where repeated sequential presentation of two neighboring retinotopic stimuli (with <20-ms delay) shifts the spatial location of V1 receptive fields toward the retinotopic location activated first. The direction and timing dependence of this plasticity is consistent with Hebbian STDP at intracortical connections (Fu et al., 2002). Retinotopic map plasticity also occurs in adults in response to focal retinal lesions that binocularly deprive a small V1 region of visual input. Postlesion visual experience causes neurons in the deprived V1 region to acquire novel receptive fields outside the deprived region of visual space

(Gilbert and Wiesel, 1992). This reflects functional and anatomical reorganization of intracortical horizontal connections (Yamahachi et al., 2009). A computational study found that the spatial pattern of acquired receptive fields was consistent with intracortical reorganization via STDP, but not with classical CDP (Young et al., 2007). However, whether these mechanisms contribute to retinotopic refinement during development is unknown.

Stronger evidence links STDP to development of motion direction selectivity. Like in *Xenopus*, motion direction tuning is absent at eye opening and develops soon thereafter as a result of visual experience (White and Fitzpatrick, 2007). Training with visual motion stimuli immediately after eye opening induces motion direction tuning in V1 of young ferrets (Li et al., 2008). This is consistent with STDP driven by spatiotemporal spike patterns evoked in V1 inputs (Buchs and Senn, 2002). However, whether STDP is the causal mechanism, and whether it explains the emergence of direction selectivity during normal development, is unclear. Some support for this hypothesis derives from a careful analysis of motion-selective properties of receptive fields in V1 complex cells in adult cats (Fu et al., 2004). Fu et al. found that complex cells received stronger rightward (leftward) motion input from visual field locations to the left (right) of receptive field center. This anisotropy in intracortical circuits is exactly as predicted by STDP driven by natural visual motion and suggests that STDP was active during the development of the circuits for motion direction tuning (Fu et al., 2004). However, cellular studies that demonstrate that STDP is the causal process for development of motion selectivity are lacking.

Similar evidence exists for plasticity of orientation tuning. Orientation tuning exists at eye opening but is robustly plastic in response to early postnatal sensory experience, with experienced orientations gaining representation in the orientation map (Hirsch and Spinelli, 1970; Sengpiel et al., 1999). To test whether orientation tuning could by altered via STDP, Schuett et al. paired oriented visual stimuli with extracellular electrical stimulation to elicit postsynaptic spikes in V1 in anesthetized kittens. When visually evoked responses preceded electrical stimulation, cortical neurons shifted their orientation toward the presented orientation; when visually evoked responses followed electrical stimulation, orientation shifted away from the presented orientation, characteristic of Hebbian STDP. The effect, which required several hundreds of pairings to be induced, occurred predominantly in L2/3 and L5–6, suggesting a locus in intracortical connections (Schuett et al., 2001). In a similar study in adults, stimulus timing-dependent plasticity was induced by flashing a conditioned oriented stimulus <20 ms before or after the presentation of the preferred orientation. This training caused the peak of the orientation tuning to shift toward or away from the conditioned orientation, respectively. The temporal order and timing

dependence was consistent with Hebbian STDP at horizontal projections between neurons tuned to the trained orientations (Yao and Dan, 2001; Yao et al., 2004). This effect is illustrated in Figure 9.4(C). Thus, carefully controlled sensory experience can alter orientation tuning in a timing-dependent manner consistent with STDP at intracortical connections. However, whether natural visual experience uses this method to refine or maintain orientation tuning during development is unknown.

STDP may contribute to experience-dependent refinement of whisker receptive fields in developing rodent S1, but evidence is weaker than for V1. In anesthetized juvenile rats, STDP LTD occurs in L2/3 pyramidal cells in response to pairing whisker deflection with intracellularly evoked postsynaptic spikes: postsynaptic spikes that precede whisker-evoked subthreshold potentials ($\Delta t < 30$ ms) cause weakening of whisker-evoked responses, which lasts for 5–10 min. Conversely, when postsynaptic spikes follow whisker-evoked potentials, no depression, or sometimes potentiation, is observed, suggestive of Hebbian STDP (Jacob et al., 2007). In adults, spike timing-dependent depression of whisker-evoked spiking responses was observed in L2/3 and L5–6 pyramidal cells (Jacob et al., 2007). However, whether STDP is engaged by natural whisker stimuli to drive receptive field plasticity during normal development is not known. One possible role for STDP is to generate whisker direction tuning in L2/3 of S1 from natural wave fronts of whisker deflection (Andermann and Moore, 2006; Leger et al., 2009).

9.7.3.3 STDP in Deprivation-Induced Plasticity in S1 and V1 Cortex

During postnatal development, sensory deprivation drives rapid depression of cortical sensory responses to deprived inputs, followed more slowly by increased responses to spared inputs. The overall effect is to bias neural selectivity toward the most active inputs. This deprivation-induced plasticity can be explained by Hebbian weakening of synapses mediating deprived inputs, coupled with some form of competition that strengthens synapses mediating spared inputs (Feldman, 2009). It is commonly hypothesized that such plasticity utilizes the same synaptic mechanisms that drive emergence or refinement of sensory response properties during normal development. Substantial evidence indicates that deprivation-induced plasticity involves LTP and LTD at cortical synapses, coupled with synapse formation, remodeling, and removal (Feldman, 2009).

STDP appears to be one of the mechanisms driving deprivation-induced weakening of sensory responses in rodent somatosensory (S1 or barrel) cortex. Rodent S1 contains a somatotopic map of the whiskers, each represented by a cortical column. Deflection of a single whisker drives spikes in L4, followed by L2/3, of the corresponding column, due to feedforward, column-specific excitatory projections from thalamus to L4 to L2/3. In addition, whisker deflection drives weaker responses in neighboring columns via horizontal cross-columnar projections (Lubke and Feldmeyer, 2007). In juvenile rats, trimming or plucking a subset of whiskers weakens and shrinks the representation of deprived whiskers in L2/3, mediated in part by weakening L4–L2/3 excitatory synapses (Feldman and Brecht, 2005). This deprivation-induced weakening appears to represent CB1-LTD induced *in vivo* by sensory deprivation because it occludes subsequent CB1-LTD, is expressed presynaptically by reduced release probability, and is prevented by CB1 antagonist treatment *in vivo* during whisker deprivation (Allen et al., 2003; Bender et al., 2006a; Feldman, 2009; Li et al., 2009).

L4–L2/3 synapses in rat S1 exhibit LTD-biased STDP consisting of NMDAR-dependent LTP and CB1-LTD (Bender et al., 2006b; Feldman, 2000; Nevian and Sakmann, 2006). This STDP rule drives net LTD in response to either uncorrelated spiking or systematic post-leading-pre spiking (Feldman, 2000). Deprivation is likely to drive LTD *in vivo* via STDP because whisker deprivation acutely alters mean L4 and L2/3 firing rate in S1 of awake rats only modestly but powerfully alters L4–L2/3 spike timing. This was shown in anesthetized animals, where simultaneous deflection of all whiskers (to mimic normal whisking) evokes L4 spikes reliably before L2/3 spikes, whereas deflection of all but one whisker (to mimic acute whisker deprivation) immediately causes L4–L2/3 firing in the deprived column to decorrelate and firing order to reverse. These spike timing changes are quantitatively appropriate to drive spike timing-dependent LTD (Celikel et al., 2004). These findings suggest that spike timing, not spike rate, may be the key parameter driving synapse weakening in response to whisker deprivation.

STDP has also been hypothesized to drive ocular dominance plasticity in developing V1, but there is currently little direct evidence for this hypothesis. V1 neurons exhibit characteristic ocular dominance, which is a measure of the relative response to stimuli in the right versus left eye. Ocular dominance is already mature at eye opening but is highly plastic to visual experience in a defined developmental critical period (19–32 days of age in mice). During this period, closure of one eye (monocular deprivation) causes a rapid loss of responses to the deprived eye, followed by a slower gain of responses to the open eye, thus shifting ocular dominance (Wiesel and Hubel, 1963). Ocular dominance plasticity involves both rapid physiological changes in excitatory synaptic strength (e.g., LTP and LTD) and structural rearrangement of V1 synapses (Hensch, 2005; Hofer et al., 2006). While CDP can explain the basic features of ocular dominance plasticity, an STDP model has been proposed. In this model, monocular deprivation alters the precise temporal patterning of V1 spikes, thus inducing STDP

in deprived-eye or open-eye pathways (Hensch, 2005; Hofer et al., 2006). Direct evidence that STDP causally drives ocular dominance plasticity is lacking, but the dynamics of plasticity in one cell class (fast-spiking interneurons) may be consistent with STDP (Yazaki-Sugiyama et al., 2009). In addition, the STDP model may explain why, during development, the critical period does not begin until inhibitory basket cells mature sufficiently to provide an 'optimal' balance between inhibition and excitation (Katagiri et al., 2007). Basket cells make dense perisomatic synapses on pyramidal cells that potently control spike timing (Huang et al., 2007; Pouille and Scanziani, 2001). Sufficient inhibition may be required to enable the precise timing of visually evoked spikes so that experience-dependent changes in spike timing can engage STDP (Hofer et al., 2006; Kubota and Kitajima, 2010; Kuhlman et al., 2010). Similar inhibitory gating of plasticity occurs in *Xenopus*, where tectal inhibitory circuits are required to ensure that visual motion stimuli evoke precise spatiotemporal patterns of spiking in the tectum. When GABAergic transmission is blocked, precise encoding of motion stimuli is lost and spikes become highly correlated between neurons. Under these conditions, training with visual motion stimuli does not cause development of motion direction tuning (Richards et al., 2010).

Thus, STDP is a strong candidate for driving deprivation-induced weakening of synapses in S1 and may play a similar role in V1, but for this, substantially less evidence exists. Inhibitory gating of plasticity may reflect the need for optimal inhibitory–excitatory balance to precisely time spikes and enable STDP.

In summary, STDP is well suited to explain activity-dependent development of network connectivity and stimulus selectivity during initial circuit formation. Experimentally, the best evidence that STDP is involved in circuit development is in experience-dependent development of direction selectivity in the *Xenopus* retinotectal system. STDP may also contribute to deprivation-induced plasticity in developing S1 and possibly to experience-dependent development of stimulus selectivity in V1. However, direct evidence that STDP is the relevant synaptic plasticity rule for circuit development or developmental plasticity outside of the retinotectal system remains largely lacking. In contrast, stronger evidence exists for STDP in adult circuit plasticity (see Section 9.8).

9.8 FUNCTIONS OF STDP IN ADULT PLASTICITY AND LEARNING

Theoretical work suggests that STDP could mediate several forms of learning, including shaping of neuronal selectivity (Guyonneau et al., 2005), coordinating transformations of multimodal information (Davison and Fregnac, 2006), tuning of auditory response delays (Gerstner et al., 1996), reinforcement learning (Farries and Fairhall, 2007), temporal difference learning (Rao and Sejnowski, 2003), input pattern detection (Masquelier et al., 2009), and learning of temporal sequences (Fiete et al., 2010). However, whether STDP plays these roles *in vivo* in the behaving animal is not yet clear (Letzkus et al., 2007). Evidence for the involvement of STDP in sensory learning in the primary sensory cortex and in the electrosensory lobe of electric fish is strong; for other forms of learning, however, its involvement remains primarily theoretical.

9.8.1 Sensory Learning and Primary Sensory Cortex Plasticity

The occurrence of STDP has been indirectly studied in the visual cortex *in vivo* by sequentially presenting two visual stimuli at time intervals suitable for inducing STDP (Fu et al., 2002; Yao and Dan, 2001; Yao et al., 2004). The two stimuli differ in spatial location or orientation. Sensory stimulation increases the firing probability of neurons within a defined window of time, and thus the pairing of two stimuli increases the occurrence of the imposed spike timing interactions. In these studies of stimulus timing-dependent plasticity using sensory–sensory associations, pairing causes modifications of neuronal tuning that are rather small but have a temporal specificity and sign expected from STDP (see also Dahmen et al. (2008) for a similar study on the auditory cortex). These results support the idea that STDP could mediate experience-dependent modulation of receptive fields in the visual cortex *in vivo*. Parallel psychophysical experiments using similar plasticity protocols show perceptual changes that are compatible with the induced neurophysiological effects, indicating that sensory-induced STDP may drive plasticity of human visual perception (Fu et al., 2002; Yao and Dan, 2001).

In the *in vivo* somatosensory cortex of the rat, cortical map reorganization can be induced by whisker deprivation. This procedure modifies the relative timing of thalamic and cortical action potentials within a range compatible with STDP (Allen et al., 2003; Celikel et al., 2004). Thus, STDP could underlie modifications of cellular responses during experience-driven network reorganizations, although these observations should be confirmed in the adult rat. Evidence for STDP in the somatosensory cortex of adult animals *in vivo* is still scarce but Jacob et al. (2007) have shown that pairing spontaneously emitted postsynaptic spiking with subsequent whisker deflections within a brief time window leads to synaptic and functional depression specific to the paired whisker, consistent with spike timing-dependent LTD.

9.8.2 Sensory Image Cancellation in Electric Fish

Anti-Hebbian forms of STDP have been described in cerebellum-like structures containing comparable cell types to mammalian cerebellum (Bell et al., 1997; Tzounopoulos et al., 2004) and in some corticostriatal connections (Fino et al., 2005). In the electrosensory lobe of three distinct groups of electric fish, anti-Hebbian STDP at parallel fiber synapses on Purkinje-like cells has been proposed to generate a representation of predictable electrosensory input arising from motor commands. The comparison of this 'negative' image with the actual sensory inflow suppresses the expected sensory consequences of a motor act, facilitating the detection of unexpected stimuli (reviewed in Bell, 2001; Bell et al., 1999).

9.8.3 Hippocampus and Memory

The hippocampus shows prominent STDP (Bi and Poo, 1998; Wittenberg and Wang, 2006), which has been proposed to be involved in the modification of hippocampal spatial receptive fields (place fields) (O'Keefe and Dostrovsky, 1971) during exploration of novel environments (Wilson and McNaughton, 1993). Place fields of hippocampal CA1 pyramidal cells are spatially skewed such that firing is asymmetric across the spatial extent of the place field, with lower firing rates when the animal enters the field and higher firing rates when it exits. In addition, the center of gravity of place fields expands backward as an animal repetitively explores a track. These features of place fields are experience-dependent (Mehta et al., 2000). As proposed on the basis of computational models of CA3 to CA1 plasticity, these modifications of CA1 receptive fields could result from NMDA-dependent STDP of synaptic inputs to CA1 cells (Ekstrom et al., 2001; Mehta et al., 2000; Shouval et al., 2002, 2010) (see also Yu et al., 2008 for alternative biophysical models). These receptive field shifts are similar to those observed in the primary visual cortex during stimulus timing-dependent plasticity (Fu et al., 2002; Yao and Dan, 2001).

9.8.4 Olfactory Learning

Olfactory learning in the insect represents one of the most robust examples of STDP induction. In the beta-lobe of the mushroom body, a central structure of the locust olfactory system, spiking activity elicited by odor presentation associated with postsynaptic spiking of intrinsic neurons (known as the Kenyon cells) triggers STDP. This form of STDP facilitates the transmission of odor-specific information through the olfactory system by synchronizing the target neurons of the Kenyon cells, thus improving the readout of the sparse olfactory code in Kenyon cells (Cassenaer and Laurent, 2007). In moths, an appetitive associative procedure induces a conditioned response to an odor. This conditioned response is reduced, however, if the reward delivery overlaps with Kenyon cell activity induced by the odor (Ito et al., 2008). Thus, changing the temporal interval between odor and reward modifies the probability of induction of the conditioned response. This was considered as evidence that STDP in Kenyon cells alone cannot underlie the olfactory learning. However, STDP has not been directly measured in this study. An alternative possibility is to reinterpret these results within the theoretical framework of reinforcement learning where in addition to pre- and postsynaptic activity, a third element (here, an appetitive reward) provides a behavioral validation of the network state during the presentation of the odor but does not in itself induce postsynaptic action potentials (see Cassenaer and Laurent, 2012). Its permissive action is rather mediated through activation of metabotropic receptors and second messenger cascades that might interact with a sustained response (Drew and Abbott, 2006) or with some intracellular signature left by the sensory input (Izhikevich, 2007), but not with the early sensory-driven activity.

9.8.5 STDP in Human Cortex

In humans, paired association of transcranial magnetic stimulation over the somatosensory cortex (S1) and median nerve stimulation induces bidirectional changes of the median nerve somatosensory evoked potential (SSEP) (Wolters et al., 2005). See Wolters et al. (2003) for a similar study on the motor cortex. The changes were confined to the P25 component of the SSEP, which is believed to originate in the upper cortical layers of S1. Interestingly, the direction of the changes depended on the timing of the stimuli. Enhancement of the P25 component was induced by a pre–post arrangement of stimulation-induced events, while a depression was noted with a reversal of events. These observations may constitute a signature of STDP in human S1. Litvak et al. (2007) further confirmed the regional and laminar location of neuroplastic changes induced by the paired associative stimulation and reported congruent behavioral consequences of the STDP-like plasticity in human S1.

In summary, theory indicates that STDP could mediate multiple features of learning. Currently, the strongest experimental evidence for Hebbian STDP in natural learning in adults is during sensory perceptual learning in the primary sensory cortex, where it may store associations and temporal sequences in response to precisely timed sequential sensory stimuli. For anti-Hebbian STDP, evidence strongly supports a role in learning and cancelling expected sensory patterns in the

electrosensory lobe of electric fish. Additional work is needed to evaluate the biological role of STDP in other forms of adult learning and plasticity.

Acknowledgments

Glossary

AMPAR Alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid subtype of ionotropic glutamate receptor.
bAP Backpropagating action potential, that is, action potential that propagates from soma to dendrites.
CB1 Cannabinoid receptor type 1.
Correlation-dependent plasticity Form of LTP and LTD in which plasticity is determined by magnitude of correlated pre- and postsynaptic activity, but not precise pre–post timing and order.
eCB Endocannabinoid.
GABA-A receptor Gamma-aminobutyric acid receptor type A, the primary fast inhibitory receptor in the central nervous system.
IP3 Inositol trisphosphate.
LTD Long-term depression, or activity-dependent, long-term decrease in functional synapse strength.
LTP Long-term potentiation, or activity-dependent, long-term increase in functional synapse strength.
mGluR Metabotropic glutamate receptor.
NMDAR N-Methyl-D-aspartate subtype of ionotropic glutamate receptor.
PLC Phospholipase C.
S1 Primary somatosensory cortex.
Spike timing-dependent plasticity Form of LTP and LTD in which the magnitude and sign of plasticity are determined by the precise (10–100-ms scale) timing of pre- and postsynaptic action potentials.
V1 Primary visual cortex.
VSCC Voltage-sensitive calcium channel.

Introduction to Cognitive Development from a Neuroscience Perspective

H. Tager-Flusberg

Boston University, Boston, MA, USA

10.1 INTRODUCTION

Newborns depend for their survival on caregivers, almost always mothers, who provide them with food, warmth, and comfort. They come into this world equipped with a set of reflexes, basic sensory capacities and preferences, and primitive means for signaling their needs. Over the first 2 years of life, infants undergo rapid developments in cognition and behavior, and their brains undergo exponential growth and change. During these early years, infants are transformed into toddlers capable of goal-directed actions and independent mobility; they develop sophisticated concepts of the world around them, acquire the basic use and understanding of language, and become equipped to navigate their social environment with ease. Nevertheless, at the age of 2, toddlers still have a great deal to learn, and developmental changes continue, at a steadier rate, over the next two decades.

In this volume, the authors follow this remarkable journey in human development with particular emphasis on the early years. Studies of child development began almost a century ago; however, the conceptual frameworks and information about what children know as they grow have shifted over the years, driven largely by the introduction of new methods and technology that

is now opening up the possibility of asking key questions about the neural and cognitive mechanisms that drive developmental change. This chapter serves as a roadmap to the basic frameworks and methods that have guided the field of child development over the past few decades and then introduces the chapters in this volume.

10.2 FRAMEWORKS AND METHODS

10.2.1 Conceptual Frameworks

The scientific field of cognitive development began with the seminal work of Jean Piaget, though its intellectual roots go back to philosophical questions about the origins of knowledge and mind raised by Plato, Aristotle, and others in ancient Greece. Piaget, who was a biologist by training, was the first to develop a comprehensive theoretical framework for how children acquire core concepts that are the foundation of human thought. His 'constructivist' theory claimed that fundamental concepts, such as space, time, and causality, are acquired by the baby operating on the environment. Through very basic processes, complex abstract concepts are built up through *actions* and *interactions* with objects

185

and people. In Piaget's theory, children develop through a series of qualitatively distinct stages, each defined by a new form of mental representation. He was committed to a strong view on the biological contributions to cognitive development by arguing for the importance of evolution, maturation, and adaptation for understanding change over time; however, his empirical work focused exclusively on observable behavior, which clearly contributed to the significant role he attributed to action, especially as the foundation of representational knowledge (Flavell, 1996).

Piaget's work lies between the extremes of nativism and empiricism. He began writing in the early part of the twentieth century, but his work did not become well known in the English-speaking scientific community until the 1970s, when psychologists became open to ideas that were grounded in a more complex view of how biology intersects with experience. Nevertheless, even though Piaget firmly argued that developmental changes took place in children's cognition, he was not able to articulate how such changes were accomplished; instead, he focused more on generating the important questions to be addressed by developmental scientists that remain central to the field today.

Over the last few decades, developmental science has blossomed as it has taken on questions about what the starting point is for newborns, what the child knows at different ages, how this knowledge is organized and changes over time, and which factors and basic learning mechanisms contribute to these changes. These questions are being addressed using new tools that provide a more direct window into the minds and brains of babies and young children than simply observations of their behavior. While developmental scientists are informed by parallel research on other species, the unique social and linguistic abilities of humans transform the child's conceptions of the world in ways that require different frameworks and approaches for investigating developmental processes (cf. Vygotsky, 1978).

10.2.2 Eye Gaze

For Piaget, infants' actions on the world revealed their underlying knowledge; however, motor development is a slow process in humans and thus provides a very indirect assessment of their cognitive capacities. Beginning with the seminal work of Fantz (1958), researchers have been using eye gaze patterns to provide a more direct approach to what infants see, discriminate, prefer, remember, and expect. Because they have relatively good ocular-motor control, babies' eye movements are a reliable and valid way of revealing mental processing. Studies using eye gaze patterns, including measures of first fixations, time spent looking at images, and anticipatory looking patterns, have demonstrated that even

newborns are not just a bundle of reflexes with basic sensory capacities. Instead, people now know that infants have perceptual preferences that are biased toward attending to particular events and entities in their environment, and rapid changes over the first few months of life consolidate and expand on these initial biases (see Chapter 37).

For many years, researchers relied on either manual on-line coding of eye gaze patterns or videotaping of infants' looking patterns and later laborious coding their eye movements by hand. It is the most common behavioral method in use today for studies on infant perception, cognitive, social, and language development (Aslin, 2007). The recent advent of automated eye trackers, particularly ones that do not require head-mounted cameras or complex calibration procedures, has led to changes in the ability to capture the microstructure of eye gaze patterns in infants including much finer temporal and spatial resolutions, without requiring manual coding that could potentially introduce error or bias. Nevertheless, despite the advantages of using automated eye trackers to capture eye movement patterns, there are still significant challenges about how data collected from these devices should be analyzed and interpreted (Aslin, 2012).

10.2.3 Electrophysiology

If eye gaze is the method of choice for investigating the minds of babies, then electrophysiology is the method of choice for investigating their brain function. The broader field of cognitive neuroscience has relied on a range of technologies to probe brain structure and function in people; however, not all of them are easily adapted for use with infants. Electrophysiological recordings, including electroencephalography (EEG) and event-related potentials (ERPs), provide relatively good measures of temporal processing and dynamics of cognitive processes. Their primary advantages for their use in studying infants and young children include safety, ease of use, and tolerance of some movement.

The EEG signals collected from multiple electrodes placed over the scalp reflect ongoing electrical activity in the brain; ERPs are signals that occur in response to a specific stimulus and are most widely used as a neural assessment for a range of cognitive processes. The analysis of EEG activity is generally not time locked, but can be decomposed into constituent frequencies to quantify power in specific bandwidths, each of which reflects different aspects of neural processing related to cognition. ERPs are thought to detect postsynaptic potentials from pyramidal cells summed over a large number of neurons. Invariant stimulus-related electrical activity is extracted through an averaging process over a large

number of trials in order to reduce the noise due to random components. The average ERP is then analyzed temporally, as a series of positive and negative components characterized by their polarity, peak latency, amplitude, and distribution over the scalp (Csibra et al., 2008). The introduction of high-density arrays, which include a large number of electrodes embedded in a net that is quickly and easily fitted over the scalp, provides more complete spatial coverage and has led to new methods of analysis with better spatial and temporal resolutions.

Different components in the ERP signal have been linked to specific behavioral tasks including, for example, attention, face processing, and a range of linguistic processes from speech to syntax (see, for example, Chapter 32 and Rubenstein and Rakic, 2013). Much of what is known about the cognitive processes associated with specific ERP components comes from studies of adults. There are significant developmental changes in the latency, morphology, and topography in the known ERP components, and while the precise roots of these changes are not yet fully understood, they are thought to reflect a combination of cognitive advances and more efficient neural processing. While electrophysiological methods are now widely used in human developmental neuroscience, they do have several limitations including their poor spatial resolution and lack of sensitivity to processing in subcortical brain areas.

10.2.4 Magnetic Resonance Imaging and Other Imaging Methods

The growing field of cognitive neuroscience has relied most extensively on magnetic resonance imaging (MRI) as the single most effective, noninvasive, and safe method for examining *in vivo* human brain structure and function. MRI provides high-resolution spatial information, and its application in developmental science has given people detailed information about volumetric changes in regional gray and white matter. The advent of diffusion tensor imaging (DTI), a variant of conventional MRI, has led to advances in the ability to identify and characterize developmental changes in white matter pathways (Wozniak et al., 2008).

Functional aspects of brain development, particularly in older children, have been tracked using functional MRI (fMRI), which measures changes in blood oxygenation levels (BOLD response), an indirect measure of increases in regional neuronal activity. fMRI provides excellent spatial resolution when local differences in the BOLD response are analyzed between tasks or groups. Advances in analytic methods such as connectivity analyses have led to new ways of tracking developmental changes in systems-level cortical representations.

Despite their importance in developmental cognitive neuroscience, there are several challenges in using MRI with young children, not least of which is the requirement to lie completely still in a noisy enclosed tunnel for relatively long time periods while the scan data are collected. This involves a good deal of cooperation from an awake child, which is possible in children over the age of 5 who have been carefully prepared, or the use of alternative approaches such as scanning during sleep or sedation. It is also not clear how developmental changes in brain morphology and metabolism may influence the BOLD response, and there are other technical concerns that need to be carefully considered when interpreting findings from fMRI studies conducted on young children or children with neurodevelopmental disorders (Casey et al., 2005).

The newest technology that has been introduced to investigate functional brain development, particularly in infants, is near-infrared spectroscopy (NIRS), which, like fMRI, measures changes in hemodynamic responses that are assumed to be related to regional brain activity. Optical probes placed on the scalp measure changes in blood oxygenation levels that reflect surface cortical activity, offering moderately good spatial resolution, depending on the number and location of the probes. Considerable methodological and technological advances have been made, and the number of studies using NIRS to investigate functional activity in the brains of very young infants is increasing each year (cf. Gervain et al., 2011). It has been used in studies of infant perception, cognition, and language; however, it cannot detect neural responses generated in structures that lie below the cortical surface, which limits its use in studying key aspects of memory, emotion, or social perception.

10.2.5 Summary

Important advances in developmental cognitive neuroscience have been made in recent years based on the introduction of new conceptual frameworks and methods for probing cognition and brain processes. People are now beginning to be able to link behavioral and brain changes in ways that allow them to test theoretically grounded hypotheses about the neural bases of cognitive development. Yet, progress can only be made if their methods and technologies are used in the context of well-designed experiments and an appreciation of the limitations in the application and interpretation of findings from each available method. As noted, there are real challenges in using all the methods surveyed here with pediatric populations: they all require a considerable amount of cooperation and minimal movement. While young infants and older children can tolerate the requirements for most of these methodologies, toddlers and preschoolers are far more active than infants and far

less compliant than school-aged children, and therefore, relatively less is known about development during these critical years. It is expected that technological innovations in the coming years will help to fill in these gaps to provide a more complete picture of cognitive development from birth through adolescence.

10.3 OVERVIEW OF CHAPTERS

This volume provides comprehensive and detailed coverage of the current state of research on cognitive development including both behavioral and neuroscience perspectives on the field. Each chapter highlights key developmental questions and illustrates the primary methods that have been used to address them. Throughout this volume, the emphasis is on typical development, but applications to atypical populations are discussed, particularly in those areas where more significant work has been conducted on children with neurodevelopmental disorders. The field is still young, and studies that attempt to address the developmental relationship between cognitive and neural processes have really only begun in earnest during the past decade. Each chapter concludes with a discussion of the future directions that people can expect to see in the coming decades.

In the opening chapter, Mark Johnson (see Rubenstein and Rakic, 2013) discusses the theories that have dominated the newly emerging field of developmental cognitive neuroscience. He highlights the importance of having theoretically driven research and evaluates the predictions and evidence from each theory using research from different cognitive domains. He concludes that the theory of interactive specialization, which has its roots in the Piagetian theory, offers the most promise of a framework that captures biological developmental change that is grounded in experience.

The next two chapters summarize the foundations of brain and behavioral development. Colby and his colleagues provide a detailed summary of what is currently known about postnatal structural changes in the brain based primarily on studies using MRI and DTI. They describe the very different trajectories in gray and white matter development, emphasizing the significance of developmental timing and key genetic and experience-dependent factors driving the dynamic processes of brain development that continue through late adolescence. Lamy and Saffran (see Rubenstein and Rakic, 2013) take on the central question about how infants learn, in particular, how they can acquire abstract and complex cognitive structure based on inputs from the environment. They focus on infants' capacities to extract different types of statistical regularities from the perceptual information that are central to the formation of linguistic and object categories. Evidence from studies conducted over the past decade suggests that infants actively use probability distributions, sequential structure, correlations, and associations in auditory and visual inputs, beginning early in the first year of life. These active learning mechanisms, which are presumably basic capacities that evolve via experience, are the building blocks that drive cognitive development.

For humans, vision is arguably the most important perceptual system that drives conceptual development, particularly for growth in understanding objects and events. It is also the system that is most well studied and understood across different species. In his chapter, Scott Johnson (Chapter 37) discusses how infants come to experience a world of stable objects beginning with limited but organized vision at birth that undergoes rapid functional changes during the first year of life driven by brain maturation coupled with learning from experience and manual explorations. More advanced aspects of visuospatial abilities are taken up by Stiles and her colleagues who discuss the development of ventral and dorsal neurocognitive processes including global and local pattern perception, spatial construction, localization, attention, and manipulation. The last part of their chapter describes research on these processes, particularly the vulnerability of the dorsal stream in children who have experienced brain injury or with neurogenetic syndromes.

Human memory serves a range of important functions that are carried out by different systems. In her chapter, Bauer describes the major forms of memory, each of which follows distinct developmental trajectories. She summarizes recent studies that document the emergence of both declarative and nondeclarative memory systems during the first 2 years of life, which is far earlier than has previously been thought. At the same time, Bauer argues that some aspects of declarative memory have a more protracted course not reaching maturity until middle childhood, paralleling what is known about the development of the underlying neurobiology of memory processing systems as demonstrated in studies of ERPs in children.

The earliest autobiographical memories are sparse and usually for events that took place during the preschool years. One reason that has been offered for this phenomenon is that encoding and retrieving these memories depend on language. By the time most children are 3 years old, they have mastered the fundamentals of language from sounds to words to grammar, which allow them to form narrative memories of their lives. In the next chapter, Tager-Flusberg and Seery (Chapter 32) describe the development of language covering the major milestones, as well as how language intersects with aspects of motor, conceptual, and social cognitive development. Much is known about the importance of left-hemisphere frontal/temporal cortical systems in adult language processing. These left lateralized systems

emerge during the first year of life in typically developing children according to studies using ERP and NIRS with infants. Failure to lateralize language functions to the left hemisphere during this early sensitive period appears to be one hallmark finding among children with developmental language disorders.

The next four chapters are concerned with different aspects of social–emotional development. This has become a very active area of research in developmental science, in part because of the complexity and richness of human social lives and in part because of the important consequences when development in the social domain is impaired in children with genetic syndromes or specific forms of psychopathology. Righi and Nelson (see Rubenstein and Rakic, 2013) focus on the development of face-processing skills. They describe the initial rapid developments that take place during the first year of life in the foundational cognitive processes for identifying faces and facial expressions that depend on dedicated neural architecture in the fusiform region of the temporal cortex. At the same time, these early acquired abilities are followed by a more protracted period of development during which time more subtle behavioral advances are accompanied by volumetric changes in the fusiform 'face area' as well as temporal and morphological changes in the signature ERP signal elicited by faces, the N170. The development of the neural systems underlying more complex aspects of social perception, including the evaluation of a person's intentions, communicative signals, and psychological disposition from eye gaze and body motion cues, is addressed by Voos and his colleagues (see Rubenstein and Rakic, 2013) in the next chapter, drawing heavily on fMRI studies of school-aged children. This is followed by Gweon and Saxe's chapter (see Rubenstein and Rakic, 2013), which focuses on the development of children's theory of mind: the ability to reason about people's actions based on mental states such as thoughts or beliefs. The classic studies in this area concluded that the theory of mind emerges at about the age of 4 based on behavioral and ERP studies that used a task evaluating children's understanding of false beliefs. Gweon and Saxe review more recent behavioral studies suggesting that this understanding may already be in place at least in an implicit form by around 18 months. At the same time, fMRI studies suggest that the brain region that is crucially involved in the theory of mind processing, the right temporal–parietal junction, continues to show functional developmental changes through middle childhood, providing another example of the early emergence of a cognitive achievement followed by a more protracted developmental period into middle childhood. Decety and Michalska (see Rubenstein and Rakic, 2013) focus more on the affective components of social behavior: the development of the capacity to respond to another person's distress, or empathy. Their chapter summarizes the normal course of development in the psychological processes and neurobiological mechanisms that drive empathic behavior, and then how these might go awry in children with conduct disorder or related forms of psychopathy.

The next three chapters focus on the aspects of executive processing that cut across different developmental domains. Posner and his colleagues (see Rubenstein and Rakic, 2013) review the development of the complex set of networks that is involved in executive attentional processes and self-regulation from early infancy through middle childhood. An exciting recent advance in this area is a research that finds associations between common genetic variants with individual differences in specific attentional components; in turn, these differences influence environmental experiences of children as mediated, for example, by parenting behaviors. Lahat and Fox explore the development of two aspects of cognitive control that play important roles in decision-making and social behavior: inhibitory control and self-monitoring. The neural substrates for these advanced cognitive systems, as indexed by fMRI and ERP measures, depend on areas in the prefrontal cortex that do not reach the end point of development until late adolescence. Hughes (see Rubenstein and Rakic, 2013) summarizes the research on classic executive function measures in both typical and atypical children. She argues that because the executive functions and their neural substrates, which encompass multiple brain regions, develop incrementally over the entire period of childhood and adolescence, they are more susceptible to environmental influences. Her chapter describes examples of such influences including studies of training, parent–child interaction, and clinical populations.

The final two chapters in this volume are concerned with primary influences on behavioral and brain development. Gunnar and Davis (see Rubenstein and Rakic, 2013) focus on the effects of stress, drawing heavily on what is known from animal models to investigate whether the findings from that body of literature can be extended to current work on prenatal and postnatal stress responses in human development. Then, Beltz and her colleagues (see Rubenstein and Rakic, 2013) take up the issue of sex differences in development, which has important implications for understanding many neurodevelopmental disorders that differentially affect males and females for reasons that are still not well understood.

The cognitive neuroscience of human development is still in its formative years. The exponential growth of this field, as evidenced by the numbers of papers, journals, and books published over the past decade, has largely been driven by methodological advances that allow people to view more directly the minds and brains of babies

and children and observe how they change over time. As these methods develop further, it is expected that greater progress will be made by asking broader questions about the significance of the developmental trajectories and timing within and across cognitive domains, the constraints that operate on individual variation and developmental plasticity, and the precise ways in which biological and nonbiological factors influence the developmental course of brain and cognitive development.

CHAPTER

11

Theories in Developmental Cognitive Neuroscience

M.H. Johnson

Birkbeck College, University of London, London, UK

11.1 INTRODUCTION

Recently a new field of science has emerged at the interface between developmental neuroscience and developmental psychology. This field has come to be known as developmental cognitive neuroscience (DCN) (Johnson, 2010). The exciting mix of these previously separate fields has led to a burgeoning of new observations, methods, and ideas. However, a characteristic shared with most newly emerging interdisciplinary areas in the biological sciences is the feeling that the knowledge acquired to date is rather fragmentary, with many intuitively surprising observations remaining unexplained. How can one understand these phenomena, and interpret and explain them within a broader context of other findings with different methods and populations? To do this, one needs to develop theories, and, the author will argue that these theories need to be of a particular kind to be useful.

As a scientific discipline, DCN sits at the convergence of two of the oldest philosophical and scientific debates of mankind. The first of these questions concerns the relation between mind and body, and specifically between the physical substrate of the brain and the mental processes it supports. This issue is fundamental to the scientific discipline of cognitive neuroscience. The second debate concerns the origin of organized biological structures, such as the highly complex structure of the adult human brain. This issue is fundamental to the study of development. Light can be shed on these two fundamental issues by tackling them both simultaneously, and specifically by focusing on the relation between the postnatal development of the human brain and the cognitive processes it supports.

The second of the two debates above, that of the origins of organized biological structure, can be posed in terms of phylogeny or ontogeny. The phylogenetic

(evolutionary) version of this question concerns the origin of the characteristics of species, and has been addressed by Charles Darwin and many others since. The ontogenetic version of this question concerns individual development within a life span. The ontogeny question has been somewhat neglected relative to phylogeny since some influential scientists have held the view that once a particular set of genes has been selected by evolution, ontogeny is simply a process of executing the instructions coded for by those genes. By this view, the ontogenetic question essentially reduces to phylogeny (a position sometimes termed 'nativism'). In contrast to this view, many now agree that ontogenetic development is an active process through which biological structure is constructed afresh in each individual by means of complex and variable interactions between genes and their environments. The information is not in the genes, but emerges from the constructive interaction between genes and their environment (see also Oyama, 2000).

What actually is ontogenetic development? Many introductory biology textbooks define development in terms of an increasing restriction of fate. This refers to the basic observation that as the biological development of an individual organism (ontogeny) proceeds, the range of options for further specification or specialization available to the organism at that stage decreases. Structural or functional specialization is an end state in which there are few or no options left to the organism. By this view, plasticity can be defined as a developmental stage in which there are still options available for alternative developmental pathways (Thomas and Johnson, 2008). Another dimension of ontogenetic development is that it involves the construction of increasingly complex hierarchical levels of biological organization, including the brain and the cognitive processes it supports. As is seen later in this chapter, organizational processes at one level, such as cellular interactions, can establish new emergent functions at a higher level, such as that associated with overall brain structure. This characteristic of ontogeny means that a full picture of developmental change requires different levels of analysis to be investigated simultaneously. The author argues that the developmentalist needs to go beyond statements such as a psychological change being due to maturation, and actually provide an account of the processes causing the change at cellular and molecular levels. Thus, in contrast to most other areas of psychology and cognitive science, a complete account of developmental change specifically requires an interdisciplinary approach.

Given the above considerations, it is perhaps surprising that only recently has there been renewed interest in examining relations between brain and cognitive development. Although the field of developmental psychology was originally founded by biologists (such as Darwin

and Piaget), biological approaches to human behavioral development fell out of favor in the 1970s and 1980s for a variety of reasons, including the widely held belief among cognitive psychologists in that period that the software of the mind is best studied without reference to the hardware of the brain (see section 11.2 for the details of this argument). However, the recent explosion of basic knowledge on mammalian brain development makes the task of relating brain to behavioral changes considerably more viable than previously. In parallel, molecular and cellular methods, along with theories of self-organizing dynamic networks, have led to great advances in our understanding of how vertebrate brains are constructed during ontogeny. These advances, along with those in noninvasive structural and functional neuroimaging, have led to the recent emergence of DCN.

11.2 WHY DO WE NEED THEORIES?

Some might argue that, as a subfield of biology, investigators in DCN should proceed with their empirical investigations of human development unbiased by any perspective or theory, or simply wait until enough data are in before speculating on its significance. However, even a cursory read of philosophy of science tells you that this view is, at best, somewhat naïve. While Victorian naturalists simply made observations about the animals and plants they studied, when one moves to a modern science led by experiments, the rules change. The experiments choosen to conduct (out of the many millions of potential experiments that could be done) are inevitably guided by implicit assumptions and biases. For example, many of the earliest functional MRI experiments with children professed to be neutral and exploratory while also assuming that new brain regions becoming on-line with increased development would be seen. As will be seen later, in many cases this basic starting assumption was violated. In addition, theories in science do not just attempt to explain sets of data *post hoc*, but they should actually generate predictions and direct whole lines of empirical investigation.

Having emphasized the importance of theories, we must also be sure to achieve an appropriate balance with data gathered from a variety of different sources and methods. In one of the parent disciplines of DCN, cognitive development, several grand theoretical castles have been built on the shaky sands of just one particular type of behavioral test. In most of the biological sciences, confidence in an observation or conclusion is greatly increased by seeking multiple different sources of converging evidence.

Interdisciplinary fields such as DCN face a formidable challenge in the development of adequate theories since scientists are required to develop theories that not only cross different levels of observation (such as genetic,

neural, and behavioral), but also relate those different levels together in some way. Ideally, DCN theories should relate evidence from different levels of observation in terms of one level of explanation. As mentioned earlier, for several decades in the field of cognitive development, it was generally considered inappropriate to attempt to relate different levels of explanation. Rather, the aim was to explain one level of observation (change in behavior) in terms of one level of explanation (cognitive). This widespread view was taken for a variety of reasons, but one influential source was the work of Marr (1982). Marr argued that because the same computation can, in principle, be implemented on different computer or neural architectures, a computational account of cognition could, and should, be constructed independently of the details of its implementation on hardware. This influential argument led to the view that considering the role of the brain in cognitive development was reductionist in the sense that molecular and cellular processes could never provide an adequate explanation of cognitive processes.

While the case against a simple reductionist view is clearly correct, as stated earlier, theories of biological development critically need to explain the reverse process (to reductionism) of the emergence of higher-order structures of organization. Thus, while not denying Marr's antireductionist point, constructing a specific type of neural computer hardware will constrain the range of possible computations that could be supported. With these considerations in mind, Mareschal et al. (2007), among others, argue that there are constraints on computation imposed by its detailed implementation. Further, when attempting to bridge levels of explanation, mechanistic accounts of processes of computation and developmental change should be consistent across different levels, that is, there is a need for isomorphism between levels of description. Since the goal of DCN is to relate the genetic, neural, cognitive, and behavioral accounts of human development, devising theories that relate the different levels of observation seems crucial. Mareschal et al. (2007, p. 209) thus describe it "We would argue that strong pragmatic considerations mean that what is achievable in real time at one level of description strongly constrains the appropriate theories of what is going on at other levels. What is more easily achievable in the brain will strongly constrain the character of cognition. More specifically, the brain can implement much more readily certain representational states and transformations more than others. It is these primitives that the researcher should initially use to construct theories of cognition."

Theories come in different shapes and sizes. Specifically, the amount and range of DCN data accounted for can independently vary along at least two dimensions: (a) how domain specific or domain general (domain here is used in a general sense to refer to an aspect of cognition) a theory is, and (b) how many levels of explanation are incorporated or integrated. It is a defining feature of DCN, as opposed to traditional cognitive development, that multiple levels of observation are considered and related in terms of a single process or causal mechanism. One reason for this is that the parent discipline of cognitive development had been built on the strategy of explaining changes in behavior during development in terms of cognition – a level of explanation that is not itself directly observable. While the scientific strategy of theorizing at a level that is not directly observable is not unique to cognitive psychology, constraining theories of this kind by only one level of observation is of high risk because of the lack of constraints it imposes. In other words, a very wide variety of theories can successfully account for data at one level of observable only. It is proposed that a better strategy is to sandwich a nonobservable level of explanation (such as cognition) between two levels of observable, such as those of brain and behavior.

Theories in DCN could potentially vary enormously in the scope of data that they account for, from a single cognitive domain in a single population to an account that crosses domains of cognition and populations (typical and atypical development). Often, in biology, the broader the scope of a theory, the less clearly it makes detailed domain-specific predictions. Thus, some have referred to such broad-scope theories as frameworks (Kuhn, 1996). Put simply, frameworks are ways of thinking about, or viewpoints on, a large body of data. Frameworks may have some testable elements but primarily serve as a coherent set of assumptions that, taken together, offer an account of a wide range of phenomena. In addition, within a framework, more specific and detailed theories (and thence hypotheses) can be constructed. Further, they guide lines of research and the kinds of hypotheses that are explored. In a young and newly emerged field, it is suggested that the first priority should be to develop appropriate and useful frameworks, since adopting the wrong framework could be an expensive diversion in terms of both time and money.

11.3 THREE FRAMEWORKS FOR UNDERSTANDING HUMAN FUNCTIONAL BRAIN DEVELOPMENT

A review of the literature reveals that three different frameworks on human postnatal functional brain development are currently commonly adopted and explored (Johnson, 2001).

11.3.1 Maturational Viewpoint

According to the maturational viewpoint, newly emerging sensory, motor, and cognitive functions are related to the maturation of particular areas of the brain,

usually regions of cerebral cortex. Much of the research to date attempting to relate brain to behavioral development in humans has taken this approach. Evidence concerning the differential neuroanatomical development of brain regions should then predict the age when a particular region is likely to become functional. Conversely, success in a new behavioral task at given age is attributed to the maturation of a new brain region. Functional brain development is, in this sense, depicted as the reverse of adult neuropsychological studies of patients with brain damage, with specific brain regions being added-in during development (with the converse effects from being depleted by damage).

Despite the intuitive appeal and attractive simplicity of the maturational approach, it does not successfully explain many observations on human functional brain development. For example, recent evidence (discussed later) suggests that some of the regions that are slowest to develop by neuroanatomical criteria can be activated shortly after birth and appear to mediate cognitive functions even before they would be considered anatomically mature. Thus, the emergence of new behaviors is not necessarily linked to a previously immature, silent neural region becoming active when it matures. In fact, where functional activity has been assessed by fMRI during a behavioral transition, multiple cortical and subcortical areas appear to change their response pattern (e.g., Luna et al., 2001; Supekar et al., 2009) rather than a few specific areas becoming active. Another difficulty for the maturational viewpoint is that associations between neural and cognitive changes based on age of onset are theoretically weak because of the great variety of neuroanatomical and neurochemical measures that change at different times in different regions of the brain. Thus, as the brain is continuously developing until the teenage years, it is nearly always possible to find a potential neural correlate for any behavioral change in development.

11.3.2 Interactive Specialization

In contrast to the maturational viewpoint, the interactive specialization (IS) viewpoint assumes that postnatal functional brain development, at least within cerebral cortex, involves a process of organizing patterns of interregional interactions (Johnson, 2000, 2001, 2010). According to this view, the response properties of a specific cortical region are partly determined by its patterns of connectivity to other regions, and their patterns of activity. During postnatal development, changes in the response properties of cortical regions occur as they interact and compete with each other to acquire their role in new computational abilities. From this perspective, some cortical regions may begin with poorly defined broad functions, and consequently are partially

activated in a wide range of different stimuli and task contexts. During development, activity-dependent interactions between regions sharpen the functions and response properties of cortical regions such that their activity becomes restricted to a narrower set of circumstances (e.g., a region originally activated by a wide variety of visual objects may come to confine its response to upright human faces). The onset of new behavioral competencies during infancy will, therefore, be associated with changes in activity over several regions, and not just by the onset of activity in one or more additional region(s).

11.3.3 Skill Learning

The third perspective on human functional brain development, skill learning, involves the proposal that the brain regions active in infants during the onset of new perceptual or motor abilities are similar, or even identical, to those involved in complex skill acquisition in adults. For example, Gauthier and colleagues have shown that extensive training of adults to identify individual artificial objects (called greebles) eventually results in activation of a cortical region previously preferentially activated by faces, the fusiform face area (Gauthier et al., 1999). This indicates that this region is normally activated by faces in adults, not because it is prespecified to do so, but because of our extensive expertise with that class of stimulus. Extended to development, this view would argue that development of face processing during infancy and childhood could proceed in a similar manner to acquisition of perceptual expertise for a novel visual category in adults (see Gauthier and Nelson, 2001). While the degree to which parallels can be drawn between adult expertise and infant development remains unclear, to the extent that the skill-learning hypothesis is correct it presents a clear view of a continuity of mechanisms throughout the life span.

11.4 ASSUMPTIONS UNDERLYING THE THREE FRAMEWORKS

Underlying these frameworks are differing sets of key assumptions.

11.4.1 Deterministic Versus Probabilistic Epigenesis

Gottlieb (1992) distinguished between two approaches to the study of development; deterministic epigenesis in which it is assumed that there is a unidirectional causal path from genes to structural brain changes and then to psychological function, and probabilistic epigenesis in which interactions between genes, structural brain

changes, and psychological function are viewed as bidirectional, dynamic, and emergent. In many ways, it is a defining feature of the maturational approach that it assumes deterministic epigenesis; region-specific gene expression is assumed to effect changes in intraregional connectivity that, in turn, allows new functions to emerge. A related assumption commonly made within the maturational approach is that there is a one-to-one mapping between brain and cortical regions and particular cognitive functions, such that specific computations come on-line following that maturation of circuitry intrinsic to the corresponding cortical region. In some respect, this view parallels mosaic development at the cellular level in which simple organisms (such as *Caenorhabditis elegans*) are constructed through cell lineages that are largely independent of each other (see Elman et al., 1996 for discussion). Similarly, different cortical regions are assumed to have different maturational timetables, thus enabling new cognitive functions to emerge at different ages.

In contrast to the maturational approach, IS has a number of different underlying assumptions. Specifically, a probabilistic epigenesis assumption is coupled with the view that cognitive functions are the emergent product of interactions between different brain regions. In this respect, IS follows current trends in adult functional neuroimaging. For example, Friston and Price (2001) point out that it may be an error to assume that particular functions can be localized within a certain cortical region. Rather, they suggest that the response properties of a region are determined by its patterns of connectivity to other regions as well as by their current activity states. By this view, "the cortical infrastructure supporting a single function may involve many specialized areas whose union is mediated by the functional integration among them" (p. 276). Similarly, in discussing the design and interpretation of adult functional MRI studies, Carpenter and collaborators have argued that "In contrast to a localist assumption of a one-to-one mapping between cortical regions and cognitive operations, an alternative view is that cognitive task performance is subserved by large-scale cortical networks that consist of spatially separate computational components, each with its own set of relative specializations, that collaborate extensively to accomplish cognitive functions" (Carpenter et al., 2001, p. 360). Extending these ideas to development, the IS approach emphasizes changes in interregional connectivity as opposed to the maturation of intraregional connectivity. While the maturational approach may be analogous to mosaic cellular development, the IS view corresponds to the regulatory development seen in higher organisms, in which cell–cell interactions are critical in determining developmental fate. While mosaic development can be faster than regulatory, the latter has several advantages. Namely, regulatory development

is more flexible and better able to respond to damage, and it is more efficient in terms of genetic coding. In regulatory development, genes do not code directly, but need only orchestrate cellular-level interactions to yield more complex structures (see Elman et al., 1996).

11.4.2 Static Versus Dynamic Mapping

As well as the mapping between structure and function at one age, it can also be considered how this mapping might change during development. When discussing functional imaging of developmental disorders, Johnson et al. (2002) point out that many laboratories have assumed that the relation between brain structure and cognitive function is unchanging during development. Specifically, in accord with the maturational view, when new structures come on line, the existing (already mature) regions continue to support the same functions they did at earlier developmental stages. The static assumption is partly why it is sometimes considered acceptable to study developmental disorders in adulthood and then extrapolate back in time to early development. Contrary to this view, the IS approach suggests that when a new computation or skill is acquired, there is a reorganization of interactions between different brain structures and regions. This reorganization process could even change how previously acquired cognitive functions are represented in the brain. Thus, the same behavior could be supported by different neural substrates at different ages during development.

Stating that structure–function relations can change with development is all very well, but it lacks the specificity required to make all but the most general predictions. Fortunately, the view that there is competitive specialization of regions during development gives rise to expectations about the types of changes in structure–function relations that should be observed. Specifically, as regions become increasingly selective in their response, properties during development patterns of cortical activation during behavioral tasks may therefore be more extensive than those observed in adults, and involve different patterns of activation. Additionally, within broad constraints, successful behavior in the same tasks can be supported by different patterns of cortical activation in infants and adults. Evidence in support of this view will be discussed later.

The basic assumption underlying the skill-learning approach is that there is a continuity of the circuitry underlying skill acquisition from birth through to adulthood (see Poldrack, 2002; Ungerleider, et al., 2002 for review of the neural systems involved in perceptual and motor skill learning in adults). These circuits are likely to involve a network of structures that retains the same basic function across developmental time

(a static brain–cognition mapping). However, other brain regions may respond to learning with dynamic changes in functionality similar or identical to those hypothesized within the IS framework. For example, neuroimaging studies of adults acquiring the skill of mirror reading show both increases and decreases in cortical activity over widespread regions during learning: unskilled performance is associated with activation in bilateral occipital, parietal, and temporal lobes and cerebellum, with acquisition of skill leading to decreases in bilateral occipital and right parietal activation and to increases in inferior temporal lobe and caudate nucleus activation (Poldrack, 2002). According to the skill-learning view, similar dynamic changes in brain activation would occur as skills emerge during development.

11.4.3 Plasticity

Another way in which the three perspectives differ is with regard to the concept of, and assumptions about, plasticity. Plasticity in brain development is a phenomenon that has generated much controversy, with several different conceptions and definitions having been presented. According to the maturational framework, plasticity is a specialized mechanism that is activated following brain injury. According to the IS approach, plasticity is simply the state of having a region's function not yet fully specialized. That is, there is still remaining scope for developing more finely tuned responses. As mentioned earlier, this definition corresponds well with the view of developmental biologists that development involves the increasing restriction of fate. Finally, according to the skill-learning hypothesis view, the functional plasticity present in early development may share many characteristics with the plasticity underlying acquisition and retention of skills in adults (Karni and Bertini, 1997). Thus, unlike the IS approach, plasticity does not necessarily reduce during development.

11.4.4 Summary

To summarize, the maturational view is characterized by the interrelated assumptions that (1) cortical areas are a mosaic of regions with independent developmental timetables; (2) deterministic epigenesis means that inherent structural development in a region causes or allows functional changes; (3) there is fixed regional structure/function mapping; and (4) plasticity involves specialized mechanisms triggered by injury. In contrast, the IS approach is based on the assumptions that (1) cortical areas are inextricably linked through dense patterns of interconnections that contribute to coordinated sequences of development; (2) probabilistic epigenesis gives a vital role to intrinsically and extrinsically generated activity in sculpting anatomical development; (3) combinations of cortical regions may support similar or identical behaviors in different ways during the course of development; and (4) plasticity is the inherent state of an unspecialized neural system. The third perspective, skill learning, is based on the assumptions that (1) specific cortical areas or networks are specialized for perceptual and motor skill acquisition from early on; (2) the acquisition of these skills shapes the response functions of the same or other cortical regions; (3) dynamic changes occur in the neural substrate of a skill as the brain becomes expert; and (4) plasticity is retained at fairly constant level throughout development.

11.5 PREDICTIONS AND EVIDENCE

Frameworks are useful for a variety of reasons, but particularly so when they help to generate predictions that direct research (albeit that they will not always make opposing predictions), and when they offer coherent explanations of previously puzzling observations. This section presents, three of the sources of evidence that an adequate account of human functional brain development will need to address. Before this, however, the author reviews the types of predictions that arise from the three approaches. The first set of predictions concerns the neural correlates of the onset of new abilities during development. According to a maturational view, new behavioral abilities are mediated by new components of cognition that are, in turn, enabled or allowed by the maturation of one or more brain regions. A consequence of this is a general increase in the number of structures that can be activated in tasks with development. In contrast to these predictions, in the IS approach, it is anticipated that widespread networks of brain regions will change their patterns of activation in association with the onset of new behavioral abilities. Specifically, regions become more specialized (finely tuned) in their response properties with experience. A consequence of this specialization is that on at least some occasions, fewer brain regions will be activated with specific stimulus or task contexts. Turning to the skill-learning approach, here it is anticipated that the onset of new abilities will often be associated with activation of a network of skill acquisition areas. As the new behavioral ability is acquired, a different network of brain regions may become involved.

With regard to the issue of how functions are mapped on to patterns of brain activity, according to the maturational approach, if two age groups are compared in a task for which they show identical behavioral performance, it should also be expected to see identical patterns of brain activation. This is not necessarily the case for the IS approach since the exact patterns of brain

activation that support a function will change according to the degree of specialization of component regions within the supporting network. Indeed, the IS approach predicts that the patterns of regional brain activation supporting a function will change during development. While the exact nature of this change will depend on the degree of specialization achieved in different component structures, the IS view predicts a general trend for a decrease in the extent of cortical activation with increasing development/experience. The skill-learning view invokes the reactivation of one or more skill-learning circuits at the onset of a task, followed by a different pattern of activation after the skill is acquired. In this case, in many comparisons between age groups, the younger group will have acquired the skill in less depth than the older group, giving rise to different patterns of underlying brain activation. Interestingly, however, patterns of changing brain activation while adults acquire new skills should mirror the changes seen during development as infants and children acquire simpler skills.

11.6 FUNCTIONAL BRAIN IMAGING

Elsewhere, evidence from functional imaging pertaining to the development of face perception and social cognition (Cohen-Kadosh and Johnson, 2007; Johnson, 2010; Johnson et al., 2009) has been reviewed in detail. In this section, evidence is reviewed from the functional neuroimaging of normal development that pertains to the three perspectives on functional brain development described above. The author suggests that the evidence currently available does not offer much support to the maturational view, at least not without substantial modification. Instead, behavioral change often seems to be accompanied by large-scale dynamic changes in the interactions between regions, and different cortical regions become more specialized for functions as a consequence of development.

A maturational approach to human postnatal functional brain development predicts that a neural correlate of increasing behavioral abilities is an increasing number of active cortical areas. In functional imaging paradigms, therefore, infants and children should show fewer regions active in tasks where they show poorer behavioral performance than adults. In contrast, if new behaviors require changes in interregional interaction, a greater or equal extent of cortical activation can be predicted, and different patterns of activation might be found early in development even in task domains where behavioral performance is similar to that of adults. Which of the three approaches is adopted not only has theoretical implications, but also practical implications for data collection. For example, if one adopts the maturational approach and is expecting a particular area to become

active during development for a particular task, then brain imaging may be focused on that region rather than on the whole brain. As a consequence, any possible changes in more distant brain structures would not be detected. By contrast, if one adopts the IS approach, then the importance of whole-brain imaging is clearly apparent.

A number of authors have described developmental changes in the spatial extent of cortical activation in a given situation during postnatal life. Event-related potential experiments with infants have indicated that for both word learning (Neville et al., 1992) and face processing (de Haan et al., 2002), there is increasing localization of processing with age and experience of a stimulus class. That is, electrophysiological recordings reveal a wider area of processing for words or faces in younger infants than in older ones whose processing has become more specialized and localized. From the IS framework, such developmental changes are accounted for in terms of more pathways being partially activated in younger infants before experience with a class of stimuli. With increasing experience, the specialization of one or more of those pathways occurs over time. Taking the example of word recognition, ERP activity differentiating between comprehended and noncomprehended words is initially found over widespread cortical areas. This narrows to left temporal leads after children's vocabularies have reached a certain level, irrespective of maturational age (Mills et al., 1993). Changes in the extent of localization can be viewed as a direct consequence of specialization. Initially, multiple pathways are activated for most stimuli. With increasing experience, fewer pathways become activated by each specific class of stimulus. Pathways become tuned to specific functions and are therefore no longer engaged by the broad range of stimuli, as was the case earlier in development. Additionally, there may be inhibition from pathways that are becoming increasingly specialized for that function. In this sense, then, there is competition between pathways to recruit functions, with the pathway best suited for the function (by virtue of its initial biases) usually winning out.

Further evidence to support the IS view comes from functional MRI studies in children. For example, Luna et al. (2001) tested participants aged 8–30 years in an occulomotor response-suppression task. Their behavioral results showed that the adult level of ability to inhibit prepotent responses developed gradually through childhood and adolescence. The difference between prosaccade and antisaccade conditions was investigated with functional MRI, and revealed changing patterns of brain activation during development. Both children and adolescents had less activation than adults in a few cortical areas (superior frontal eye fields, intraparietal sulcus), and several subcortical areas, a finding broadly consistent with maturational hypotheses. However, both children and adolescents also had differential

activation in regions not found to show differences in adults. Children displayed increased relative activation in the supramarginal gyrus compared to the other age groups, and the adolescents showed greater differential activity in the dorsolateral prefrontal cortex than children or adults. These findings illustrate that the neural basis of behavior can change over developmental time, with different patterns of activation being evident at different ages, a pattern consistent with the IS and the skill-learning viewpoints.

A similar conclusion can be reached after examination of the developmental fMRI data produced by Casey and colleagues. These authors (Casey et al., 1997; Thomas et al., 1999) administered a go/no-go task to assess inhibitory control and frontal lobe function to healthy volunteers from 7 years of age to adult. The task involved participants responding to a number of letters, but withholding their response to a rarely occurring 'X.' More than twice the volume of prefrontal cortex activity (dorsolateral prefrontal cortex) was observed in children compared to adults. One explanation of this finding is that children found the task more difficult and demanding than adults. However, children with error rates similar to those in adults showed some of the largest volumes of prefrontal activity suggesting that task difficulty was not the important factor. It is difficult to account for these decreases in the extent of cortical activation in terms of the progressive maturation of prefrontal cortical areas. The finding that children and adults appeared to show different patterns of activation even when performance was equated is inconsistent with the skill-learning viewpoint, but is in line with expectations from the IS viewpoint.

The third example of the use of fMRI to study the development of cortical activation patterns during childhood comes from studies of verbal fluency tasks in which participants are asked to generate words in response to a cue (e.g., to generate examples of a target category, or generate a verb that relates to a cued noun). Several studies have shown that adults (Lehéricy et al., 2000) and school-age children (Gaillard et al., 2000; Hertz-Pannier et al., 1997, 1999) typically activate left hemisphere frontal cortical networks including Broca's area, premotor, prefrontal, and supplementary motor areas as well as, less consistently, temporal cortical areas including superior temporal, middle temporal, and supramarginal gyri. In addition, some degree of activation in homologous right frontal regions is almost always found both in adults (Pujol et al., 1999; Springer et al., 1999) and in children (Gaillard et al., 2000; Hertz-Pannier et al., 1997, 1999). Two studies have found that both the degree to which activation is bilateral (rather than left dominant) and the extent of this activation is greater in children than in adults (Gaillard et al., 2000; Holland et al., 2001). Thus, as in the other examples discussed above, typical development is associated with a reduction in the extent of activation of cortical areas and, as a consequence, an increased lateralization of activation to the left hemisphere with age (Holland et al., 2001).

In sum, the balance of evidence to date suggests that (1) new behavioral skills are accompanied by widespread changes across many regions of cortex, and (2) functional brain development involves the twin process of increasing localization and increasing specialization.

11.7 CRITICAL OR SENSITIVE PERIODS

The three perspectives on human functional brain development differ in their views as to the effects of early atypical experience. By the maturational view, differences in experience might influence the speed at which a function matures or the ultimate level of performance; in the skill-learning view, any atypical early experiences can potentially be compensated for later in development as the mechanisms for learning remain in operation in the same way; in the IS view, atypical early experiences could have long-lasting effects because they could affect the specialization and localization of function, which may not be able to be altered later in life when there is less scope for plasticity.

There have only been a limited number of studies examining the effects of atypical early experience in humans. Some studies have investigated the perception of facial information in children who experienced deprivation of patterned visual input in the early months of life due to bilateral, congenital cataracts. These patients were tested years after their cataracts were removed and they were fitted with contact lenses (i.e., years after visual input had been restored), thus any effects of the few months of deprivation following birth would likely be absent or very minimal according to the maturation or skill-learning views. However, investigation of these patients reveals persistent deficits in selective aspects of face processing. One study found that patients showed impairments in matching facial identity over changes in viewpoint (and tended to show an impairment in recognizing identity over changes in emotional expression), but performed normally on tests of lip-reading, perception of eye gaze, and matching of emotional expressions (Geldart et al., 2002). The second study demonstrated that this difficulty in processing facial identity may be due to deficits in processing the spacing among facial features since patients performed normally in discrimination of faces that differed only on individual features (e.g., mouth) but they were impaired in discrimination of faces that differ only in the spacing of the features (Le Grand et al., 2001). This was not due to a general impairment in perception of spacing of features, as they performed normally in discriminating nonface patterns whether they differed by the shape

of the features or the spacing of the features. The fact that these impairments persisted even after years of visual input to compensate for the early deprivation is not consistent with the maturational or skill-learning views, but is consistent with the IS view that early atypical experience may have long-lasting consequences.

The three perspectives that have been discussed yield different types of predictions about the consequences of perinatal brain damage. According to the maturational view additional mechanisms of plasticity are activated following early damage. Specific additional explanations are then required to account for incidents of recovery of function. In addition, it is not obvious why the extent of plasticity is greater earlier in life. From the IS perspective, there is a parsimonious explanation of recovery of function following perinatal damage since the regional specialization of the remaining brain regions will be altered to compensate, particularly, the corresponding regions in the other hemisphere. In cases of bilateral or extensive damage, recovery is less likely. From the skill-learning perspective, plasticity is a life-long feature of the brain. Damage to the general circuits critical for skill acquisition will have long-lasting and widespread consequences, whereas damage to circuits specific to acquisition of particular skills or their retention may result in more isolated impairments. Of the three approaches, IS gives the simplest account of sensitive periods for plasticity since plasticity is reduced when specialization of corresponding regions is achieved.

In sum, with regard to the long-term effects of atypical early experience, or even variations of experience within the normal range, once again the three frameworks lead to different sets of expectations. From the skill-learning perspective variations in early experience will determine the extent of skills acquired. Early deprivation will be potentially reversible since the same mechanisms of skill acquisition are available later in life. From the IS perspective, long-term effects of atypical early experience can result from atypical patterns of regional specialization arising early in life. Such atypical patterns of specialization may be difficult to reverse once established. Finally, under the maturational view, a primary variable influenced by the environment is the speed of maturation that may affect the level or maintenance of a skill. It is sometimes argued that early sensory deprivation may have a general slowing effect on the sequence of maturation.

11.8 ATYPICAL DEVELOPMENT: FROM GENETICS TO BEHAVIOR IN DCN

It has been seen in earlier sections that IS is a promising framework for understanding human functional brain development. While this level of explanation may be appropriate for characterizing the proximal causes of atypical cognition or behavior in developmental disorders such as autism or Williams's syndrome, when development goes awry, a satisfactory explanation of the disorder also requires an account of the causal mechanisms that initiate the atypical development trajectory. This usually entails hypotheses about how an atypicality at one level (such as genetics) causes or induces the onset of atypical development at other levels (brain, cognitive, behavior). An initial attempt to provide a framework for unraveling these complex causal pathways in developmental disorders came with the causal modeling approach of Morton and Frith (1995). According to its originators, causal modeling provided a theory-neutral system for modeling different theories about the paths of causation from a biological level to cognitive and behavioral levels. The models were represented in a graphical notation that allowed for easy comparison between competing explanations, but the framework itself did not involve the construction of computational or neural network models (although a theory represented in the notation could potentially be implemented this way).

Causal modeling is a useful way to compare different theories where these theories are based on the assumption of predetermined epigenesis (a one-way causal pathway from genetics to behavior), but it is a less natural format for capturing the complexities of probabilistic epigenesis (Gottlieb, 2007) in which cause can also run in reverse – for example, sensory experience or internal states such as stress are known to affect gene expression profiles. In addition, causal modeling is intended as a notation for comparing different theories, and as such does not provide an explanation or generate testable hypotheses itself.

A different perspective on identifying causal factors in development involves using implemented computational models that can capture complex nonlinear interactions that are hard to conceptualize with just schematic illustrations or verbal descriptions. Here, the assumption is that multiple factors can interact in complex ways to determine outcome. In one of several initial attempts to apply neural networks to developmental disorders, Oliver and colleagues charted the different ways in which the 'normal' formation of structured representations in the cerebral cortex can go wrong (Oliver et al., 2000). These models were originally designed to investigate the mechanisms underlying the IS process discussed earlier. Several groups have used simple cortical matrix models to investigate the factors and mechanisms responsible for cortical specialization (e.g., Kerszberg et al., 1992; Oliver et al., 2000; Shrager and Johnson, 1995). In these artificial neural networks, connections between nodes are pruned according to variations of Hebbian learning: links between nodes that are often active together are strengthened, whereas links between nodes that are not often coactive get weaker and are pruned. In some of these

models, the degree of pruning of connections during learning approximately matches that seen during the course of human brain development. During exposure to patterned input (roughly equivalent to sensory stimulation), nodes become more selective in their response properties, and under certain conditions, clusters of nodes with similar response properties emerge. Thus, in these computational models, selective pruning plays a role in the emergence of clusters of nodes (localization) that share common specific response properties (specialization).

In order to explore developmental disorders, Oliver and colleagues made simulations with a simple cortical matrix model in which one or other of the parameters known to be important for the emergence of structured representations was deliberately changed. In this case, when the authors manipulated an aspect of the intrinsic structure of the network, the relative length of excitatory and inhibitory links, this initial state change totally disrupted the formation of structured representations. In other simulations, structured representations emerged, but were distorted in different ways relative to the typical development case. Oliver et al. (2000) aimed to generate taxonomy of the ways that structured cortical representations could go awry in development, with the long-term aim that some of these artificial developmental disorders could potentially map onto those that occur in the real world.

A criticism of the Oliver et al. (2000) approach, and several related models, is that while they could potentially provide an explanation at the level of brain structure and function, they do not capture the genetic, cognitive, and behavioral levels. Very recent models have begun the ambitious task of simulating from the genetic to the behavioral levels, albeit within a restricted domain of cognition (past tense acquisition) (Thomas et al., submitted).

11.9 IS: FUTURE CHALLENGES

To recap on the basis of the IS view, it argues that early in postnatal development, many areas begin with poorly defined functions, and consequently can be partially activated by a wide variety of sensory inputs and tasks. During development, activity-dependent interactions between regions result in modifications of the intraregional connectivity such that the activity of a given area becomes restricted to a narrower range of circumstances. As a result of becoming more finely tuned, small-scale functional areas become increasingly distinct from their surrounding cortical tissue, and this will be evident in functional imaging studies as increasing localization of function. In summary, according to the IS view, small-scale areas of cortex become tuned for certain functions as a result of a combination of factors, including (i) the

suitability or otherwise of the biases within the large-scale region (e.g., transmitter types and levels, synaptic density, etc.); (ii) the information within the sensory inputs (sometimes partly determined by other brain systems); and (iii) competitive interactions with neighboring regions (so that functions are not duplicated).

To date, the majority of the research on the emergence of specialized functions in human cortex has focused on specific regions. However, it is clear from the IS viewpoint that the next step is to understand how networks involving different regions, each with their own different specializations, emerge. In other words, while understanding the functional brain development at the level of individual cortical regions is beginning, still the knowledge about how the larger scale of cortical function in terms of networks of regions develops (Johnson and Munakata, 2005) is lacking. This section reviews, some initial evidence and theory that may begin to address this intriguing issue.

However, before considering the empirical evidence, one needs to consider what makes a network of functional nodes more or less successful. A branch of mathematics called graph theory concerns itself with the relative efficiency of different kinds of networks. While it may seem at first that a lattice or grid pattern is the optimal design for a network, formal analysis of measures of local network connectivity and the average path length from one node to another show that so-called small-world networks are the most efficient (Bassett and Bullmore, 2006). In contrast to the grid pattern of streets found in many American cities, small-world networks are more like the clusters of small streets in a village that is then linked to other such villages by fast highways. Although the overall balance of the small local streets and highways can vary, most biological systems (and even the World Wide Web) are small-world networks. Several studies have shown the regional interconnectivity of the adult brain is a highly efficient small-world network, but how does this efficient network emerge?

The first piece of the jigsaw comes from recent work by Fair et al. (2007, 2009) who used functional connectivity analyses in fMRI to study resting state control networks in school-age children and adults. Their analysis allows them to infer the nature and strength of functional connections between 39 different cortical regions. They found that development entailed both segregation (i.e., decreased short-range connectivity) and integration (i.e., increased long-range connectivity) of brain regions that contribute to a network. In a similar study, the general developmental transition from more local connectivity to greater and stronger long-range network connectivity was confirmed using slightly different methods and 90 different cortical and subcortical regions (Supekar et al., 2009; but see Power et al., 2012; Van Dijk et al., 2012 for technical limitations of these analyses).

The decrease in short-range interregional functional connectivity is readily explicable in terms of the IS view. As neighboring regions of cortical tissue become increasingly specialized for different functions (e.g., objects vs faces), they will less commonly be coactivated. This process may also involve synaptic pruning and, as heard in the last section, has been simulated in neural network models of cortex in which nodes with similar response properties cluster together spatially distinct from nodes with other response properties (Oliver et al., 1996). Thus, decreasing functional connectivity between neighboring areas of cortex is readily predicted by models implementing the IS view. More challenging from the current perspective is to account for the increase in long-range functional connections.

A maturational explanation of the increase in long-range functional connectivity would suggest that this increase is due to the establishment or strengthening of the relevant fiber bundles. However, the increase in functional connectivity during development may occur after the relevant long-range fiber bundles are in place (see Fair et al., 2009; Supekar et al., 2009 for discussion). While increased myelination is likely to be a contributory factor, (1) myelination itself can be a product of the activity/usage of a connection (Markham and Greenough, 2004); and (2) a general increase in myelin does not in itself account for the specificity of interregional activity into functional networks that support particular computations (but see Nagy et al., 2004). Thus, the strengthening and maintenance of long-range brain connections is also likely to be an activity-dependent aspect of brain development. This raises the question of why and how do particular anatomically distant brain regions begin to cooperate in a functional network?

A key to answering this question may lie in scaling up the basic mechanisms of Hebbian learning. Instead of cells that fire together wiring together, regions that tend to be coactivated in a given task context strengthen or maintain the neural pathways between them. While each region is becoming individually specialized for a particular function, this intraregion change in tuning is modulated and influenced by its presence within an emerging network of coactivated structures. For example, in a task that requires visually guided action, a variety of visual and motor areas will be coactivated along with multimodal integration areas. If the task is repeated sufficiently often then these patterns of coactivation will be strengthened, and specialization of individual regions will proceed within this context of overall patterns of activation.

The second source of coactivation in the developing human brain is commonly overlooked – spontaneous activity during the resting state (with no current task demands). Although there has been great interest in the resting state or default network in adults, only recently has this been studied using fMRI in children (although there is a long history of studying resting EEG in children). It seems likely that the oscillatory resting activity of the brain, which probably occupies more waking hours than those when the child is engaged in any specific tasks, may play a key role in strengthening and pruning the basic architecture of long-range connections.

The third reason why anatomically distant regions may strengthen and maintain their connectivity relates to the fact that most of the long-range functional connections studied by Fair et al. (2007) involved links to parts of the prefrontal cortex (PFC). This part of the cortex is generally considered to have a special role during development in childhood and skill acquisition in adults (Gilbert and Sigman, 2007; Thatcher, 1992). Indeed, Prefrontal Cortex (PFC) may play a role in orchestrating the collective functional organization of other cortical regions during development. While there are several neural network models of PFC functioning in adults (e.g., O'Reilly, 2006), few if any of these have addressed development. However, another class of model intended to simulate aspects of development may be relevant both to PFC and to the issue of how networks of specialized regions come to coordinate their activity to support cognition. Knowledge-based cascade correlation (Shultz et al., 2007) involves an algorithm and architecture that recruits previously learned functional networks when required during learning. Computationally, this dynamic neural network architecture has a number of advantages over other learning systems. Put simply, it can learn many tasks faster, or learn tasks that other networks cannot, because it can recruit the knowledge (computational abilities) of other self-contained networks as and when required. In a sense, it selects from a library of available computational systems to orchestrate the best combination for the learning problem at hand. While this class of model is not intended to be a detailed model of brain circuits (Shultz and Rivest, 2001; Shultz et al., 2007), it has been used to characterize frontal systems (Thivierge et al., 2005) and may capture important elements of the emerging interactions between PFC and other cortical regions at an abstract level. In addition, it offers initially attractive accounts of (1) why PFC is required for the acquisition of new skills; (2) why PFC is active from early in development, but also shows prolonged developmental change; and (3) why early damage to PFC can have widespread effects over many domains.

Although much work remains to be done to understand in more detail, the factors that lead to the emergence of long-range networks, the graph theory analyses of changes during the school-age years are generating important insights. While, as described earlier, there are differences in the balance of short and long connections between children and adults, it is important to note that the network organization of children's brains is

as efficient as that of adults. In other words, while children's brains are wired differently from those of adults, they are still optimally geared for the rapid and high-fidelity transmission of information. Whether the same is true in infancy and early childhood remains unknown.

Aside from the shift from local to long-range connectivity, another change in network structure observed using graph theory analysis during development is in the hierarchical structure. Adult networks have a more hierarchical structure that is optimally connected to support top-down relations between one part of the network and another (Supekar et al., 2009). While hierarchical networks have a number of computational advantages to be discussed below, they are known to be less plastic and more vulnerable to damage or noise in the particular nodes at the top of the hierarchy. Thus, the network arrangement of children may be more flexible and plastic in response to unusual or atypical sensory input or environmental context. Further, the response to focal brain damage, particularly in the prefrontal cortex, may be more clearly understood in the light of these different network structures.

One of the features of a hierarchical network is the capacity for one region to feedback highly processed sensory or motor input to the earlier stages of processing. In much the same way as we hypothesized that lateral interregional interactions help shape the intrinsic connectivity of areas to result in functional specialization, interactions between regions connected by feedback and feed-forward connections may also help shape the specialization of the areas involved. Top-down effects play an important role in sensory information processing in the adult brain (e.g., Siegel et al., 2000). For example, during perception, information propagates through the visual processing hierarchy from primary sensory areas to higher cortical regions while feedback connections convey information in the reverse direction. In a neuro-computational model of feedback in visual processing in the adult brain, Spratling and Johnson (2004) demonstrated that a number of different phenomena associated with visual attention, figure/ground segmentation, and contextual cueing could all be accounted for by a common mechanism underlying cortical feedback. Extending these ideas to development, there are potentially two important implications of feedback that will benefit from future exploration. The first of these will be to examine how the specialization of early sensory areas is shaped by top-down feedback, and vice versa, during development. The second topic for investigation will be to examine the consequences of relatively poor or diffuse cortical feedback in the immature cortex.

Top-down feedback from PFC may also have a direct role in shaping the functional response properties of posterior cortical areas. In cellular recording studies from both humans and animals, evidence has accrued that the selectivity of response of neurons in areas such as the fusiform cortex may increase in real time following the presentation of a stimulus. For example, McCarthy et al. (1997) measured local field potentials in face-selective regions of lateral fusiform cortex in human adults and found that responses of these neurons go from being face selective at around 200 ms after stimulus presentation, to being face identity or emotion selective at later temporal windows. This suggests that top-down cortical feedback pathways, in addition to their importance in attention and object processing (Spratling and Johnson, 2004, 2006), may increase the degree of specialization and localization in real time, as well as in developmental time. Thus, some of the changes in functional specialization and localization seen in face-sensitive regions may reflect the increasing influence of interregional coordination with other regions, including the PFC.

A final aspect of the transition from child brain network to the adult one is the greater connectivity between cortical and subcortical structures seen at younger ages (Supekar et al., 2009). This observation may be fundamental for our understanding of the emergence of the social brain and memory systems as it implies that the specialization of some cortical areas may be initially more dominated by structures such as the amygdala and hippocampus. As adulthood is approached, more networks become intrinsic to the cortex and develop a complex hierarchical structure more dominated by PFC.

11.10 SUMMARY, CONCLUSIONS, AND RECOMMENDATIONS

Now that DCN has become established as an interdisciplinary field in its own right, it has become time to evaluate and question the directions one is going in. One of the most common criticisms leveled at the newly emerging field is that it is primarily being driven forward by the powerful new methods for imaging brain structure and function in an infant- and child-friendly way (as well as new techniques for genetic analyses), and that it lacks the theory-driven approach that characterizes much of the best work in cognitive development. Similar concerns are expressed, albeit less directly, by students who can be daunted by the somewhat fragmentary islands of data that have been acquired to date about human functional brain development. Where is the overarching theory or framework within which they can make sense of disparate observations? A related concern sometimes expressed by those in cognitive science is that the hypotheses which are presented in DCN are reductionist, or otherwise impoverished as a cognitive explanation of infant or child behavior. In other words, this criticism is that what hypotheses and theories there are in the field are of the wrong type, and do not offer a

satisfactory explanation of behavioral change in development.

Starting with the criticism of a relative lack of theories in DCN, acknowledgement has to be made that, at least compared to the parent discipline of cognitive development, work in DCN is generally less theory driven (albeit with the exceptions discussed in this chapter). Why is this? A large part of the explanation is believed to be due to the sudden increase in the volume and diversity of data available because of the new methods that have become available. Many theories that successfully accounted for sets of behavior observations in child development founder on the rocks when attempts are made to account for neuroscience data relating to the same behavioral tasks. For one thing, when one more than doubles the quantity of data to be accounted for, then many previously successful theories will no longer offer a satisfactory explanation, simply because the chance of observing refuting evidence is much higher. Bringing powerful new methods into a field is analogous to a catastrophic environmental change during evolution – the majority of species (theories) simply cannot adapt and, therefore, die off. It takes generations for the better-adapted species to emerge.

The second issue is that of accommodating to new types of data. When one begins to study brain function directly, the first thing that strikes is the complexity of the processes involved. For example, neuroscience evidence indicates that the brain has at least three partially independent routes for executing eye movements. While these routes may have slightly different attributes, duplication of computations and (apparent) redundancy seems to be a basic feature of how the brain does things. Thus, at a sweep, simple single-route cognitive models appear less plausible. Add to this the complexity of feedback routes interacting with sensory-driven information, and the undoubted importance of temporal synchrony, and many existing theories of cognitive development look hopelessly simplistic. Of course, a common reaction to this is that theories of cognitive development are not intended to account for neuroscience data – that is, merely a matter of implementation. However, if you accept this argument, I contend that you are not doing DCN (and I would argue that satisfactory explanations of development necessitate bridging between levels of observation (see Johnson, 2010)).

This leads us to the second common criticism of theory in developmental science; the theories are of the wrong type to be of relevance for explaining the development of human behavior. Commonly, the view is expressed that theories in DCN are reductionist and, therefore, do not offer good explanations of cognitive change. As discussed earlier, it has been argued following Marr (1982), that cognition is a level of explanation independent from the underlying neuroscience. Recent directions in neuroscience suggest that, to the contrary, there is a large degree of interdependence between levels in real complex biological systems such as the brain. This has led to the proposal that theories that are consistent between different levels of explanation should be sought (see Mareschal et al., 2007, for a detailed discussion of this point). Ultimately, theories that are consistent with both behavioral and brain development evidence will have greater explanatory power than those confined to one level of observation.

In considering the issues above, the current dearth of plausible theories in DCN seems unsurprising. After all, new fields in the biological sciences (in contrast to some physical sciences) often go through a natural history phase in which collection of basic data is the priority. However, in this chapter, it was argued that one needs to strive to bring more adequate and appropriate theories into the field. Thus, three positive suggestions for hallmarks of a good theory in DCN are offered.

1. The theory advanced should genuinely relate neural observations to behavioral ones, and can be equally well tested (and refuted) by either neural or behavioral level observations. I suspect that a variety of different types of theories will emerge to serve this bridging function, but that they are unlikely to look like many existing cognitive development theories. Theories that have been developed purely on the basis of behavioral data are unlikely to naturally map on to brain imaging data, and there is a danger in seeking only confirmatory data. Ideally, theories of functional brain development that are equally compatible with brain and behavioral observations should be developed.

2. Theories in developmental science should involve mechanisms of change. This suggestion is not new (e.g., Karmiloff-Smith, 1998; Mareschal and Thomas, 2007), but it is still surprisingly common to see theories that explain the state of affairs before and after a developmental transition, but that do not specify the mechanisms of the transition itself (other than using the terms such as maturation or learning). Theories of development need to be theories focused on change.

3. Given that theories in DCN are accounting for several levels of observation, and that they also need to be compatible with undoubtedly complex and dynamic aspects of neural processing, we need to find ways to elucidate and present those theories so that they are both comprehensible and clarifying. This is the attraction and importance of formal computational modeling, be it symbolic, connectionist or hybrid (see Mareschal et al., 2007). While theories may initially develop as informal ideas, ultimately we should aim to implement them as computational models.

Finally, the author cautions against being too prescriptive. In the long term it is probably good for the field to have a heterogeneous mix of different types of theories and let the data, and time, select those with the best fit to reality. After all, despite their prolonged domination, the dinosaurs did not inherit the globe.

12.1 INTRODUCTION

Human brain development is a dynamic process that begins *in utero* and continues prominently through childhood, adolescence, and young adulthood. While strongly influenced by genetic factors, the environment also prominently affects brain maturation by acting on the cellular and macroscopic levels. This experiential learning impacts both brain structure and function through forms of neuronal plasticity that continue throughout our lifetimes. However, despite the fact that investigating brain development is undoubtedly one of

the keys to appreciating how we emerge as unique human beings and how this process can go awry in disease, our understanding of this important period has historically been hindered by two main factors. First, there has been a lack of reliable postmortem data as, thankfully, children are generally healthy during development. Second, technological limitations of past methods such as positron emission tomography (PET) and computed tomography (CT) often imposed some modest risk of harm to the subject (e.g., ionizing radiation), which made the study of healthy, typically developing children ethically questionable. The situation changed dramatically with the dissemination of magnetic resonance imaging (MRI) technology during the 1980s, which not only offers higher-quality images of the brain parenchyma than ultrasound, x-ray, CT, or PET, but also does so in a way that is remarkably safe for the subject (see Chapter 34).

This discussion will begin with a review of the historical postmortem and histological literature, and will then move on to the groundbreaking neuroimaging investigations of the 1990s, that first examined brain development with this MRI technology. A collection of more detailed phenomena will then be examined, which have been uncovered with advanced brain mapping techniques and have come together as a set of classic features that characterize typical brain development. Finally, we will conclude with a discussion of the cutting-edge efforts being made to integrate these diverse observations within a more generalized 'multimodal' imaging framework and to relate them to advancements in cognitive development. A focus on prominent sex-specific, regional and temporal variations will be continually threaded throughout this discussion.

12.2 POSTMORTEM STUDIES AND HISTOLOGY

12.2.1 Comparison to MRI

Although datasets were sparse, postmortem and histological studies were able to provide key insight into normal brain structure and development, as well as pathology, decades before the introduction of neuroimaging methods like PET and MRI. Further, the rich literature that developed from this early effort has provided a strong foundation of data against which newer imaging modalities can be validated. Compared to a modern imaging method like MRI, there are several distinct advantages and disadvantages of these postmortem studies. Not only are datasets relatively small in postmortem-samples, as mentioned above, but longitudinal studies – valued for their statistical power to detect changes over time within individuals among the highly variable population – are also impossible to conduct. Conversely, because postmortem methods can directly visualize the

brain tissue, spatial resolution far exceeds even the best neuroimaging protocol, and there is less validation needed to ensure that the raw signal being measured faithfully represents the underlying neuronal architecture. Artifacts, though, are an important concern for either method. While postmortem methods may introduce artifacts due to cell death, fixation/staining procedures, and morphological changes due to osmotic pressure and mechanical damage, MRI data suffer artifacts from other sources like magnetic susceptibility effects (signal loss in regions near large caverns of air), local image distortions caused by magnetic field inhomogeneities, and partial volume effects that occur when different structures fall within the same voxel. Many of these issues present less of a problem for the interpretation of larger data sets obtained with MRI, relative to postmortem data, as effects of artifacts generally become small as the number of samples becomes large. However, it should still be remembered that MRI only offers a wide-angle indirect view of tissue, which cannot reach down to the cellular level and must be observed through the complex lens of magnetic resonance.

12.2.2 Synaptogenesis and Pruning

By the time an infant is born, the human brain already contains on the order of 100 billion neurons (Kandel et al., 2000). The period of rapid overall brain growth that began *in utero* continues after birth through the first years of life. Surprisingly, however, postmortem studies during the early part of the twentieth century showed that total brain volume and weight actually plateau early and reach approximately 90% of their adult values by age 5 (Dekaban, 1978; Riddle et al., 2010; Vignaud, 1966; and is discussed extensively in Rubenstein and Rakic, 2013).

Even during this early period of pronounced overall growth, brain development is characterized as a dynamic process with both progressive and regressive changes that are influenced by complex genetic influences as well as experience-dependent plasticity due to environmental influences. As the infant brain grows in size, it also grows in complexity. Neurons undergo dendritic branching, forming an arbor of neural connections through synaptogenesis and then ultimately refine this global brain network through the processes of myelination and synaptic pruning. Much of our understanding of the complex balance between synaptogenesis and synaptic pruning has evolved from the seminal histological work performed by Huttenlocher and colleagues, who mapped synaptic density in different areas of the brain throughout childhood. Overall synaptic density is comparable to the adult level at birth. It then rises even further through the first year of life to its peak at 12–18 months and then decreases during late childhood and

young adulthood towards a stable adult plateau of $\sim$1 billion synapses*mm^{-3} (Huttenlocher, 1979). This has helped to form the theory that the flexible ground-work laid through an initial overabundance of connections gives way to a reduced – but more targeted and efficient – network through experience-dependent synaptic pruning. Interesting regional variations were also observed during these studies, with primary visual and auditory cortex reaching their peak synaptic densities earlier than prefrontal cortex (Huttenlocher, 1979; Huttenlocher and Dabholkar, 1997; Huttenlocher et al., 1982). The extended period of synapse elimination also has regional variations, with pruning ending by age 12 in the auditory cortex but continuing through mid-adolescence in the prefrontal cortex. This temporal pattern parallels concurrent gains in the cognitive domains that are thought to relate to these regions (Luna et al., 2004; Spear, 2000).

12.2.3 Myelination

Myelination of axonal projections by oligodendroglia is also a prominent component of early brain development. This process begins *in utero*, continues rapidly through the first 5 years of life, and remarkably extends – although at a slower rate – through young adulthood. Intracortical histological preparations by Kaes in 1907 were some of the first to demonstrate this prolonged trajectory of myelination, along with its striking regional variability in timing (Kaes, 1907; Kemper, 1994). His work not only demonstrated earlier trajectories in some areas (posterior temporal, precentral, and postcentral cortex) than others (superior parietal, anterior temporal, and anterior frontal cortex), but also showed that regions with a more protracted developmental trajectory have more pronounced changes during older age. This has helped to form the 'first-in-last-out' theory of aging (Davis et al., 2009), which suggests that higher-order cognitive manifestations (e.g., problem solving and logical reasoning) – some of the last to develop (Luna et al., 2004) – are some of the first to degenerate in old age. Furthermore, the visible spread of myelin outwards into the cortex results in an apparent cortical thinning, which suggests that normal developmental decreases in cortical thickness (discussed in Section 12.4.3) may be due, in part, to this progressive increase in myelin and not simply to regressive changes like synaptic pruning and cell loss (see Rubenstein and Rakic, 2013).

These initial observations in intracortical tissue were extended to the white matter in the pioneering work performed by Yakovlev and Lecours in the 1960s. They demonstrated that white matter myelination begins *in utero* during the second trimester of pregnancy and continues throughout young adulthood (Yakovlev and Lecours, 1967). Additionally, they extended the earlier observations of regional variations in the timing of myelination and described a general posterior-to-anterior trend in the timing of white matter myelination during development that has also been replicated in other samples (Kinney, 1988). Later independent research, targeting the hippocampal formation, has also noted striking increases in myelination, with a 95% increase observed in the extent of myelination relative to brain weight during the first two decades of life. Surprisingly, the authors noted that expanding myelination continued even through the fourth to sixth decades of life (Benes et al., 1994). Taken together, these observations suggest that structural white matter development, in the form of advancing myelination, proceeds in tune with overall cognitive development – with areas involved in lower-order sensory and motor function myelinating earlier than areas involved with higher-order executive function. This correlated timing implies there may be some relationship between advancing brain function and increased myelination; however, postmortem studies are limited from investigating this directly.

12.2.4 Sex-Specific Differences

A pronounced sexual dimorphism in overall brain size emerges during the first 5 years of human brain development, with males having brains that are, on average, approximately 10% larger than females at their adult plateau (Dekaban, 1978). This simple and widely reproducible observation has served as a catalyst for continued interest in the study of sex-specific differences during brain development in order to (1) map other detailed components of brain development that may also show sex-specific differences, (2) determine if there are any cognitive correlates with these findings (Kimura, 1996), (3) establish what – if not total volume of brain matter – are the driving structural contributors to individual cognitive differences in areas like language skills and overall intelligence, and, perhaps most importantly, (4) better understand and clinically address the range of neuropsychiatric disorders that tend to emerge during adolescence with prominent sex-specific affinities (Marsh et al., 2008). Interestingly, while some of this sex-specific variance in brain size can be attributed to height, which is consistent with broader trends across different mammalian species, there remains a significant sex-specific effect on brain size even when differences in body size are taken into account (Peters et al., 1998). Although the brains of adult males tend to be larger than adult females, this increase is actually smaller than what would be predicted based on differences in adult height alone. Histological findings indicating a 15% higher neuronal density in males than females are consistent with

this (Rabinowicz et al., 2002), although conflicting reports from other studies prohibit firm conclusions on this point (Haug, 1987; Pakkenberg and Gundersen, 1997). A consideration of the fact that females actually tend to be taller than males during late childhood, perhaps due to faster pubertal maturation in girls, further weakens the idea of such a simple allometric relationship when age-matched males and females are compared (Giedd et al., 2006). These discrepancies highlight the diversity that exists among the postmortem literature on the topic of sex differences in brain development, which is also likely to be influenced by a variety of confounds (including cohort effects and observational bias) that have made interpretation challenging (Peters et al., 1998). Additionally, these reports are limited to either simple global measures, like total brain volume or weight, or very local measures, like neuronal density, and generally do not account for regional variations in measures like cortical thickness and folding complexity (Luders et al., 2004; Sowell et al., 2007) (see Chapters 35 and 38).

12.2.5 Summary

The central theme that emerges from this early postmortem work is that brain development from birth through adolescence is a uniquely dynamic process, encompassing both progressive and regressive events, with varying magnitudes and timing across different regions of the brain. In particular, the concurrent decrease in synaptic density and increase in white matter myelination is consistent with the principle of selective specialization, which has been postulated to be the driving force behind the creation of cognitive networks and thought to form the foundation for higher cognitive processes (Fuster, 2002; Post and Weiss, 1997; Tsujimoto, 2008). The initial overabundance of neurons and synapses during infancy is thought to provide a flexible substrate through which activity-dependent plasticity can fine-tune neural network activity via processes like synaptic pruning, which continue robustly through adolescence and, in some form, throughout life.

12.3 *IN VIVO* VOLUME ANALYSES

With the development of MRI, not only were clinicians provided with a superior technology for the diagnosis of brain injury and disease (Barkovich, 2006; Panigrahy and Blüml, 2009; Prager and Roychowdhury, 2007), but researchers were also provided with an unparalleled technology for the study of typical brain development *in vivo*. This, together with the expansion of computing technology during the 1980s, led to the first wave of

structural neuroimaging studies aimed at extending previous postmortem results. Much of this early work utilized volumetric parcellation methods, whereby brain images are segmented according to different anatomical landmarks, and the volumes and tissue content (gray matter, white matter, cerebrospinal fluid) of these different regions are computed and compared between subject groups or throughout development. This parcellation step has been performed with a variety of methods, including the use of stereotactic coordinates (Jernigan et al., 1991a,b; Reiss, et al., 1996), manually drawn regions of interest (ROIs) (Giedd et al., 1996c; Sowell et al., 2002b), and automated protocols (Giedd et al., 1996a, 1999a) (see Chapter 28).

12.3.1 Gray Matter Decreases in Development

Given the previous postmortem observations of regional and temporal variations in synaptic density and myelination throughout the brain, the gray and white matter volume estimates extracted through these volumetric parcellation methods would be expected to show similar age-related developmental trajectories and regional differences. This was first demonstrated by Jernigan and Tallal, who observed that a group of children aged 8–10 had significantly more cortical gray matter than a group of young adults, as well as a higher gray matter to white matter ratio (Jernigan and Tallal, 1990). A subsequent study extended these findings to confirm that the group differences were due to continuous age-related decreases in gray matter volume with time – independent of brain size – and localized these effects to superior frontal and parietal cortices (Jernigan et al., 1991a,b). These studies marked the first *in vivo* morphological evidence in support of the earlier postmortem histological work by Huttenlocher and colleagues. While not a direct measure of synaptic density, the volumetric MRI finding of decreased gray matter volume is consistent with the regressive synaptic pruning changes previously described and aligns with the theory that evolutionarily more complex regions like the frontal lobe show more protracted timing in their development than evolutionarily simpler regions like primary motor/visual cortex. Even this early on, Jernigan and colleagues were also aware of the possible relationship between their *in vivo* MRI findings and the postmortem white matter myelination studies of Yakovlev and Lecours and suggested that an 'apparent' cortical thinning could be due, in part, to progressing myelination. Thus, a component of these observed changes might not be a gray matter loss, *per se*, but a transition of unmyelinated 'gray' matter into white matter, which, on MRI, would appear as a gray matter volume 'loss' during the childhood and adolescent years.

12.3.2 Regional and Temporal Dynamics

Since these initial observations of childhood and adolescent gray matter volume loss, other investigations have confirmed the general trend (Caviness et al., 1996; Giedd et al., 1999a; Ostby et al., 2009; Pfefferbaum et al., 1994; Reiss et al., 1996; Sowell et al., 2002b; Wilke et al., 2007) and extended these observations in several important ways. In a large cross-sectional sample of 161 subjects aged 3 months to 70 years, Pfefferbaum and others were able to demonstrate the early rise and plateau in total brain volume by approximately age 5, as well as the late childhood and adolescent decline in cortical gray matter volume. The extended age range of the sample allowed them to characterize the trajectory of the gray matter volume decline as curvilinear, which suggested an overall inverted 'U'-shaped curve consisting of early childhood gray matter increases followed by a relatively early peak and then late childhood and adolescent reductions (Pfefferbaum et al., 1994). This general time course of cortical development is a feature that has gone on to become one of the hallmarks of structural brain development (Courchesne et al., 2000; Paus et al., 2001; Sowell et al., 2003).

Other studies have investigated the relative volume changes (controlling for global increases in total brain volume) more closely in broader age samples and in specific cortical and subcortical structures. In doing so, this work has demonstrated further heterogeneity in maturational timing and trajectory complexity across the brain. Importantly, the relative gray matter volume reduction during adolescence was confirmed to be most concentrated in the frontal and parietal lobes (Sowell et al., 2002b). Meanwhile, subcortical gray matter structures like the basal ganglia also generally showed a relative volume reduction, although with a simpler linear trajectory than the cortex over the age range of late childhood to young adulthood (Ostby et al., 2009; Sowell et al., 2002b). Tzarouchi et al. recently applied some of the modern spatial normalization methods to align each individual's structural MRI brain data to a group average of all individuals studied and conducted an analysis in the vein of these classical volumetric studies by examining volume change over time in over 100 regions throughout the cortex. Using an exponential nonlinear function to model the upstroke portion of the developmental curve, they were able to estimate the age at which these different gray matter regions reached full development. In doing so, they provided a compelling demonstration of the previously theorized maturational sequence, with primary somatosensory and visual cortices maturing the earliest and then posterior-to-anterior and inferior-to-superior trends in the developmental timing of the remaining temporal, parietal, and frontal lobes (Tzarouchi et al., 2009).

12.3.3 White Matter Increases in Development

Interestingly, while gray matter volume was observed to peak early, researchers began to consistently observe that white matter volume continues to steadily increase roughly linearly from birth through adolescence and young adulthood (Caviness et al., 1996; Paus et al., 2001; Pfefferbaum et al., 1994; Sowell et al., 2002b; Wilke et al., 2007). The timing of these changes shows a posterior-to-anterior gradient, which generally parallels the overlying gray matter and has led to continued investigation into the interaction between these processes (Barkovich et al., 1988). The white matter volume increase is consistent with the widespread reports of relative gray matter reductions during later childhood and adolescence, as a protracted increase in underlying white matter volume (due, in part, to increased oligodendroglial wrapping of axonal fibers) will increase total brain volume and, therefore, decrease the relative gray matter volumes of specific structures compared to this total. The midsagittal corpus callosum was one of the first white matter areas to be examined in more detail, with volumetric analyses showing robust increases in total area throughout adolescence (Bellis et al., 2001; Giedd et al., 1999b) and a surprising anterior-to-posterior trend in the timing of the growth curve when the corpus callosum was subdivided into seven distinct segments (Giedd et al., 1996a). This protracted nature of white matter development is a thread that we will see repeated in the following sections, as imaging modalities and analysis techniques have advanced (Giedd et al., 1999a; Lebel et al., 2008b; Sowell et al., 2003), and as one that has gained increasing interest as more attention is being focused on the network properties of the brain as a potential, important mediator for the late cognitive development seen in domains like risk/reward processing, cognitive control, and working memory (Spear, 2000).

12.3.4 Sex Differences

Sex-specific differences in brain structure were also extended with these structural imaging techniques. Total brain volume was confirmed to be approximately 10% larger in males than females at the plateau of overall brain volume that is reached during childhood (Caviness et al., 1996; Courchesne, et al., 2000; Durston et al., 2001; Gur et al., 2002; Lenroot and Giedd, 2010), and the significant sex-specific effect remains even when height and weight are covaried (Giedd et al., 1996b). However, more detailed regional volumetric observations of different cortical regions have been inconsistent – with varying reports of increased or decreased volumes in males and females that are further complicated by whether or not absolute or relative changes (to total brain volume differences) were reported (Sowell et al., 2007).

Despite this variation, strong evidence suggests that there may be sexual dimorphism in the timing of the developmental trajectory in the cortex, such that males and females have similar overall trajectories of regional brain maturation (both with an inverted 'U'-shaped curve) but differing gender effects with time because of a difference in the timing of this trajectory (Giedd et al., 1999a). Specifically, there appears to be approximately a 1–2 years' phase difference between girls and boys, with peaks in gray matter occurring earlier in girls than boys and regional variations in both phase and the actual differences between the sexes (Lenroot et al., 2007). Because this is a temporally dynamic period of development (and not a static one, e.g., like comparing fully mature adults), assessing sex differences during childhood and adolescence has become a more complicated problem, which requires the dissociation of phase differences (particularly those caused by differences in age of pubertal onset) from sex differences in the maturational trajectories. An additional challenge is identifying those differences that persist into adulthood and actually have functional relevance.

Observations of sex differences in subcortical regions have also been somewhat more reproducible. In particular, over the course of development, the amygdala seems to increase in volume more in males and the hippocampus more in females (Giedd et al., 1996b,c, 1997; Wilke et al., 2007). This is in line with animal studies that have shown high densities of steroid hormone receptors in the medial temporal lobe (Sarkey et al., 2008) and also that sex steroids exert trophic effects on these structures (Cooke, 2006; Galea et al., 2006; Zhang et al., 2008). In one recent study specifically targeted to investigate the degree to which the rise of gonadal hormones during puberty contributes to the emergence of these sex-specific differences, we examined subcortical volume measures among a group of 80 adolescent boys and girls matched on sexual maturity within a relatively narrow age range (Bramen et al., 2011). This focused analysis revealed an interaction between sex and the effect of puberty in predicting amygdala and hippocampal volumes: While females actually had larger left amygdala and right hippocampal volumes than boys during early puberty (relative to total brain size), by late puberty, the amygdala volume had increased in males but stayed relatively stable in females. In the right hippocampus, the effect of puberty was also to increase the volume in males but, surprisingly, to decrease the volume in females. This reiterates the importance of considering the timing in the interpretation of developmental phenomena like sexual dimorphisms. Furthermore, these results suggest that the sex-specific differences in amygdala volume previously observed across a broader age sample (Giedd et al., 1996c) are likely due, in large part, to the effects of puberty, but that the previous observation of relatively larger hippocampal volumes in females may be due to nonpubertal influences, as the direct contribution of puberty, demonstrated in our recent observations, would be to blunt this effect. These findings are particularly important in the context of adolescent brain development, as maturation of these processing centers and their connections to areas like the prefrontal cortex may contribute to the dramatic changes seen in social and emotional domains during this period of development (Dahl, 2004; Steinberg, 2005). The caudate nucleus has also been shown to be relatively larger, controlling for total brain volume, in females across several distinct samples (Giedd et al., 1996b, 1997; Sowell et al., 2002b; Wilke et al., 2007). Put another way, the caudate is spared the reduction in volume that is typically shown by other structures in female brains. This observation of sexual dimorphism in the basal ganglia is also important, as it may relate to the emergence of similar sex differences in the incidence of several neuropsychiatric disorders (e.g., attention deficit hyperactivity disorder, Tourette syndrome) that are thought to involve these structures (Marsh et al., 2008) (see Chapters 35 and 38).

12.4 BRAIN MAPPING APPROACHES

12.4.1 Advantages

The early volumetric MRI imaging observations by Jernigan and others helped lay the foundation for the next wave of neuroimaging studies designed to further characterize the anatomical changes that occur during normal development. While the volumetric protocols were able to validate much of the classical postmortem literature, as well as provide further evidence for gray matter loss, white matter gain, and regional/temporal dynamics, they are unable to precisely localize where these maturational changes are taking place within the relatively large ROIs studied. Instead, these methods collapse entire regions of the brain down into one or several summary descriptive statistics that may not be characteristic of all functional and structural brain circuits within these large lobar regions. In contrast, newer methods like voxel-based morphometry (VBM) and cortical thickness analysis are distinct in that they allow for statistical analysis at many points throughout the entire brain volume or at many points across the entire cortical surface and allow the creation of whole-brain 'maps' to visualize these data. These enhanced analysis modalities, together with the traditional methods discussed in Sections 12.2 and 12.3, have contributed greatly to our understanding of normal brain development and provide an important context for the further study of neurodevelopmental and psychiatric disease (Eliez and Reiss, 2000; Marsh et al., 2008) (see Chapters 30, 35 and 38).

12.4.2 Voxel-Based Strategies

In VBM, the local fractional gray matter volume is analyzed in the neighborhood around each voxel in the brain to generate whole-brain maps of gray matter 'density' or 'concentration' (Ashburner and Friston, 2000). Spatial normalization algorithms are applied to align the brains of individual subjects so that each voxel then can be compared throughout development or between groups. Consistent with the previous volumetric studies and postmortem examples, whole-brain mapping strategies utilizing VBM show decreasing gray matter density during later development. In line with the coarse frontal and parietal lobar localizations of the earlier volumetric reports, the regions showing the most protracted changes in these new analyses include clusters in the dorsal frontal and parietal cortices during the transition from childhood to adolescence (Sowell et al., 1999a), as well as a distinct grouping of dorsal, medial, and orbital frontal cortical areas during the later transition from adolescence into young adulthood (see Figure 12.1; Sowell et al., 1999b). The relative specificity of these later changes to the frontal lobes is consistent with the similarly protracted time course of cognitive development in executive function domains, which are also typically thought to involve these frontal regions (Casey et al., 2005; Luna et al., 2004, 2010; Spear, 2000).

This notion of gray matter density was extended to allow for analysis on the cortical surface through the method of cortical pattern matching, where sulcal landmarks are manually identified and used to drive accurate nonlinear spatial normalization into a common template, while helping to account for regional, gender, and individual variability (Ashburner et al., 2003; Luders et al., 2004). Using this technique, protracted postadolescent gray matter density decreases were again demonstrated in dorsal frontal cortex (Gogtay et al., 2004; Sowell et al., 2001b), and, for the first time, shown to correlate significantly with underlying relative brain growth in these regions (Sowell et al., 2001b). This suggests the combined influences of both regressive processes like synaptic pruning, as well as progressive processes, like myelination, are acting in these areas. Using similar gray matter density measurement techniques, and a powerful longitudinal design that tracked individuals prospectively for 8–10 years, Gogtay et al. provided further evidence that the lower-order somatosensory and visual areas develop earlier than the higher-order association cortices that integrate these processes and also that phylogenetically older areas develop earlier than younger areas (Gogtay et al., 2004). Surprisingly, however, gray matter density increases were actually observed in bilateral perisylvian regions

Child to adolescent

Adolescent to adult
FIGURE 12.1 Gray matter density maturation. Voxel-based morphometry (VBM) measurements of fractional gray matter density/concentration show typical decreases during development. Colored volumes within a transparent cortical surface rendering represent the extent of significant decreases in gray matter density during the transition from childhood to adolescence (top panel) and adolescence to adulthood (bottom panel). Color-coding indicates which changes occurred in the frontal lobe (purple), parietal lobe (red), occipital lobe (yellow), temporal lobe (blue), and subcortical regions (green). *Sowell ER, Thompson PM, Holmes CJ, Batth R, Jernigan TL, and Toga AW (1999a) Localizing age-related changes in brain structure between childhood and adolescence using statistical parametric mapping.* Neuroimage *9: 587–597; Sowell ER, Thompson PM, Holmes CJ, Jernigan TL, and Toga AW (1999b) in vivo evidence for post-adolescent brain maturation in frontal and striatal regions.* Nature Neuroscience *2: 859–861.*

during the transition from adolescence to adulthood and shown to correlate with both lateralized differences in sylvian fissure morphology and concomitant local brain growth (Sowell et al., 2001b, 2002a). This suggests the presence of a particularly extended developmental trajectory in these gray matter regions beyond that in the dorsal frontal lobe and perhaps implies a unique position for these canonical language areas in the developmental landscape – with the typical inverse correlation between density and volume (decreasing density, increasing volume) reversed to give a direct relationship (increasing density, decreasing volume) in these areas during this age range (Sowell et al., 2003). Taken together, these findings again highlight both regional as well as temporal complexities to the normal developmental sequence of brain structure.

12.4.3 Cortical Thickness

The investigation of apparent cortical gray matter decreases during development reached full stride with the development of MRI cortical thickness measurement techniques. These automated algorithms extract mesh models of the white-matter/gray-matter boundary surface and the pial (i.e., cortical) surface and then directly calculate the cortical thickness at many points throughout the cortical sheet (see Figure 12.2; Fischl and Dale, 2000). Unlike the rather abstract interpretation of fractional gray matter 'density' estimates, cortical thickness estimates are in physical units of millimeters and validate exceptionally well against the historical postmortem cortical thickness maps – with average measurements in children ranging from 1.5 mm in occipital cortex to 5.5 mm in dorsomedial frontal cortex (see Figure 12.2; Sowell et al., 2004a; Von Economo, 1929).

In addition to their strong agreement with postmortem data in terms of absolute thickness estimates, reports using this method are also in line with the mounting evidence from postmortem, volumetric, and VBM density measurements, which support the picture that gray matter thickness peaks early and then declines due to a combination of progressive events, like enhanced myelin penetration into the cortical neuropil, and regressive events, like continued synaptic pruning (O'Donnell et al., 2005; Shaw et al., 2008; Sowell et al., 2004a; Tamnes et al., 2010). In a longitudinal study of

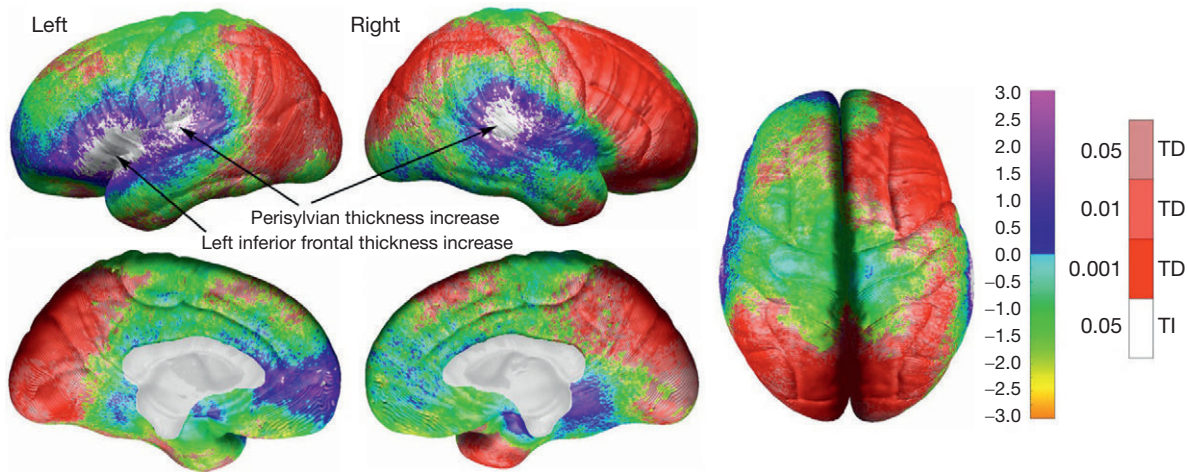
45 typically developing children aged 5–11 years, who were scanned 2 years apart, these techniques were able to demonstrate gray matter thinning of ~0.15–0.30 mm year^{-1} coupled to relative brain volume increases in right frontal and bilateral parietooccipital regions (see Figure 12.3). This study was also able to reproduce the surprising earlier findings of gray matter increases in bilateral perisylvian language areas (Wernike's area) and extended these observations to the left inferior frontal gyrus – another language area (Broca's area) (Sowell et al., 2004a). Cortical thickening was estimated to be at a rate of 0.10–0.15 mm year^{-1} in these areas. This unique pattern of cortical thickening in the canonical language regions could be related to parallel gains in language processing made during this period of development. In another large longitudinal study of 375 children and young adults, changes in cortical thickness were modeled with a low-order polynomial basis set in order to investigate regional differences in the complexity of the developmental trajectory (Shaw et al., 2008). Patterns of varying complexity were found to parallel the established histological maps of cytoarchitectonic complexity and agree with the previous literature (Gogtay et al., 2004; Sowell et al., 2004a) – with simpler laminar areas, like the limbic cortex, having simpler trajectories and more complex laminar areas, like association cortex, having more complex trajectories. Although cortical thinning during adolescence reflects developmental processes like myelination and synaptic
FIGURE 12.2   Cortical thickness analysis. (a–c) show a single representative slice for one subject: (a) Raw T1-weighted anatomical MRI scan. (b) Gray/white matter tissue segmentation. (c) Gray matter thickness image, with thickness (mm) coded by color (warmer colors overlie the areas with the thickest cortex). (d) shows an *in vivo* average cortical thickness map generated by performing this analysis on a cross-sectional sample of 45 subjects. The brain surface rendering is color-coded according to the underlying cortical thickness (mm) and the color bar on the right. The regional variations in cortical thickness can be compared to an adapted version of the classical Von Economo postmortem cortical thickness map (e), which has been color-coded in a similar manner over the original stippling pattern to highlight the similarity between the two maps. *Sowell ER, Thompson PM, Leonard CM, Welcome SE, Kan E, and Toga A W (2004a) Longitudinal mapping of cortical thickness and brain growth in normal children.* Journal of Neuroscience 24: 8223–8231; Von Economo CV (1929) The Cytoarchitectonics of the Human Cerebral Cortex. *London: Oxford Medical Publications.*


FIGURE 12.3 Gray matter thickness maturation. Statistical maps showing the significance of cortical thickness change in a longitudinal sample of 45 children scanned twice between the ages of 5 and 11. Areas showing significant thickness decrease (TD) are displayed in red, and areas showing significant thickness increase (TI) are displayed in white (see color bar and significance thresholds at right). Nonsignificant areas are coded by their t-statistic according to the left rainbow color bar. Arrows highlight the relative specificity of thickness increases during this age range to canonical language areas in the left inferior frontal gyrus (Broca's area) and perisylvian region (Wernike's area). *Sowell ER, Thompson PM, Leonard CM, Welcome SE, Kan E, and Toga AW (2004a) Longitudinal mapping of cortical thickness and brain growth in normal children.* Journal of Neuroscience *24: 8223–8231.*

pruning, it is important to note that cortical thinning also continues in some form throughout the rest of the lifespan (Sowell et al., 2003). This likely belies a shift in etiology to degenerative changes associated with aging (Sowell et al., 2004b), and recent work has sought to delineate this inflection point more precisely. By analyzing local gray and white matter signal intensities in the context of cortical thinning, the timing of the developmental peak was found to range from 8 to 30 years of age in different regions of the cortex, with the regional pattern following the general posterior-to-anterior gradient discussed in Section 12.3.2 (Westlye et al., 2010).

12.4.4 White Matter

Even before the widespread adoption of diffusion imaging, which will be discussed in Section 12.5, researchers were able to adapt traditional anatomical MRI analysis techniques to study white matter development (Wozniak and Lim, 2006). Magnetization transfer ratio imaging is sensitive to the 'bound' protons found on the phospholipids of myelin (Wolff and Balaban, 1989) and reflects the increasing myelination during early development (Engelbrecht et al., 1998) as well as the posterior-to-anterior trend in the timing of this process (Buchem et al., 2001). T2 relaxometry, which estimates the fraction of water in the brain, that is associated with the phospholipid bilayer of myelin (MacKay et al., 1994), has also been used to demonstrate the caudal-to-rostral wave of myelination (Lancaster et al., 2003). In an application of the VBM technology to the white matter, Paus and colleagues were able to powerfully interrogate the rather general 'global white

matter increases' observation previously described to obtain a much richer localization of the precise anatomical regions involved. In an 88-subject sample of children aged 4–17 years, they observed a prominent increase in white matter density in the internal capsule bilaterally, as well as the in left arcuate fasciculus, suggesting continued maturation of corticospinal and frontotemporal fibers through this age range (Paus et al., 1999). This work agrees with the postmortem data from Yakovlev and Lecours and demonstrates the unique progressive changes that occur in the white matter while the cortex shifts to undergo predominantly regressive events. Confirming the surprising corpus callosum results of the classical volumetric study by Giedd et al., which was discussed in Section 12.3.3, Thompson and colleagues applied a continuum mechanics approach to obtain maps of local tissue deformation in the corpus callosum during development. Their longitudinal design studied 6 children aged 3–11 with a follow-up interval of up to 4 years and again demonstrated an anterior-to-posterior wave in the timing of maximal local growth (see Figure 12.4; Thompson et al., 2000). This contrasts with the general posterior-to-anterior trend that has been observed in gray matter cortical regions and suggests a unique pattern of development in this region of interhemispheric fiber connectivity.

12.4.5 Sex Differences

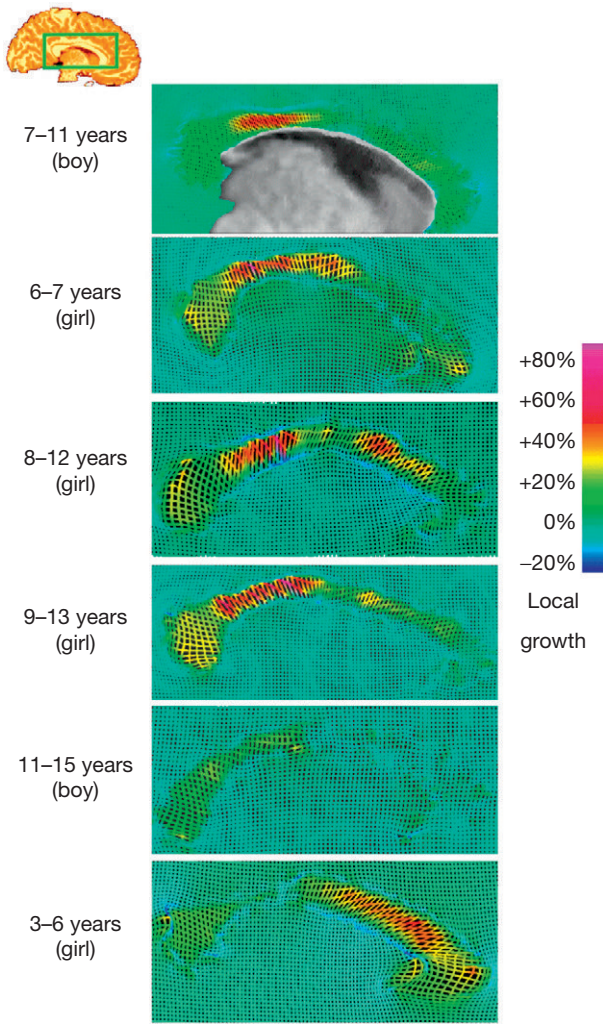
Continuing the trend from volumetric results, VBM gray matter density and cortical thickness observations of sex-specific effects during development have also been variable (Wilke et al., 2007). However, this topic


FIGURE 12.4   Corpus callosum maturation. Maps of the local volume changes in the corpus callosum are shown for six individuals aged 3–15 years, who were scanned twice longitudinally with an interval of up to 4 years. Maturation includes outward tissue expansion (warmer colors), with a dynamic wave in timing such that more frontal regions show prominent change early, and more posterior regions show prominent change later. *Thompson PM, Giedd JN, Woods RP, MacDonald D, Evans AC, and Toga AW (2000) Growth patterns in the developing brain detected by using continuum mechanical tensor maps.* Nature *404: 190–193.*

remains a critical issue, as sex-specific differences in brain development are likely to contribute to the sexually dimorphic susceptibilities of a variety of psychiatric disorders – like schizophrenia and major depression – that emerge during adolescence (Durston et al., 2001; Lenroot and Giedd, 2010). Returning to the issue of gender differences in development, Sowell et al. analyzed cortical thickness and local brain size (taken as the distance from the center of the brain) in a large sample of 176 healthy subjects aged 7–87 years (Sowell et al., 2007). In line with previous studies, male brains were larger than females, at all locations. Strikingly, however, absolute cortical thickness was greater in females in right inferior parietal and posterior temporal regions even without accounting for the smaller overall size of female

brains. This finding was not significantly modulated by age and was demonstrated even more robustly across broad right temporal and parietal regions when an age-matched and brain-volume-matched subset of 18 males and 18 females was evaluated (see Figure 12.5). These findings suggest that there are both regional- and sex-specific differences in cortical thickness that appear relatively early in childhood, and support earlier reports of selective relative increases in gray matter volumes in females (Allen et al., 2003; Goldstein et al., 2001; Gur et al., 2002; Im et al., 2006; Nopoulos et al., 2000; Sowell et al., 2002b). Although the corpus callosum is also a frequent target for brain mapping research into sex-specific effects on brain development, no consensus has been reached and the topic remains frequently debated (Giedd et al., 2006) (see Chapters 35 and 38).

Because of the overall smaller brain volume in females, it has also been proposed that there may be evolutionary pressure to develop other compensatory mechanisms. Through sulcal delineation and cortical-pattern-matching techniques, it has been shown that females tend to develop a greater degree of cortical 'complexity' by young adulthood (Luders et al., 2004). This suggests that there is more cortical surface per unit volume in females and may be one mechanism through which female brains have become optimized for their smaller size.

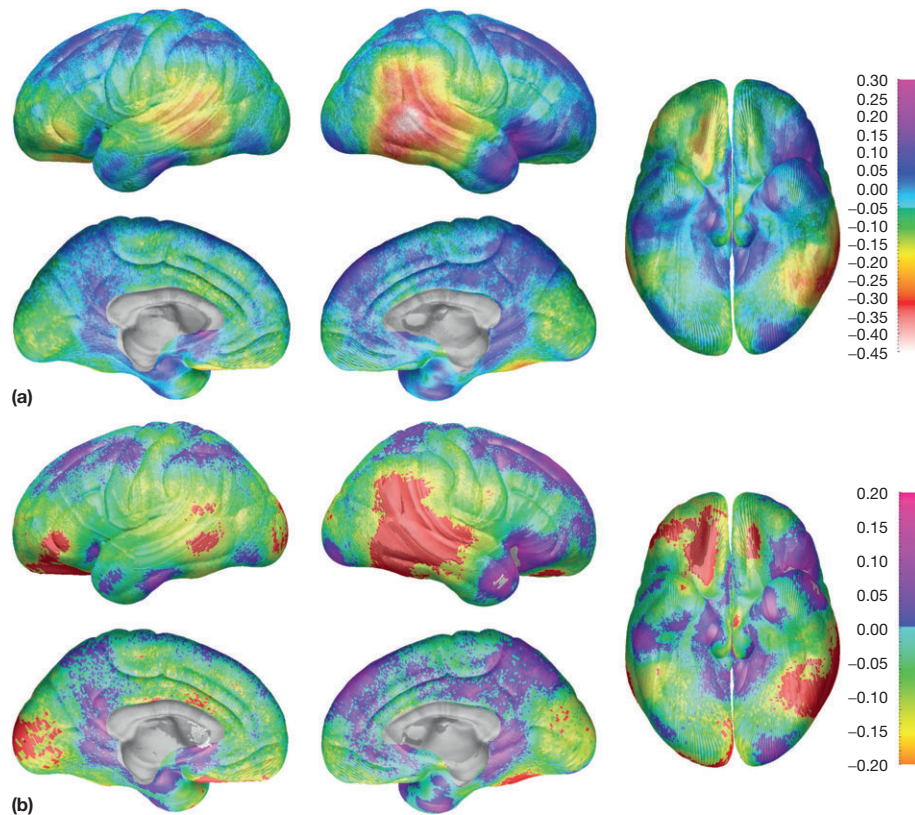
An increasing focus is also being shifted away from sex-specific differences, *per se*, to the known differences in pubertal timing and sex steroid levels that are likely to be major contributors to observed sex-specific effects and their frequently observed modulation by age (Giedd et al., 2006; Lenroot et al., 2007). The emerging picture suggests that puberty and sex steroids do indeed have organizing effects on brain development (Bramen et al., 2011; Neufang et al., 2009; Peper et al., 2009a; Witte et al., 2010). One recent study of 107, 9-year-old monozygotic and dizygotic twin pairs noted strong overall heritability in regional brain volumes but also demonstrated decreased frontal and parietal gray matter density among the subgroup of individuals who had begun to develop secondary sexual characteristics of puberty (Peper et al., 2009b). Further investigation among the same cohort revealed that the serum level of luteinizing hormone, one of the first indicators of puberty, is associated with both increased overall white matter volume and increased white matter density in the cingulum, middle temporal gyrus, and splenium of the corpus callosum (Peper et al., 2008). The splenium observation is particularly intriguing, as this is the same region shown to have maximal growth over the 9–13 age range in a different study (Thompson et al., 2000). These results – observed between otherwise very well-matched groups – suggest that the onset of puberty and sex steroid levels may directly contribute to the decreases in gray matter and increases in white matter that are prominent features of normal brain development during late childhood and adolescence.


FIGURE 12.5 Sex-specific differences in cortical thickness. (a) Sex differences in cortical thickness (mm) among an age- and brain volume-matched sample of 18 males and 18 females. Warmer colors (<0 on the color bar at right) are regions where females have thicker cortex, and cooler colors (>0 on the color bar at right) are regions where females have thinner cortex, relative to males. (b) Statistical maps showing the significance of these sex differences. Areas where the cortex is significantly thicker in females are shown in red, and include right inferior parietal and posterior temporal, and left posterior temporal and ventral frontal regions. Areas where the cortex is significantly thinner in females are shown in white, and are limited to small regions in the right temporal pole and orbitofrontal cortex. The correlation coefficient is mapped for nonsignificant regions according to the color bar at right. *Sowell ER, Peterson BS, Kan E, et al. (2007) Sex differences in cortical thickness mapped in 176 healthy individuals between 7 and 87 years of age.* Cerebral Cortex 17: 1550–1560.

12.4.6 Summary

Taken together, these structural imaging studies represent a powerful evolution in our understanding of brain development during childhood and adolescence. The overall picture remains one of early overall brain growth, followed by a transition around age 5 to gray matter decreases coupled with persistent white matter increases. These processes continue through adolescence but relatively balance each other in magnitude. Thus, while overall net brain volume changes relatively little past the age of 5, adolescence remains a period of dynamic change beneath the pial surface.

12.5 DIFFUSION MRI

One of the remarkable discoveries to emerge from these developmental neuroimaging studies is the continued expansion of white matter volume well into adulthood (Giedd et al., 1999a; Sowell et al., 2003). This robust and protracted increase has rewritten the age range associated with brain development (Pujol et al. 1993) and has driven an increasing focus on the white matter and its network connectivity as a possible mediator for the late cognitive gains seen in executive function domains during typical development (Liston et al., 2006), as well as a possible mechanism for neuropathology (Le Bihan, 2003) and training-induced increases in performance (Bengtsson et al., 2005; Carreiras et al., 2009).

12.5.1 Diffusion Tensor Imaging Theory

Simultaneously with this growing interest in studying the white matter, as it relates to connectivity between still-maturing brain regions and cognitive function, diffusion imaging was maturing as an MRI variation specifically tuned to examine the white matter (Basser et al., 1994; Bihan et al., 1986; Pierpaoli et al., 1996). Since the diffusion properties of water within neural tissue are affected by the geometry of the neuronal microenvironment, it is intuitive that diffusion imaging can provide a sensitive lens through which the microstructural properties of the white matter can be investigated. Specifically,

differences in microstructural properties like fiber coherence, axon packing, and myelination have all been shown to manifest as changes in the diffusion MRI signal (Beaulieu, 2002). By viewing this diffusion landscape within the brain from multiple angles, a more complete 'tensor' model of diffusion can be generated for each voxel (Basser et al., 1994). This can be thought of geometrically as a diffusion ellipsoid, with diffusion components in the radial (RD, radial diffusivity) and axial (AD, axial diffusivity) directions (see Figure 12.6). The size of this ellipsoid corresponds to the overall mean diffusivity (MD). The shape of the ellipsoid corresponds to the directionality of diffusion and is termed fractional anisotropy (FA). It can vary from 0, for perfectly isotropic diffusion, to 1, for perfectly anisotropic diffusion (e.g., the ventricles have low FA, while the corpus callosum has high FA). Because it has been shown to be sensitive to myelination, this FA metric has received considerable attention as a way to track the developmental maturation within the white matter and investigate disease. See Le Bihan (2003) for an excellent review.

12.5.2 Diffusion Parameters in Development

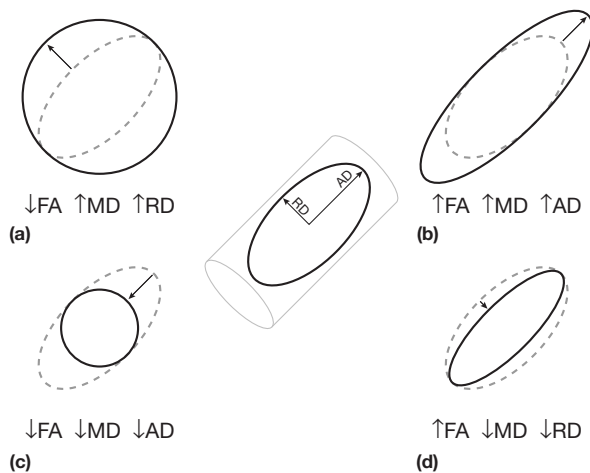
Using this unique framework, there has been a surge in research aimed at more deeply characterizing the normal developmental processes in these important regions


FIGURE 12.6   Diffusion tensor imaging (DTI) metrics. DTI metrics include fractional anisotropy (FA), which is a unitless measure of the directionality of diffusion, and mean diffusivity (MD), which is the overall magnitude of diffusion. The center panel shows a cross-section of the DTI ellipsoid model of diffusion, which is assumed to be oriented along the fiber axis (shown here as a cylinder). Individual diffusion components along the axial (AD) and radial (RD) directions contribute to the FA and MD values at each point in the brain. (a–d) show different changes in the individual diffusion parameters, and their varying effects on FA and MD. Note that changes in different diffusion components (AD or RD) can lead to the same effect on one diffusion metric, but have opposite effects on the other. (d) represents the prevailing regime during development, where decreasing RD – due, in part, to advancing myelination – leads to increasing FA (a more pointed ellipsoid) and decreasing MD (a smaller ellipsoid).

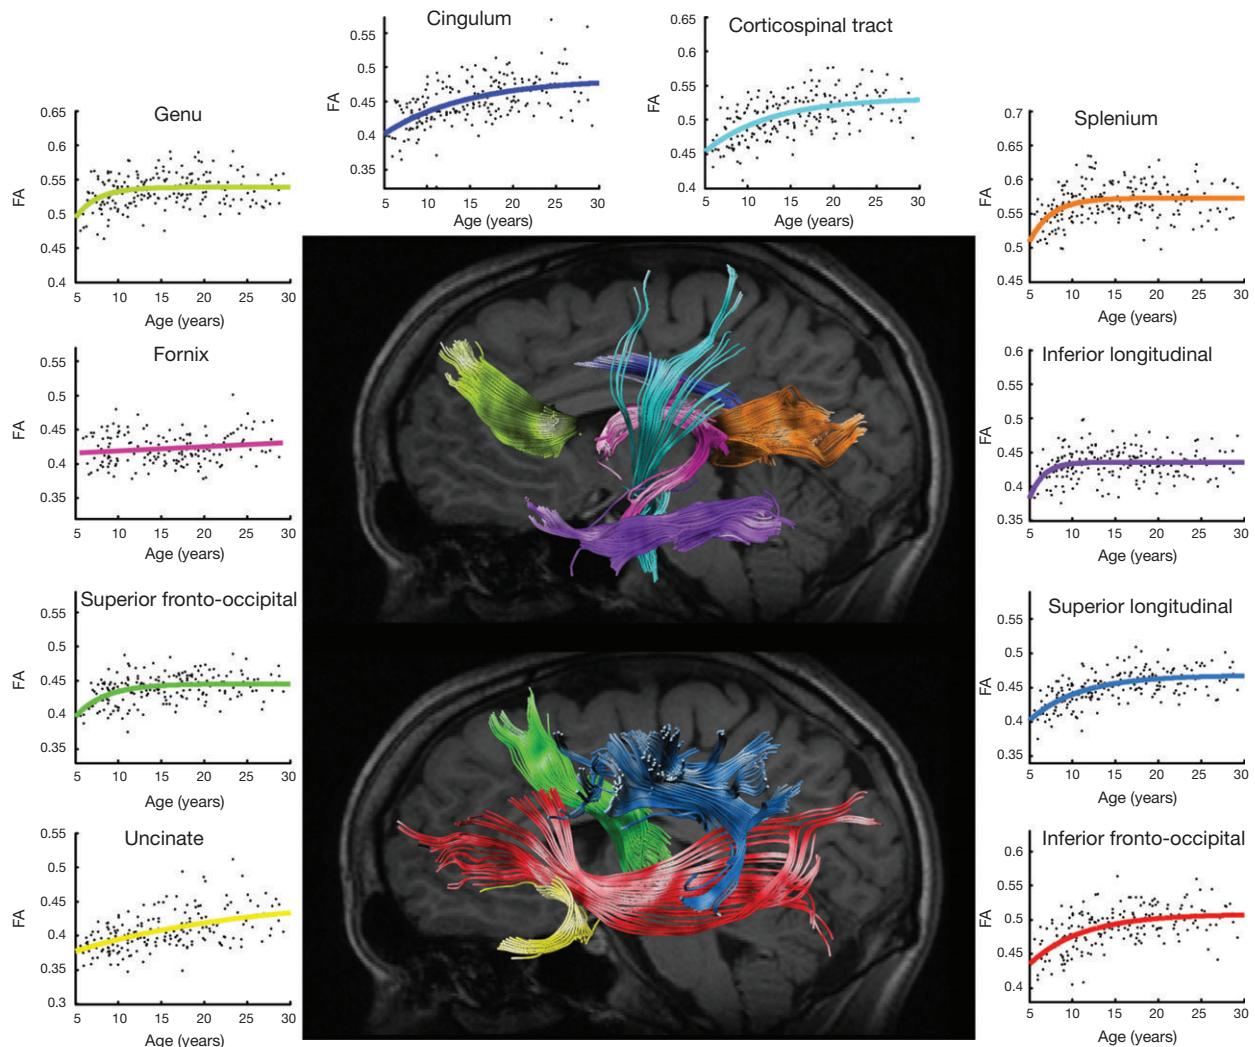
of connectivity that were previously obscured by low contrast within the white matter on traditional T1-weighted anatomical MRI. Similar to the general description in the overlying gray matter, the developmental trajectory within the white matter is both a nonlinear function of time and has prominent regional variations (Lebel et al., 2008b; Mukherjee et al., 2001; Snook et al., 2005). From birth, there is a rapid rise in diffusion directionality (FA; see Figure 12.7), coupled with a decrease in overall diffusivity (MD) (Bava et al., 2010; Engelbrecht et al., 2002; Hüppi et al., 1998; Löbel et al., 2009; Morriss et al., 1999; Mukherjee et al., 2001; Neil et al., 1998; Schmithorst and Yuan, 2010; Schneider et al., 2004). In an interesting contrast to this general pattern within the white matter, gray matter cortical regions actually have been observed to have decreasing FA in a sample of preterm infants (McKinstry et al., 2002). This could reflect the fact that changes in FA are not highly specific for myelination and may also occur in response to cortical maturational processes, like synaptogenesis. Further, these observations may be related to the perinatal period of selective vulnerability in neural tissue, which has been demonstrated in animal studies and confirmed in humans through MRI (Miller and Ferriero, 2009). The white matter pattern of increasing FA and decreasing overall diffusion, although not universally reported in later development (Schneiderman et al., 2007), generally continues in a decelerating fashion throughout childhood, adolescence, and, in some areas, into adulthood (Bonekamp et al., 2007; Klingberg et al., 1999; Schmithorst et al., 2002; Zhang et al., 2007). There is a relatively stable plateau of these parameters during adulthood, which then eventual declines later in life (Davis et al., 2009; Salat et al., 2005). Accordingly, the developmental rising portion of this arc has been modeled as a linear (Snook et al., 2005), polynomial (Hsu et al., 2010), or exponential (Lebel et al., 2008b; Mukherjee et al., 2001; Schneider et al., 2004) function. The earliest reports utilized an ROI approach to look at diffusion properties averaged across specific anatomical locations and were able to reproduce the 'increasing FA, decreasing MD' pattern across a broad variety of regions within the brain and during different periods of development. In one example, Suzuki and colleagues examined ROIs placed bilaterally in the frontal and parietal white matter of 16 children and young adults. They observed increased FA and decreased overall diffusivity with age but went on to make the important determination that the etiology of these changes in FA and MD was a primary decrease in both radial (RD) and AD diffusion components, with a larger decrease along the radial direction (Suzuki et al., 2003). This explains the overall decreased diffusivity that was observed (both components decreased) but also the increased diffusion directionality (one component decreased more than the other). The dominance of changes in radial diffusivity (RD) during development is an important phenomenon that has been broadly replicated (Giorgio


FIGURE 12.7 White matter maturation. Diffusion tensor imaging (DTI) tractography was used to identify ten major white matter tracts in 202 individuals aged 5–30 years (center panels show the extracted tracts for a representative subject). Broad age-related increases in fractional anisotropy (FA), a DTI index of white matter maturation that is sensitive to myelination, were observed across all tracts. Maturational trajectories generally followed an exponential rise, with regional variations in mean FA as well as developmental timing. The surrounding scatterplots demonstrate these relationships, and are color-coded according to the tracts in the center panels. *Lebel C, Walker L, Leemans A, Phillips L, and Beaulieu C (2008b) Microstructural maturation of the human brain from childhood to adulthood.* Neuroimage 40: 1044–1055.

et al., 2008; Lebel et al., 2008b; Löbel et al., 2009; Qiu et al., 2008), although not universally (Ashtari et al., 2007; Giorgio et al., 2010), and is thought to relate to the primary role that extended myelination plays during this age range (Song et al., 2002).

Paralleling the advancements made in the analysis of the cortex, methods have quickly adapted to include whole-brain mapping techniques that are able to examine the brain in a spatially continuous manner and better localize developmental changes. In general, these later efforts using VBM and similar techniques have both confirmed and extended the earlier ROI findings of broadly increasing FA and decreasing MD (Snook et al., 2007). Tract-based spatial statistics (TBSS) is an evolution of these methods that is tailored specifically to the analysis

of diffusion tensor imaging (DTI) data and has been used successfully to demonstrate age-related changes in diffusion imaging parameters (Bava et al., 2010; Burzynska et al., 2010; Giorgio et al., 2008, 2010). By projecting the imaging data onto a tract 'skeleton' consisting of the cores of the white matter tracts, TBSS avoids some of the alignment problems that arise when the high-contrast FA maps are compared using traditional voxel-by-voxel techniques (Smith et al., 2006, 2007). In a sample of 75 children through young adults that were analyzed using this approach, widespread FA increases and diffusivity decreases were again demonstrated spanning the frontal, temporal, and parietal lobes and the cerebellum (Qiu et al., 2008). Recognizing the need to synthesize these reports into a

normative reference standard against which to judge clinical abnormalities, effort has also been directed towards generating developmental brain atlases that integrate this diverse set of information (Hermoye et al., 2006; Löbel et al., 2009; Mori et al., 2008; Verhoeven et al., 2010).

12.5.3 Fiber Tractography

By making the assumption that the direction of the diffusion ellipsoid (i.e., the direction of principal diffusion) is pointing in the same direction as the neuronal fiber axis, streamlines can be generated passing from voxel to voxel along the path of principal diffusion. In this manner, the DTI technology has been extended to allow for *in vivo* fiber tractography (Behrens et al., 2003; Catani et al., 2002; Conturo et al., 1999; Mori et al., 1999). This allows for individualized measurements to be made that are tailored to each subject's anatomy, which circumvents many of the problems associated with attempting to register a diverse set of brains to a single template. Although these algorithms have generally validated well against postmortem dissections for many major white matter tracts, specific limitations related to issues, like partial volume averaging and complex fiber geometries, must be considered (Pierpaoli et al., 1996). Using this technology, together with standardized protocols for delineating the major white matter tracts of interest (Wakana et al., 2007), researchers have mapped the development of white matter fiber connectivity from before birth (Huang, 2010; Huang et al., 2006, 2009), through childhood, adolescence, and adulthood (Behrens et al., 2003; Liu et al., 2010; Wakana et al., 2004) and even through evolution (Rilling et al., 2008). Like other developmental neuroimaging efforts, these data provide important insight into human brain development in their own right and, additionally, serve as important normative markers against which pathology can be judged (Adams et al., 2010; Lebel et al., 2008a; Thomas et al., 2009). In a seminal report on the typical developmental trajectories within 10 major white matter tracts in a large sample of 202 subjects aged 5–30 years, Lebel et al. observed continually increasing FA in all regions (generally approximated well by an exponential function), but regional variations in timing such that the time to reach 90% of the adult plateau varied from approximately 7 years old in the inferior longitudinal fasciculus to beyond 25 years old in the cingulum and uncinate fasciculus (see Figure 12.7; Lebel et al., 2008b). Overall, they note that frontotemporal connections were the slowest to develop. In a representative example of the degree of intersubject diversity that exists even within tracts, DTI tractography has been used to demonstrate lateralization of different white matter tracts (Bonekamp et al., 2007). In one particular study, left lateralization was shown for the arcuate fasciculus (temporoparietal part of the superior longitudinal fasciculus), with higher FA and more streamlines in the left hemisphere (Lebel and Beaulieu, 2009). These findings are in line with previous observations of left lateralization of perisylvian regions (Geschwind and Levitsky, 1968; Pujol et al., 2002) and are thought to relate to the left hemisphere language dominance that exists in the majority of the population. Interestingly, this same pattern has been demonstrated even in neonates, suggesting that the structural basis of left hemisphere language dominance is present long before the development of speech (Liu et al., 2010). Previous morphometric findings of local volume increases within the corpus callosum (Giedd et al., 1996a; Thompson et al., 2000) have also been explored with tractography. In a large sample of 315 subjects aged 5–59 years, Lebel and others demonstrated the typical trajectory of increasing FA and decreasing MD in the fiber tracts leading from all midsagittal sections of the corpus callosum (Lebel et al., 2010). They also observed an 'outer-to-inner' trend in the timing of these maturational arcs, which contrasts with the anterior-to-posterior volumetric trend observed on T1-weighted MRI (Thompson et al., 2000) and highlights the additional insight that can be uncovered when the full extent of a tract is considered.

12.5.4 Sex Differences

Diffusion imaging also reveals sex-specific structural differences within the white matter (Lenroot and Giedd, 2010; Schmithorst et al., 2008). In one tractography study of 114 children, adolescents, and young adults, Asato et al. found generally decreasing radial diffusivity (RD) and protracted maturation past adolescence, in projection and association fibers that included connections between the prefrontal cortex and the striatum. Furthermore, they observed that white matter microstructural maturation proceeded in parallel with pubertal changes, with females having overall earlier maturation of white matter tracts than males (Asato et al., 2010). This suggests that there may be hormonal influences on white matter maturation and that by considering these aspects, one may obtain a more appropriate estimate of developmental progress than by only considering chronological age. This notion is supported by concurrent findings with structural MRI that demonstrate that white matter volume increases during adolescence, especially in boys, are affected by testosterone levels and androgen receptor genes (Paus et al., 2010; Perrin et al., 2008).

12.5.5 Summary

Taken together, diffusion imaging studies generally show increasing diffusion directionality (FA) and decreasing overall diffusion (MD) during development. These changes are predominantly due to decreasing diffusivity in the radial direction (i.e. radial diffusivity; RD) from the fiber axis, which suggests a primary role for myelination in this process. These changes progress rapidly from birth through childhood and, eventually, level off to a relatively stable adult plateau. Paralleling what has been observed in the cortex and through volumetric observations, there are regional variations in the timing of this developmental trajectory that follow a roughly posterior-to-anterior trend. Sexual dimorphism is also present, with females exhibiting earlier white matter maturation than males – a trend that mimics their differences in pubertal timing.

12.6 CONNECTING DIFFERENT TECHNIQUES

12.6.1 Multimodal Imaging

Although the development of cortical gray matter and the development of white matter microstructure have been investigated independently, one needs to consider their dynamics jointly in order to determine what relationships exist between them. This challenge returns to one of the original questions that stemmed from the postmortem histological findings – that is, 'To what degree do myelination and synaptic pruning (and other cellular processes) contribute to the decreasing gray matter and increasing white matter that is found during brain development?' While these phenomena are undoubtedly linked, it remains unclear which is dominant and exactly how they interact. The maturation of DTI and structural MRI analysis techniques has now made it possible to investigate these questions using *in vivo* imaging data; however, in the end, it will likely be necessary to complete the circle and validate these observations back in histological preparations.

In a study focusing on adolescence, Giorgio et al. began by using the TBSS method, discussed in Section 12.5.2, to demonstrate broad increases in FA that were driven predominantly by decreases in radial diffusivity (RD). They then made an important and innovative step by incorporating both DTI tractography and gray matter VBM to show that the putative fibers leading from the white matter regions, with the strongest developmental effects, connect with regions showing significantly decreased gray matter density in the cortex. Further, they observed that the gray matter density decreases were significantly correlated with the FA increases in the connected white matter (Giorgio et al., 2008). By following the structural connectivity present in the actual data, and using these patterns to guide their comparisons, this protocol links the concurrent phenomena of white matter FA increases and gray matter density decreases more convincingly than was possible with previous qualitative visual inspections. Tamnes et al. investigated this same general question in a different manner by integrating cortical thickness, volumetric, and DTI measurements derived from a single sample of 168 participants, aged 8–30 years (see Figure 12.8; Tamnes et al., 2010). As expected, they were able to demonstrate a combination of the phenomena seen in earlier individual studies, including broad cortical thickness decreases, white matter volume increases, FA increases (predominantly decreases in radial diffusion), and MD decreases. Most importantly, however, they were able to go on to demonstrate that, of the three measures, cortical thickness had the strongest relationship with age. Further, although the DTI and volume measures explained some of the variance in cortical thickness and each other, none of the measures were redundant. This implies that each may be sensitive to different microstructural processes and that all are useful indicators of brain development and microstructural integrity (Fjell et al., 2008). This reiterates the likely mixed regime of both synaptic pruning within the cortex and advancing myelination at the gray–white cortical interface, which contributes to the brain morphological changes seen during adolescence.

12.6.2 Brain–Behavior Relationships

While important neuroanatomical insights can be gleaned from these structural brain mapping observations, perhaps the most significant outgrowth of this research has been an expanded understanding of the cognitive and behavioral changes that accompany this underlying maturation of brain structure. There has been a long tradition of investigation into the cognitive correlates of brain structure, but unfortunately many of the early findings – which commonly focused on differences between ethnic or social groups – are unreliable because of data collection and analysis bias (Gould, 1978, 1981). With the advent of MRI, however, volumetric measurements of total brain size have shown a modest but reproducible correlation with general intelligence that emerges over the course of development (Peters et al., 1998; Reiss et al., 1996; Willerman et al., 1991; Witelson et al., 2006). However, the correlational nature of these findings does not at all suggest that groups with different brain sizes, like males and females, will have different intelligence. Indeed, independent of the possible relationships with neuroanatomy, it remains exceptionally controversial whether there is even any overall
FIGURE 12.8   Multimodal imaging: volumes, cortical thickness, and DTI. Concurrent volumetric, cortical thickness, and diffusion tensor imaging (DTI) analyses were performed in the same sample of 168 participants aged 8–30. The percent changes in cortical thickness, white matter volume, fractional anisotropy (FA), mean diffusivity (MD), axial diffusion component (AD), and radial diffusion component (RD) are mapped by region and color coded according to the color bar on the right. Medial structures and corpus callosum are masked out. *Tamnes C, Ostby Y, Fjell A, Westlye L, Due-Tønnessen P, and Walhovd K (2010) Brain maturation in adolescence and young adulthood: Regional age-related changes in cortical thickness and white matter volume and microstructure.* Cerebral Cortex *20: 534–548.*

gender effect on intelligence (Blinkhorn, 2005; Hedges and Nowell, 1995; Irwing and Lynn, 2006; Jorm et al., 2004; Lynn and Irwing, 2004; Neisser et al., 1996) and, if so, whether the small effect magnitudes that have been reported are relevant, given the possible biases that may have contributed. An important additional phenomenon to consider is that both brain structure and intelligence are highly heritable (Shaw, 2007; Thompson et al., 2001). Both are further impacted by environmental influences in a process that begins *in utero*, continues throughout life, and contributes to individual variations in structural brain development and cognitive function that exist even among monozygotic twins. Although not exclusive, the orchestration of structural brain development by these genetic and environmental factors is one way in which they can converge to influence cognitive development (Toga and Thompson, 2005) (see Chapter 26).

Since there is evidence that brain development takes place through selective elimination and connectivity optimization, with prominent regional and temporal variability, it is not surprising that a global measure like total brain volume may not be the optimal choice for investigating the structural basis of cognitive development. Fortunately, the brain mapping strategies, discussed in Sections 12.3–12.5, have had more success examining brain-region-specific relationships between structure and function. This work has supported many

of the classical structure–function relationships discovered through lesion studies – for example, that the prefrontal cortex is related to cognitive control (Damasio et al., 1994) – and also has extended these findings by (1) providing more detail, (2) including more normative subjects without pathology, and (3) allowing for broader investigation in the pediatric population. In this way, these modern neuroanatomical imaging studies, together with complementary results from functional neuroimaging methods that can measure task-dependent blood flow response within the brain (Casey et al., 1995; Luna et al., 2010), have formed a powerful framework to investigate how brain development relates to cognitive function during childhood and adolescence. In this vein, continued investigation into the structural basis of general intelligence has revealed age-variable relationships between intelligence quotient (IQ) and regional brain structure. In line with the total brain volume results, a correlation between IQ and gray matter volume develops by adulthood (Wilke et al., 2003). However, regional relationships between IQ and gray matter structural measures appear earlier and have been reported to include the anterior cingulate during childhood (Wilke et al., 2003), the orbitofrontal cortex during adolescence (Frangou et al., 2004), and the frontal lobe – particularly the prefrontal cortex – by adulthood (Haier et al., 2004; Reiss et al., 1996; Thompson et al., 2001). Interestingly, these regional relationships between

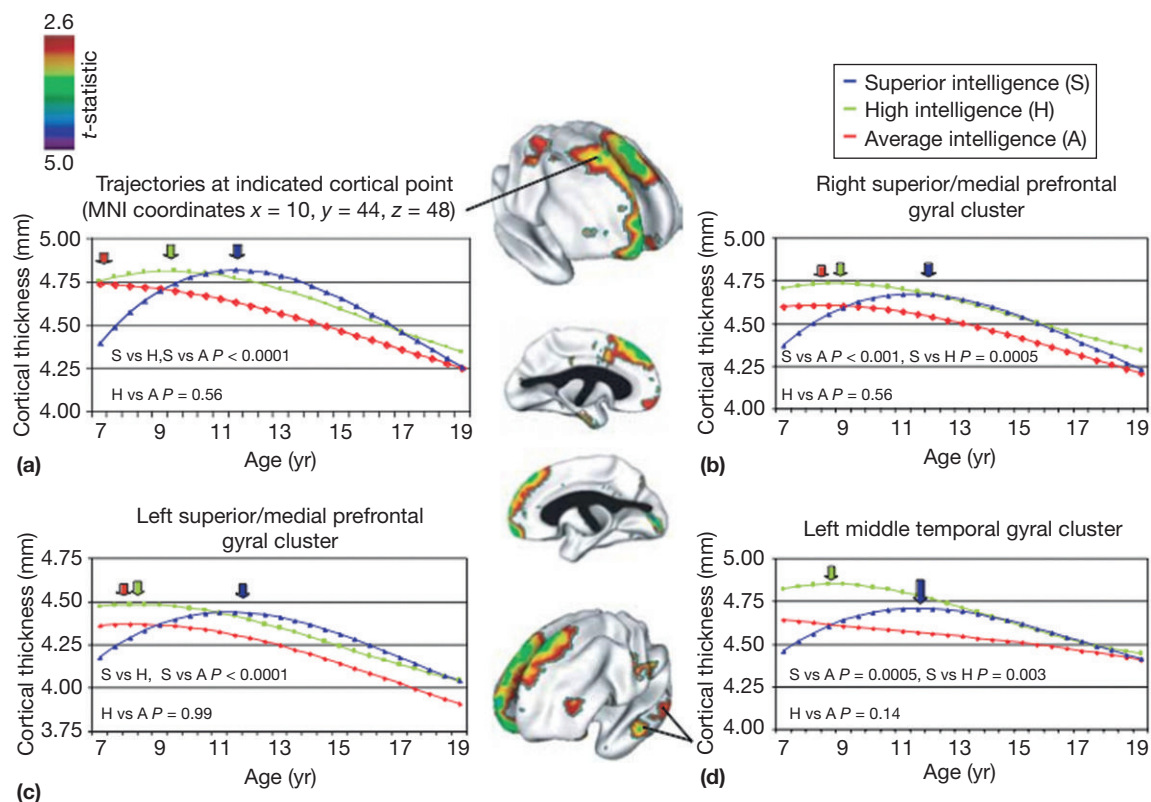
gray matter development and IQ appear to be modulated by sex, although the specific regions reported to be most associated with IQ for each sex have been variable (Haier et al., 2005; Narr et al., 2007). In one important study, which investigated the relationship between cortical thickness maturation and IQ in a large longitudinal sample of 307 children and adolescents, IQ was observed to correlate most closely not with cortical thickness, *per se*, but rather with the shape of the developmental trajectory in cortical thickness change (see Figure 12.9; Shaw et al., 2006). The subjects that had the highest IQs tended to have the most dynamic cortical maturation, with more rapid cortical thickening during early childhood and more rapid cortical thinning during late childhood and adolescence. However, in terms of absolute thickness, the superior intelligence group actually had thinner cortex at the start of the age range studied (approximately age 7), peaked later, and then had relatively equal thickness to the others by the end of the age range (approximately age 19). This observation highlights the notion that, like the pattern of structural maturation itself, the relationships between brain structure and cognitive ability are complicated by their dependency on age during the course of development. In another example, Choi et al. took a multimodal approach, as described in Section 12.6.1, and investigated correlations between intelligence and both cortical thickness *and* functional MRI (fMRI) blood flow response during a reasoning task. Because both sets of scans were performed on the same sample of subjects, the authors were able to go a step further than single modal studies and examine if different intelligence subcomponents correlated more with one imaging modality or the other. Their findings quite eloquently demonstrated that the *crystallized* component of intelligence (related to our ability to utilize previously acquired knowledge and past experiences) correlated more strongly with cortical thickness, while the *fluid* component of intelligence (related to our problem-solving and critical-thinking ability in novel situations, independent of past experience) was more strongly related to functional blood flow response (Choi et al., 2008). While the specific pattern and methodologies of these studies have varied widely, the common pattern that has emerged is a relationship between frontal lobe structural brain development and general intellectual ability.


FIGURE 12.9 Trajectory of cortical thickness change versus IQ. Higher IQ was associated with a more dynamic trajectory (more rapid thickening and thinning) in cortical thickness maturation among a sample of 307 children and adolescents scanned longitudinally. The center panel shows regions where there was a significant interaction between IQ group (superior, high, or average) and a cubic age[3] term in the regression analysis, which implies a varying trajectory shape in these regions. These individual trajectories are plotted in panels (a–d), and are color-coded according to intelligence group. Arrows indicate the age at peak cortical thickness for each trajectory. *Shaw P, Greenstein D, Lerch J, et al. (2006) Intellectual ability and cortical development in children and adolescents.* Nature *440: 676–679.*

Other studies have investigated more specific cognitive functions and their relation to gray matter structure. In the same longitudinal sample of 45 typically developing children, that was described previously, we observed inverse correlations between performance on the vocabulary subtest of the Wechsler Intelligence Scale for Children (Wechsler, 2003) – a test of general verbal intellectual functioning – and gray matter thickness in left dorsolateral frontal and lateral parietal regions (see Figure 12.10; Sowell et al., 2004a). This is consistent with the language dominance of the left hemisphere and suggests a possible relationship between these concurrent structural and cognitive developmental processes. While originally interpreted as possibly relating to developmental cortical thinning, the results of the Shaw et al. (2006) study suggest that the individuals with the greatest verbal intellectual function here may still have been on the upstroke of their developmental arc in our much younger sample (age 5–11 years) and simply had thinner cortex at the time sampled. This nuance is also reflected in another study, which had an older sample (age 6–18 years), during the later period of development where increased cortical thickness is associated with higher IQ (Karama et al., 2009). Further studies, again in the young sample of 5–11-year-olds, have investigated even more targeted cognitive subtests, including phonological processing and motor speed and dexterity (Lu et al., 2007). Structural development in the inferior frontal gyrus (a phylogenetically more complex area that matures slower and is still on the upward stroke of cortical thickening) was expected to relate to advances in phonological processing, which has been shown to involve this area on functional imaging studies (Bookheimer, 2002) but not to relate to advances in motor processing.

Conversely, structural development in the hand motor region (a phylogenetically simpler area that matures earlier and is already experiencing cortical thinning) was expected to relate to advances in motor processing but not phonological processing. This predicted double dissociation was demonstrated as expected, which not only illustrates a specific alignment between language development and structural development in the inferior frontal gyrus but also reiterates the regionally specific definition of 'structural development' during childhood – with some cortical regions thinning but some relatively specific language areas still exhibiting thickening. A similar analysis has also revealed relationships between cortical thinning and both delayed verbal recall functioning and visuospatial memory ability, which is again consistent with the functional neuroimaging literature that suggests the dorsolateral prefrontal cortex is involved with memory recall (Casey et al., 1995; Sowell et al., 2001a). The relationship between cognitive development and structural brain development is further supported by intervention/training studies, which suggest even relatively short periods of cognitive or motor training can be associated with, at least, short-term morphological changes in brain structure (Draganski et al., 2004).

Diffusion imaging indicators of white matter development also relate to cognitive function. In a sample of 23 children and adolescents, there was a significant direct relationship between diffusion characteristics (FA) and working memory ability in inferior frontal and temporooccipital regions and the genu of the corpus callosum (Nagy et al., 2004). This relationship existed above and beyond the correlation of each individual measure with age, which suggests that the maturation
FIGURE 12.10 Cortical thickness versus language functioning. Statistical maps showing the significance of the relationship between changes in cortical thickness and changes in vocabulary scores in a longitudinal sample of 45 children scanned twice between the ages of 5 and 11. Areas with a significant negative relationship (cortical thinning was associated with improved language performance) are color-coded according to their *P* value, with the significance thresholds shown in the color bar on the right. No positive correlations were observed. *Sowell ER, Thompson PM, Leonard CM, Welcome SE, Kan E, and Toga AW (2004a) Longitudinal mapping of cortical thickness and brain growth in normal children.* Journal of Neuroscience *24: 8223–8231.*

of the white matter in specific areas – as indexed by FA – may play a role in the development of (or simply reflect the development of) specific cognitive domains. In another study related to structure–function specialization within the brain, others have shown correlations between Chinese reading score and FA in the anterior limb of the left internal capsule and English reading score and FA in the corona radiata (Qiu et al., 2008). While a preliminary interpretation, this dissociation could represent that distinct brain networks are more or less involved with language development, depending on the specific language or mode of acquisition. For instance, it is quite reasonable to hypothesize that learning written Chinese, with symbolic characters representing whole words that are generally independent of pronunciation, could drive development (or reflect development) of different brain regions compared to learning written English, which uses an alphabetic system to describe how words sound. As a final example, in the arcuate fasciculus lateralization tractography study discussed in Section 12.5.3, greater leftward lateralization was associated with better performance on cognitive tests of receptive vocabulary and phonological processing (Lebel and Beaulieu, 2009). These studies suggest that diffusion imaging is not only a useful technique for tracking normal anatomical maturation within the white matter, but also that regional DTI metrics can provide reflections of cognitive development in specific domains.

12.7 CONCLUSIONS AND FUTURE DIRECTIONS

Our understanding of human brain development has accelerated over the last 20 years through the use of MRI and *in vivo* human brain mapping. Postmortem and histological studies have demonstrated that brain maturation, on the cellular level, encompasses both progressive and regressive events. These include synaptic pruning and protracted myelination, which continue to shape the underlying neural microstructure and regional brain morphology long after overall brain volume begins to plateau, around age 5. Brain development, in general, can be characterized as both nonlinear with respect to time, and also variable with respect to region. The hallmark of structural brain development during childhood is a striking change in the relative proportions of gray and white matter – with a peak and then decline in gray matter volume and cortical thickness but a relatively sustained increase in white matter beyond adolescence. Across these different regions, there is a general posterior-to-anterior and inferior-to-superior trend in the timing of maturation, such that primary somatosensory and phylogenetically older areas of the brain tend to

mature earlier than higher-order association cortices – particularly areas in the frontal lobe. Within the white matter, diffusion imaging indicators show decreasing diffusivity (MD) and increasing directionality (FA), which suggests that myelination continues through young adulthood and perhaps even beyond. Performance across a variety of cognitive domains has also been shown to relate to these structural changes, with the specificity of these relationships generally in line with classic functional neuroanatomical localizations.

Although the complexity of the regional and temporal patterns of structural brain development makes investigating and interpreting these brain–behavior relationships challenging, future work should continue to focus on the possible functional manifestations of structural brain development. Particularly, by integrating different structural and functional imaging modalities with thorough cognitive assessments, we can investigate the ways in which these processes interact with each other within a more inclusive framework that more realistically encompasses the full developmental landscape. With the increasingly broad array of radiological features of development that have been characterized, there is additionally a growing need to reintegrate a firm neurobiological understanding of the cellular mechanisms that facilitate these changes. Finally, effort should continue to be directed towards uncovering the ways in which this basic neuroscientific knowledge concerning human brain development can be translated into a better context for the understanding and clinical treatment of neurodevelopmental disorders.

Statistical Learning Mechanisms in Infancy

J. Lany[1], J.R. Saffran[2]

[1]University of Notre Dame, Notre Dame, IN, USA; [2]University of Wisconsin-Madison, Madison, WI, USA

While psychologists long imagined that infants experience the world as a bewildering array of sights, sounds, and sensations (James, 1890), research since the 1950s has shown that infants are born with more advanced perceptual and cognitive abilities than was once thought. For example, infants' visual, auditory, tactile, and vestibular systems are functional at birth, and their discrimination abilities in these areas are already remarkably acute (see Kellmann and Arterberry, 2000 for a comprehensive discussion). They show evidence of processing and remembering stimuli in their environment; even very young infants differentially attend to repeated stimuli versus novel stimuli (e.g., Fagan, 1970). Infants also exhibit differential attention to stimulus features. For example, newborns prefer complex, patterned stimuli to homogeneous ones (Olson and Sherman, 1983), facelike stimuli to nonfacelike ones (Valenza et al., 1996), and speech to other acoustic stimuli (Vouloumanos et al., 2010).

In addition to advances in our understanding of infants' perceptual abilities, there has been great progress in the last two decades in the study of the mechanisms by which infants learn about their environment. Scientists began studying whether infants can learn via classical and operant conditioning, and by the 1970s, researchers had made substantial progress in discovering the conditions under which such learning occurred (Rovee-Collier, 1986; Sameroff, 1971). In the decades since, researchers have continued to make exciting discoveries about the nature of the learning mechanisms by which infants become sensitive to structure in their environment. In this chapter, the focus is on recent research on infants' ability to learn four different kinds of statistical structure: probability distributions, sequential

structure, correlations between stimulus dimensions, and associations between different forms of information. These types of statistical structures appear to be foundational to many aspects of development, including auditory and visual perception, language development, early cognition, and event processing. Much of our discussion is focused on the role of these learning mechanisms in language acquisition, though connections are also made between language learning and learning in other domains. Whenever possible, research investigating the relationships between behavioral findings and underlying neural processes has also been presented. The studies reviewed in this chapter reveal the power, nuance, and complexity of infant statistical learning mechanisms and contribute to an understanding of their role in early cognitive development.

13.1 LEARNING PROBABILITY DISTRIBUTIONS

13.1.1 Tracking Probability Distributions in Speech Sounds

A basic form of learning available to infants is sensitivity to the frequencies with which events occur in the environment. Early research on infant perceptual development revealed that infants can differentiate between frequent and infrequent events: when presented with successive trials of two pictures side by side in which one is repeated while the other changes, infants spend more time looking toward the novel picture (Fantz, 1964). Recent studies revealed that by the time they are about 8 months old, infants can do something potentially much more powerful than tracking frequencies of individual events: they can track the relative frequencies of items within a set, or probability distributions.

Differences between speech sounds, or phonemes, that correspond to differences in the meanings of words are called 'phonetic contrasts.' For example, the English sounds /r/ and /l/ are considered to be different phonemes, representing a phonetic contrast, because a switch from one to the other changes the meaning of a word (i.e., 'right' vs. 'light'). However, while /r/ and /l/ are perceived differently by adult speakers of English, they are not by speakers of Japanese, as these speech sounds do not correspond to a meaningful difference in their language. Thus, adults' ability to discriminate among speech sounds reflects the phonetic organization of their native language; adults are best able to discriminate between sounds that embody phonetic contrasts.

While adults' phonetic perception differs according to their native language, landmark research in the 1970s revealed that early in development, infants across languages readily discriminate among almost all of the speech sounds of the world (e.g., Eimas et al., 1971; for review, see Aslin et al., 1998a). Within the first year of life, however, infants' phonetic discrimination patterns become closely matched to the phonetic contrasts relevant in their native language (Kuhl et al., 1992; Werker and Tees, 1984). Within a given language, the distribution of speech sounds along a particular continuum appears to reflect phonetic category information (e.g., Lisker and Abramson, 1964). Specifically, every production of a speech sound differs on a variety of acoustic dimensions, influenced by the characteristics of individual speakers' vocal tract, speech rate, coarticulation, and phrase or sentence-level prosody. However, for acoustic dimensions that are critical in the perceived differences between phonemes, the values will tend to form nonuniform distributions, in which some values along a dimension are much more frequent than others (i.e., forming a bimodal or trimodal distribution). Interestingly, the differences relevant for highlighting phonemic contrasts may be exaggerated in infant-directed speech (Burnham et al., 2002; Kuhl et al., 1997; Werker et al., 2007). Adults can capitalize on nonuniform variation in speech sounds to discriminate between phonemes (Kluender et al., 1998), and computational modeling studies suggest that sensitivity to probability distributions may play an important role in learning phonetic contrasts (McMurray et al., 2009; Valhaba et al., 2007).

Maye et al. (2002) tested whether experience with unevenly distributed sound profiles influences phonetic perception in English learning in infants at 6 and 8 months of age. They created a set of eight speech sounds forming a continuum between [da] and [ta]. The endpoints of the continuum differed in the amount of voicing in the initial aspiration, from [da] (voiced) to [ta] (unvoiced), with six intermediate values. Infants in the unimodal condition heard a distribution in which the intermediate values (tokens 4 and 5) occurred most frequently, with decreasing frequencies toward the tails of the distribution. For infants in the bimodal condition, tokens 2 and 7 occurred with high frequency, while the tokens at the midpoint and endpoints were relatively less frequent.

After the infants were familiarized to the unimodal or bimodal distribution, they were tested to determine whether they discriminated between sounds at the opposite endpoints of the [da] – [ta] continuum, using a preferential listening task. In this procedure, the presentation of an auditory stimulus is contingent on infants' attention to a visual stimulus, such as a flashing light or a checkerboard. As long as the infants continue to look toward the visual stimulus, the auditory stimulus continues to play, but once they look away, it stops and a new trial begins. If infants' phonetic discrimination is affected by the distributional properties of the speech

sounds, they should continue to discriminate between stimuli at the endpoints when the distributional information supports the maintenance of two phonetic categories. However, when the values of the tokens form a unimodal distribution, infants should treat the sounds as belonging to a single phonetic category, ignoring variation in voicing. Only infants in the bimodal condition showed discrimination of the endpoints, suggesting that experience with unimodal distributions along an acoustic continuum may play a role in the loss of sensitivity to phonetic contrasts not relevant in their language.

Recent research suggests that experience with distributional variation in speech input can also result in an enhancement or sharpening of discrimination. For example, Kuhl et al. (2006) found that at 6–8 months of age, both English- and Japanese-learning infants discriminate between /r/ and /l/, a phonetic contrast present only in English. By 10–12 months of age, the Japanese-learning infants showed reduced discrimination, consistent with other studies showing a loss of discrimination of nonnative language contrasts at this age. the English-learning infants, on the other hand, showed better discrimination between /r/ and /l/ at 10–12 months than at 6–8 months. Moreover, infants who hear speech in which acoustic differences in phonemic contrasts are exaggerated also show enhanced speech discrimination skills (Liu et al., 2003), suggesting that they capitalize on acoustic information differentiating speech sounds.

Maye et al. (2008) tested the role of distributional learning in the enhancement of speech-sound discrimination using a contrast that is difficult for infants to discriminate: the contrast between pre-voiced and short-lag stop consonants, such as [da] versus [ka] (Aslin et al., 1981). They found that 8-month-old infants learning English failed to discriminate the endpoints when given no additional exposure to speech sounds on the continuum, confirming that this is a difficult distinction for infants. Infants exposed to a unimodal distribution of tokens in the lab also failed to show discrimination. However, infants exposed to a bimodal distribution showed evidence of discrimination, suggesting that sensitivity to distributional information can lead to enhanced discrimination of difficult speech-sound contrasts. Interestingly, at 10–12 months of age, just after the period of perceptual reorganization, infants' speech-sound discrimination abilities show diminishing effects of experience with distributional information. Specifically, they need more extensive experience with a bimodal distribution to show evidence of discrimination of speech sounds that are not contrastive in their native language (Yoshida et al., 2010).

In sum, developmental changes in infants' phonetic perception appear to result, at least in part, from their ability to track distributional regularities in their native language. Kuhl (2004) has proposed that infants' experience with acoustic and distributional cues works in concert with maturational changes in neural development to produce such changes. Data from neurophysiological recordings suggest that there are neural changes in infants' processing of nonnative phonetic contrasts. Cheour et al. (1998) used an oddball paradigm to test Finnish infants' discrimination of native and nonnative vowel contrasts at both 6 and 12 months of age. In these studies, a vowel present in the infants' native language was repeated, with another 'oddball' vowel presented on about 1 in 10 trials. The oddball was either another native-language vowel, which differed in the frequency of the second formant, or a vowel that does not occur in Finnish. Evoked-response potential (ERP) studies using the oddball paradigm have shown that when infants detect a change to the repeating stimulus, the ERP wave shows a negative deflection beginning at about 200 ms, called a mismatch negativity, or MMN. At 6 months of age, Finnish infants showed a similar MMN to both the native and nonnative oddball vowels, but by 12 months, they showed a much greater MMN response to the native vowel. Using a similar paradigm in a longitudinal study with English-learning infants, Rivera-Gaxiola et al. (2005b) found an enhancement in the neural response to native-language contrasts between 7 and 11 months. They also found that infants continued to show a neural response indicative of discrimination for nonnative vowels, though the neural manifestation of the discrimination took two different forms. In one group of infants, the oddball elicited a negative component, similar to their response at 6 months of age, while in a second group, it elicited a greater positive component. Interestingly, Rivera-Gaxiola et al. (2005a) found that infants who continued to show a negative component in response to nonnative oddball phonemes later had smaller native-language vocabularies, while those that showed a positive response had larger vocabularies. The authors hypothesized that the development of the positive response in infants who later developed more advanced language skills reflects neural reorganization in response to native-language patterns. These data are in line with Kuhl's (2004) hypothesis that changes in neural organization may play a role in changes in phoneme perception during infancy.

In sum, experience with distributional information plays an important role in the dramatic changes in speech-sound discrimination that take place between 8 and 10 months of age. While infants remain sensitive to distributional cues marking nonnative phonemic contrasts after the period of reorganization, these findings suggest that neural changes, increased experience with the distributional properties of one's native language, or a combination of these factors, reduces their impact on discrimination. It is important to note that the social

context in which infants experience nonnative language distributional patterns may also modulate the effects of such patterns, but by increasing sensitivity to novel phonetic contrasts – infants show greater sensitivity to difference in nonnative contrasts after listening to a native speaker in person than after watching and listening to a native speaker on a video tape (Kuhl et al., 2003). These findings suggest that although reorganization takes place early and has dramatic effects on speech perception, the capacity to learn novel contrasts is maintained and can be facilitated through social interaction.

13.1.2 Tracking Probabilities in Sampling Events

The studies described so far suggest that distributional information may facilitate perceptual reorganization in the auditory realm over the first year. Another line of recent research suggests that sensitivity to the distributional regularities plays a pervasive role in learning and cognition across diverse areas of development. Inductive learning involves encountering a finite set of examples (a sample), and using that information to extrapolate beyond the sample to behave flexibly when encountering new examples. To do so, learners must use information about the distribution of samples to learn about the underlying properties of the population from which the samples were drawn.

In a recent series of studies, Xu and Garcia (2008) explicitly tested infants' sensitivity to the relationship between the distribution of individual samples and the underlying populations they belong to. In one experiment, 8-month-old infants watched an experimenter bring out a covered box and remove 5 balls of mostly one color, either 4 red and 1 white, or 4 white and 1 red ball with her eyes closed. After she had removed the 5 balls, the experimenter removed the box's cover. Thus, the infants could not see the composition of balls in the box until after the sample balls were removed. The infants looked at the box longer on trials when the sample was unlikely under conditions of random sampling (i.e., when the container contained mostly red balls after the experimenter had just drawn mostly white balls from it). This suggests that infants' knowledge of the properties of the sample influenced their expectations about the properties of the population (i.e., the covered box). Interestingly, when the same experiment was repeated, but the experimenter drew the ping-pong balls from her pocket, infants showed no differences in looking times toward boxes containing mostly red versus mostly white balls. In other words, when the test balls were not sampled from the box, infants did not respond differentially to the contents of the box as a function of the properties of the sample. This suggests that in the

initial experiment, infants were responding to the relation between a sample and the population they were drawn from, rather than to more superficial perceptual relationships between the sample balls and the balls in the box.

Teglas et al. (2007) also investigated whether infants' processing of sampling events is affected by population information. Twelve-month-olds viewed a movie depicting a container with a small opening at its base, with four objects bouncing inside. Critically, three of the objects were identical, and one was unique. Next, an occluder covered the container, and one of the objects exited the container through the opening. On half of the trials, the infants saw events with probable outcomes (one of the three identical objects exited), and on the other trials, they saw the less probable outcome (the unique object exited the container). The infants looked longer at the improbable than the probable outcome, suggesting that the composition of objects in the container influenced their processing of the outcomes. However, when the container was partitioned such that only the unique object was physically capable of exiting, the infants looked longer when one of the three identical objects exited the container. This suggests that they were not simply responding to surface information about object frequency, looking longer toward a less common or less familiar object, but rather were responding to the relationship between the population of objects in the container and the outcome of the sampling event.

These studies also hint that infants are sensitive to information about the sampling process itself. For example, when the sampling process is random, as when an experimenter with her eyes closed picked balls out of a box in Xu and Garcia (2008), infants expect the sample to reflect the global properties of the population. However, when the sampling was not random, infants showed evidence of adjusting their expectations about the relations between a sample and the population. For example, when an occluder made some sampling events impossible in Teglas et al. (2007), infants did not appear to expect that the more frequent elements would be sampled. Moreover, Xu and Denison (2009) found that infants use information about an individual's preferences (e.g., for red balls) to guide their sampling behavior, and they are not surprised when she looks into a box containing mostly white balls and picks out mostly red ones.

Taken together, these findings suggest that across domains, infants are highly sensitive to the probabilities of individual events and can integrate this information in order to track the probabilities of sets of items related to one another in an underlying distribution or population. In the domain of speech perception, this process appears to facilitate differentiation between random noise and meaningful variations in similar sounds. In the

domain of event perception, sensitivity to distributional information allows infants to generalize from individual experiences to anticipate future scenarios.

13.2 LEARNING CO-OCCURRENCE STATISTICS

Within a given domain, the reliable co-occurrence of elements is typically a surface manifestation of a meaningful relationship between those elements. Co-occurrence information thus has the potential to play a pervasive role in learning, as long as learners are sensitive to it. Despite the seemingly simple nature of such associative relationships, tracking sequential associations in most environmental patterns can be quite challenging. It entails encoding a stimulus, as well as those that precede and follow it, and maintaining memory representations across multiple occurrences of each stimulus. This might not seem difficult to do for one item that occurs in a reliable context, but consider tracking this information for a set of 100, or even 1000 different items that occur in highly variable contexts.

Natural language provides a compelling illustration of this difficult problem. Given that the sounds comprising words and sentences unfold over time, as opposed to being expressed simultaneously, spoken language is rich with sequential structure. Language is hierarchically organized, consisting of patterns at both very fine-grained and larger-grained levels, and there are sequential regularities at each level of structure. In part because of the high demands that tracking such complex sequential structure would place on infants, the potential role of co-occurrence learning mechanisms in language acquisition has been the object of a great deal of interest. Numerous studies have tested two related hypotheses: (1) tracking sequential associations could lead to the discovery of language structure, both within words as well as across words and in simple grammatical patterns, and (2) infants have sufficient computational resources to track such complex information.

13.2.1 Sequential Learning: Phonotactics

At a very fine-grained level, languages are organized according to phonotactic patterns: regularities in how sounds are structured within words. What makes these regularities interesting is that they differ across languages, and thus must be learned. For example, English syllables can begin with some consonant clusters (e.g., /st/ and /fr/), but not others (e.g., /fs/ and /ng/). However, none of these sequences can appear in syllable onsets in Japanese. Infants appear to be sensitive to phonotactic patterns by 9 months of age (Friederici and Wessels, 1993; Jusczyk et al., 1993, 1994). In addition, 9-month-old infants can learn novel phonotactic patterns given brief laboratory experience with novel languages (e.g., Saffran and Thiessen, 2003). Following exposure to lists of novel words in which the initial consonant within a syllable was always voiced (e.g., /g/, /d/, /b/) and the final consonant was unvoiced (e.g., /k/, /t/, /p/), infants were able to distinguish between novel words consistent with those patterns and ones that followed the opposite pattern. However, when voicing was not a consistent feature of syllable onsets and offsets (i.e., /g/, /b/, and /t/ occur in syllable-initial position, while /k/, /d/, and /p/ occur in syllable-final position), infants failed to show evidence of learning the phonotactic regularities. This suggests that infants can learn positional regularities when they follow a consistent pattern, but that learning restrictions on the positions of individual elements is taxing for infants at this age.

Interestingly, by 16.5 months, infants successfully learn individual restrictions on sound locations within syllables (Chambers et al., 2003). These results suggest that with age and linguistic experience, infants' ability to learn more specific regularities is enhanced. Because learning an abstract pattern typically results from the ability to track regularities or similarities across individual exemplars, it is often more demanding than tracking information about specific exemplars. However, when exemplars share a salient feature, the need for tracking exemplar-specific information can be reduced and may lessen the computational demands on learning. This may be why younger infants were able to track phonological regularities only when they conformed to a phonological generalization.

13.2.2 Sequential Structure: Word Segmentation

Another source of sequential regularity in language pertains to how syllables are combined to form words. Syllables that reliably co-occur often belong to the same word, while syllables that rarely co-occur are more likely to span word boundaries (e.g., Swingley, 2005). Because of this feature of language, transitional probabilities between syllables tend to be higher within words than between words. The transitional probability (TP) of a co-occurrence relationship between two elements, X and Y, is computed by dividing the frequency of XY by the frequency of X. This yields the probability that if X occurs, Y will also occur. Saffran et al. (1996) tested whether 8-month-old infants, who are just beginning to learn their first words, can capitalize on TP cues. Infants listened to a stream of synthesized speech in which the only potential cue to word boundaries was the TPs between adjacent syllables (1.0 within words; 0.33 at word boundaries). The infants listened to the

stream for about 2 min and were then tested on their ability to discriminate between the syllable sequences with high TPs ('words') and novel combinations of the familiar syllables ('nonwords'). Infants listened longer to the strings containing nonwords, suggesting they distinguished between syllable sequences that were attested in their input (TPs = 1.0) and sequences that did not occur (TPs = 0). A second group of infants was familiarized in the same manner and tested on sequences with high TPs 'words' (all internal TPs were 1.0), and 'part-words': sequences of syllables that had occurred across word boundaries (e.g., the final syllable of one word and the first two syllables of another word), which had lower TPs of 0.33. Infants again displayed a novelty preference, suggesting that they can also discriminate sequences that contain highly reliable transitions from those that contain less reliable ones.

Subsequent studies more specifically probed the kinds of sequential statistics that infants are sensitive to in these studies, in particular, distinguishing between the frequency of a sequence and its transitional probability. The frequency of a sequence is simply the number of times it occurs, while the transitional probability of a co-occurrence relationship provides a measure of how tightly linked or connected X and Y are, controlling for the raw frequency of X. If X occurs many times without Y, then no matter how many times it occurs with Y, the conditional probability will be relatively low. Conversely, a sequence can have low frequency but a high conditional probability.

In the Saffran et al. (1996) study, the syllable transitions within words were both more frequent and had higher TPs than the syllable transitions in part-words. Aslin et al. (1998b) thus investigated whether infants can track TPs, or just frequencies. Specifically, they modified the design of Saffran et al. (1996) such that two of the words occurred twice as often as the other words. This manipulation permitted a design in which the four test items – two words and two part-words – were equally frequent; however, the TPs within words were 1.0, and the TPs spanning the word boundaries were still 0.33. Infants showed discrimination between the words and part-words, despite the fact that the syllable sequences occurred equally often in both types of test items. This suggests that by 8 months of age, infants have a powerful mechanism for tracking co-occurrence relationships and for distinguishing potentially spurious co-occurrences from ones in which there is a very tight connection.

Another recent study further specified the nature of the regularities that infants can use to learn reliable co-occurrence relationships. The TPs in these studies have primarily been described as prospective relationships, or the probability that, given the occurrence of a syllable, another syllable will follow (i.e., the probability that the

syllable '*by*' will follow the syllable '*ba*,' as in the word *baby*). However, infants could also be sensitive to the probabilities of retrospective relationships (i.e., the probability that the syllable '*ba*' will precede the syllable '*by*'). In the studies of sensitivity to TPs reviewed so far, the words contained forward TPs (FTPs) and backward TPs (BTPs) of 1.0, and thus infants could have used either or both to discriminate words from part-words. Moreover, in natural languages, FTPs and BTPs are both likely to be reliable cues to word boundaries, and thus tracking both would potentially be advantageous to infants. Pelucchi et al. (2009a) thus familiarized 8-month-old infants with a corpus in which HTP and LTP words differed in their BTPs, but both had FTPs of 1.0. Thus, infants could only use BTPs to distinguish between the HTP and LTP words. Infants showed significant discrimination between HTP and LTP words, suggesting that they were sensitive to the BTPs of the syllable sequences. While FTPs may facilitate anticipating upcoming stimuli, infants' sensitivity to BTPs may help them to remember what came before a particular element. Thus, infants' sensitivity to both types of relationships potentially enhances word segmentation and other tasks that require sequential learning and processing.

In most of the studies described so far, infants were given limited exposure to artificial languages, produced as synthetic speech, which is not as engaging as naturally spoken infant-directed speech. More recent studies have investigated whether infants also use these cues to segment speech when there are many more competing regularities to attend to, and many more individual segments over which to compute TPs. For example, Pelucchi et al. (2009b) tested whether infants can track forward TPs in a natural language. They presented English-learning 8-month-olds with Italian sentences spoken with infant-directed prosody. Embedded in these sentences were two words with high internal TPs (1.0) and two words with low internal TPs (0.33). Over the course of the 2-min familiarization phase, infants heard each of these words presented just 18 times. When tested, infants discriminated between high TP words and low TP words, suggesting that they were able to track TPs despite the complexity and variability of the materials. Pelucchi et al. (2009a), described above, also used naturally spoken Italian in their work showing that infants can track backward TPs.

In another study examining how statistical learning mechanisms scale up to the complexity of natural language, Johnson and Tyler (2010) tested infants' ability to use TPs in a corpus in which the words varied in syllable number. They familiarized 8- and 5.5-month-old infants to a synthesized speech stream in which two bisyllabic words and two trisyllabic words were concatenated in a continuous stream. Interestingly, infants failed to discriminate words from part-words

under these conditions. This suggests that infants benefit from the presence of other regularities beyond TPs (i.e., consistent syllable length). Indeed, learners also appear to benefit from rhythmic patterns that point to word boundaries, though the degree to which this occurs depends on the infants' age, presumably reflecting the amount of native-language knowledge the infant has acquired (e.g., Johnson and Jusczyk, 2001; Theissen and Saffran, 2003, 2007).

Altogether, these results provide strong evidence that infants are sensitive to sequential relationships between phonemes and syllables. The extent to which such cues interact with other potential cues to word boundaries, such as stress patterns, sentential prosody, and the occurrence of words in isolation, are areas particularly in need of further study.

13.2.3 Sequential Learning: Grammatical Patterns

At yet another level up in the hierarchy of language structure, sensitivity to sequential relationships appears to play a role in learning grammatical patterns, such as learning how words can be combined into phrases and sentences. For example, Saffran and Wilson (2003) asked whether sensitivity to word boundaries arising from tracking TPs between syllables provides a foundation for tracking word combinations. They played 12-month-old infants synthesized speech strings in which the TPs between syllables served as a reliable cue to word boundaries (i.e., TPs within words were 1.0, while TPs of syllables spanning word boundaries were 0.25). The strings also contained word-order patterns that were not directly cued by relationships between syllables, but could only be detected by tracking the TPs between the words. Infants were then tested on their ability to discriminate novel grammatical strings from ungrammatical ones. Despite the fact that the TPs of adjacent syllables could not be used to distinguish between the grammatical and ungrammatical test strings, infants showed significant discrimination. These findings suggest that sensitivity to sequential relationships resulting in segmentation may bolster subsequent learning by helping infants to learn sequential relationships between words.

Gómez and Gerken (1999) also tested whether 12-month-old infants can learn TPs within multiword 'sentences.' They created an artificial language in which nonsense words were combined to form sentences in which there were probabilistic regularities in the ordering of words. Infants were then tested on novel grammatical and ungrammatical strings that contained familiar words. Infants successfully discriminated between grammatical and ungrammatical strings, providing evidence that they learned the probabilistic co-occurrence relationships between words. In a subsequent experiment, infants were also able to distinguish between grammatical and ungrammatical strings when the strings were instantiated in a novel vocabulary. This finding suggests that learning sequential statistics can lead not just to knowledge of individual sequences but also potentially to a more abstract level of structure.

13.2.4 Learning Nonadjacent Co-occurrence Probabilities

The studies on sequential learning described thus far suggest that infants readily track predictive relationships between adjacent segments such as syllables and words. However, in natural languages, predictive relationships can also occur between nonadjacent elements. For example, grammatical dependencies marking tense are often nonadjacent, as in the relationship between auxiliaries such as 'is' and the progressive inflection 'ing,' as they are necessarily separated by a verb (e.g., 'is running,' 'is eating,' 'is talking'). Likewise, a plural noun predicts plural marking on the subsequent verb, but the noun and verb can be separated by modifiers, as in 'The kids who were late to school are in trouble.' Tracking nonadjacent dependencies places greater demands on memory than tracking adjacent dependencies, as elements must be remembered long enough to be linked to other elements occurring later in time. In addition, because nonadjacent dependencies can be separated by several word elements, there are many potentially irrelevant relationships for the learner to track, presenting a considerable computational burden.

Given the demands involved in detecting nonadjacent regularities, it is perhaps unsurprising that both infants and adults have substantial difficulty learning them. For example, while infants can track the relationships between adjacent elements well before they turn a year old, infants start showing sensitivity to grammatical relationships involving nonadjacent elements in their native language only at about 18 months of age (Santelmann and Jusczyk, 1998), suggesting that some combination of language experience and maturation of neural substrates for memory is needed to facilitate nonadjacent dependency learning.

Gomez (2002) investigated the conditions that promote sensitivity to nonadjacent relationships. In particular, she hypothesized that there is a relationship between the presence of salient adjacent structure and the tendency to track nonadjacent structure. Because tracking adjacent relationships appears to be relatively easy for infants, they are likely to focus on adjacent structure as long as it is reliable. However, when the variability in adjacent relationships is high (i.e., when adjacent TPs are low),

infants may be less likely to track those relationships and more likely to track reliable nonadjacent regularities.

To test this hypothesis, Gomez (2002) exposed 18-month-olds to artificial language strings containing nonadjacent dependencies with TPs of 1.0. Critically, these dependencies were separated by an intervening element drawn from a set of 3, 12, or 24 different elements, and thus the adjacent TPs between words varied across conditions: relatively high (0.33, set size 3), medium (0.08, set size 12), or very low (less than 0.01, set size 24). Only infants in the set size 24 condition, in which the predictability of adjacent sequences was very low, successfully discriminated between familiar grammatical strings and strings that violated the nonadjacent relationships.

In subsequent research, Gómez and Maye (2005) found that 15-month-old infants track nonadjacent dependencies even under conditions of high variability but that 12-month-olds fail to do so. This developmental pattern suggests that increases in memory capacity over the second year facilitate nonadjacent dependency tracking. In addition to developments in memory, another factor in the development of nonadjacent dependency learning is prior language experience. Just as segmentation facilitates learning higher-order patterns in which those elements are combined, Lany and Gómez (2008) found that prior learning about adjacent relationships facilitates infants' detection of nonadjacent patterns. In particular, when 12-month-old infants were first given experience with adjacent relationships between word categories, they then successfully detected novel nonadjacent relationships between words from those categories.

13.2.5 Learning Co-occurrence Statistics in Other Domains

The studies described so far suggest that infants' sensitivity to sequential regularities could play a role in detecting multiple layers of language structure, from phonotactics to grammar. Far from being specific to learning in the auditory domain, infants' sensitivity to sequential structure plays an important role in learning across domains. Sequential relationships are important dimensions of event structure, such as in brushing one's teeth (e.g., picking up the toothbrush, applying toothpaste, wetting the brush, and brushing), making coffee, or opening a toy container. The subcomponents of the action tend to co-occur in reliable sequences, and thus tracking sequential structure in the visual domain may play a role in both detecting event boundaries and in learning their internal structure.

Indeed, Baldwin et al. (2008) found that adults can use statistical information to learn regularities in dynamic

action sequences. Employing a design similar to studies investigating word segmentation (e.g., Saffran et al., 1996), adults viewed a series of discrete actions spliced together. There were action triplets embedded within the stream such that within a sequence of individual actions (e.g., poke, scrub, drink), TPs were 1.0, and across action sequences, the TPs between actions were 0.33. The only cues to the action sequence boundaries were the TPs. Adults were able to discriminate trained action sequences (TPs of 1.0) from unattested sequences of familiar actions (TPs of 0.0), as well as from sequences spanning boundaries (TPs of 0.33). They also showed evidence of detecting sequential regularities in action sequences when the individual actions (e.g., the action of drinking) varied considerably in their perceptual features across training.

While similar studies with action sequences have not yet been done with infants, numerous studies suggest that infants track sequential statistics in other domains of visual processing. For example, Kirkham et al. (2002) tested infants' ability to detect sequential relationships in a series of shapes. In these experiments, 2-, 5-, and 8-month-old infants were habituated to a series of six shapes that appeared sequentially on a screen. The objects were grouped into three sets of sequential pairs. Within a pair, one shape was reliably followed by another shape; the TPs between objects within a pair were 1.0, while the TPs at pair boundaries were 0.33. At all of the ages tested, infants discriminated between strings that preserved the statistical regularities and sequences in which the sequential regularities were violated. While infants in this experiment could use either frequency of co-occurrence or TPs to distinguish the test trials, Marcovitch and Lewkowicz (2009) found that by 4 months of age, infants can separately track frequency of shape co-occurrence as well as the conditional probability of shape pairs. These findings suggest that the ability to track sequential co-occurrence relationships in the visual domain emerges quite early in development.

Other studies have focused on infants' ability to learn sequential regularities in dynamic events. Kirkham et al. (2007) showed 8- and 11-month-old infants a spatiotemporal sequence in which a red dot appeared consecutively in the six positions of a 2×3 grid. There were reliable 'location pairs' in the sequence: for example, if the dot first appeared in the top left, it always subsequently appeared in the top middle. After the second element in a pair, the dot could appear in one of three locations. Thus, within the continuous sequence, the TPs within a location pair were 1.0, and TPs spanning pairs were 0.33. Only the 11-month-olds distinguished between sequences in which location pairs were preserved and sequences containing the unattested transitions. However, when each location in the habituation sequence was occupied by a different object, 8-month-olds

distinguished between test sequences in which the location pairings were preserved and those in which they were violated. Eye tracking data revealed that infants were also faster to reach the second element in a location pair, which was predictable given the previous element, than to initial elements, which were not predictable given the last object/location, providing additional evidence that they had learned the spatiotemporal regularities. These results suggest that learning location-based co-occurrence relationships is challenging, developing between 8 and 11 months of age, despite robust abilities to track purely temporal co-occurrence relationships that develop many months earlier. However, infants can succeed at younger ages when the sequential relationships are also marked by featural cues, or when the occurrence of the object at one location predicts not just a subsequent location but also the identity of the object that will appear next.

13.2.6 Neural Correlates of Learning Sequential Structure

Given the behavioral results amassed over the past decade, researchers have become extremely interested in the neurophysiological processes involved in tracking sequential regularities. Cunillera et al. (2006, 2009) recorded ERPs as adults listened to a continuous stream of 3-syllable words cued by TPs, similar to the materials used by Saffran et al. (1996). They observed an increased negativity (an N400) occurring just after the onset of syllables in word-initial position appearing over the course of familiarization with the stream. Abla et al. (2008) found a similar pattern when learners were presented with continuous streams of 'tone words,' an effect that was more pronounced in participants who showed better discrimination in a subsequent forced-choice test. This is similar to behavioral studies by Saffran et al. (1999), which showed successful segmentation of tone sequences using TPs. Sanders et al. (2002) measured ERPs to trisyllabic words presented in isolation before and after hearing those words presented in continuous strings with TPs as the only cues to word boundary locations. Despite the difference in their methods, they also found that words evoked a greater N400 after training, as well as an N100 at syllable onset. Moreover, ERP recordings of sleeping newborn infants who were played similar streams of continuous syllables show a negative deflection of the ERP wave during the first syllable of a word (Teinonen et al., 2009). These findings suggest that there is a reliable neural signature related to tracking TPs in the auditory domain.

Interestingly, similar ERP signatures have been observed in adults learning sequential co-occurrence relationships in *visually* presented stimuli. For example, Abla and Okanoya (2009) found that triplet onsets within

a visually presented stream of shapes also evoked an N400. In other words, just as in the case of syllable and tone streams, the first element of a statistically defined unit within a stream of shapes evoked a distinctive response. There was also overlap in the areas in which the increased N400 was observed across these studies – specifically middle frontal and central sites – across both auditory and visual modalities.

Together, the findings suggest that the N400 reflects something about learning reliable sequences across domains. In many studies of language processing, N400 components reflect the occurrence of an unexpected word, and thus its appearance at the first syllable of statistically defined words could reflect the fact that its occurrence was less predictable than the internal syllables. It could also reflect a search for the representation of the sequence as the first syllable is heard.

13.3 LEARNING CORRELATIONAL STRUCTURE

Another form of learning involves tracking correlations among properties of objects and events. Similar to tracking a sequence of events such as syllables or objects, tracking correlational structure entails learning associations, and thus there is potential overlap in the learning mechanisms involved. In the case of learning correlational structure, however, the relevant associations lie between features or dimensions of an object or event (such as an object or its label) rather than sequential components as they unfold over time. First, recent research suggesting that tracking correlations facilitates word segmentation and learning grammatical categories is described. Research suggesting that sensitivity to correlational structure plays an important role in segmenting the visual world, as well as in forming object categories (such as learning to distinguish between cats and dogs or between plates and spoons) is also discussed.

13.3.1 Sensitivity to Correlated Cues in Language Acquisition

In the previous section, evidence that tracking sequential structure facilitates finding word boundaries in fluent speech (Aslin et al., 1998a,b; Saffran et al., 1996), as well as some evidence suggesting that sensitivity to sequential TPs may interact with other phonological regularities in word forms was reviewed. Specifically, Johnson and Tyler (2010) found that when word length is consistent, even 5.5-month-old infants can track TPs in continuous speech. However, when word length varies, infants have a harder time using TPs to segment the stream. This suggests that infants' ability to use TPs as

a segmentation cue may be facilitated by the presence of correlated cues such as regular word length.

Sahni et al. (2010) investigated whether sensitivity to TPs marking word boundaries can facilitate learning other correlated cues relevant to segmentation. They exposed 9-month-old infants to a continuous stream of bisyllabic words in which TPs within words were 1.0 and TPs across word boundaries were 0.25. Critically, all the 'words' began with /t/ (e.g., *tohsigh, teemay, tiepu*). The question of interest was whether infants could use TP information to learn enough about the speech stream to discover the /t/-initial cue. Infants successfully discriminated between novel words that had /t/ onsets and words in which /t/ occupied a medial location, suggesting they had learned that words begin with /t/. Critically, infants failed this same discrimination test when they had no prior familiarization to the speech stream, or when they were familiarized with a stream in which every other syllable began with /t/ but there were no TPs indicating word boundaries. These results suggest that infants can learn correlations between word properties to aid segmentation – in this case, using a known cue (TPs) to discover a novel correlated cue to word boundaries (/t/-onsets).

Evidence that infants can learn sequential relationships between words by 12 months of age has already been reviewed (Gómez and Gerken, 1999; Saffran and Wilson, 2003). However, a critical property of grammatical structure is that it pertains not just to how individual words are combined (e.g., '*the cat*' is grammatical, but '*cat the*' is not) but also to how words from different grammatical categories can be combined (e.g., determiners like '*the*' and '*a*' precede nouns rather than follow them). While tracking distributional information is useful for learning word-order patterns, learning grammatical categories with distributional cues alone can be very difficult (Braine, 1987; Smith, 1969). Importantly, in natural languages, words from different syntactic categories are distinguished both by distributional (Cartwright and Brent, 1997; Mintz, 2003; Mintz et al., 2002; Monaghan et al., 2005; Redington et al., 1998) and phonological cues (Farmer et al., 2006; Kelly, 1992; Monaghan et al., 2005). In other words, words from the same grammatical category share correlated distributional and phonological features. For example, nouns tend to occur after both 'a' and 'the,' and to have a strong–weak stress pattern. Critically, Braine (1987) found that the presence of correlated cues facilitates learning the category-level co-occurrence relationships in adults. Braine hypothesized that the presence of the additional cues reduces the computational demands involved in tracking a large number of individual co-occurrence relationships between specific words. Rather than tracking and accurately remembering each individual co-occurrence relationship, the presence of correlated cues may allow learners to detect the associations between the phonological features shared by words within a category.

To test whether infants can also use correlated cues to form grammatical categories, Gerken et al. (2005) exposed 17-month-old English-learning infants to Russian words drawn from two grammatical categories. In Russian, words have complex morphological structure, often consisting of a stem plus multiple grammatical morphemes. The familiarization set consisted of six feminine and six masculine words, and all of the words contained additional grammatical morphemes: feminine words ended in the case markers '*oj*' and '*u*' and masculine words ended in the case markings '*ya*' and '*em*.' The case markings provided distributional cues to the feminine and masculine categories. An additional phonological cue marking the category distinction was present on half of the words: three of the feminine words contained a derivational suffix '*k*,' and three of the masculine words contained the suffix '*tel*.' Thus, in many feminine words, '*k*' was followed by '*oj*' and '*us*' (e.g., '*polku*' and '*polkoj*'), while in many masculine words, '*tel*' was followed by '*ya*' and '*em*' (e.g., '*zhitelya*' and '*zhitelyem*'). Infants familiarized with these words were subsequently able to distinguish between novel grammatical words containing those relationships and ungrammatical ones: for example, even if they had not heard '*zhitelyem*,' they were able to distinguish it from the ungrammatical '*zhitelu*.' They were also able to distinguish between '*vannoj*' (grammatical combination) and '*vannya*' or '*vannyem*' (ungrammatical combinations). In this case, they could not have been using the co-occurrence relationships between the case markers and derivational morphemes (the '*telya*' and '*koj*' sequences), but were generalizing based on distributional information.

Thus, when word categories are marked by correlated cues sharing phonological properties and distributional characteristics, infants successfully learn and generalize the category relationships. While 17-month-olds show evidence of generalizing based on distributional information, Gerken et al. (2005) found that 12-month-olds failed to do so. However, using a similar category-learning paradigm, Gómez and Lakusta (2004) found that 12-month-olds can learn correlations between distributional and phonological features. These findings are consistent with the hypothesis that category learning may initially involve tracking the correlations between distributional and phonological features of words.

13.3.2 Learning Correlational Structure in the Visual Domain

Infants' visual environments are exceptionally complex. Nevertheless, elements that reliably co-occur across time and space tend to belong to the same object

and thus provide information about object boundaries. Thus, just as in the case of segmenting words from continuous speech, the co-occurrence of features in the visual field is potentially a powerful cue that could be used to learn what clusters form objects. To test whether infants can track such conditional probabilities in complex visual displays, Fiser and Aslin (2002) showed 9-month-old infants scenes containing three elements. In each scene, three discrete shapes were presented simultaneously in a 2×2 grid. Two of the elements formed a 'base pair': those objects always occurred together in a consistent spatial orientation (the probability of co-occurrence, or TP, was 1.0). The two elements of each base pair also occurred with a third element, but its position relative to the base pair varied (TP = 0.25). Infants were then tested on scenes containing two elements – either base pair elements in their proper configuration or two elements that did not form a base pair. Infants were able to discriminate between base pairs and nonbase pairs when they differed in the frequency with which they appeared during habituation, and also when they were equally frequent but differed in their TPs. This suggests that sensitivity to statistical information facilitates object perception and raises the question of whether such learning can support object perception in younger infants.

Category learning is another domain in which sensitivity to correlations between object attributes might facilitate learning. Object categories (e.g., cups, dogs, birds, and trees) are structured such that properties characteristic of the category tend to co-occur within individual instances of the category. For example, the presence of one feature of a tree (branches, leaves, bark, trunk) is correlated with the presence of the others, but less strongly correlated with the presence of features associated with objects from other categories (e.g., ceramic handles, fur, and beaks).

Younger (1985) asked whether infants' sensitivity to such correlations plays a role in category learning. Ten-month-old infants viewed drawings of a set of animals that were composed of several continuously varying features (i.e., leg length, tail width, neck length, and ear separation). In the 'broad' condition, infants were exposed to a set of animals with features that were uniformly distributed (e.g., animals with long necks had both long and short legs), forming one category with a broad distribution of feature values. In the 'narrow' condition, the feature values formed two correlated clusters: for example, long-necked animals all had short legs, while short-necked animals had long legs. In this condition, the animals clustered together into two potential categories, each with a narrow range of features.

Infants were habituated to a set of these animals and then tested with novel animals. One animal contained feature values that were the average of all the animals in the familiarization set for the broad condition, but falling in between the average of the two narrow categories. The second animal contained a set of features that were closer to the average of one of the categories in the narrow condition, but farther from the average of the broad category. Infants in the narrow condition dishabituated to the broad stimulus, while infants in the broad condition dishabituated to the test animal closer to the average of one of the narrow categories. This suggests that when feature values formed two clusters, infants formed categories corresponding to correlations between values on these dimensions. However, when feature values were randomly distributed, infants did not group the animals into separate categories.

In similar studies, Younger and Cohen (1986) found that 7-month-olds, but not 4-month-olds, are sensitive to correlations among object features. However, Mareschal et al. (2005) noted that because 4-month-old infants appear to have learned some perceptually defined categories, for example, the difference between squares and diamonds (Bomba and Siqueland, 1983), and cats and dogs (Eimas and Quinn, 1994), the studies of Younger and colleagues may have underestimated infants' categorization abilities. They hypothesized that for young infants with limited memory, longer exposures to individual animals may make it more difficult to keep all the animals in memory. In particular, if infants can only retain information about one animal at a time, they would be unable to detect the correlations between object features across a set of animals. Thus, they modified the habituation phase such that the individual animals were presented for briefer durations. Under these conditions, 4-month-olds showed evidence of forming categories based on correlations between features.

These findings suggest that tracking correlated cues plays an important role in learning perceptually based object categories. There is also a potentially important connection between infants' ability to track correlations between features and their sensitivity to distributional information. Specifically, studies of distributional learning, such as Maye et al. (2002, 2008), suggest that infants can use the frequencies across a single dimension of a complex stimulus to form groupings. In these studies, infants show evidence of tracking correlations among the values of several distributions.

Quinn et al. (2006) began to investigate the neural underpinnings of categorization in infants. In particular, 6-month-old infants were presented with a set of images of cats and then tested on their looking behavior toward a set of pictures of dogs interspersed with novel cat pictures while ERPs were recorded. When tested, infants looked longer to the novel dogs than to the novel cats, suggesting they treated the within-category images (the novel cats) as more similar to the images from familiarization, despite the fact that all images were novel.

The ERPs to the pictures of cats and dogs also suggested that infants were sensitive to category information. In particular, the ERPs to the cats viewed early on during familiarization, as well as to the set of novel dog images, showed a negative slow wave (or a negative deflection of the ERP wave) between 1 and 1.5 s after the picture appeared. The decrease of these components to cats during the latter part of familiarization indicates that infants were beginning to respond to novel cats as though they were familiar. In other words, infants were responding to category-level information, not just item-level features. In addition, the dog pictures, but not the novel cat pictures, elicited a negative central component between 300 and 750, a component thought to reflect attentional allocation to novel stimuli in infants (Nelson, 1994). Quinn et al. suggest that this component may be related to the behavioral differences in looking to the dog and cat pictures, specifically the novelty preference for pictures of dogs observed after infants have been viewing only pictures of cats. Noting that the negative slow wave indexing categorization occurs after the component reflecting novelty detection, they suggest that recognizing similarity between within-category objects is a more complex process than recognition of novelty.

Using a similar procedure, Grossmann et al. (2009) also investigated the ERP signatures involved in infant categorization. The ERP recordings revealed a negative component at 300–500 ms in anterior cortical regions when infants were shown an image from a novel category, similar to the findings of Quinn et al. (2006). Grossmann et al. (2009) also found that novel exemplars of the familiarized category evoked a late positive component relative to the response to repeated items from the category. The authors suggest that this component may reflect updating of the category representation.

In sum, infants can track correlated properties of elements by the time they are 4 months of age. This ability plays a role in object perception, both in object segmentation and categorization, as well as in forming grammatical categories in the auditory domain. The data from the ERP recordings add to our understanding of the behavioral findings by showing real-time learning, helping to isolate different aspects of the process (responding to familiarity, novelty, and memory updating), and by shedding light on the neural processes underlying discrimination observed at test. In future studies, it will be important to test the neural correlates of learning novel categories, as current evidence pertains to categories that infants are familiar with prior to the experiment. In addition, it will be interesting to test whether there are parallels between the neural correlates observed in the visual domain and in grammatical category formation, as well as whether the signatures of category learning differ from those of learning sequential structure.

13.4 LEARNING ASSOCIATIONS BETWEEN WORDS AND REFERENTS

A central problem facing infant language learners is that of forming associations between words and their referents. One possibility is that this process begins no differently than the process of learning correlated object properties, as described in the previous section. Indeed, one might think of a label as simply another feature that is shared by objects within a category (Sloutsky and Robinson, 2008). Others have suggested that words are not simply a feature like any other but that they have a privileged role because they are inherently symbolic (Waxman and Gelman, 2009). On this view, words have a different relation to objects than do other features of objects, such as their appearance, from the very beginning of word learning. In either case, it is clear that learning the associations between words and their referents is a highly complex process, requiring a powerful but selective associative learning mechanism. Even the occurrence of a word with a very concrete and observable meaning, such as 'rabbit,' will coincide with many objects and events in the environment, sometimes, but not always, including an actual rabbit (e.g., Quine, 1960). Thus, establishing the referent of a novel word poses a formidable challenge. Even if the infant is fixating on a rabbit, she still must determine that the label refers to the animal itself, as opposed to its floppy ears, or to its color. Thus, the challenge facing the infant is to form an association between the word and some aspect of the environment that contains the referent, but that is neither overly broad nor too narrow.

While the demands of learning words are substantial, recent research suggests that infants' ability to form associations is both remarkably powerful and highly selective. Infants' sensitivity to the reliability of co-occurrence relationships between words and particular aspects of the environment may facilitate learning in such complex environments. Smith and Yu (2008) tested whether infants in the early stages of word learning can capitalize on these relationships using a cross-situational learning paradigm. They presented 12- and 14-month-old infants with six words whose referents were embedded in complex scenes. On each trial, infants heard a label (e.g., 'bosa') while viewing a scene consisting of the referent along with a distractor object. Given just a single trial of this nature, infants would be unable to determine which object was the referent. However, on other trials in which 'bosa' was presented, one of the same objects was presented along with a *different* distractor. On other trials, the label 'manu' was presented, and the object that

consistently occurred with it served as a distractor on other trials. Thus across trials, each label consistently occurred with one object. After infants were familiarized with the label–object training trials, they were tested using a preferential looking procedure. On each trial, infants were shown two objects simultaneously while the label for one of them was repeated. Infants looked significantly longer toward the object that matched the label at both ages, with stronger effects for the 14-month-olds than for the 12-month-olds.

These findings suggest that infants are sensitive to the reliability of label–object pairings across occurrences and can use information gathered across trials to settle on the most probable referent. However, it is important to note that words often occur in the absence of their referent and vice versa. Voloumanos and Werker (2009) thus tested whether infants learn label–object associations under more stochastic conditions. They presented 18-month-old infants with three word–object pairings, with each object labeled 10 times. One of the objects was labeled by the same word all 10 times, but the other two objects were labeled stochastically: most of the time, they occurred with one label (8 times), but on two occurrences, they were paired with a label that occurred predominantly with the other object. Infants were then tested on how well they learned the associations using a preferential looking task. The results suggest that infants were able to find the referent of words labeled stochastically: performance for word labeled 10 times or 8 times was the same when the correct referent was paired with a distractor object that had never occurred with the label. However, when a word labeled 8 times was tested with the correct referent (the object it had co-occurred with 8 times) paired with a distractor object that it had co-occurred with 2 times, infants' performance was at chance. Thus, experiencing the distractor object paired with the label just twice over the course of training disrupted recognition of the more frequent word/object pairing. Together, these findings suggest that probabilistic co-occurrences between labels and objects are harder for infants to learn than deterministic pairings, but that infants nonetheless develop some sensitivity to the association.

Recent work has shed light on the neurophysiological correlates of detecting reliable word–object associations during infancy. Friedrich and Friederici (2008) recorded ERPs while 14-month-olds were presented with two novel nonsense words, each occurring 8 times. One word was always presented with the same novel object (consistent referent), while the other was presented with a new object on each occurrence (inconsistent referent). After the first four exposures to each word, they found an early fronto-laterally localized negative component (N200-500) that was greater for the word with a consistent referent than for the word that had inconsistent

referents. Over the course of the second set of four exposures, this component diminished, and the words with consistent referents began to evoke an N400 in parietal regions. Infants were also tested on their memory for the consistent pairings 24 h later. On these trials, those words were paired with either the correct or incorrect referent. A larger N400 was observed when the words were presented with an incorrect referent.

The authors suggest that the N200-500 reflects early-occurring associative processes that begin to link together the auditory and visual features of the consistent events, and that the N400 reflects semantic integration: a stronger encoding of and memory for the word-referent relation. This interpretation is consistent with the finding that when 14-month-olds are presented with familiar words from their own language, there is a larger N400 to words presented with incongruous labels than congruous ones (Friedrich and Friederici, 2005). Taken together, these findings suggest that infants are sensitive to consistent co-occurrence relationships between words and objects, and that distinctive neural processes may underlie the formation of these referential associations.

13.4.1 Sensitivity to the Statistics of Objects Taking the Same Label

Another way infants' associations become more refined is in terms of the kinds of referents they associate with novel words. While infants are initially flexible in the kinds of referents they consider, recent studies suggest that this process rapidly becomes constrained by prior learning. Smith and colleagues (Colunga and Smith, 2003, 2005; Jones and Smith, 2002; Smith et al., 2002) suggest while learning novel words may initially require repeated associations between objects and labels, once a critical mass of labels has been acquired, they detect statistical regularities that characterize those associations. For example, object labels such as '*cup*,' '*ball*,' and '*phone*' refer to a set of objects that have a common shape, and many of the words in children's early vocabularies are objects that are organized by shape (Samuelson and Smith, 1999). However, as children learn more words, a higher-order abstraction emerges from these specific associations: object labels tend to pick out groups of things with similar shapes. Such a generalization would allow children to extend object labels on the basis of shape as opposed to other features, such as color or texture. As a result, upon hearing the label '*crayon*' referring to a red crayon, they can use it to refer to new crayon-shaped objects regardless of their color.

Based on these considerations, Smith et al. (2002) hypothesized that teaching children words from shape-based categories should result in increased word learning. They tested this hypothesis by bringing

17-month-old infants, who do not yet show a systematic shape bias, into the lab several times over 2 months, and teaching them names for novel objects. In one condition, the object categories were shape based: objects given the same names had similar shapes. In a control condition, objects that shared names did not have shape in common, but rather had some other property, such as their material, in common. Infants taught shape-based categories extended trained words to novel items based on shape, while infants in the nonshape-based conditions, or given no training, did not. Moreover, infants in the shape-based category training rapidly extended novel labels based on shape as well and showed a greater increase in their overall vocabularies over the 2-month training period than infants in the other conditions. These findings suggest that infants' experience with well-structured label–object pairings facilitates the rapid formation of new label–object associations, and the appropriate extension of those labels. Critically, this process results in rapid gains in vocabulary size and word-learning skill.

Just as increases in vocabulary size lead to more efficient word learning (Smith et al., 2002), the neurophysiological processes underlying word learning also appear to change as infants' vocabulary size increases. Torkildsen et al. (2008b) investigated the ERP signatures of 20-month-old infants in a novel word-learning task as a function of whether infants had fewer or more than 75 words in their productive vocabularies, a period that typically precedes a period of rapid vocabulary growth. In this task, infants were exposed to training blocks in which they viewed three familiar pictures, each labeled by the correct referent. They also saw three pictures of imaginary animals, each paired with a nonsense word. After each word had been presented with its referent five times, the pictures were presented with incongruous labels. All infants showed a larger N400 to the pairings of real words with incongruous objects at central and parietal recording sites, suggesting that the infants recognized the mismatch between label and referent. For the newly trained words, only the high-vocabulary infants showed an N400 when they were paired with an incongruent referent. This suggests that the low-vocabulary infants either did not learn the words or were able to form only a very weak association. The high-vocabulary infants showed more robust evidence of learning the novel mappings, though the N400 response was more broadly distributed than for the familiar words, suggesting that their sensitivity to the novel words differed from that to more established word–referent pairings. Torkildsen et al. (2008a) also examined the ERPs during the five training trials. Consistent with the fact that only high-vocabulary infants showed an N400 indicative of successful learning at test, they found that only the high-vocabulary infants showed an increase in an early

negative component (N200-400) as the novel words repeated during training. This component has previously been associated with the early stages of learning the meaning of a word (see Friedrich and Friederici (2008)). While these findings do not suggest a neural mechanism by which infants narrow in on specific features as they gain skill in word learning, they do confirm that the process becomes more efficient as infants' vocabulary grows.

13.4.2 Sensitivity to the Internal Statistics of Labels in Word Learning

Additional constraints on the associations that infants are likely to form during word learning come from the properties of potential labels themselves. Graf Estes et al. (2007) tested the hypothesis that experience with statistical cues to word boundaries influences infants' ability to learn word–object pairings. In this study, 16-month-old infants were first familiarized with a stream of syllables in which the only cues to word boundaries were the TPs between adjacent syllables. Infants were then habituated to two label–object pairs. For some infants, the labels corresponded to the words (TP = 1.0), and for the other infants, the labels were equally frequent part-words (TP = 0.33) from the speech stream. After habituation to the label–object pairings, infants were tested using a Same-Switch procedure (Werker et al., 1998). The Same trials preserved the label–object pairings present during habituation, while the label–object pairings were switched on Switch trials. Learning is measured by the degree of increased looking to Switch trials, which is evidence of dishabituation. Only infants for whom the labels corresponded to words showed longer looking to the Switch trials, suggesting that learning words composed of syllables with high TPs is easier than learning labels that had internal statistics suggesting that the syllables did not cohere into a word. Likewise, Graf Estes et al. (2010) found that infants learn word–object associations better when the labels conform to the predominant phonotactic patterns of the native language. Experience with regularities in fluent speech may thus facilitate word learning by providing infants with candidate sound sequences to map to referents, and by promoting more accurate processing of those sound sequences, facilitating subsequent recall.

Data from ERP recordings in word-learning tasks also suggest that semantic processing is influenced by phonotactic information. As previously discussed, between 12 and 14 months of age, infants show a larger N400 when familiar words are presented with incongruous referents. Friedrich and Friederici (2005) found that both 12- and 19-month-old infants showed an early negative component that differed between real and

phonotactically legal nonsense words and phonotactically illegal nonsense words presented without referents, which likely reflects sensitivity to the relative familiarity of the words. At 19 months, infants also show an N400 response when novel words that are phonotactically legal in their language are presented with objects that have known labels, suggesting they recognize the label–object mismatch. However, phonotactically illegal words did not elicit an N400, suggesting that they may not have been perceived as potential labels. These findings are consistent with the hypothesis that the N400 response reflects an advance or change in word-learning skill, and specifically that phonotactic information plays an important role by the end of the second year.

Another potential source of information guiding word learning is the overlap between words' statistical and semantic properties at the level of grammatical categories. Words from different lexical categories are correlated with different semantic regularities (e.g., nouns tend to refer to objects and people, adjectives to properties such as color or texture, and verbs to actions or events). As previously discussed, words from different lexical categories can also be distinguished by a constellation of statistical cues, including distributional and phonological regularities (e.g., Christiansen et al., 2009; Kelly, 1992; Mintz et al., 2002; Monaghan et al., 2005).

A recent study tested whether infants can capitalize on experience with such cues in a word-learning task (Lany and Saffran, 2010). In this study, 22-month-old infants first listened to an artificial language that contained two word categories, disyllabic *X-words* and monosyllabic *Y-words*. For infants in the experimental group, phrases took the form *aX* and *bY*, and thus words from the *X* and *Y* categories were reliably marked by correlated distributional and phonological cues. Infants in the control group also heard *aX* and *bY* phrases, but in addition, they heard an equal number of *aY* and *bX* phrases. Thus, for the control infants, the word categories were not marked by correlated cues. Infants were then trained on pairings between phrases from the language and pictures of unfamiliar animals and vehicles. For both experimental and control groups, familiar *aX* phrases were paired with animal pictures, and familiar *bY* phrases were paired with vehicle pictures. Infants were then tested using a preferential looking procedure.

Interestingly, only the experimental infants were able to learn the trained associations between phrases and pictures, despite the fact that control infants had the same amount of experience with them. Moreover, only the experimental infants successfully generalized to novel pairings: when hearing a word with distributional and phonological properties of other words referring to animals, they mapped the word to a novel animal over a novel vehicle. These findings suggest that infants' experience with statistical cues marking word categories lays

an important foundation for learning the meanings of those words.

In sum, infants' ability to form associations is remarkably powerful, but it is also selective. Infants do not simply form an association between a word and object that happen to co-occur, but rather they form an association only when that object reliably occurs across other presentations of that word. And, while infants are initially relatively flexible in the kinds of associations they form between words and referents, recent studies suggest that this process rapidly becomes constrained by prior learning. For example, by 17 months of age, words with good sequential statistics are more readily associated with referents than sound sequences that do not have the characteristics of typical words in that language (Graf Estes et al., 2007). Moreover, once infants have begun to learn associations between words and referents, this knowledge influences the associations that infants will subsequently form. For example, infants rapidly begin to associate novel nouns with objects' shape over objects' color (e.g., Smith et al., 2002). Likewise, words that have statistical properties of a particular category are readily mapped to new referents from that category (Lany and Saffran, 2010).

13.5 CONCLUSIONS

The research reviewed in this chapter suggests that infants' sensitivity to statistical structure is powerful and nuanced and plays a role in diverse aspects of learning over the first several months of life. We have discussed infants' sensitivity to four different kinds of statistical structure: probability distributions, sequential structure, correlations between stimulus dimensions, and associations between different forms of information. While we have discussed these types of structure separately, these are likely not independent learning processes. For example, there are important similarities between learning sequential structure in word segmentation and in learning correlational structure in object segmentation. Tracking sequential structure within words may share important properties with learning sequential regularities between words and word categories. Likewise, the processes involved in learning word–label associations may be similar to those in learning feature co-occurrences in object categorization. Furthermore, real-world learning processes tap a combination of these learning mechanisms – for example, learning word–object associations critically relies on a complex interaction of sensitivity to phonotactic regularities, word segmentation, object categorization, word-order patterns, and grammatical categories.

A related point is that statistical learning mechanisms are tuned through experience. For example, in the

auditory domain, infants' sensitivity to reliable TPs between syllables facilitates segmenting words from fluent speech. In turn, this makes it possible to learn phonological regularities correlated with TPs, which may further facilitate segmentation in natural speech (Sahni et al., 2010). Likewise, segmentation facilitates learning word-order patterns, and tracking correlations between such distributional properties of words and their phonological properties can facilitate learning grammatical structure. In the domain of visual perception, tracking the co-occurrence of features may facilitate segmenting objects within complex scenes (Fiser and Aslin, 2002), and tracking how these features co-occur across instances facilitates the formation of object categories (Younger, 1985). In other words, as learners track simple structure, they build a foundation for tracking more complex, higher-order structure. They also appear to highlight relevant structure, which can facilitate learning more computationally challenging regularities (Lany and Gómez, 2008).

These studies also raise many intriguing questions for future research. For example, many studies manipulate the statistical properties of infants' input and show that this influences learning, but this does not suggest that infants are tracking input statistics veridically. Indeed, studies with older children suggest that they, unlike adults, tend to distort input statistics, maximizing probabilities rather than matching them (e.g., Hudson Kam and Newport, 2005). It also leads to questions of how infants encode these statistical regularities and how fine-grained their sensitivity is. Also, learning inherently entails perceiving, remembering, acting on the environment, and interacting with others, and thus in future research, it will be important to relate infants' statistical learning abilities to other developmental processes, such as perception, memory, and social interaction.

Another important area for future research is the underlying neurophysiology of statistical learning. Researchers have just begun to investigate the neurophysiological substrates of the behavioral findings, namely, how ERPs to stimuli consistent with familiarized patterns differ from ERPs to stimuli that are inconsistent. Given the challenges inherent in ERP research in infants, much of this work has tested learning in adults. However, recent advances in neurophysiological methodology in infants suggest that these techniques hold much promise for investigating learning mechanisms directly. Indeed, while the discrimination tasks typically used in infant behavioral studies can only probe the endpoint (or other static snapshot) of the learning process, psychophysiological techniques are particularly well suited to observing the process of learning.

In sum, infants' environments are rich with meaningful statistical structure, and infants readily track it. Far from being limited to simple associative learning, such as the stimulus–response learning of classical learning theory, the studies reviewed in this chapter reveal a sensitivity to statistical structure that is powerful and nuanced, capable of not only tracking fine-grained detail but also forming generalizations. Advances in the study of statistical learning mechanisms have shed new light on many aspects of development, such as auditory and visual perception, language development, and event processing. Continued study of infants' statistical learning mechanisms holds great promise for advancing the study of early cognitive development.

CHAPTER

14

Development of the Visual System

S.P. Johnson

University of California, Los Angeles, CA, USA

OUTLINE

The purpose of vision is to obtain information about the surrounding environment so that we may plan appropriate actions. Consider, for example, a stroll on the beach vs. a hike in the Grand Canyon (Figure 14.1). Both activities involve locomotion, but each places very different demands on the perceptual and action systems, including the visual system. In the case of the stroll, the beach is wide, there are few obstacles and little risk. In the case of the hike, in contrast, the path is narrow; rocks, vegetation, and abrupt precipices must be avoided. To remain safe, the hiker must know what the risks are, and this invariably involves knowing what objects there are in the visual scene. The importance of accurate perception of our surroundings is attested by the allotment of cortical tissue devoted to vision: By some estimates,

over 50% of the cortex of the macaque monkey (a phylogenetically close cousin to *Homo sapiens*) is involved in visual perception, and there are perhaps 30 distinct cortical areas that participate in visual or visuomotor processing (Felleman and Van Essen, 1991; Van Essen et al., 1992).

This chapter reviews theory and data concerning development of the human visual system with an emphasis on object perception. As will be seen, infants are prepared to see objects and understand many of their properties (e.g., permanence, coherence) well in advance of locomotion, so that by the time infants begin to crawl and walk, they have a good sense of what and where obstacles might be, even if the hazards these objects pose remain unknown.

FIGURE 14.1   Two visual scenes.

There is much else to learn. Visual scenes, for example, tend to be very complex: a multitude of overlapping and adjacent surfaces with distinct shapes, colors, textures, and depths relative to the observer. Yet our visual experience as adults is not one of incomplete fragments of surfaces, but instead one of objects, most of which have a shape that can be inferred from partial views and incomplete information. Is the infant's visual system sufficiently functional and organized to make sense of the world from the onset of visual experience at birth, able to bind shapes, colors, and textures into coherent forms, and to perceive objects as regular and predictable and complete across space and time? Or does the infant's visual system require a period of maturation and experience within which to observe and learn about the world?

These 'nature versus nurture' questions begin to lose their steam when the details of visual development are examined and explained, because visual development stems from growth, maturation, and experience from learning and from action; all happen simultaneously and all influence one another. Infants free of disability or developmental delay are born with a functional visual system that is prepared to contribute in important ways to learning, but incapable of perceiving objects in an adult-like fashion. Developmental processes that lead to mature perception and interpretation of the visual world as coherent, stable, and predictable are an area of active investigation and are only beginning to be understood.

14.1 CLASSIC THEORETICAL ACCOUNTS

Discussions of the nature versus nurture of cognitive development are entrenched and persistent. Such discussions are particularly vigorous when concerning infant cognition and have tended to be long on rhetoric but short on evidence, in part because the evidence has been, until recently, relatively sparse. Research on visual development, in contrast, has tended to focus on developmental changes in neural mechanisms, with much of the evidence coming from animal models (Kiorpes and Movshon, 2004; Teller and Movhson, 1986). Research on human infants' visual development has often been motivated by two theoretical accounts, each of which considers seriously both the starting point for postnatal development and the mechanisms of change that yield stable, mature object perception: Piagetian theory and Gestalt theory.

14.1.1 Piagetian Theory

The first systematic study of infants' perception and knowledge of objects was conducted by Jean Piaget in the 1920s and 1930s (Piaget, 1952/1936, 1954/1937). According to Piaget, knowledge of objects and space developed in parallel, and were interdependent: One cannot perceive or act on objects accurately without awareness of their position in space relative to other objects and to the observer. Knowledge of the self and of external objects as distinct, coherent, and permanent entities grew from active manual search, initiated by the child. When the child experiences her own movements, she comes to understand them as movements of objects through space and applies the same knowledge to movements of other objects.

Initially, prior to any manual action experience, infants understand the world as a 'sensory tableaux' in which images shift unpredictably and lack permanence or substance; in an important sense, the world of objects that we take for granted does not yet exist. Active search behavior emerges only after 4 months and marks the beginnings of 'true' object knowledge. Over the next few months, infants reveal this knowledge, for example, by following the trajectory of thrown or dropped objects, and by retrieval of a desired object from under a cover

where it had been seen previously. Later in infancy, infants are able to search accurately for objects even when there are multiple potential hiding places, marking the advent of full 'object permanence.'

Piaget placed more emphasis on the importance of manual search for developmental changes in object perception than visual skills, yet the lessons from his theory for questions of development of the visual system could not be more relevant. Upon the infant's first exposure to patterned visual input, he does not inhabit a world of objects, but rather a world of disconnected images devoid of depth, coherence, and permanence. Building coherent things from these disconnected images comes from action and experience with objects over time.

14.1.2 Gestalt Theory

Piagetian theory can be contrasted with a coeval, competing account. The Gestalt psychologists, unlike Piaget, were not strictly developmentalists, but they did have much to say about how visual experience might be structured in the immature visual system. They suggested that subjective experience corresponds to the simplest and most regular interpretation of a particular visual array in accord with a general 'minimum principle,' or Prägnanz (Koffka, 1935). The relatively basic shapes of most objects are more coherent, regular, and simple than disconnected and disorganized forms. The minimum principle and Prägnanz were thought to be rooted in the tendency of neural activity toward minimum work and minimum energy, which impel the visual system toward simplicity (Koffka, 1935).

The minimum principle is a predisposition inherent in the visual system, and so it follows that young infants should experience the visual environment as do adults. In one of the few sections of Gestalt writings to focus on development, a 'primitive mentality' was attributed to the human infant (Koffka, 1959/1928; Köhler, 1947), implying that one's perceptual experience is never one of disorganized chaos, no matter what one's position in the lifespan. Hebb (1949) noted, in addition, the neonate's electroencephalogram was organized and somewhat predictable, perhaps reflecting organized sensory systems at birth and serving as a stable foundation for subsequent perceptual development. Gibson (1950) suggested that visual experience begins with 'embryonic meanings,' a position echoed by Zuckerman and Rock (1957), who argued that an organized world could not arise from experience in the form of memory for previously encountered scenes and objects, because experience cannot operate in an organized fashion over inherently disorganized inputs. Necessarily, therefore, the starting point of visual organization is inherently organized. Like Piaget, Gestalt psychologists proposed that development of object perception *per se* involved active manual exploration, which imparts additional information about specific object kinds (Koffka, 1959), but the starting point for visual experience is necessarily quite different on the two accounts. On the Gestalt view, perceptual organization precedes object knowledge; on the Piagetian view, object knowledge and perceptual organization develop in tandem.

Piagetian and Gestalt accounts specify a starting point for postnatal development, and each has particular views about how development of the infant's visual world might proceed. Neither account is wholly on one side of the nature–nurture issue, and both accounts have offered testable predictions that have guided subsequent research, and as will be seen later in this chapter, both accounts have influenced important research on object perception in infants. Yet neither can be taken as complete, in part because neither took a sufficiently comprehensive approach to vision. A quote from Gibson (1979) helps explain why this is so: The visual system comprises "the eyes in the head on a body supported by the ground, the brain being only the central organ of a complete visual system. When no constraints are put on the visual system, we look around, walk up to something interesting and move around it so as to see it from all sides, and go from one vista to another" (p. 1). Vision is not passive, even in infancy; at no point in development are infants simply inactive recipients of visual stimulation. Instead, they are active perceivers, and active participants in their own development, from the beginning of postnatal life (von Hofsten, 2004). Young infants do not have all the action systems implied by Gibson's quote at their disposal, but eye movements are a notable exception, and as will be seen in a later section, there are strong reasons to suspect a critical role for oculomotor behavior in cognitive development.

14.2 PRENATAL DEVELOPMENT OF THE VISUAL SYSTEM

The mammalian visual system, like other sensory and cortical systems, begins to take shape early in prenatal development. For example, in humans, the retina starts to form around 40 days postconception and is thought to have a relatively complete set of cells by 160 days, though the growth of individual cells and their lattice-like organization characteristic of mature structure continue to develop well past birth (Finlay et al., 2003). The distinction between foveal and extrafoveal regions (viz., what will become thalamus and cortex) is present early; like the retina, the topology and patterning of receptors and neurons continue to change throughout prenatal development and the first year after birth. Foveal receptors

are overrepresented in the cortical visual system, and detailed information about different parts of the scene is enabled by moving the eyes to different points (see Section 14.4.3). The musculature responsible for eye movements develops before birth in humans, as do subcortical systems (e.g., superior colliculus and brainstem) to control these muscles (Johnson, 2001; Prechtl, 2001).

Many developmental mechanisms are common across mammalian species, including humans, though the timing of developmental events varies (Clancy et al., 2000; Finlay and Darlington, 1995). Data from humans are sparse, but the few cases where deceased embryos and fetuses are available demonstrate that many major structures (neurons, areas, and layers) in visual cortical and subcortical areas are in place by the end of the second trimester *in utero* (e.g., Zilles et al., 1986). Later developments consist of the physical growth of neurons and the proliferation and pruning of synapses, which is, in part, activity dependent (Greenough et al., 1987; Huttenlocher et al., 1986).

14.2.1 Development of Structure in the Visual System

The visual system consists of a richly interconnected yet functionally segregated network of areas specializing in processing different aspects of visual scenes and visually guided behavior: contours, motion, luminance, color, objects, faces, approach versus avoidance, and so forth. Areal patterns are present in a rudimentary form during the first trimester, but the final forms continue to take shape well after birth; like synaptic pruning, developmental processes are partly the result of experience. Some kinds of experience are intrinsic to the visual system, as opposed to outside stimulation. Spontaneous prenatal activity in visual pathways contributes to retinotopic mapping (Sperry, 1963) and the preservation of sensory structure, beginning in the retina and extending through the thalamus, primary visual cortex, and higher visual areas. Waves of coordinated, spontaneous firing of retinal cells have been observed in chicks and ferrets (Wong, 1999). Waves travel across the retinal surface and are then systematically propagated through to the higher areas. This might be one way by which correlated inputs remain coupled and dissimilar inputs become dissociated, prior to exposure to light.

As soon as neurons are formed, find their place in cortex, and grow, they begin to connect to other neurons. There is a surge in synaptogenesis in visual areas around the time of birth and then a more protracted period in which synapses are eliminated, reaching adult-like levels at puberty (Bourgeois et al., 2000). This process is activity dependent: Synapses are preserved in active cortical circuits and lost in inactive circuits. Auditory cortex, in contrast, experiences a synaptogenesis surge several months earlier, which corresponds to its earlier functionality relative to visual cortex (viz., prenatally). Here, too, pruning of synapses extends across the next several years. (In other cortical areas, such as frontal cortex, there is a more gradual accrual of synapses without extensive pruning.) For the visual system, the addition and elimination of synapses, the onset of which coincides with the start of visual experience, provides an important mechanism by which the cortex tunes itself to environmental demands and the structure of sensory input.

14.3 VISUAL PERCEPTION IN THE NEWBORN

Human infants are born with a functional visual system. The eye of the newborn is sensitive to light, and if motivated (i.e., awake and alert), the baby may react to visual stimulation with head and eye movements. Vision is relatively poor, however: acuity (detection of fine detail), contrast sensitivity (detection of different shades of luminance), color sensitivity, and sensitivity to direction of motion all undergo improvements after birth (Banks and Salapatek, 1983). The field of view is also relatively small, so that newborns often fail to detect targets too distant or too far in the periphery. In addition, as far as we know, neonates lack stereopsis, perception of depth from binocular disparity (differences in the input to the two eyes). Maturation of the eye and cortical structures (see previous section) supports developments in these visual functions, and learning plays an important role as well, as discussed in greater detail in Section 14.5.

14.3.1 Visual Organization at Birth

Testing newborn infants is not for the faint of heart. Success is entirely dependent on the baby's mood; this is at its most capricious early in postnatal life, and there is no predicting neonate behavior. Having said this, a number of patient scientists have conducted careful experiments with neonates; these experiments have revealed that despite relatively poor vision, neonates actively scan the visual environment. Early studies, summarized by Haith (1980), revealed systematic oculomotor behaviors that provided clear evidence of visual organization at birth. Newborns, for example, will search for patterned visual stimulation, tending to scan broadly until encountering an edge, at which point scanning narrows so that the edge can be explored. Such behaviors are clearly adaptive for investigating and learning about the visual world.

In addition, newborn infants show consistent visual preferences. Fantz (1961) presented newborns with pairs of pictures and other two-dimensional (2D) patterns and recorded member of the pair which attracted the infant's visual attention, which he scored as proportion of fixation times per exposure. Infants typically showed longer looking at one member of the pair: bull's-eyes versus stripes, or checkerboards versus solid forms, for example. Visual preferences have served as a method of choice ever since, in older infants as well as neonates. Slater (1995) described a number of newborns' preferences: patterned versus unpatterned stimuli, curvature versus rectilinear patterns, moving versus static patterns, 2D versus 3D forms, and high- versus low-contrast patterns, among others. In addition, perhaps due to the relatively poor visual acuity of the newborn visual system, there is a preference for 'global' form versus 'local' detail in newborns (Macchi Cassia et al., 2002).

14.3.2 Visual Behaviors at Birth

Fantz (1964) reported that repeated exposure to a single stimulus led to a decline of visual attention, and increased attention to a new stimulus, in 2- to 6-month-olds. A substantial number of subsequent investigations examined infants' preferences for familiar and novel stimuli as a function of increasing exposure, and these in turn led to standardized methods for testing infant perception and cognition, such as habituation paradigms (Cohen, 1976), as well as a deeper understanding of infants' information processing (Aslin, 2007; Hunter and Ames, 1989; Sirois and Mareschal, 2002).

Neonates (and older infants) will habituate to repeated presentations of a single stimulus; habituation is operationalized as a decrement of visual attention across multiple exposures according to a predetermined criterion. Following habituation, infants generally show preferences for novel versus familiar stimuli, implying both discrimination of novel and familiar stimuli and memory for the stimulus shown during habituation. Neonates and older infants also recognize visual constancies or invariants, the identification of common features of a stimulus across some transformation, for instance, shape, size, slant, and form (Slater et al., 1983). Recognition of invariants forms the basis for categorization.

14.3.3 Faces and Objects

Newborns prefer faces and face-like forms relative to other visual stimuli and are thus well prepared to begin engaging in social interactions with conspecifics. Some have speculated that there is an innate representation

Stimuli	Total fixation time	Number of discrete looks
	53.86 s vs. 37.62 s $p < 0.03$	10 vs. 8.09 $p < 0.05$
	34.70 s vs. 41.08 s $p > 0.20$	7.6 vs. 8.3 $p > 0.30$
	44.15 s vs. 22.89 s $p < 0.003$	10.43 vs. 6.5 $p < 0.01$

FIGURE 14.2 Face-like stimuli from experiments on neonates' preferences. *Reproduced from Turati C, Simion F, Milani I, and Umiltà C (2002) Newborns' preference for faces: What is crucial? Developmental Psychology 38: 875–882.*

for facial structure (Morton and Johnson, 1991); others have suggested that the preference stems from general-purpose visual biases that guide attention toward stimuli of a particular spatial frequency, with a prevalence of stimulus elements in the top portion, as seen in Figure 14.2 (Turati et al., 2002; Valenza et al., 1996).

Newborns' object perception is not so precocious. Neonates perceive segregation of figure and ground (i.e., seeing objects as distinct from backgrounds), but there are limits in the ability to perceive object occlusion, as seen in Figure 14.3(a). Adults and older infants perceive this display as consisting of two objects, one moving back and forth behind the other (Kellman and Spelke, 1983). Neonates, however, seem to perceive this display as consisting of three disconnected parts (Slater et al., 1990). In these experiments, infants were habituated with the partly occluded rod display, followed by two test displays. One test display (Figure 14.3(b)) consisted of the whole rod (no occluder), and the other consisted of two rod parts, separated by a gap in the space where the occluder was seen, corresponding to the visible rod portions in the habituation stimulus (Figure 14.3(c)). For 4-month-olds, longer looking at the broken rod is taken as evidence that they perceived unity of the rod parts as unified behind the box, but for neonates longer looking at the complete rod implies perception of disjoint surfaces in similar displays. The developmental processes underlying this shift in perceptual abilities are discussed in Section 14.5.1. See also Chapters 18 and 19.
FIGURE 14.3 Rod-and-box displays from experiments on infants' perception of partly occluded objects: (a) habituation stimulus and (b and c) test stimuli.

14.4 POSTNATAL VISUAL DEVELOPMENT

As noted in Section 14.2, visual development begins prenatally; in this section, some of the ways in which it continues after birth are described. Both infants and adults scan visual scenes actively – on the order of 2–4 eye movements per second in general (Johnson et al., 2004; Melcher and Kowler, 2001) – but visual function is relatively poor at birth in terms of processing and analyzing visual information. Functional visual development has been explained in terms of visual maturation (Atkinson, 2000; Johnson, 1990, 2005). Acuity, for example, improves in infancy with a number of developments, all taking place in parallel: migration of receptor cells in the retina toward the center of the eye, elongation of the receptors to catch more incoming light, growth of the eyeball to augment the resolving power of the lens, myelination of the optic nerve and cortical neurons, and synaptogenesis and pruning. See also Chapter 12.

14.4.1 Visual Physiology

The visual system, like the rest of the brain, is organized modularly and hierarchically. Incoming light is transduced into neural signals by the retina, which passes information to the lateral geniculate nucleus (part of the thalamus), and then to primary visual area (V1) in cortex and higher visual areas. Successively higher visual areas code for visual attributes in larger portions of visual field and participate in more complex visual functions (see Figure 14.4). For example, visual pathways extending from V5 (also known as area MT, or medial temporal) through parietal cortex are largely responsible for coding motion. Infants younger than 2 months appear unable to discriminate different directions of motion until maturation of pathways extending to and originating in V5 (Johnson, 1990). For motion

processing, therefore, development centers on a limited number of visual areas and a relatively small number of mechanisms (e.g., myelination, synaptic growth, and pruning). Object perception, in contrast, is far more complex, involving many areas, each of which is responsible for processing one or more of the many visual attributes that defines edges, surfaces, and objects.

14.4.2 Critical Periods

A critical period refers to a time in an individual's ontogeny when some function or ability must be stimulated or it will be lost permanently (see Daw, 1995). This notion can be contrasted with a sensitive period, similar in concept but generally referring to scenarios in which effects of deprivation are not so severe. The formal study of critical periods was initiated by Wiesel and Hubel (1963), who covered or sutured one eye in kittens from birth for a period of 1–4 months and examined the effects of visual deprivation by patching the unaffected eye and observing visual function of the affected eye alone. The deprived eye was effectively blind, as revealed by both behavioral and neural effects. Behavioral effects included an inability to navigate visually or respond to objects introduced by the experimenters, though the animals behaved normally under these circumstances when permitted to use the unaffected eye. Neural effects were examined by recording from single cells in visual cortex; in general, few cortical cells could be driven by the deprived eye in cortical regions normally responsive to input from both eyes, such as the postlateral gyrus. Wiesel and Hubel also reported the effects of eye closure in animals that were allowed some visual experience prior to deprivation, highlighting the distinction between critical and sensitive periods. The unaffected eye dominated activity of cells in the visual cortex but depended on both the extent of visual experience prior to deprivation and the duration of deprivation.

Stereopsis, the detection of distance differences in near space (e.g., threading a needle), seems to emerge
FIGURE 14.4 Cortical areas in the macaque monkey showing an outer view of the left hemisphere (upper left) and a flattened representation of sensory and motor regions. Visual areas are depicted in red, orange, and yellow. PS, prestriate area; VIP, ventral intraparietal area; MST, medial superior temporal area; POa, parieto-occipital area; IT, inferotemporal area; VP, ventral posterior area. *Reproduced from Van Essen DC and Maunsell JHR (1983) Hierarchical organization and the functional streams in the visual cortex.* Trends in Neurosciences *6: 370–375.*

during a critical period. Stereopsis relies on slight differences in the inputs to the two eyes when they are directed to the same point, also known as disparity. Cells in the primary visual cortex are organized into 'ocular dominance' columns that receive inputs from the two eyes and register the amount of disparity between them. These require binocular function early in life – the two eyes must be directed consistently at the same points and focus on them. This can be disrupted by amblyopia (poor vision in one eye) or strabismus (misalignment of the eyes). Normally, mature visual cortex contains cells responsive to both eyes, and a few to only one eye. Abnormal visual experience can produce a preponderance of cells responsive to only one or the other eye, but not to both. In typically developing infants, stereopsis emerges at about 4 months, as inputs from the two eyes into the ocular dominance columns become segregated (Held, 1985). (Prior to this time, the inputs are more likely to be superimposed, which may result in frequent diplopia, or double vision, early in life.) The critical period for development of stereopsis in humans is estimated to be 1–3 years (Banks et al., 1975).

14.4.3 Development of Visual Attention

Visual attention – eye movements – is a combination of saccades and fixations. During a saccade, the point of movements sweeps rapidly across the scene, and during a fixation, the point of gaze is stationary. Analysis of the scene is performed during fixations. Eye movements can also be smooth rather than saccadic, as when the head translates or rotates as the point of gaze remains stabilized on a single point in space (the eyes move to compensate for head movement), or when following a moving target.

Visual attention in infancy has attracted a great deal of interest, because it is a behavior that is relatively mature, even at birth, and because it is relatively easy to observe (Johnson, 2005; Richards, 1998). Oculomotor behaviors that have been examined include detection of targets in the periphery, saccade planning, oculomotor anticipations, sustained versus transient attention, effects of spatial cuing, and eye/head movement integration; other tasks examined inhibition of eye movements, such as disengagement of attention, inhibition of return, and spatial negative priming. Bronson (1990, 1994) examined

scanning patterns as infants viewed simple geometric forms, and reported changes with development in attention to distributed visual features, including a greater tendency to scan between features, to direct saccades with greater accuracy, and in general to engage in more 'volitional' scanning, starting at 2–3 months.

There are important developments also in viewing complex scenes. In my lab, we recently recorded eye movements of infants and adults as they watched segments of an animated cartoon, *A Charlie Brown Christmas*, that was rich in social content (Frank et al., 2009). Three-month-olds' attention was captured most by low-level image salience (variations in color, luminance, and motion), and by 9 months, there was a stronger focusing of attention on faces. There were no reliable differences between age groups in measures such as mean saccade distance and fixation duration. One interpretation of these results is a developmental transition toward attentional capture by semantic content – the 'meaning' inherent in social stimuli. See also Chapter 22.

14.4.4 Cortical Maturation and Oculomotor Development

Gaze control in mature primates is accomplished with a coordinated system of both subcortical and cortical brain areas, as seen in Figure 14.5. Control of eye movements originates in areas with outputs that are connected to the brainstem, which sends signals to the oculomotor musculature. Development of visual attention has often been interpreted as revealing development of cortical systems that control it. Visual attention has been suggested to be largely under subcortical control until the first few months after birth, after which there is increasing cortical control (Atkinson, 1984; Colombo, 2001; Johnson, 1990).
FIGURE 14.5 Subcortical and cortical structures involved in oculomotor control. FEF, frontal eye fields; MEF, medial eye fields. *Reproduced from Schiller and Tehovnik (2001).*

For example, oculomotor smooth pursuit and perception of motion direction have been proposed to rely on a common cortical region, area V5, and their development of these visual functions in infancy has been tied to maturation of V5, as noted previously (Johnson, 1990). Smooth pursuit is maintenance of gaze on a moving target with nonsaccadic, eye movements; motion direction perception is often tested with random-dot displays to control for the possibility that motion following is not simply a detection of change in position. Perceiving motion and performing the computations involved in programming eye movements to follow motion are thought to be founded on the same cortical structures (Thier and Ilg, 2005). This suggestion was tested empirically by Johnson et al. (2008), who observed infants between 58 and 97 days of age in both a smooth pursuit (Figure 14.6, top panel) and a motion direction discrimination task (Figure 14.6, center panel). Individual differences in performance on the two tasks were strongly correlated and were also positively correlated with age (Figure 14.6, bottom panel), consistent with the maturation theory. Other visual functions in infancy that have been linked to cortical maturation include development of form and motion perception, stemming from maturation of parvocellular and magnocellular processing streams, respectively (Atkinson, 2000), and development of visual memory for object features and object locations, stemming from maturation of ventral and dorsal processing streams (Mareschal and Johnson, 2003).

14.4.5 Development of Visual Memory

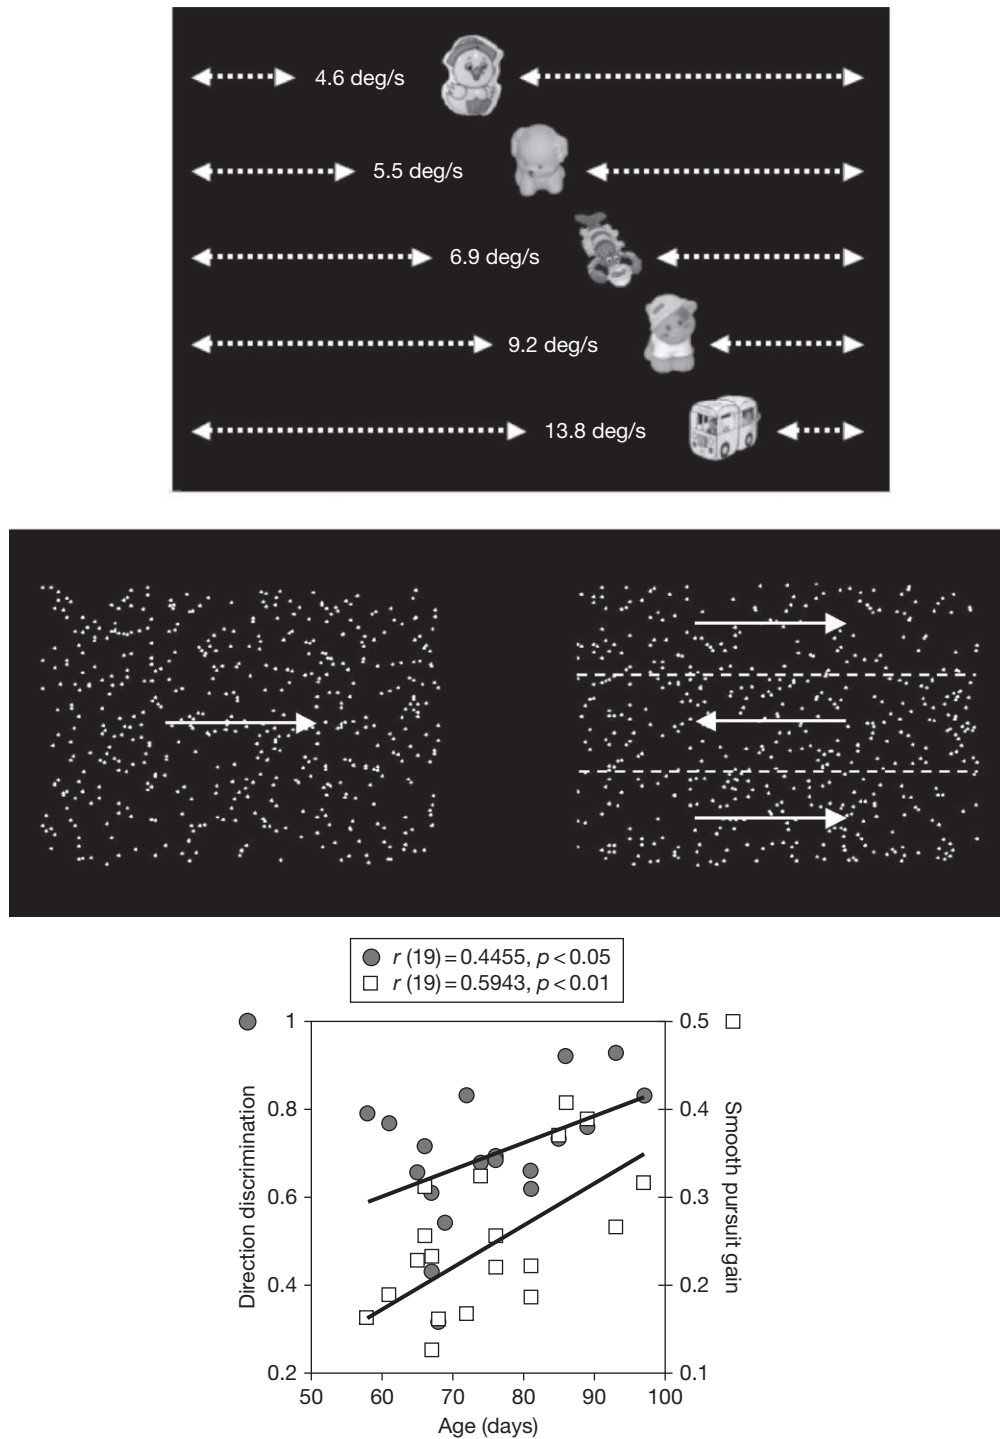
Memory for events, object features, and locations improves over the first several postnatal months (Rose et al., 2004). As noted previously, newborns will habituate to repeated presentations of a visual stimulus and recover interest to a novel one, clear evidence for a functional short-term visual memory store available at birth. Visual short-term memory in older infants has been examined with a 'change-detection' task in which infants viewed a pair of displays side by side, each of which contained one or more shapes. On one side, the object or objects underwent color changes every 250 ms (Ross-Sheehy et al., 2003). When there was one object per side, 4-month-olds looked longer toward the side with color changes, implying a short-term store of the color information across the 250-ms temporal gap. Visual short-term memory develops rapidly: 10-month-olds retained color information across a set size of four, all different colors (Ross-Sheehy et al., 2003), and 7.5-month-olds retained information about color-location combinations (set size of three) across a 300-ms delay (Oakes et al., 2006).


FIGURE 14.6 Top: schematic depiction of stimuli used to examine smooth pursuit in young infants. A toy moved laterally at one of five speeds in one of five vertical positions on the screen. Only one toy was shown at a time. Center: Random-dot kinematograms used to examine motion direction discrimination in young infants. Dotted lines and dots, shown here to demarcate regions of motion, were not present in the stimulus. Bottom: Individual infant's performance in smooth pursuit and direction discrimination tasks were correlated with age. *Adapted from Johnson SP, Davidow J, Hall-Haro C, and Frank MC (2008) Development of perceptual completion originates in information acquisition.* Developmental Psychology *44: 1214–1224.*

Studies of infant memory employing operant conditioning paradigms, in which infants are trained to kick their legs to move a mobile, have demonstrated long-term visual recognition stores that are available from at least 2 months under some conditions; the memories formed can last for several days or even weeks given sufficient training with the mobile and reminders (Rovee-Collier, 1999). Infants at 6 months can imitate observed behaviors after 24 h, and the retention interval is considerably longer in older infants (Barr et al., 1996). Developments in visual memory, like many other visual functions, have been proposed to stem from cortical development, in particular areas of the medial temporal lobe such as hippocampus, perirhinal and entorhinal cortices, and amygdala (Bauer, 2004; Nelson, 1995; Rose et al., 2004). See also Chapter 16.

14.4.6 Development of Visual Stability

Our gaze moves frequently from point to point in the visual scene, and our bodies move from place to place. Despite these continual disruptions and interruptions in visual input, we experience the visual world as an inherently stable place. Consider, for example, the difference in your visual experience when you read this page while shaking your head back and forth (as if you wanted to signify 'no' to someone). Reading is not much compromised. Now shake the page back and forth while holding your head steady. You will discover reading to be more difficult, yet the spatial relation between your head and the page in the two situations is similar. When you rotate your head, compensatory eye movements known as the vestibulo-ocular response (VOR) allow the point of gaze to remain fixed or to continue moving volitionally as desired (as when reading). When the page moves, there is no such compensatory mechanism.

Evidence from three paradigms suggests that visual stability emerges gradually across the first year after birth. First, young infants have difficulty discriminating optic flow patterns that simulate different directions of self-motion (Gilmore et al., 2004). Infants viewed a pair of random-dot displays in which the dots repeatedly expanded and contracted around a central point to simulate the effect of moving forward and backward under real-world conditions. On one side, the location of this point shifted periodically, which for adults specifies a change in heading direction; the location on the other side remained stationary. Under these circumstances, adults detected a shift simulating a 5° change in heading, but infants were insensitive to all shifts below 22°, and sensitivity was unchanged between 3 and 6 months. Gilmore et al. speculated that optic flow sensitivity may be improved by self-produced locomotion after 6 months of age, or by maturation of the ventral visual stream.

Second, young infants' saccade patterns tend to be retinocentric, rather than body centered, in a 'double-step' tracking paradigm (Gilmore and Johnson, 1997). Retinocentric saccades are programmed without taking into account previous eye movements. Body-centered eye movements, in contrast, are programmed while updating the spatial frame of reference or coordinate system in which the behaviors occur. Infants first viewed a fixation point that then disappeared, followed in succession by the appearance and extinguishing of two targets on either side of the display. The fixation point was located at the top center of the display, and targets were located below it at the extreme left and right sides. As the infant viewed the fixation point and targets in sequence, there was an age-related transition in saccade patterns. Three-month-olds tended to direct their gaze downward from the first target, as if directed toward a target below the current point of gaze. In reality, the second target was below the first location – the original fixation point – not the current point of gaze. Seven-month-old infants, in contrast, were more likely to direct gaze directly toward the second target. These findings imply that young infants' visual–spatial coordinate system, necessary to support perception of a stable visual world, may be insensitive to extraretinal information, such as eye and head position, in planning eye movements.

Third, there are limits in the ability of infants younger than 2 months to switch attention flexibly and volitionally to consistently maintain a stable gaze. Movement of one's body through the visual environment can produce an optic flow pattern, as can head movement while stationary (recall the head-shaking example). The two scenarios may produce similar visual inputs from optic flow, yet we readily distinguish between them. In addition, adult observers can generally direct attention to either moving or stationary targets, nearby or in the background, as desired. These are key features of visual stability, and four eye movement systems work in concert to produce it. Optokinetic nystagmus (OKN) stabilizes the visual field on the retina as the observer moves through the environment. OKN is triggered by a large moving field, as when gazing out the window of a train: The eyes catch a feature, follow it with a smooth movement, and saccade in the opposite direction to catch another feature, repeating the cycle. The VOR, described previously, helps maintain a stable gaze to compensate for head movement. (OKN and the VOR are present and functional at birth, largely reflexive or obligatory, and are likely mediated by subcortical pathways; Atkinson and Braddick, 1981; Preston and Finocchio, 1983.) The others are the saccadic eye movement system and smooth pursuit, to compensate for or cancel the VOR or OKN as appropriate. Aslin and Johnson (1994) observed suppression (cancellation) of the VOR to fixate a small moving target in 2- and
FIGURE 14.7 Ball-and-box displays from experiments on infants' perception of existence constancy: (a) habituation stimulus and (b and c) test stimuli.

4-month-olds, but not 1-month-olds, and Aslin and Johnson (1996) observed suppression of OKN to fixate a stationary target in 2-month-olds, but not in a younger group.

14.4.7 Object Perception

As noted previously in Section 14.3.3, 'piecemeal' or fragmented perception of the visual environment extends from birth through the first several months afterward under some conditions, implying a fundamental shift in the infant's perceptual experience. Because neonates and 4-month-olds appear to construe rod-and-box displays differently – as disjoint surfaces and as occluded objects, respectively – an important step in understanding development of perceptual completion is investigations of performance in 2-month-olds. In the first such investigation, 2-month-olds were found to show an 'intermediate' pattern of performance (no reliable posthabituation preference), consistent with the possibility that spatial completion is developing at this point but not yet in final form (Johnson and Náñez, 1995). A follow-up study examined the hypothesis that 2-month-olds may perceive unity if given additional perceptual support. We simply increased the amount of visible rod surface revealed behind the occluder by reducing box height and by adding gaps in it, and under these conditions, 2-month-olds provided evidence of unity perception (Johnson and Aslin, 1995). Adopting this approach with newborns, however, failed to reveal similar evidence: Even in 'enhanced' displays, newborns seemed to perceive disjoint rather than unified rod parts (Slater et al., 1994, 1996).

A number of studies have shown that young infants can maintain representations of the solidity and location of fully hidden objects across brief delays (e.g., Aguiar and Baillargeon, 1999; Spelke et al., 1992). Yet newborns provide little evidence of perceiving partly occluded objects, begging the question of how perception of complete occlusion, or existence constancy, emerges during the first few months after birth. To address this question, experiments have examined infants' responses to objects that move forward on a trajectory, disappear behind an occluder, reappear on the far side, and reverse direction, repeating the cycle (Figure 14.7(a)). Following habituation to this display, infants viewed test displays consisting of continuous and discontinuous trajectories (Figures 14.7(b) and 14.7(c)), analogous to the broken and complete test stimuli described previously. Four-month-olds appeared to treat the ball-and-box display depicted in Figure 14.7(a) as consisting of two disconnected trajectories, rather than a single, partly hidden path (Johnson et al., 2003a,b), but by 6 months, infants perceived this trajectory as unitary. When occluder size was reduced, however, 4-month-olds' posthabituation preferences (and thus, by inference, their percepts of spatiotemporal completion) were shifted, partway by an intermediate width, and fully by a narrow width, so narrow as to be only slightly larger than the ball itself. Reducing the spatial gap, therefore, supported perception of a complete trajectory in 4-month-olds. In 2-month-olds, this manipulation appeared to have no effect, implying a lower age limit for trajectory completion in infants, just as there may be for spatial completion.

14.4.8 Face Perception

As noted in Section 14.3.3, infants are better prepared to perceive faces than objects at birth, showing preferences for faces and face-like structures. Research on face perception in infants provides additional insights on mechanisms of recognition. In adults, face recognition is near ceiling when faces are upright, but when faces are inverted, performance is relatively poor – the inversion effect (Yin, 1969). This appears to be specific to faces; other visual configurations normally seen upright, such as houses, are not vulnerable to the effect. These findings are thought to reflect a difference in processing 'strategies' when viewing upright versus inverted faces. When faces are upright, they are processed in terms of both the individual features and the spatial relations among features (viz., both piecemeal and holistic processing), but when inverted, these relations are more difficult to access, forcing greater reliance on only a single source of

information for recognition – the features – and thus impairing performance.

Carey and Diamond (1977) reported that children younger than 10 years of age do not show the inversion effect. This led to the suggestion that young children process faces according to features only, and that piece-meal-to-holistic processing develops during childhood, perhaps from experience viewing faces or maturation of the right cerebral hemisphere implicated in complex visual–spatial tasks. Consistent with these findings, children's discrimination of faces was impaired more by a mismatch in the spacing of features than by a mismatch in the features themselves (eyes, nose, and mouth) or faces' outer contours, as seen in Figure 14.8 (Mondloch et al., 2002), and there were dramatic improvements in performance from 6 years through adulthood in matching identity of faces across changes in facial expression,

orientation, and 'lip reading' (mouthing different vowels), all of which require sensitivity to spatial relations among features (Mondloch et al., 2003).

Other reports, however, provide evidence for a much earlier piecemeal-to-holistic shift in processing faces. First, Younger (1992) found that 10-month-old infants were sensitive to correlations among facial attributes in a face discrimination task; 7-month-olds provided evidence of discrimination from featural variations only. Second, evidence from a 'switch' paradigm showed that 7-month-olds processed configurations of facial features that were disrupted by inversion (Cohen and Cashon, 2001). In the switch design, infants are habituated to a pair of distinct stimuli (in this case, faces); at the test, selected features are switched from one stimulus to the other, and infants are observed for recovery of interest to the new configuration. A more recent study using this

FIGURE 14.8 Stimuli used to test recognition of faces in which the spacing of features is varied (top row), the features (but not their spacing) are varied (center row), or the outer contours (but not features or spacing) are varied (bottom row). The faces in the leftmost positions of each row are identical; other faces in each row are variations of it. *Reproduced from Mondloch CJ, Le Grand R, Maurer D (2002) Configural face processing develops more slowly than featural face processing.* Perception *31: 553–566.*

design found a developmental progression toward processing configurations between 4 and 10 months (Schwarzer et al., 2007). Third, the inversion effect was found in face recognition tasks with 5-, 7-, and 9-month-olds, but when outer contours and inner facial features were inverted in separate experiments, only the 2 older age groups showed impairment from inversion, suggesting a greater flexibility in their processing – utilizing either internal or external features to recognize the faces (Rose et al., 2008).

14.4.9 Critical Period for Development of Holistic Perception

Evidence for a critical period for holistic face perception comes from a study of individuals born with cataracts who underwent surgery to correct the problem (Le Grand et al., 2001). Each individual had at least 9 years of visual experience after surgery. The individuals were tested with face recognition tasks as described in the previous section, including tests of inversion effects, using some of the stimuli shown in Figure 14.8. There was a specific deficit in recognition from configurational information – the spacing of features – but not from featural information, where performance was not reliably different from controls. A particularly striking characteristic of these findings concerns the timing of cataract replacement, which for every patient was less than 7 months of age – and in a few cases, as little as 2–3 months. The critical period for development of holistic processing, therefore, appears to be exceedingly brief. Interestingly, infants at 2–3 months show no signs of the inversion effect (Cashon and Cohen, 2003), and sensitivity to some kinds of holistic information in faces is not adultlike until several years after this time, as noted previously.

Some kinds of holistic object perception appear to be comprised by visual deprivation, but the evidence is complex. On the one hand, patients treated for cataracts showed no deficits, relative to controls, in identifying pictures of houses on the basis of both featural and configurational information, in contrast to face recognition (Robbins et al., 2008). And a case study of SRD, a woman who had cataracts removed at age 12, revealed few obvious deficits in object perception when tested 22 years later on shape matching, visual memory, and image segmentation tasks (Ostrovsky et al., 2006). Her performance at face recognition was impaired relative to controls, as expected from the Le Grand et al. (2001) study, but she was not tested explicitly for holistic object perception.

On the other hand, a case study of MM, a man who lost his vision at 3.5 years and had cataract replacement nearly 40 years later, revealed marked deficits in object perception skills (Fine et al., 2003). Five months after surgery, MM was unable to detect transparency in overlapping forms, to see depth from perspective in a Necker cube, or to identify a shape defined by illusory contours (a Kanizsa square) – the latter a paradigmatic instance of holistic processing, the binding of visual features across a spatial gap. He was also limited in recognition of everyday objects and had difficulty discriminating faces and identifying emotional expression, reporting to rely on individual features rather than a 'Gestalt' for these purposes. Cortical areas that give strong responses in normally sighted observers when viewing faces and objects (lingual and fusiform gyri) were largely inactive in MM. (Other visual functions were well preserved, such as contrast sensitivity, color perception, and motion perception, implying that they may have been more established and consequently robust to deprivation by the time MM was blinded in childhood.)

A recent study of illusory contour perception in cataract replacement patients provides additional evidence for severe compromise in feature binding from early visual deprivation (Putzar et al., 2007). Patients were divided into two groups, one with cataract replacement prior to 6 months and the second after this time, and their performance was compared to controls. The patient group treated after 6 months showed elevated reaction times and greater miss rates when searching for illusory shapes among distracters, relative to real shapes; the other groups showed reliably less of a difference on these measures. Interviews conducted after testing revealed that the post-6-month patient group did not perceive the illusory figures at all, but rather adopted a strategy of finding regions in the scenes where the inducing elements pointed inward. Consistent with experiments on face perception described previously, these results point to the first several months after birth as a critical period for spatial integration of visual information.

14.5 HOW INFANTS LEARN ABOUT OBJECTS

14.5.1 Learning from Targeted Visual Exploration

Infants in the transition toward spatial completion in rod-and-box displays – 2–3 months of age – have been observed for evidence that scanning patterns are associated with unity perception. These links are clear. Amso and Johnson (2006) and Johnson et al. (2004) observed 3-month-old infants in a perceptual completion task using the habituation paradigm described previously. Infants' eye movements were recorded with a corneal reflection eye tracker during the habituation phase of the

experiment. We found systematic differences in scanning patterns between infants whose posthabituation test display preferences indicated unity perception and infants who provided evidence of perception of disjoint surfaces: 'Perceivers' tended to scan more in the vicinity of the two visible rod segments and to scan back and forth between them. In a younger sample (58–97 days), Johnson et al. (2008) found a reliable correlation between posthabituation preference (viz., our index of spatial completion) and targeted visual exploration, operationalized as the proportion of saccadic eye movements directed toward the moving rod parts, obviously the most relevant aspect of the stimulus for perception of completion. Spatial completion was not predicted by other measures of oculomotor performance, including mean number of fixations per second, mean saccade distance (to assess overall scanning activity), mean vertical position of each infant's fixations (to assess a bias for the upper portion of the stimulus), and mean dispersion of visual attention (to assess scanning of limited portions of the stimulus vs. scanning more broadly). Nor was spatial completion associated with another measure of oculomotor control, smooth pursuit. Rather, spatial completion was best predicted by saccades directed toward the vicinity of the moving rod parts. This can be a challenge for a developing oculomotor system, attested by the fact that targeted scans almost always followed the rod as it moved, rarely anticipating its position.

Targeted visual exploration develops with time, stems from increasing endogeous control of oculomotor behavior, and consists of both selection of desired visual targets and inhibition of everything else in the visual scene. Evidence for development of selection comes from studies of orienting, discussed previously in Section 14.4.3. Evidence for development of its complement, inhibition, is relatively scarce. Newborns exhibit inhibition of return of the point of gaze to recently visited locations (Valenza et al., 1994), but inhibition of eye movements to covertly attended locations develops more slowly across the first year (Amso and Johnson, 2005, 2008). How selection and inhibition work together to maximize effective uptake of visual information is not yet known, but the experiments on spatial completion and eye movements begin to provide important insights. Very young infants' ability to perceive occlusion may be precluded by insufficient access to visual information for unity: alignment, common motion, and other Gestalt cues such as similarity and interposition. An alternate view stressing developmental mechanisms that are independent of learning and experience might posit that emergence of spatial completion stems exclusively from maturation of neural structures responsible for object perception, and, as infants begin to perceive occlusion, their eye movement patterns support or confirm this percept. Amso and Johnson (2006) found that both spatial completion and scanning patterns were strongly related to performance in an independent visual search task in which targets were selected from among distracters. This finding is inconsistent with the possibility that scanning patterns were tailored specifically to perceptual completion, and instead suggests that a general facility with targeted visual behavior leads to improvements across multiple tasks – precisely the pattern of performance that was observed.

How might developing object perception systems benefit from targeted scans? Eye movements may serve as a vital binding mechanism due to the relatively restricted visual field and poor acuity characteristic of infant vision. Visual information in the periphery is more difficult to access with a single glance, increasing the need to scan between features to ascertain their relations to one another. The developmental timing of targeted visual exploration in infants seems just right for another reason: the critical period for development of holistic object processing. It may be that motor feedback from scanning eye movements serves as a trigger for consolidation of neural circuits in areas that represent the stimulus, enabling association of the separate parts of an object seen on sequential fixations (Rodman, 2003). As an observer views salient object features, the point of gaze falls in rapid succession on components that will later be perceived as part of a coherent whole. Motor feedback signaling a series of sequential fixations within the central visual field could thus be a powerful cue to bind features together, a possibility consistent with close relations in adults between scan paths and pattern recognition (Noton and Stark, 1971; Rizzo et al., 1987) and scene perception (Henderson, 2003).

14.5.2 Learning from Associations Between Visible and Occluded Objects

By 6 months, infants' short-term representations of unseen objects are sufficiently robust to guide reaching and oculomotor systems prospectively to intercept objects on hidden trajectories (Clifton et al., 1991; Johnson et al., 2003a; von Hofsten et al., 1998). At 4 months, prospective behavior – anticipations from eye and head movements to the place of reappearance of an object seen to move behind an occluder – is adapted to variations in occluder width and object speed, implying that under some conditions, infants may track with their 'mind's eye' (von Hofsten et al., 2007). Yet, under other circumstances, 4-month-olds process partly occluded trajectories in terms of visible components only, not complete paths (Figure 14.7). Representations of occluded objects in 4-month-olds, therefore, appear to be rather fragile and not completely established.

To examine the possibility that learning can facilitate spatiotemporal completion, my colleagues and I presented

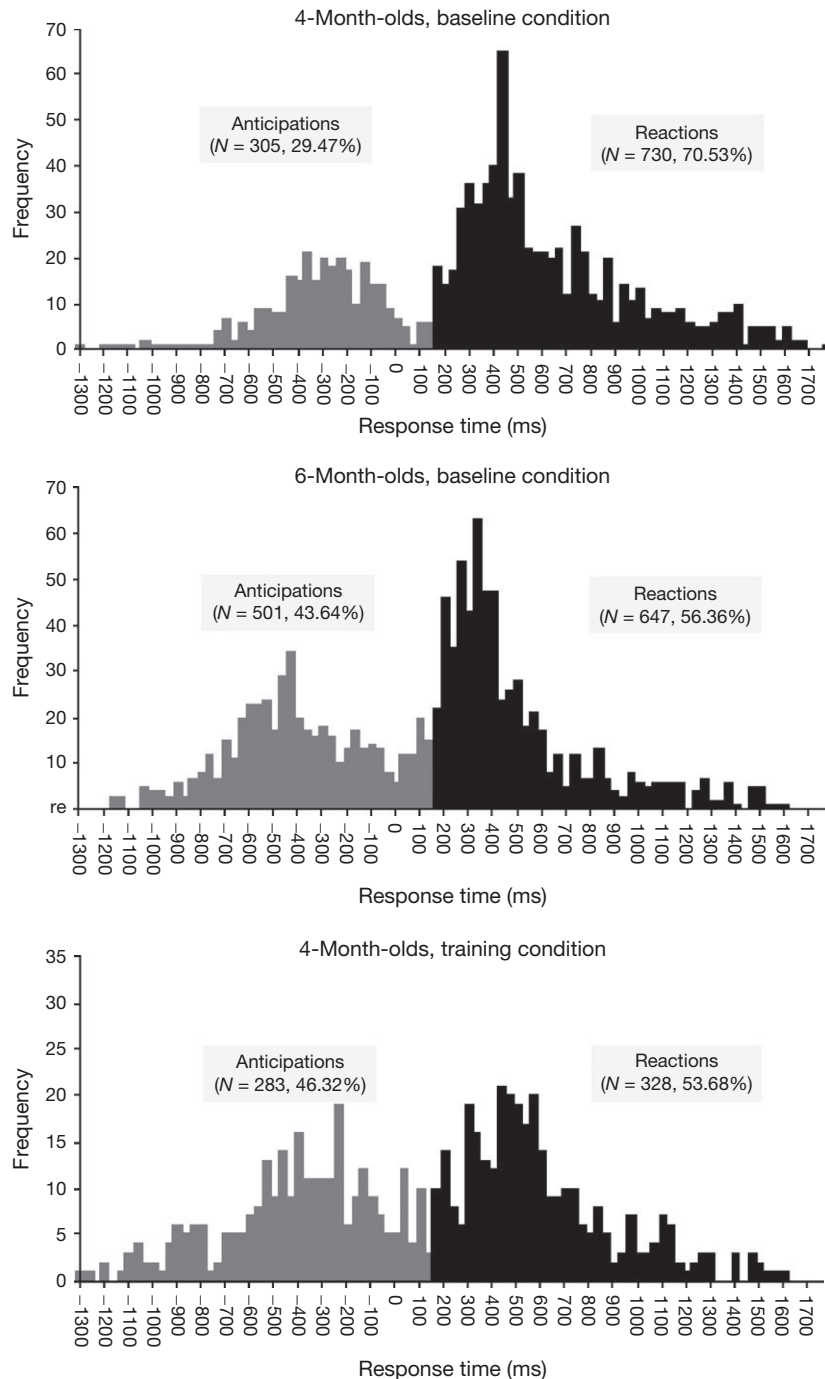
ball-and-box displays to 4- and 6-month-olds as we recorded their eye movements (Johnson et al., 2003a). We reasoned that a representation of the object and its trajectory under occlusion would be reflected in a consistent pattern of anticipatory eye movements toward the place of reemergence, before the object's appearance. The stimulus was identical to the displays used by Johnson et al. (2003b) to investigate spatiotemporal completion (Figure 14.7(a)). Because 6-month-olds provided evidence of spatiotemporal completion in these displays when tested with an habituation paradigm, we predicted that oculomotor anticipations would be more frequent in the older age group. This prediction was supported. A higher proportion of 6-month-olds' object-directed eye movements was classified as anticipatory (i.e., initiated prior to the ball's emergence from behind the occluder; Figure 14.9, top panel) relative to 4-month-olds (Figure 14.9, center panel), corroborating the likelihood that spatiotemporal completion strengthens between 4 and 6 months.


FIGURE 14.9 Histograms showing oculomotor anticipations (gray bars) versus reactions (black bars) as infants view ball-and-box displays. Each eye movement is coded for latency with respect to the emergence of the ball from behind the box, time 0. Eye movements initiated prior to this time are anticipations, and eye movements initiated after this time are reactions. Top panel: 4-month-olds. Center panel: 6-month-olds. Bottom panel: 4-month-olds after 'training' with a fully visible trajectory. *Adapted from Johnson SP, Amso D, Slemmer JA (2003) Development of object concepts in infancy: Evidence for early learning in an eye tracking paradigm.* Proceedings of the National Academy of Sciences of the United States of America *100: 10568–10573.*

Evidence for learning as an important contributor to this developmental change came from a new group of 4-month-olds in a 'training' condition. These infants were first presented with an unoccluded, fully visible ball trajectory (no occluder) for 2 min followed by the ball-and-box display as per the other conditions, and their eye movements were recorded. Here, the proportion of anticipations was reliably greater than that observed in the 'baseline' conditions with untrained 4-month-olds, but not reliably different from that of untrained 6-month-olds (Figure 14.9, bottom panel). In other words, 2 min of exposure led to behaviors characteristic of infants who are 2 months older. This rapid learning may stem from the ability to form associations between fully visible to partly or fully hidden objects.

In the real world, infants are exposed to many different objects moving in different ways, presenting multiple opportunities for learning. For associative learning about occlusion to be a viable means of dealing with real-world events, associations between visible and partly occluded paths must be committed to memory. How long do such rapidly acquired associations last? To address this question, the Johnson et al. (2003b) methods were replicated with new groups of 4-month-olds and a nearly identical pattern of anticipatory behaviors in baseline and training conditions were observed (Johnson and Shuwairi, 2009). A third group received a half hour break between training and test, and performance reverted to baseline, implying that memory for the association was lost during the delay. But a fourth group, provided with a single 'reminder' trial after an identical delay, showed a recovery of oculomotor anticipations equivalent to the no-delay training condition. (A fifth group, provided only a single training trial, showed no benefit in the form of anticipatory looking.) These findings suggest that accumulated exposure to occlusion events may be an important means by which existence constancy arises in infancy.

14.5.3 Learning from Visual–Manual Exploration

Spatial and spatiotemporal completions involve occlusion of far objects by nearer ones. Solid objects also occlude parts of themselves, meaning we cannot see the opposite surfaces from our present vantage point. Perceiving objects as solid in 3D space constitutes 3D object completion, and we recently asked whether young infants perceive objects in this way (Soska and Johnson, 2008). Four- and 6-month-olds were habituated to a wedge rotating through 15° around the vertical axis such that the far sides were never revealed (Figure 14.10). Following habituation infants viewed two test displays in alternation, one an incomplete, hollow version of the wedge, and the other a complete, whole version, both undergoing a full 360° rotation revealing the entirety of the object shape. Four-month-olds showed no consistent posthabituation preference, but 6-month-olds looked longer at the hollow stimulus, indicating perception of the wedge during habituation as a solid, volumetric object in 3D space.

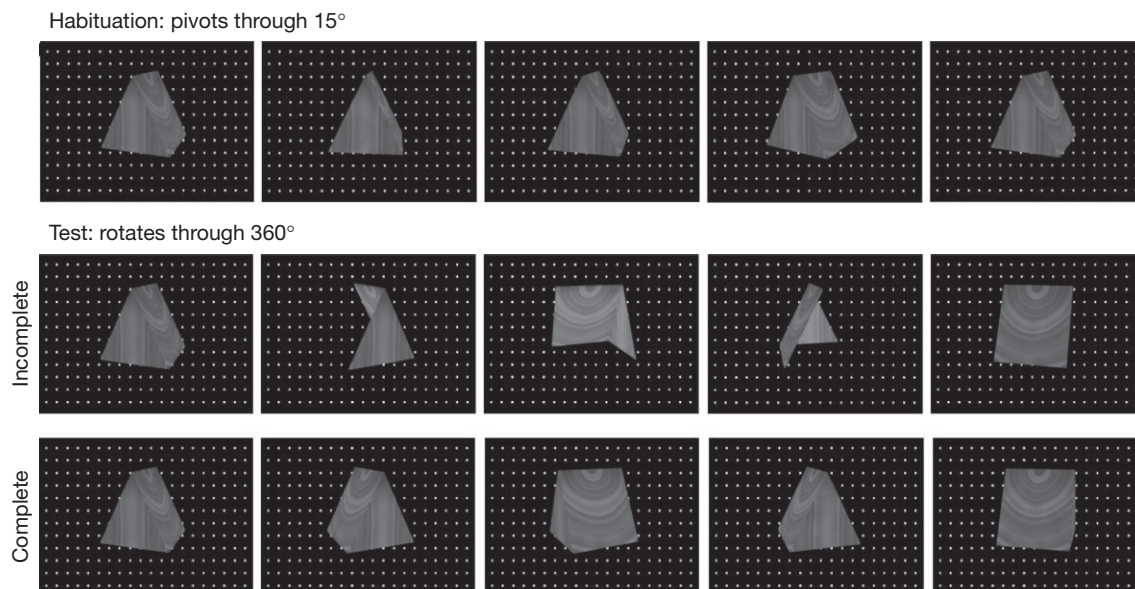
How does 3D object completion arise? One possibility is that developmental changes in infants' motor skills


FIGURE 14.10 Rotating object displays from experiments on infants' perception of three-dimensional object completion. Top panels: habituation stimulus. Center and bottom panels: test stimuli. *Adapted from Soska KC and Johnson SP (2008) Development of 3D object completion in infancy.* Child Development *79: 1230–1236.*

might underlie the ability to perceive the unseen parts of objects. Two types of motor skill, self-sitting and coordinated visual–manual object exploration, seem particularly important, because independent sitting frees the hands for play and promotes gaze stabilization during manual actions (Rochat and Goubet, 1995). Thus, self-sitting might spur improvements in coordinating object manipulation (e.g., rotating and transferring hand to hand) with visual inspection, providing infants with multiple views of objects. We tested these hypotheses in a group of 4.5- to 7.5-month-olds by replicating the Soska and Johnson (2008) methods and evaluating the infants' motor skills (self-sitting and manipulation of different objects) on the same day (Soska et al., 2010). Strong and significant relations were found between both self-sitting and visual–manual coordination (from the motor skills assessment) and the measure of 3D object completion (from the habituation paradigm). (Other motor skills we recorded, such as holding skill and manual exploration without visual attention to the objects, did not predict 3D object completion.) These results provide evidence for a cascade of developmental events following from the advent of visual–motor coordination, including learning from self-produced experiences.

Evidence from spatial completion experiments reveals that newborns perceive surface segregation even under conditions in which older infants and adults see the identical surfaces as unified (Slater et al., 1990), yet under other circumstances, say, when stationary surfaces are directly adjacent, their connectivity or segregation may be ambiguous (Needham, 1997). This was demonstrated by Needham and Baillargeon (1998) for 4.5-month-olds' interpretation of stimulus displays containing two dissimilar but adjacent, stationary objects (Figure 14.11). After viewing these objects during a familiarization trial, infants were presented with test events in which a hand pulled the cylinder; the box either remained stationary or moved with the cylinder.

The authors reasoned that infants would look longer at the event that was unexpected (e.g., the 'move-apart' event if the objects were perceived as connected), a result found with 8-month-olds (Needham and Baillargeon, 1997), but the 4.5-month-old infants looked about equally at the two test events, providing no evidence for either interpretation on the infants' part.

Needham and Baillargeon (1998) asked whether 4.5-month-olds would learn from a brief prior exposure to either object in isolation and subsequently perceive the two as segregated. Their hypothesis was confirmed: Either a 5-s exposure to the box or a 15-s exposure to the cylinder alone supported segregation of the adjacent cylinder-and-box display into two separate units when infants were tested immediately afterward. Some effects of such training last as long as 72 h (Dueker et al., 2003). This learning effect has been extended in a number of important ways. For example, the effect generalizes from exposure to objects in different orientations (Needham, 2001), but not to objects with distinct features, unless infants are introduced to the different objects in a variety of settings or contexts prior to testing, prompting formation of a perceptual category for the objects (Dueker and Needham, 2005). Categorization is facilitated as well by increasing the number or variety of exemplars during the learning phase of the experiment (Needham et al., 2005).

14.6 SUMMARY AND CONCLUSIONS

From its prenatal origins to its postnatal refinement, learning to see is a mixture of developmental mechanisms, some of which operate outside of experience, and some of which are dependent on it. Although newborn infants can see fairly well upon their first exposure to patterned visual stimulation, as best we can tell the initial inputs are not bound into a stable, predictable,

Move-apart event

Move-together event

coherent visual world. The visual world as we adults know it emerges across the first year after birth. Developmental mechanisms are not limited only to cortical maturation, or to experience, or to learning, but instead comprise all of these and their interactions.

The theoretical views most relevant to questions of visual cognitive development described previously – the views of Piaget and the Gestalt theorists – forecasted some of the research described here. As Piaget proposed, an infant's experience of the visual world begins with a limited capacity to detect object boundaries, particularly under occlusion, and develops in part as a result of the infant's interactions with the environment. And as the Gestalt theorists proposed, visual perception is organized at birth and elaborated with experience; many of the organizational principles characteristic of adult vision appear to be operational in infants (if not at birth). These theories have proven prescient and have given direction to many investigations of infant perception and cognition, yet neither theory is fully adequate to explain the foundations of vision and its development.

Although our understanding of visual cognitive development continues to grow, the current state of knowledge is substantial, and the outlines of a comprehensive account can now be realized. This account, described in this chapter, can be summarized as follows:

- To understand how infants come to experience a stable and predictable world of substantial, volumetric objects, overlapping and extending in depth – the visual world that we adults experience – we must look to experiments that elucidate visual development.
- Visual development begins well before birth. The visual system begins to develop within weeks after conception and continues to develop rapidly prior to the onset of patterned visual stimulation.
- Vision is partially organized at birth. Neonates show systematic scanning patterns and visual preferences, in particular preferences for areas of high contrast and motion. These preferences are well suited for directing attention to features of the visual world relevant to learning about objects. But neonates do not perceive objects as do adults – as solid and substantial entities.
- Newborns' experience of the visual world is fragmented and unstable. Visual and motor systems that yield an experience of coherent objects and the position of the observer relative to a stable environment emerge across the first postnatal year.
- There is a critical period for development of face and object perception. Normal visual experience during this time is essential to their development, as are patterns of eye movements, and other action systems, in binding features into wholes.

- Developmental mechanisms include cortical maturation, visual experience, and learning, and the interplay between these developmental events.
- Developments in some visual functions have been linked directly to maturation of specific cortical regions and visual pathways. Development of smooth pursuit eye movements and motion direction discrimination are thought to stem from maturation of cortical area V5 (also known as MT), form and motion perception from parvocellular and magnocellular processing streams, respectively, and visual memory from structures in the medial temporal lobe. These developments occur between birth and 6 months of age.
- Infants have multiple means of learning at their disposal, and learning is an indispensable part of understanding the visual world. Infants learn from their own behavior as well as by observing relevant events in the environment.

The Development of Visuospatial Processing

J. Stiles, N. Akshoomoff, F. Haist

University of California San Diego, La Jolla, CA, USA

Visual input is a critical source of knowledge about the organization and structure of the spatial world. It provides information about everything from the structure of objects and scenes to their location or movement in space. Visuospatial processing encompasses a wide variety of neurocognitive abilities ranging from the basic ability to analyze how parts or features of an object combine to form an organized whole, to the dynamic and interactive spatial processes required to track moving objects, to visualize displacement, and to localize, attend, or reach for objects or visual targets in a spatial array. These varied processes work in concert to provide a seamless and immediate perception of the intricacies of the visual world. This perception provides an essential basis for precise and effective action in the world as well as a rich source of input for cognitive functions across many domains.

A complex neural architecture involving dozens of interrelated visual areas in the posterior cortices supports visuospatial processing (Van Essen et al., 1992). Ungerleider and Mishkin (1982) first proposed a model for understanding the organization of this complex set of cortical areas and functions in the early 1980s (Ungerleider, 1995). In their model, the cortical visual system is anatomically and functionally subdivided into the ventral and dorsal processing pathways or streams (see Figure 15.1). The ventral stream is dominant for processing information about patterns and objects, while the dorsal stream mediates spatial processing associated with attention to movement and location. Subsequent models describe dorsal stream functions as specialized for supporting visual processing related to action (e.g., Andersen et al., 1997; Goodale and Milner, 1992; Goodale and Westwood, 2004; Rizzolatti and Matelli, 2003).

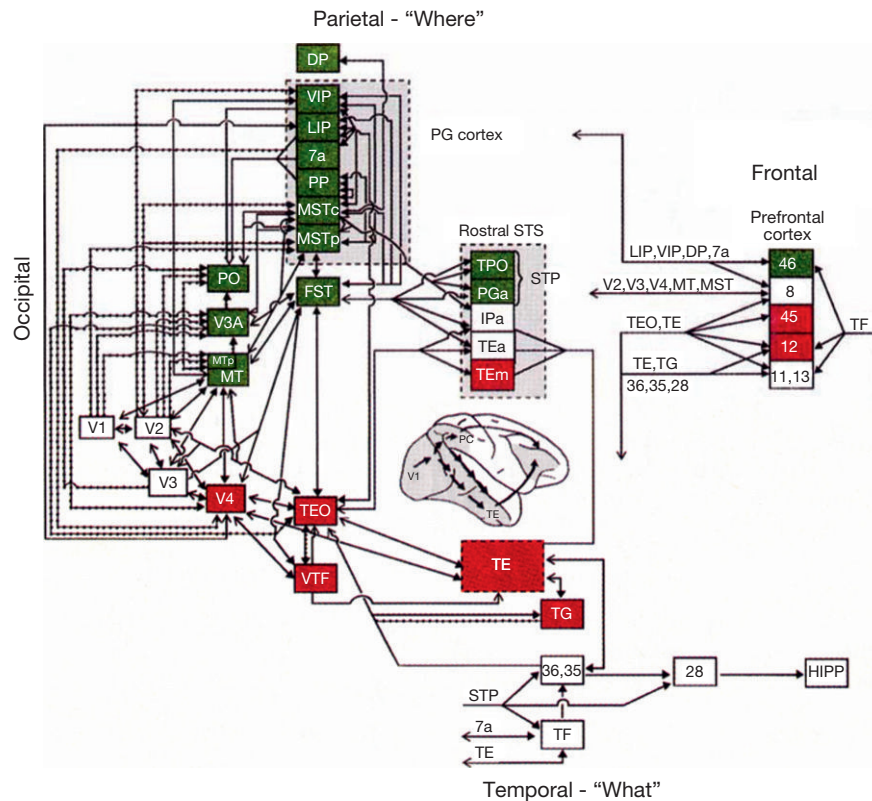
This chapter begins with a summary of the neuroarchitecture of the ventral and dorsal visual streams. The summary focuses on the flow of visual information beginning, for both streams, in the primary visual cortex and then extending to the temporal and parietal lobes for the ventral and dorsal streams, respectively. Connections between the two major visual pathways as well as connections with the frontal lobes are also considered.


FIGURE 15.1 Dorsal and ventral visual-processing pathways in monkey. Solid lines indicate connections arising from both central and peripheral visual field representations; dotted lines indicate connections restricted to peripheral field representations. Red boxes indicate ventral stream areas related primarily to object vision; green boxes indicate dorsal stream areas related primarily to spatial vision; and white boxes indicate areas not clearly allied with either stream. Shaded region on the lateral view of the brain represents the extent of the cortex included in the diagram. Abbreviations: DP, dorsal prelunate area; FST, fundus of superior temporal area; HIPP, hippocampus; LIP, lateral intraparietal area; MSTc, medial superior temporal area, central visual field representation; MSTp, medial superior temporal area, peripheral visual field representation; MT, middle temporal area; MTp, middle temporal area, peripheral visual field representation; PO, parietal–occipital area; PP, posterior parietal sulcal zone; STP, superior temporal polysensory area; V1, primary visual cortex; V2, visual area 2; V3, visual area 3; V3A, visual area 3, part A; V4, visual area 4; and VIP, ventral intraparietal area. Inferior parietal area 7a; prefrontal areas 8, 11–13, 45, and 46, perirhinal areas 35 and 36; and entorhinal area 28 are from Brodmann (1909). Inferior temporal areas TEO and TE, parahippocampal area TF, temporal pole area TG, and inferior parietal area PG are from Von Bonin and Bailey (1947). Rostral superior temporal sulcal (STS) areas are from Seltzer and Pandya (1978), and VTF is the visually responsive portion of area TF (Boussaoud et al., 1991). *Reproduced from Ungerleider LG (1995) Functional brain imaging studies of cortical mechanisms for memory. Science 270(5237): 769–775, with permission.*

The next two sections consider the development of cognitive processes associated with the two principal brain visual systems. The section on ventral stream processing examines the development of visual pattern processing from infancy through adolescence focusing on changes in the perception of visual patterns and faces, and in the ability to construct spatial arrays. The section on dorsal stream processing examines the development of spatial attention, location processing, and mental rotation. The final section of the chapter turns the focus to neurodevelopmental disorders where visuospatial processing is a primary feature. It examines both the effects of frank neural insult on the development of spatial processes and the effects of specific genetic abnormalities on the development of the neural systems that underlie the development of spatial processes. The original descriptions of ventral and dorsal stream organization came from studies of adults with injury to various subsystems within the cortical visual pathways. Data from children with neurodevelopmental disorders provide insight into the emergence of visual system organization following early pathology, and can address questions about how specific neural compromise and neural plasticity interact to affect the developmental trajectories of basic visuospatial functions and the neural systems that mediate them.

15.1 ANATOMICAL ORGANIZATION OF THE PRIMARY VISUAL SYSTEMS

The organization of the primary visual pathways has been most fully described for rhesus macaque monkeys; thus, the description presented here uses the nomenclature typically used for nonhuman primates.

However, the basic pathways in humans and monkeys appear to be largely homologous (Brewer et al., 2002; Orban et al., 2004). The ventral visual pathway begins at the retina and projects via the lateral geniculate nucleus (LGN) of the thalamus to the primary visual cortex, area V1. From there, the pathway proceeds to extrastriate visual areas V2 and V4, and then projects ventrally to the posterior (PIT) and anterior (AIT) regions of the inferior temporal lobe. Input to the ventral pathway is derived principally, though not exclusively, from P-type retinal ganglion cells that project to the parvocellular layers of the LGN and then to layer 4C beta of V1. Parvocellular input to V1 organizes into distinct areas called the blob and interblob regions (Kaas and Collins, 2004; Livingstone and Hubel, 1984; Wong-Riley, 1979). Cells in the blob regions are maximally sensitive to form, while cells in the interblob regions respond principally to color. The ventral stream processes information about visual properties of objects and patterns, and has been described as the 'what' pathway.

The dorsal visual pathway also begins at the retina and projects via the LGN to area V1. From there, the pathway proceeds to extrastriate areas V2 and V3, then projects dorsally to the medial (MT/V5) and medial superior (MST) regions of the temporal lobe, and then to the ventral inferior parietal (IP) lobe. Input to the dorsal pathway is derived principally, though not exclusively, from the large M-type retinal ganglion cells that project to the magnocellular layers of LGN and then to layer 4C alpha of V1. Cells in this pathway are maximally sensitive to movement and direction and are less responsive to color or form. The original functions identified for the dorsal stream involved processing of information about spatial location, optic flow, and motion, and allocation and maintenance of spatial attention. It was thus described as the 'where' pathway. More recently, work examining the dorsal stream's role in visually guided movements suggests that the pathway is and also involved in the integration of visual and motor functions. It has thus been called the 'how' system (e.g., Andersen et al., 1997; Goodale, 2011; Goodale and Milner, 1992; Rizzolatti and Matelli, 2003).

The dorsal and ventral pathways project rostrally to common and distinct, albeit adjacent, areas of the prefrontal cortex. Imaging studies suggest that these prefrontal networks are involved in a variety of dorsal and ventral stream functions (Farivar, 2009). For example, spatial working memory and attention rely on networks connecting the dorsolateral prefrontal cortex (DLPFC) and posterior parietal cortex (Awh and Jonides, 2001; Corbetta et al., 2002; Curtis, 2006), whereas object memory relies on systems connecting the prefrontal cortex with inferior temporal areas (Ranganath, 2006; Ranganath and D'Esposito, 2005; Ranganath et al., 2004). At least three principal projection pathways from the parietal lobe have

been described: a parietal–prefrontal pathway mediating eye movement and spatial working memory, a parietal premotor pathway mediating visually guided movement (eye movement, reach, and grasp), and a parietal medial temporal pathway that processes complex spatial information for navigation (Kravitz et al., 2011). There is substantial evidence that the dorsal and ventral pathways are richly interconnected and at least partially overlapping in the mature (e.g., Dobkins and Albright, 1994, 1995, 1998; Marangolo et al., 1998; Merigan and Maunsell, 1993; Rosa et al., 2009; Sincich and Horton, 2005; Thiele et al., 2001; Zanon et al., 2010) and the developing (Dobkins and Anderson, 2002; Dobkins and Teller, 1996a,b) visual system. The dissociation of function across the two pathways may be less complete than originally thought. Subregions within each system may respond to functions typically associated with the other pathway (Husain and Nachev, 2007; Kawasaki et al., 2008; Konen and Kastner, 2008; Lehky and Sereno, 2007). For example, regions in the parietal lobe may respond to color and shape features (Kawasaki et al., 2008), and area MT/V5 in extrastriate visual cortex may show object-selective responses (Konen and Kastner, 2008).

15.2 VENTRAL STREAM PROCESSES

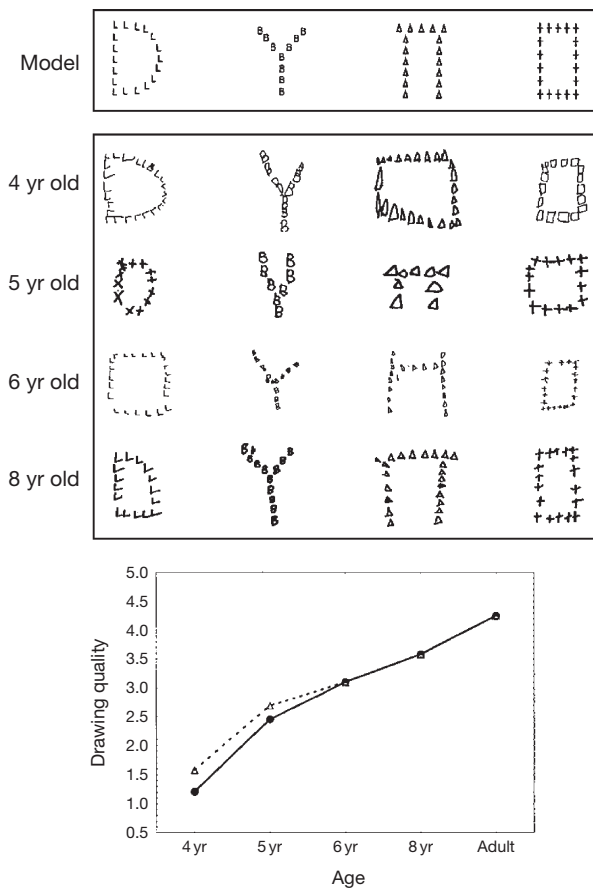
A major function of the ventral visual stream is the analysis of pattern information. Here, findings from three specific functions within the ventral stream are summarized: global–local processing, face processing, and spatial construction. Behaviorally, visuospatial analysis is defined as the ability to specify the parts and the overall configuration of a visually presented pattern, and to understand how the parts are related to form an organized whole (e.g., Delis et al., 1986, 1988; Palmer, 1977, 1980; Palmer and Bucher, 1981; Robertson and Delis, 1986; Smith and Kemler, 1977; Vurpillot, 1976). Thus, it involves the ability to segment a pattern into a set of constituent parts (referred to as featural or local-level processing), and integrate those parts into a coherent whole (referred to as configural or global-level processing). Different approaches to the study of spatial analysis have focused on level of processing and type of input. Perceptual processing studies focus largely on issues of global versus local or configural versus featural processing. Much of the data on perceptual processing of global and local aspects of objects and patterns come from hierarchical form-processing tasks (e.g., see Figure 15.2). Perceptual processing of faces is a related but generally distinct line of study. Faces constitute a critically important class of social stimuli for which most individuals acquire considerable processing expertise. Because of the importance of the information faces provide to typical social interaction and communication, faces may be


FIGURE 15.2   The model forms (top) provide examples of hierarchical form stimuli. Hierarchical form stimuli have two levels of organization: a large global/configural level comprised of appropriately arranged smaller forms constituting the local/featural level. A series of hierarchical form stimuli (the models) were presented one at a time and children were given 10 s to study the form. After a 30 s delay, they were asked to reproduce the forms from memory. The graph illustrates that systematic improvement in the accuracy of reproductions was observed among typically developing 4–8-year-old children, and also that there are no differences at any age in the relative accuracy of reproducing the global and local levels of the forms. At each age, children are equally accurate in their reproduction of global and local pattern information. *Reproduced from Dukette D and Stiles J (2001) The effects of stimulus density on children's analysis of hierarchical patterns.* Developmental Science *4(2): 233–251, with permission.*

processed differently compared to other classes of visual objects. Construction tasks provide a window to children's conceptual organization of spatial arrays. The processes and strategies children use to recreate spatial scenes can provide insight into their understanding of their spatial world.

15.2.1 Perception of the Global and Local Levels of Visual Pattern Structure

Differential laterality for global and local processing is well documented for adults with right hemisphere (RH) dominance for global and left hemisphere (LH)

dominance for local processing (e.g., Han et al., 2002; Martin, 1979; Martinez et al., 1997; Sergent, 1982; Volberg and Hubner, 2004; Yovel et al., 2001). Sergent (1982) suggested that these differences arise from preferential processing of lower spatial frequencies in the RH and higher spatial frequencies in the LH. Several experiments have presented sinusoidal gratings containing a single spatial frequency presented to the right visual field (RVF) or left visual field (LVF) to evaluate this hypothesis with generally positive results. Low spatial frequencies elicit faster responses when presented to the LVF-RH than the RVF-LH, while high spatial frequencies elicit the opposite pattern (Kitterle and Selig, 1991; Kitterle et al., 1990, 1992). Event-related potential (ERP) and other functional imaging studies have supported these basic patterns of lateralization (e.g., Fink et al., 1997; Heinze et al., 1998; Martinez et al., 1997).

In addition to the evidence for the laterality of global- and local-level processing, there is also strong evidence of a global–local processing asymmetry. Specifically, inconsistent or competing information at the global level interferes with local processing, but inconsistent local information does not affect global processing. These two findings led to the postulation of a global precedence effect in visual pattern processing, which states that global-level information is processed prior to local-level information (Navon, 1977). Although many factors may mitigate the global precedence effect in adults, it remains a robust finding within the standard task (Ivry and Robertson, 1998; Kimchi, 1992; Navon, 2003; Robertson and Delis, 1986; Robertson and Lamb, 1991; Robertson et al., 1993).

The ability to analyze spatial patterns begins to emerge in the first year of life. Newborns exhibit configural preferences and rudimentary part–whole processing (Cassia et al., 2002; Farroni et al., 2000; Quinn et al., 1993; Slater et al., 1991). There are dramatic changes in the complexity of visual pattern processing reflecting a systematic improvement in the infant's ability to process global- and local-level pattern information across the first year of life (Cohen and Younger, 1984). These patterns of change appear to reflect early hemispheric differences in processing. Infants as young as 4 months exhibit lateralized processing differences on global and local-processing tasks similar to those observed in adult neuroimaging studies (Deruelle and de Schonen, 1991, 1998).

Studies using the standard hierarchical form stimuli (see Figure 15.2) have also consistently documented a protracted period of developmental change in global–local processing that extends well into adolescence (Dukette and Stiles, 1996, 2001; Harrison and Stiles, 2009; Mondloch et al., 2003; Moses et al., 2002; Porporino et al., 2004; Vinter et al., 2010). The classic global precedence effect emerges slowly over the course

of development. Although some studies of children report a global processing bias (Cassia et al., 2002; Mondloch et al., 2003; Moses et al., 2002; Porporino et al., 2004), others report only modest effects that are modulated by altering task and stimulus demands. For example, increased task demands (Harrison and Stiles, 2009) and selective degradation of the global-level stimulus induce a shift in processing bias from the global to the local level that is much more pronounced in children than in adults (Dukette and Stiles, 1996). The combined data from studies of hierarchical form processing show that children are clearly able to engage in global- and local-level processing from a very early age. However, stable and mature levels of visuospatial processing emerge slowly over a protracted period of development. Variations in stimulus and task demands play an important role in modulating the dominant level of processing. Thus, the functional role of a global or local-processing bias or advantage may be different during development than it is later in life, and may reflect growing expertise and facility in processing complex visuospatial patterns.

Imaging studies of typical children confirm the behavioral findings and suggest that the neural systems associated with spatial analytic processing undergo a protracted period of development. Moses et al. (2002) tested children between 11 and 15 years of age using a hemifield reaction time (RT) task and functional magnetic resonance imaging (fMRI) protocols identical to those used by Martinez et al. (1997) with adult subjects. The pattern of RT data obtained from children across this age range differed from that of adults. Similar to the findings from the Mondloch et al. (2003) study, children were faster with global than with local targets and did not manifest the kinds of hemifield RT differences observed among adults. Importantly, children's profiles of activation in the fMRI study differed from those of the adults. For the global and local tasks, children showed statistically greater activation in the RH than in the LH. Overall activation among children was greater than among adults, and children showed considerably more bilateral activation particularly on the local-processing tasks than adults. Thus, at least for these perceptually demanding tasks, children showed a global processing advantage and overall RH dominance.

Anatomical changes are shown to be associated with the shift from local to global processing biases in children. In one study, 6-year-old children were assigned to one of two groups depending on performance on a behavioral global–local processing task (Poirel et al., 2011). One group of children exhibited the mature profile of global-level bias, and the other the more immature local-level bias profile. The investigators used voxel-based morphology to assess group gray matter density differences in brain regions implicated in global processing, specifically the calcarine

sulcus, the inferior occipital gyrus, the RH occipital lingual gyrus, the right parietal precuneus, and the precentral gyrus. The group of children exhibiting the behaviorally more mature 'global bias' showed reduced gray matter density in all of the brain regions associated with global-level processing. These findings suggest a link between brain maturation and performance on this important spatial-processing task.

15.2.2 Perception of Faces

The ability to recognize a face is essential for everyday social exchange. Although such recognition depends on the discrimination of subtle differences among faces, the task of identifying a face is effortless for adults, suggesting considerable expertise with this important class of stimuli (see also Chapter 18 for a more extended discussion of the development of face processing). Face processing is thought to rely disproportionately on configural cues such as the spacing between features. For example, unlike other objects, face recognition is significantly impaired when the stimuli are turned upside down (Rossion and Gauthier, 2002). It has been suggested that face inversion selectively disrupts facial configural information processing (Yin, 1969). Consistent with this interpretation, neuroimaging studies with adults find a strong RH bias for face activation within what has been described as the core brain network for face processing (Epstein et al., 2006; Gauthier et al., 2005; Grill-Spector et al., 2004; Kanwisher et al., 1997, 1999; Mazard et al., 2006; Rhodes et al., 2004; Wojciulik et al., 1998; Xu, 2005; Yovel and Kanwisher, 2004, 2005). The core face network is a ventral–occipital–temporal (VOT) system that includes the middle aspects of the lateral fusiform gyrus, often referred to as the fusiform face area (FFA), the inferior occipital gyrus in Brodmann's area 18, often referred to as the occipital face area (OFA), and the posterior superior temporal sulcus (Haxby et al., 2000a).

Preference for face stimuli has been documented from the first hours of life (Johnson et al., 1991). Infants as young as 2–3 months show selective cortical responses to faces (Halit et al., 2004; Tzourio-Mazoyer et al., 2002). Some studies suggest that infants show an RH bias for faces (de Schonen and Deruelle, 1991; de Schonen and Mathivet, 1990; De Schonen et al., 1996). Despite these early competences, there is overwhelming evidence for developmental change in face processing that extends at least through the school-age period (Chung and Thomson, 1995; Taylor et al., 2001). Early studies suggested that changes in face processing might reflect a shift from a more feature-based to a more configural or analytic strategy (Carey and Diamond, 1977; Diamond and Carey, 1986; Tanaka and Farah, 1993). However, accumulating evidence supports a pattern of

slower, quantitative age-related change (Itier and Taylor, 2004; Taylor et al., 1999) and increasingly more effective use of the same types of cues used by adults (Baenninger, 1994; Freire and Lee, 2001). These kinds of change may be associated with the acquisition of greater expertise in processing faces and other visual objects (Carey, 1996; Diamond and Carey, 1986; Gauthier and Nelson, 2001).

Recent developmental fMRI studies of face processing suggest that the core brain network for face processing undergoes a protracted change that extends through the school-age period into adolescence (Aylward et al., 2005; Gathers et al., 2004; Golarai et al., 2007; Grill-Spector et al., 2008; Passarotti et al., 2003). Most developmental studies have focused on individual components within the core VOT network, particularly the FFA. The preponderance of evidence indicates that school-age children may produce reliable FFA activation, but the patterns of activation within the fusiform gyrus region vary considerably from those observed among adults. Systematic increases in fMRI blood oxygen level dependent (BOLD) signal activation both in terms of the extent (Brambati et al., 2010; Golarai et al., 2007; Peelen and Kastner, 2009) and intensity of activation (Brambati et al., 2010; Cohen Kadosh et al., 2011; Golarai et al., 2007; Joseph et al., 2011) have been reported from the early school-age period through adulthood. These developmental activation changes correlate with improvement in recognition memory for faces (Golarai et al., 2007, 2010) and with task demand (Scherf et al., 2011). A small number of studies have looked at changes in the organization of brain networks for face processing, and report that young children appear to nonselectively recruit much more extensive networks. With age and growing expertise, these networks become more focused and task specific (Joseph et al., 2011).

15.2.3 Spatial Construction

Spatial construction tasks such as drawing or block assembly provide insight into an individual's conceptualization of the organization of spatial arrays. They can reveal how the participant construes both the parts of an array and the relations among parts that combine to form the overall configuration. Studies of adults with unilateral brain injury use construction tasks extensively. These studies consistently report lateralized differences in the kinds of construction errors produced. Specifically, adults with injury to right posterior brain regions are able to identify, or segment, the parts of spatial forms but have difficulty organizing these parts into integrated spatial configurations. In contrast, adults with injury to left posterior brain regions are able to reproduce the overall pattern configuration, but fail to incorporate pattern detail and tend to simplify the spatial arrays (Akshoomoff et al., 1989; Delis et al., 1986, 1988; Piercy et al., 1960b; Shorr et al., 1992).

Studies of children's spatial construction activities suggest that before 12 months children engage in very little systematic organization of objects (Forman, 1982; Gesell, 1925; Guanella, 1934; Langer, 1980). In block construction tasks, stacking begins at about 12 months, and by 18 months, children begin to arrange blocks in lines by placing the blocks next to one another (Bayley, 1969; Forman, 1982; Gesell, 1925; Stiles-Davis, 1988). It is not until 3–4 years that children regularly build both vertical and horizontal components within a single spatial construction (Guanella, 1934; Stiles-Davis, 1988). There is also systematic change in processes used to generate block constructions (Stiles and Stern, 2001; Stiles-Davis, 1988). At 24 months, children rely upon a simple repetitive process with a single relation (e.g., stacking). By 36 months, they can use more than one relation (e.g., including a stack and a line in the same construction), but they typically generate them in sequence (e.g., completing the stack, and then the line). By 48 months, children are able to produce multicomponent constructions, with multiple spatial relations, extending in multiple directions in space, and with multiple points of contact between components (e.g., shifting between the line and the stack while building; creating multicomponent construction such as a bridge and several roads). Similar changes are observed in studies of children's drawings. For example, Prather and Bacon (1986) showed that children can attend to either the parts or the whole of a spatial pattern, but their performance can be influenced by specific task and stimulus manipulations. Data from a large series of studies using different measures with children ranging in age from 3 to 12 years show that initially children segment out well-formed, independent parts and use simple combinatorial rules to integrate the parts into the overall configuration (Akshoomoff and Stiles, 1995a,b; Feeney and Stiles, 1996; Stiles and Stern, 2001; Tada and Stiles, 1996). Across the preschool and school-age period, change is observed in both the nature of the parts and the relations children use to organize the parts. Further, pattern complexity affects how children approach the problem of analysis. In a study using the Rey-Osterrieth Complex Figure and simplified variants (see Figure 15.3), it was shown that simplification of the pattern induced more advanced reproduction strategies (Akshoomoff and Stiles, 1995a,b).

15.3 DORSAL STREAM PROCESSES

A variety of spatial processes have been associated with dorsal visual stream processing. We consider three of these processes in this section: spatial localization, spatial

Rey-Osterreith complex form

Representative copies

8-years

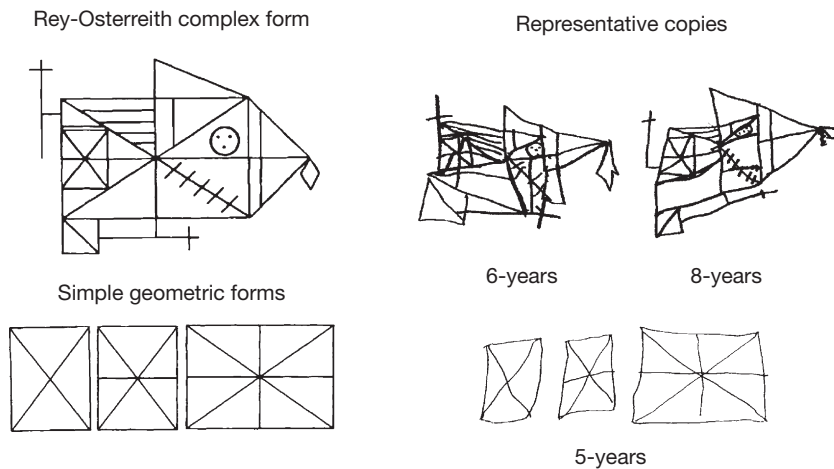
5-years


FIGURE 15.3 Models of the Rey-Osterrieth Complex Figure (ROCF) and the three simple geometric forms are shown on the left. Children were given unlimited time to copy each model form. On the right side are examples from 6- and 8-year-old children's copies of the ROCF, and a representative example of a 5-year-old child's copies of the simple geometric forms. Although the simpler forms are contained within the ROCF, children are more accurate in reproducing them in isolation than in the context of the more complex form. *Reproduced from Akshoomoff NA and Stiles J (1995) Developmental trends in visuospatial analysis and planning: I. Copying a complex figure.* Neuropsychology 9(3): 364–377, *with permission.*

attention, and mental rotation. The characterization of these basic dorsal system processes as independent and distinct from those of the ventral stream is somewhat artificial in that, for example, localization of an object may also require a shift in spatial attention, and mental translation of an object must involve both localization and attention in space. Nonetheless, there is substantial evidence for functional and anatomical independence of key features of each process.

15.3.1 Spatial Localization

Evidence from human and animal studies shows that the dorsal stream plays a critical role in perceptual localization (Belger et al., 1998; Chiba et al., 2002). In a series of studies using positron emission tomography (PET) imaging, Haxby and colleagues examined profiles of posterior brain activation using tasks that required adults to compare the location of objects in two visually presented arrays (Haxby et al., 1991, 1994). In addition to activation in bilateral extrastriate cortex presumed to be involved in early visual processing, there was also robust activation of bilateral regions of parietal lobe, including posterior superior parietal areas extending rostrally to the intraparietal sulcus (Brodmann's area 7). These human brain activation findings on location processing are consistent with animal studies (Colby and Duhamel, 1996; Colby and Goldberg, 1999; Rizzolatti and Matelli, 2003), and have been largely replicated in subsequent fMRI, PET, and transcranial magnetic stimulation studies (Belger et al., 1998; Casey et al., 1998; Ellison and Cowey, 2006; Jonides et al., 1993; Nelson et al., 2000; Oliveri et al., 2001; Smith et al., 1995, 1996). Moreover, subsequent studies identified the IP lobe as important in perceptual processing of location (Colby and Duhamel, 1996; Courtney et al., 1996). A large number of functional neuroimaging studies have demonstrated the importance of frontal regions in spatial working memory for locations. Two regions that appear

to be particularly important for spatial working memory in humans include the superior frontal cortex (Courtney et al., 1998; Curtis, 2006; Haxby et al., 2000b; Sala et al., 2003) and DLPFC (Curtis, 2006; Postle et al., 2000).

The task of looking or reaching to a spatial location involves a complex network of neural areas within the dorsal frontoparietal system (Colby and Duhamel, 1996; Colby and Goldberg, 1999; Johnson et al., 1996; Pierrot-Deseilligny et al., 2004; Rizzolatti and Matelli, 2003; Wise et al., 1997). Prefrontal motor areas mediate planning and preparation for motor action; activation of these areas typically precedes the actual motor event. There is considerable evidence for superior parietal input to dorsal premotor and motor cortices; activation in frontal and superior parietal areas is concordant, suggesting a network of spatial-motor control (Rizzolatti and Matelli, 2003; Rizzolatti and Sinigaglia, 2010). In addition, IP areas connect to frontal premotor areas and play an important modulatory role in spatial-motor activity (Andersen et al., 1997). Rizzolatti and Matelli (2003) have suggested that the dorsal system may comprise two separate but interrelated systems: an IP system dominated by visual perceptual inputs and a superior parietal system governed by somatosensory information that is used to guide action.

Location processing is postulated to rely on the computation of two distinct types of relations: categorical and coordinate (Kosslyn, 1987, 2006; Kosslyn et al., 1989, 1992). Categorical relations provide generalized abstract positional information about the relative location of two elements, such as above/below or right/left. Coordinate relations provide precise metric information about spatial relations. Neuroimaging studies have implicated posterior parietal regions for both categorical and coordinate relational processing (Kosslyn et al., 1989, 1995a, 1998; Trojano et al., 2002) but the laterality of the two processes appears to differ. Specifically, categorical processing is LH dominant, while coordinate processing is RH dominant (Kosslyn, 2006; Kosslyn et al., 1989, 1995a).

One of the largest bodies of data on the early development of visuospatial processing comes from a simple, spatial hiding task, originally introduced by Piaget (1952). Infants watch as a toy is hidden under one of two screens (A or B) and are then encouraged to retrieve it. Eight-month-olds easily retrieve the object hidden under A (but also see Smith et al., 1999), but when the object is then hidden under B, they continue to search at A committing what has been termed the A not B error (AB error). This error has been widely conceptualized as an index of object permanence, that is, of the infant's knowledge that objects exist independently over space and time. A wide range of factors have been shown to affect the likelihood of making the AB error. For example, the beginning of self-locomotion reduces the likelihood of AB error (Bertenthal and Campos, 1990; Horobin and Acredolo, 1986; Kermoian and Campos, 1988). In addition, healthy preterm infants are more advanced on the AB search task compared to full-term peers matched for gestational age, suggesting that extra experience in the world offers the healthy preterm infants a developmental advantage (Matthews et al., 1996). Altering task demands effects AB task performance. Some factors, such as the use of salient landmarks, distinctive screens, or increased distance between the screens, improve performance (Butterworth et al., 1982; Wellman et al., 1987). By contrast, increasing task demands by increasing the delay between hiding and search negatively impacts performance. Introduction of a delay between hiding and retrieval increases error frequency among children as old as 12 months (Diamond, 1985; Spencer et al., 2001).

Although neuropsychological data on AB task performance are limited, several studies implicate the DLPFC. In adult rhesus monkeys, bilateral lesions of the DLPFC disrupt AB search task performance (Diamond, 1991; Diamond et al., 1994). Studies using near-infrared spectroscopy to measure localized brain activation in infants provide converging evidence for the association between frontal lobe development and successful search performance (Baird et al., 2002). Electroencephalography (EEG) data have been used to examine potential markers of object representation. Gamma-band activity has been associated with maintenance of mental representations of objects among adults (Tallon-Baudry et al., 1998). Studies measuring gamma-band activity in the EEG of 6-month-old infants during object processing and object occlusion tasks suggest that the neural signature of object representation can be detected by the middle of the first year of life (Csibra et al., 2000; Kaufman et al., 2003, 2005). In summary, these data suggest that a complex network of neural systems emerge across the first year of life to support performance on this seemingly simple task. The data point to changes in both frontal and parietal regions within the dorsal stream, and suggest comparable changes within temporal and frontal regions of the ventral stream. As Johnson noted, changes within these neural regions are unlikely to be unitary events; rather, neural development likely reflects a more gradual 'coming online' of the different components of the complex neural system that progressively comes to support the range of behaviors involved in the visual search task (Johnson et al., 2001).

Although studies of location coding in toddlers suggest that they can make use of fine-grained distance information when searching for hidden objects, the tendency to subdivide space (hierarchical coding) to facilitate remembering an object's location does not emerge until approximately age 4 (Huttenlocher et al., 1994). Further, it is not until age 10 that children show reliable, adult-like spatial coding of fine-grained, multidimensional categorical information (Sandberg et al., 1996). This is consistent with other studies demonstrating improvements in location memory through mid to late childhood (Bell, 2002; Luciana et al., 2005; Orsini et al., 1987; Zald and Iacono, 1998). Increasing task demands by requiring that multiple spatial positions be recalled in a certain order extends the period of immature performance into early adolescence (Farrell Pagulayan et al., 2006; Gathercole et al., 2004; Luciana et al., 2005). Fine-tuning of location information encoded in memory is reported to extend through late adolescence (Luna et al., 2004).

Visual hemifield tasks are used to examine hemispheric specialization of categorical and coordinate image generation (Kosslyn et al., 1995b). In these studies, participants decide whether probe marks (X) presented on a blank grid (categorical task) or bracketed square (coordinate task) appeared on a previously studied letter (see Figure 15.4). Target grids or brackets are presented to either the right (RVF) or left visual hemifield (LVF). For adults, the grid task elicits an LH 'categorical' advantage, whereas the bracket task elicits an RH 'coordinate' advantage. This profile of lateralization appears to emerge gradually during middle childhood. Specifically, 8-year-olds show an RH advantage for both categorical and coordinate tasks, but 10-year-olds begin to show the profile of lateralized differences characteristic of adults (Reese and Stiles, 2005). It is notable that the overall performance of 8-year-olds is considerably poorer than that of 10-year-olds, and the RH advantage is evident primarily on less challenging trials when the probe appears in a salient location marked by global spatial cues (so-called early probes). The finding of a developmentally early RH advantage on these location-processing tasks is consistent with the finding of an RH-mediated, global-processing advantage for children on a global–local processing task discussed earlier (Moses and Stiles, 2002). It appears that the more detailed LH-mediated processing required for both local-level and coordinate spatial processing are later emerging aspects of neural specialization.

During the test phase, subjects were asked to read the lowercase letter beneath the stimulus and decide whether the corresponding block letter would cover the X mark in the grid (categorical task) or brackets (coordinate task) if it were present. *Reproduced from Kosslyn SM, Maljkovic V, Hamilton SE, Horwitz G, and Thompson WL (1995) Two types of image generation: Evidence for left and right hemisphere processes.* Neuropsychologia 33(11): 1485–1510, with permission.

15.3.2 Spatial Attention

A closely related line of investigation focuses on the neural systems associated with the ability to shift attention to different spatial locations. In contrast to work examining profiles of brain activity when subjects are required to directly perceive or remember the location of an object, spatial attention tasks investigate the brain systems engaged when attention must shift to a new location. There is considerable clinical and experimental evidence that the posterior parietal lobes play a crucial role in the ability to shift attention (Heilman and Valenstein, 1993; Hillyard and Anllo-Vento, 1998; Ivry and Robertson, 1998; Posner, 1980; Posner et al., 1984; Rafal and Robertson, 1995; Robertson, 1992). Posner's influential model of the attention system involves an interconnected network of structures that modulate and control different aspects of attention (Posner, 1980;

Posner and Petersen, 1990). The posterior parietal network plays an essential role in disengaging attention from one location and allowing a shift of attention to another location.

In the standard task used to test covert shifts of attention (Posner and Cohen, 1980), subjects are required to fixate on a point located centrally between two identical, flanking squares. After a fixed period, a visual cue is presented either centrally (e.g., an arrow) or peripherally (e.g., one box brightens), and soon after a target appears briefly in one box. The subject responds as soon as the target is detected. The critical variable is the validity of the cue. On most trials (75–80%), the cue is 'valid' and the target appears in the cued box. On the remaining trials, the cue is 'invalid,' and the target appears in the opposite box. If cueing serves to covertly shift attention, it should take less time to detect the target when the cue is valid than when it is invalid. One additional, well-established finding concerns response differences associated with the length of the interval between the valid cue and target, or stimulus onset asynchrony (SOA). With short SOAs (<200 ms), the classic facilitation of RT is observed. However, at longer SOAs (300–1300 ms), responses to the cued target are slowed (e.g., Posner et al., 1985). This phenomenon, which has been called inhibition of return (IOR), is thought to reflect the suppression of responses to an already attended location.

To examine patterns of brain activation associated with shifting attention, Corbetta used a variant of the attentional cueing task (Corbetta, 1998; Corbetta et al., 1993). The results of this study confirmed earlier reports from human and animal work on the role of the parietal lobes in shifting spatial attention. Significant foci of brain activation were observed in left and right superior parietal regions. However, the patterns of activation to stimuli presented to the RVF and LVF were not symmetrical across the hemispheres. Presentation of targets to the LVF produced significantly more activation in the RH than the LH, whereas presentation of targets to the RVF produced significant levels of activation in both the RH and LH. Furthermore, distinct activation sites for RVF and LVF targets were identified within the right superior parietal region, suggesting that different brain regions within the RH are responsible for processing information from the two sides of space.

There is a small, but growing literature on infants' ability to shift attention in the visual field (also see Colombo, 2001). A number of studies have shown that by 6 months, infants show both facilitation and IOR (Clohessy et al., 1991; Harman et al., 1994; Hood, 1993; Johnson et al., 1994; Johnson and Tucker, 1996; Varga et al., 2010). Attempts to evoke these responses from younger infants have been mixed. However, control of factors such as SOA duration and cue/target eccentricity

appears to be critical for eliciting the responses. Using 200 and 700 SOAs, Johnson and Tucker (1996) demonstrated reliable facilitation and IOR among 4-month-olds, but not among 6-month-olds. However, when a 133 ms SOA was introduced, 6-month-olds showed strong facilitation. This finding suggests that while the basic attentional responses may be robust as early as 4 months, the timing parameters that elicit the response may change with development. Consistent with this, Varga et al. (2010) reported a developmental shift from facilitation to inhibition between 4.5 and 6 months with 300 ms SOAs. Similarly, Harman et al. (1994) found no IOR response among 3-month-old children when stimuli were presented at 30° eccentricity, but a strong response at 10°. Thus, distribution of attention across the visual field may also change with development. Few studies have examined facilitation and IOR in children under 2 months. Johnson and Tucker (1996) reported only weak facilitation effects and no IOR effects among 2-month-old infants. However, Valenza et al.'s (1994) study of newborns suggests that IOR may be present in the first days of life. Further, the child's prior experience in the world, as indexed by familiarity responses, has been shown to affect individual components of the EEG response. Specifically, a negative ERP component that is measured over frontal and central electrodes (the so-called negative central or Nc component) has been shown to increase in response to novelty. Reynolds and Richards (2005) reported a smaller Nc response to familiar compared with novel stimuli in children as young as 4.5 months, suggesting that memory may have a modulatory effect on attention from very early in life. Finally, social cues can direct covert shifts of attention in children as young as 4 months of age (Reid et al., 2004). Direction of eye gaze is a potent cue for shared attention. When infants observed an adult shift gaze toward (cued) or away (uncued) from a target object, ERP responses to subsequent presentations of the cued or uncued object differed in frontotemporal brain regions. These findings suggest that a social cue can induce covert shifts in the infants' attention.

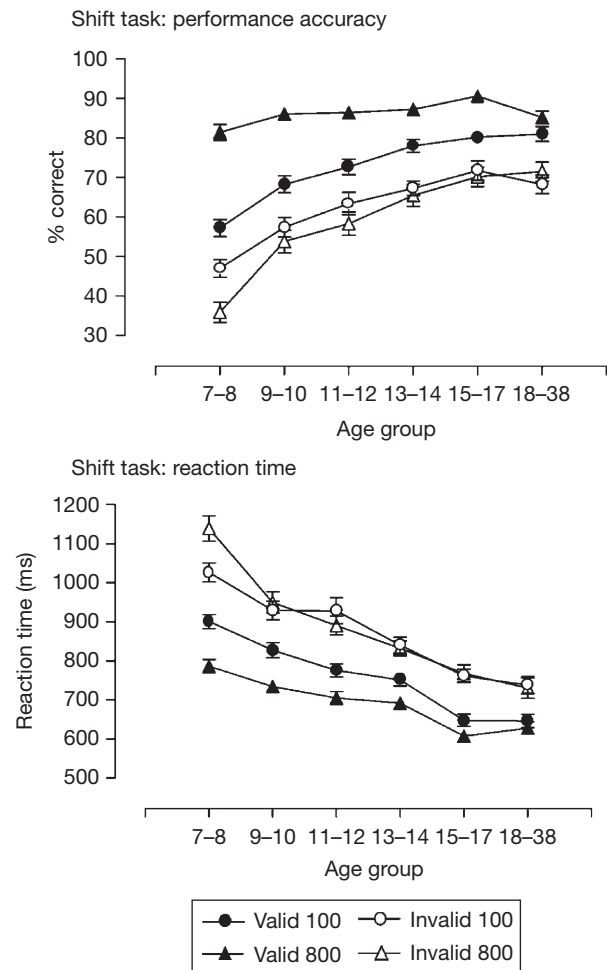
The existing literature on the development of spatial attention in the school-age period is limited, and the findings somewhat inconsistent (Brodeur and Enns, 1997; Enns and Brodeur, 1989; Nougier et al., 1992; Pearson and Lane, 1990). Schul et al. (2003) studied a large sample of children ranging in age from 7 to 17 years on a classic covert orienting task. They reported systematic developmental improvement in aspects of visual attention, including orienting, disengaging, and attending an uncued location. Across the 10-year age window, there was a systematic linear decline in response time, coupled with a linear increase in accuracy (see Figure 15.5).


FIGURE 15.5   The accuracy and reaction time performance of typically developing 7–20-year-olds on a shift attention task show a regular pattern of improvement that emerges gradually through the school-age and adolescent periods. *Reproduced from Schul R, Townsend J, and Stiles J (2003) The development of attentional orienting during the school-age years.* Developmental Science 6(3): 262–272, with permission.

15.3.3 Mental Rotation

Mental rotation is an important spatial operation that involves the ability to mentally transpose the orientation of an object in space, thus allowing for the computation of a canonical mental representation of a noncanonically presented stimulus, for example, constructing a canonical side-view image of a dog or cat when presented a noncanonical view from behind. Mental rotation requires a host of visuospatial skills including visual pattern processing, visuospatial attention, and visuospatial working memory. A common method used to study mental rotation is to present two objects, one upright and one rotated off vertical, and ask participants if the objects are the same or mirror images. The robust result is that response times vary as a linear, monotonically increasing function of angular disparity between the

two objects. This linear response time has become the hallmark characteristic of mental rotation (see Shepard and Cooper, 1986). Over the past decade, a number of neuroimaging studies have documented a neural network associated with mental rotation that includes the right superior parietal lobe, higher-order visual areas (such as MT), and the premotor area (Richter et al., 1997; Riecansky, 2004).

Children as young as age 5 can perform mental rotation (Kosslyn et al., 1990; Marmor, 1975). In an early study, Marmor (1975) found that the RT regression slopes of 5-year-olds were similar to adults and concluded that children are able to perform mental spatial transformations. Subsequent studies have replicated this basic finding (Kosslyn et al., 1990) and confirmed through verbal reports that children use mental rotation to make judgments even under conditions where no explicit instructions to mentally rotate are given (Estes, 1998). Although young children can engage in mental rotation, developmental differences are observed in speed and efficiency of processing (Hale, 1990; Kail et al., 1980; Merriman et al., 1985; Snow, 1990). Further, a wide range of factors including IQ, gender, socioeconomic status, videogame playing, stimulus type employed, and practice on the mental rotation task all impact performance (Cai and Chen, 2000; De Lisi and Wolford, 2002; Okagaki and Frensch, 1994; Waber et al., 1982; Willis and Schaie, 1988). These data suggest that the observed developmental changes could reflect improvement of initially rudimentary mental rotation skills, or they reflect changing strategies for solving the matching problems presented within the context of the standard mental rotation tasks.

Only a few studies have reported data on the neural systems that underlie mental rotation during development. In general, children show patterns of parietal activation similar to adults, but their activation appears more diffuse (Booth et al., 1999, 2000; Roberts and Bell, 2002). The distinctive patterns of activation, including greater superior parietal activation, reported for adults compared to 9- to 10-year-olds may be an index of increasing functional specialization (Booth et al., 2000). Further, an ERP study of 8-year-old children reported bilateral, but asymmetrical parietal activation (right < left) that could reflect emerging hemispheric specialization for mental rotation (Roberts and Bell, 2002). More recently, Ark (Ark, 2005) tested 9–10-year-old children using behavioral and fMRI measures of mental rotation with challenging 3D stimuli. The activation data suggested differences between adults and children in two important brain areas related to mental rotation: the parietal area and MT. Consistent with earlier studies, children produced greater bilateral and widespread activation in the parietal lobe than adults. In addition,

adults produced greater activation in MT than the low-performing children, but not the high-performing children. MT is thought to play a role in imagining the movement of the figures in the mental rotation task. Based on the behavioral data, the low-performing children did not activate MT because they were not performing mental rotation efficiently.

15.4 TRAJECTORIES OF DORSAL AND VENTRAL STREAM DEVELOPMENT

Although many studies have examined the development of ventral or dorsal stream functions separately, work comparing the developmental trajectories of these two systems is limited. The available data present contradictory views of the relative rates of maturation of the two visual systems. One body of data that draws largely from studies of infants younger than a year suggests that dorsal stream functions involved in motion and location processing emerge earlier than ventral stream functions involved in feature processing. In contrast to these findings, studies of older children tend to support the view that the ventral stream matures earlier than dorsal stream.

Much of the evidence for the early maturation of the dorsal stream comes from infant studies of object individuation in which spatiotemporal cues involving motion and location processing are pitted against featural cues. The violation-of-expectation paradigm studies contrast infant responses when spatiotemporal or featural violations are introduced during the test. Infants under about 12 months of age (8 months with simplified tasks) recognize spatiotemporal violations, but fail to notice featural changes (Bonatti et al., 2002; Feigenson and Carey, 2003; Krojgaard, 2000, 2003, 2007; Van de Walle et al., 2000; Xu and Carey, 1996; Xu et al., 2004). This has led to the suggestion that the dorsal system develops earlier than the ventral stream. Other evidence indicates that ventral stream information, such as color, is incorporated into object processing only toward the end of the first year of life (Kaldy and Leslie, 2003; Leslie et al., 1998).

In contrast to the infant work, studies of older preschool and school children generally report that the development of dorsal stream lags behind the ventral stream. In their ERP studies, Neville and colleagues reported significant effects of response latency for the motion but not color stimuli that extended across the age span (Armstrong et al., 2002; Coch et al., 2005; Mitchell and Neville, 2004). However, visual evoked potential (VEP) studies contrasting spatial frequency (Gordon and McCulloch, 1999) and chromaticity (Madrid and Crognale, 2000) found evidence of a lag

in ventral stream functioning. Other studies testing thresholds for motion and form coherence reported that ventral stream-mediated form coherence matures significantly ahead of dorsal stream-mediated motion coherence (Atkinson et al., 2005; Braddick et al., 2003; Gunn et al., 2002). Behavioral studies of children using the dual-stream framework comparing 'what' versus 'how' (Milner and Goodale, 1995) are rare. Atkinson (1998) reported data from a small sample of 4–7-year-old children using Milner and Goodale's (1995) 'postbox' task, which requires manual posting of a letter into a slot at a particular angle (dorsal) or visual matching of the perceived angle of the slot (ventral). They reported a significantly better performance with the visual-matching task. A second study using the same task but focused on 3–4-year-old children suggested a ventral stream advantage based on a similar pattern of the results (Dilks et al., 2008).

The mixed and often contradictory results from studies comparing the relative rates of dorsal and ventral stream development have led a number of investigators to suggest that it may be misleading to treat the development of either visual system as a unitary event. Quinn and Bhatt (2006) have suggested that the global dichotomy likely overlooks subtler changes that occur within each stream across development. In addition, Johnson, Mareschal, and colleagues suggest that the inconsistency

in the data may also arise from another factor related to the immaturity of the visual system (Johnson et al., 2001; Kaufman et al., 2003; Mareschal and Johnson, 2003). They note that while there is good evidence that both streams are functional from very early in development, there is little support indicating that information from the two streams is integrated until late in the first year. This lack of integration may account for some of the findings of the early dominance of spatiotemporal information in the infant literature.

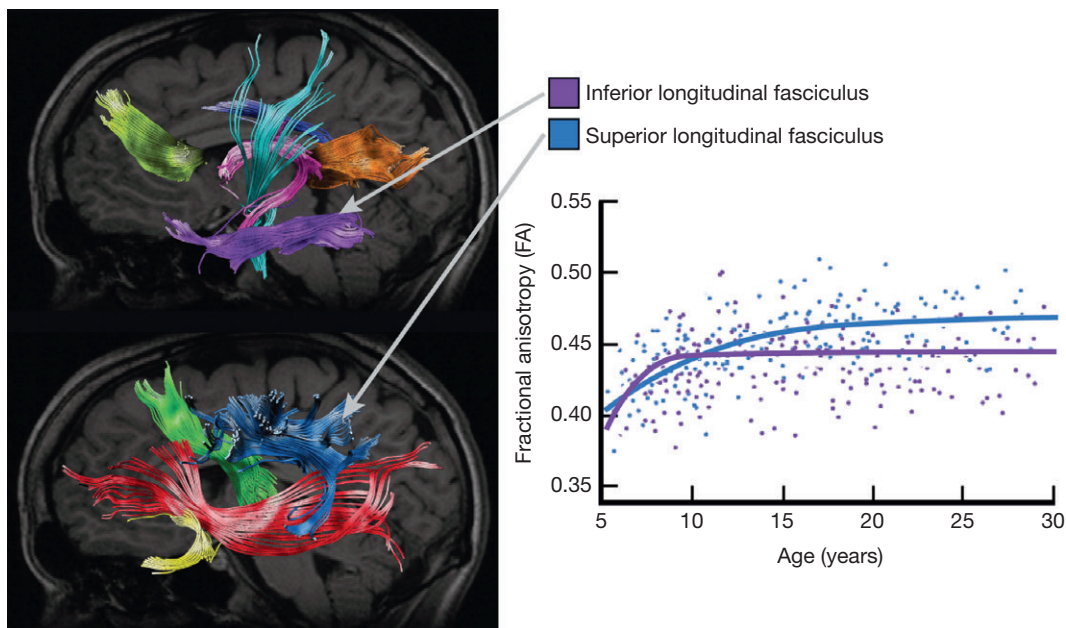
Recent neuroimaging studies of older children examining structural connectivity and functional networks provide relevant data for the developmental trajectory of the dorsal and ventral streams. In a cross-sectional study of development, Lebel et al. (2008) evaluated fractional anisotropy (FA) from diffusion tensor imaging (DTI) in multiple major white matter tracts in typically developing people aged 5–30 years. Figure 15.6 shows an example from their findings comparing FA measures from a major dorsal pathway, the superior longitudinal fasciculus, and a major ventral pathway, the inferior longitudinal fasciculus. While the inferior longitudinal fasciculus appears mature in the late childhood period, the superior longitudinal fasciculus does not reach full maturity until mid to late adolescence. An extended trajectory for dorsal stream processing was also evident in a study of functional network structure in a developmental study of face processing. Haist et al.


FIGURE 15.6 Evidence for developmental differences in dorsal and ventral stream white matter tracts from diffusion tensor imaging (DTI). Fractional anisotropy (FA) was measured in 202 healthy people ranging from 5 to 29 years in ten major white matter pathways. The tractography in these pathways from a representative adult participant is shown in the left panel. The right panel displays the FA findings across development in the superior longitudinal fasciculus (SLF; dorsal stream) and inferior longitudinal fasciculus (ILF; ventral stream), indicating an extended developmental trajectory for the dorsal stream relative to the ventral stream. Specifically, the SLF does not reach maturity until adolescence, whereas the ILF reaches maturity in late childhood. *Reproduced from Lebel C, Walker L, Leemans A, Phillips L, and Beaulieu C (2008) Microstructural maturation of the human brain from childhood to adulthood.* Neuroimage *40(3): 1044–1055, with permission.*

(2011) evaluated functional activation in children (ages 7–12), adolescents (ages 13–17), and adults (ages 18–40) during a simple face and object viewing task (i.e., no explicit memory or other cognitive task requirements). Adults produced a modestly greater extent of activation of the fusiform gyrus (FFA) relative to children but not adolescents, and there was a positive correlation with age and activation in the OFA. The striking finding was that children produced hyperactivation relative to adults in regions in the so-called extended face network (Haxby et al., 2000a), including regions in the ventral stream such as the anterior temporal pole (superior temporal gyrus) and amygdala, and dorsal stream such as the IP lobule and inferior frontal gyrus. Adolescents produced hyperactivation relative to adults only in the dorsal stream regions.

15.5 NEURODEVELOPMENTAL DISORDERS OF VISUOSPATIAL PROCESSING

Patient data have been an important source of information on the functional organization of the two major visual pathways. Studies of adult patients with frank injury to either the dorsal or ventral stream networks have been an important source of data on functional organization within the human brain. These studies rely on the logic of subtraction, looking for associations between site of lesion and specific functional loss. The study of developmental disorders requires a somewhat different perspective. Rather than simple associations, the central questions concern the multiple, alternative patterns of brain organization that can arise following early injury to the developing brain or disruption of molecular signaling pathways at critical points in early brain development. These studies thus address issues concerning neural plasticity and compromise, and their effects on the development of basic functions. This section reviews a few of the neurodevelopmental disorders that affect visuospatial functions. It examines both the effects of frank neural insult on the development of spatial processes and the effects of specific genetic abnormalities.

15.5.1 Perinatal Stroke

Perinatal stroke (PS) is a cerebrovascular event that occurs in the period just before birth or immediately after and is usually observed among infants born at term (Lynch and Nelson, 2001). The incidence rate of PS is estimated at 1 in 4000, but it is widely believed that the estimates are low reflecting only those cases that present with identifiable symptoms (Nelson and Lynch, 2004). PS most commonly involves the middle cerebral artery distribution, creating large lesions that compromise much of one cerebral hemisphere. In adults, such lesions result in significant cognitive deficits, the specific patterns of which differ depending on the side and site of the injury. However, children with such large lesions often achieve considerably better functional outcomes. They typically have normal or corrected-to-normal sensory functions, and intellectual functioning that falls within the normal range on standardized IQ tests (Aram and Ekelman, 1986; Ballantyne et al., 1994; Bates, 1999; Levine et al., 2005; Nass et al., 1989; Stiles et al., 2012).

There is, however, evidence that different neural systems and functions may vary in their capacity for adaptive reorganization, even when injury is early. While basic sensory and motor systems are capable of considerable reorganization, the residual effects on function are often greater than for other domains (Himmelmann et al., 2006; Nelson and Ellenberg, 1982; Van Heest et al., 1993; Wu et al., 2006; Yekutiel et al., 1994). Within cognitive domains, level of function is consistently superior to that of adults with comparable injury, but varies by skill domain. Early developing functions such as those associated with visuospatial processing appear to be more vulnerable than later-developing functions such as language (Reilly et al., 2008; Stiles et al., 2009, 2012). Similarly, functions such as visuospatial processing that have a long evolutionary history and are closely linked to a specific sensory system exhibit somewhat less functional plasticity.

Studies of ventral stream processing among adults with unilateral injury have shown that different patterns of spatial deficit are associated with LH and RH injury (Arena and Gainotti, 1978; Gainotti and Tiacci, 1970; McFie and Zangwill, 1960; Piercy et al., 1960a; Ratcliff, 1982; Swindell et al., 1988; Warrington et al., 1966). Injury to LH brain regions results in disorders involving difficulty defining the parts of a spatial array. For example, patients with LH injury tend to oversimplify spatial patterns and omit details when drawing. On perceptual judgment tasks, they rely upon overall configural cues and ignore specific elements. In studies of global versus local processing, LH injury is associated with local-processing deficits. By contrast, patients with RH lesions have difficulty with the configural aspects of spatial analysis. In drawing, they include details, but fail to maintain a coherent organization among the elements. In perceptual judgment tasks, they focus on the parts of the pattern without attending to the overall form. In studies of global versus local processing, RH injury results in global-level deficits (Delis et al., 1986, 1988).

Data from children with PS suggest that the basic organization of the ventral stream is established early, but is capable of at least limited adaptive organization. Children with RH and LH injury show similar patterns of impairment as adults, but their deficits are milder and performance improves with development (Stiles et al., 2008, 2012). For example, reproduction accuracy for

the global-level forms, but not local-level forms, is significantly lower than controls in children with RH injury; the reverse pattern is observed in children with LH injury (see Figure 15.7(a)). Further, while accuracy improves in all groups with development, the pattern of deficit persists for both of the groups with PS (see Figure 15.7(b) for examples at two developmental time points for one child with LH and one with RH injury). These performance differences reflect alternative patterns of brain organization that can arise following early injury. In fMRI studies of global–local processing, adolescents with PS do not show a typical profile of right posterior activation for global- and left posterior activation for local-level processing (Moses et al., 2002). Rather, regardless of the side of lesion, activation for both tasks is confined to the ventral–temporal regions of the contralesional hemisphere. As shown in Figure 15.6(c), LH (left hemisphere lesion) shows

extensive activation on the right and little or no activation on the left on both the global- and local-processing tasks, while RH (right hemisphere lesion) shows extensive activation of the LH and very little activation of the RH. These findings suggest that an alternative, lateralized pattern of brain organization emerges in the wake of early injury. While functional, this alternative pattern of activation is not optimal as reflected in the behavioral performance profiles. Similar lateralized differences in global/configural versus local/featural deficits are observed across a range of tasks including block construction (Stiles et al., 1996; Vicari et al., 1998), copying and drawing (Akshoomoff and Stiles, 2003; Akshoomoff et al., 2002), and face perception (de Schonen et al., 2005; Mancini et al., 1994; Stiles et al., 2006).

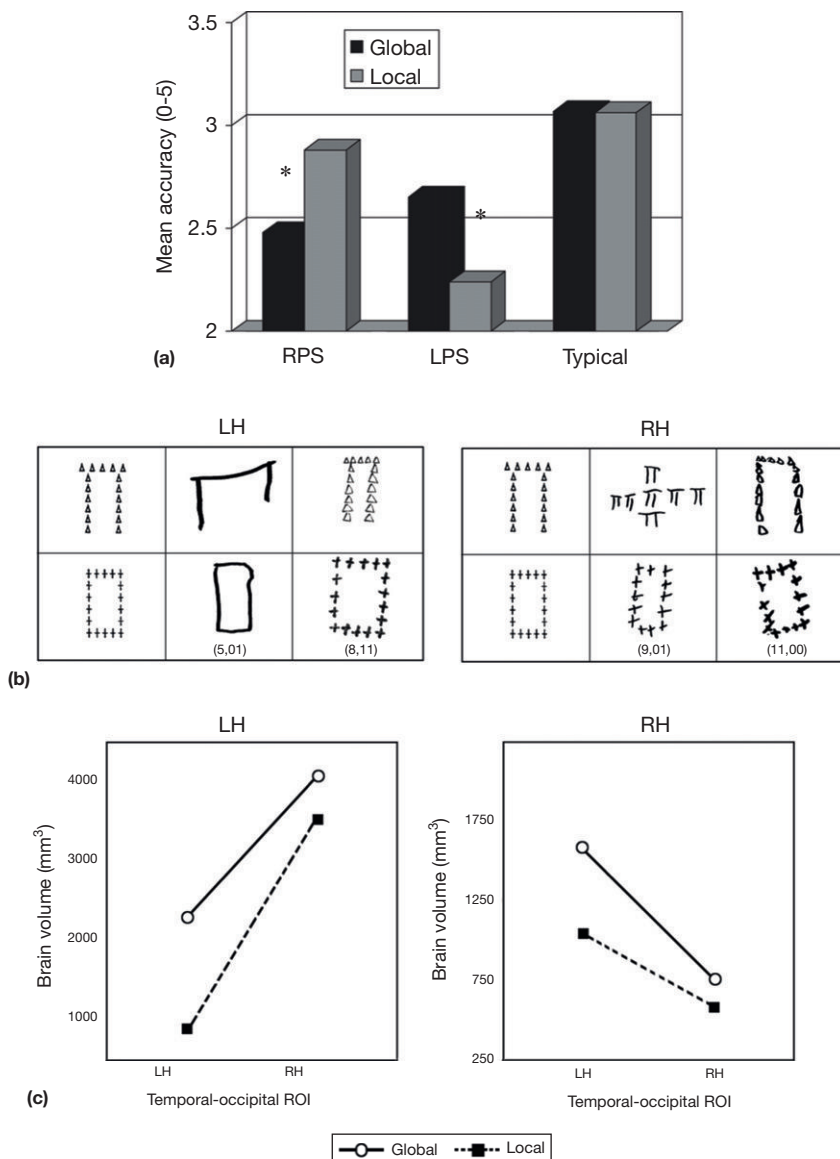
Consistent with data from ventral stream functioning, studies of children with PS report patterns of deficit for


FIGURE 15.7 Behavioral and functional brain activation data from hierarchical form-processing tasks. (a) In contrast to age- and IQ-matched controls, who are equally accurate in reproducing the global and local pattern levels, 5–12-year-old children with RPS injury were more accurate in reproducing the local pattern level, and children with LPS injury were more accurate in reproducing the global pattern level. *Reproduced from Stiles J, Stern C, Appelbaum M, Nass R, Trauner D, and Hesselink J (2008) Effects of early focal brain injury on memory for visuospatial patterns: Selective deficits of global–local processing.* Neuropsychology 22(1): 61–73, with permission. (b) Examples of reproductions from two children, one with LH injury (left) and one with RH injury (right) at two developmental time points. While performance improves with age, subtle levels of specific deficits persist. (c) Brain activation to a perceptual hierarchical-form-processing task is lateralized to the contralesional hemisphere for both global and local processing. Activation is based on an ROI analysis in a region of the posterior lateral temporal–occipital lobe. *Activation data are from the same two children whose earlier drawings are shown in panel b. Reproduced from Stiles, J., Moses, P., Passarotti, A., Dick, F. and Buxton, R. 2003. Exploring developmental change in the neural bases of higher cognitive functions: The promise of functional magnetic resonance imaging.* Developmental Neuropsychology, 24(2&3), 641–668 with permission.

dorsal stream function that are consistent with those observed among adults, though the severity of deficit is less pronounced. Here again, there is clear evidence for performance improvements from the preschool to the late adolescent period, suggesting that children may be better able to compensate for their spatial-processing deficits than adults with comparable injury. Studies of adults suggest that LH injury interferes with categorical processing of spatial locations, while RH injury interferes with coordinate processing (Laeng, 1994; Palermo et al., 2008; Postma et al., 2008; van Asselen et al., 2008). Very similar patterns of results have been reported for children with PS. In an object-retrieval task, 3-year-olds with RH injury were impaired in their use of coordinate relations, performing below the level of typical 18-month-olds (Lourenco and Levine, 2009). Performance improved with development such that by age 5 children showed mastery of this task. However, evidence of persistent subtle deficit emerges among older children on more challenging tasks. Reese et al. (in preparation) tested 10–16-year-olds on Kosslyn's visual hemifield categorical and coordinate processing task (Kosslyn et al., 1995a). Similar to findings from adults with unilateral injury, children with RH injury showed subtle deficits in coordinate processing, and children with LH injury in categorical processing. These studies focused on dorsal stream processing are consistent with those focused on ventral stream processing in that they show evidence of developmental improvement in spatial processing against a backdrop of subtle, persistent lateralized deficit.

15.5.2 Spina Bifida

Spina bifida meningomyelocele is a major neurodevelopmental disorder caused by an open lesion in the spinal cord through which the meninges protrude into a fluid-filled sac (Fletcher and Dennis, 2009; Mitchell et al., 2004). It is usually associated with a malformation of the cerebellum and hindbrain (Chiari II malformation), which in turn causes hydrocephalus. Callosal dysgenesis is also common. Each of the primary CNS abnormalities associated with spina bifida can directly affect neurobehavioral outcomes. Eye movement disorders are common. The ability to perform visually guided hand and arm movements is often affected, particularly in children with higher spinal cord lesions (Fletcher et al., 2005). These are likely a result of insult to the midbrain and tectum as well as impact to the cerebellum.

In addition to hydrocephalus, spina bifida can also be characterized by hypoplasia of the corpus callosum, cortical thinning, and/or white matter loss. The secondary effects of these abnormalities can also impact neuropsychological functioning. Although outcomes are variable, children with spina bifida generally have a relatively stronger language performance and weaker perceptual and motor skills, particularly as demonstrated by comparing their verbal and performance IQ scores (Fletcher et al., 1992).

In order to examine the visual perceptual deficits found in children with spina bifida, Dennis et al. (2005) compared the results across a series of studies on measures emphasizing object-based perception or ventral processing and those emphasizing action-based or dorsal processing. Among children with IQs at or above 70, performance was relatively better on ventral stream tasks (face recognition and visual illusions) and poorer on dorsal stream tasks, particularly those requiring action-based movement (visual pursuit, drawing, route finding, and route planning). Poorest performance relative to control subjects was found on stereopsis and visual figure-ground tasks. Results from a study of object-based visual processing also provide further support for sparing of the ventral visual stream in spina bifida, despite damage to posterior brain regions (Vinter et al., 2010). Weaknesses in both visual–spatial ability and phonological processing are related to poor math performance in preschoolers with spina bifida (Barnes et al., 2011).

The early disruption of brain development associated with spina bifida appears to lead to relatively more disruption of functions associated with the dorsal visual stream. Spatial test performance is correlated with corpus callosum measures in children with hydrocephalus, including those with spina bifida (Fletcher et al., 1996). Recent MRI and DTI results indicate disruption of the white matter and reorganization of cortical regions, with the greatest impact on posterior regions (Hasan et al., 2008; Juranek et al., 2008). Direct comparisons between neuropsychological test performance and imaging results are needed to examine specific aspects of visuospatial processing in more detail.

15.5.3 Neurogenetic Syndromes

Three neurogenetic syndromes are associated with deficits in the development of visuospatial skills, particularly those skills associated with the dorsal visual stream. Neuroimaging data from patients with these syndromes also implicate greater neurodevelopmental abnormalities and perhaps greater early neurodevelopmental vulnerability within the dorsal visual stream.

15.5.3.1 Williams Syndrome

Williams syndrome (WS) is caused by a hemizygous microdeletion of approximately 25 genes on chromosome 7q11.23. Most individuals with WS have mild to moderate intellectual impairment (IQs range from the high 50s to the low 70s). There is an unusual cognitive

profile associated with WS, with relative sparing of language and relative impairment in visuospatial and visuomotor task performance (Bellugi et al., 2000; Mervis et al., 2000; Meyer-Lindenberg et al., 2006; Sarpal et al., 2008). Difficulties with visuospatial construction tasks, particularly drawing and block construction tasks, are hallmark deficits in WS. Deficits in location-processing tasks are also found. In contrast, face processing is an area of remarkable strength in WS. These results led to the suggestion of a clear deficit in the dorsal stream with relative sparing of the ventral stream in WS (Galaburda and Bellugi, 2001; Mills et al., 2000; Sarpal et al., 2008). However, task demand differences inherent in these tasks left open the possibility that there were other explanations for this phenomenon. This was examined directly in a study of face and place processing in children and adults with WS (Paul et al., 2002). The perceptual tasks were precisely matched. Individuals with WS did not differ significantly in performance from controls in the face-processing task but were significantly worse in the place (location)-processing task, providing further evidence of a dorsal stream deficit.

Deficits on construction tasks in individuals with WS are consistent across different ages, paradigms, and samples (Bellugi et al., 2001; Donnai and Karmiloff-Smith, 2000). These deficits may be related to the considerable motor demands of such tasks in contrast to tasks that tap other ventral stream skills, such as face processing, with minimal motor demands. However, the reliance on both ventral and dorsal stream processing is an alternative explanation for these discrepancies. In order to more closely examine the dorsal stream deficit hypothesis without the possible impact of intellectual impairment, a group of adults with WS with normal intelligence participated in a series of fMRI experiments (Meyer-Lindenberg et al., 2004). One task used identical stimuli in two conditions. The object-based condition required participants to indicate if two shapes match while the visuospatial decision condition required participants to indicate if two shapes could be constructed to make a square (motor). Both control and WS participants showed comparable activation in the ventral stream during these conditions. While control participants activated bilateral regions of the parietal portion of the dorsal stream in the match minus motor contrast, individuals with WS showed no significant activation. Similar results were found in the attention to object versus attention to location condition. The authors concluded that this hypoactivation reflects a persistent functional deficit in WS that becomes rate limiting when higher demands are placed on the dorsal stream during construction tasks. A subsequent fMRI study demonstrated dorsal stream deficits as well as results that suggest that the medial ventral stream is affected more than the lateral ventral stream (O'Hearn et al., 2011).

Gray matter volume reduction was found in the adjoining parietal–occipital and intraparietal sulcus in WS. Subsequent studies have reported smaller superior parietal lobe volumes in WS (Eckert et al., 2005) as well as DTI abnormalities that suggest that the underlying white matter tracts subserving the dorsal stream of visual processing may be aberrant in WS (Hoeft et al., 2007).

15.5.3.2 Fragile X Syndrome

Fragile X syndrome is a single-gene disorder caused by an expansion of CGG repeats in the promoter region upstream of the *FMR1* gene on the long arm of the X chromosome (Walter et al., 2009). It is the most common known cause of autism, with 15–30% of males with fragile X meeting DSM-IV criteria for autistic disorder and a higher percentage showing more autistic behaviors than expected based on their developmental level. The cognitive deficits can range from mild learning disabilities to severe intellectual disability, with males more likely to be severely affected than females (Schneider et al., 2009). In addition to difficulties in social abilities and executive functions, individuals with fragile X have impaired visuospatial skills (Kwon et al., 2001).

Males and females with fragile X have difficulty with mental manipulation of the spatial relationships between objects and visuomotor coordination, as well as construction tasks and visuospatial working memory (Reiss and Dant, 2003). Children with fragile X also have difficulty with arithmetic skills, with the appearance of poor math achievement scores in early childhood (Mazzocco, 2001). In a study of the relationship between visuospatial skills and math performance, girls with fragile X showed impairment on some aspects of 'where' spatial processing, but no apparent difficulty in identifying objects (Mazzocco et al., 2006). Specifically, girls had difficulty with processing global-level information during a memory for location task and integrating parts during the visual closure task. Significant correlations between math tasks and visual perception tasks were also found. These visuospatial deficits may be tied to the dorsal stream, which in turn implicates dysfunction in the posterior parietal cortex. Evidence from both structural and functional neuroimaging supports the dorsal stream deficit hypothesis in fragile X. As shown in Figure 15.8, DTI neuroimaging has shown that dorsal stream white matter tracts, including the frontal–striatal and parietal sensory–motor tracts, are altered in fragile X (Barnea-Goraly et al., 2003). Functional MRI indicates that fragile X is associated with decreased activation in the frontal–parietal areas during math computation and working memory tasks (Reiss and Dant, 2003).
FIGURE 15.8 Example of neuroimaging evidence of a dorsal stream deficit in a neurogenetic disorder. Ten females with fragile X (mean age = 16.7 years) and ten typically developed females (age = 17.0) were examined using diffusion tensor imaging (DTI). The figure shows regions of reduced DTI fractional anisotropy (FA; colored in yellow), a measure of white matter integrity, in fragile X syndrome compared to the control participants. Specifically, abnormal FA was found in the frontal–parietal and parietal sensory–motor pathways. The caudate nucleus (colored in red) is shown for reference. Findings are shown in 3D perspective viewed from (a) superior lateral perspective of the right hemisphere and (b) inferior perspective viewed from under the frontal lobe. Rendered T1 images are shown representing the orientation of the viewing perspective. *Adapted from Barnea-Goraly N, Eliez S, Hedeus M, et al. (2003) White matter tract alterations in fragile X syndrome: Preliminary evidence from diffusion tensor imaging.* American Journal of Medical Genetics Part B: Neuropsychiatric Genetics *118B(1): 81–88, with permission.*

15.5.3.3 Turner Syndrome

Turner syndrome is caused by the partial or complete loss of one female X chromosome. Females with this condition typically have IQ scores in the average range, with performance IQ scores lower than verbal IQ scores, and specific difficulties on visuospatial and math tasks and visuomotor control (Mazzocco, 2001; Walter et al., 2009). There is decreased volume of the parietal and occipital cortices, particularly the superior parietal lobe and postcentral gyri, in Turner syndrome (Brown et al., 2004). Although full-scale IQ is correlated with volume of the postcentral gyri, the relationship between the volume of these posterior brain regions and visuospatial deficits has not been investigated.

Girls with Turner syndrome demonstrate a different pattern of performance across a battery of visuospatial tasks than females with fragile X syndrome (Mazzocco et al., 2006). Girls with Turner syndrome have difficulty with tests of both the 'what' and 'where' systems of visuospatial processing. Specifically, performance on a 'where' task was correlated with performance on a counting task, although it was not clear whether this reflected the visuospatial or the working memory demands of the enumeration task.

Reduced activation of the frontal–parietal network is associated with reduced performance on a visuospatial working memory task (Tamm et al., 2003). Reduced activation in the parietal–occipital regions of the cortex was found on a functional imaging version of the judgment of line orientation task (Kesler et al., 2004). DTI data also implicate abnormalities within the frontal–parietal network (Walter et al., 2009). There is additional evidence for abnormalities within the temporal lobe that may help to explain recent evidence of ventral stream visuospatial deficits in Turner syndrome (Kesler et al., 2003; Rae et al., 2004).

The data from these three distinct neurogenetic syndromes indicate relative deficits in visuospatial skills, particularly the skills associated with the dorsal stream or 'where' visual system. The results from available neuroimaging studies implicate greater involvement of posterior brain regions, but it is not clear how these generally similar behavioral and neurobiological findings result from such different genetic abnormalities. Walter et al. (2009) observed that disruption of the *FMR1* gene associated with fragile X and disruption of the LIMK1 gene associated with WS affect early dendritic morphology. This disruption may have a relatively greater impact on the dorsal visual stream due to its reliance on larger dendritic fields.

15.6 SUMMARY AND CONCLUSIONS

The ultimate product of typical visuospatial processing is a rich and fine-grained understanding of the visual world around us that provides the basis for efficient behavioral and cognitive interactions with the environment. This ability arises from the intricate coordinated activity of multiple brain regions organized into two generally construed neurofunctional brain systems architecturally defined as the ventral and dorsal visual-processing streams, and functionally distinguished for pattern and object processing (i.e., 'what') and spatial or action processing (i.e., 'where' or 'how'), respectively.

The basic neural systems mediating both of these aspects of spatial functioning appear to be specified in a rudimentary fashion early in development. Infants are able to track and retrieve hidden objects by the middle of the first year of life. Basic markers for control of spatial attention can be documented by 4 months and may be available earlier. Dissociable patterns of spatial analytic deficit can be documented in children with perinatal brain injury. All of these data are indicative of the early emergence of basic neural systems that are specified for processing certain types of information. However, early specification of a neural system does not imply full or optimal functioning early in development. There is ample evidence for protracted change extending throughout childhood, with some abilities not reaching maturity until adolescence. Therefore, the developmental perspective using both typical and atypical development is imperative to provide insights into the functional organization of visuospatial processing,

and to understand the plasticity and cognitive–behavioral consequences of early pathology.

Consideration of the dorsal and ventral processing systems as independent is widely believed to be too simplistic, as there is clear evidence for interaction or potential interaction between the systems at multiple points of anatomy and function. Nevertheless, the major developmental hypothesis regarding the trajectory posits that the dorsal system-dependent visuospatial processing matures after the ventral system pattern and object processing abilities. As summarized, this hypothesis is not entirely consistent with findings from infants, but is generally supported by findings in typically developing preschool to school-age children. This has profound implications in developmental disorders. Specifically, dorsal stream functions may be particularly vulnerable to insult at multiple points during development (Atkinson and Braddick, 2007). Findings from several developmental disorders, including frank neurological insult from perinatal stroke and spina bifida, and neurogenetic syndromes, including WS, fragile X syndrome, and Turner syndrome, were summarized that clearly demonstrate disproportionate deficits in dorsal-stream visuospatial functions relative to ventral stream functions. Together, the preponderance of evidence from developmental disorders converges to suggest that visuospatial dorsal-stream functions are specifically vulnerable and less capable of compensation.

There is considerable speculation regarding the neurofunctional basis for dorsal-stream vulnerability in development (Atkinson and Braddick, 2011; Grinter et al., 2010). From an anatomical perspective, evidence points to the possibility of greater vulnerability to insult in magnocellular pathways, the dominant visual cell type in the dorsal stream, relative to the parvocelluar pathway, the dominant visual cell type in the ventral stream. Thus, there is good reason to suspect that dorsal-stream vulnerability results from deficits originating from the earliest visual-processing stages and cascading to advanced spatial processing within the parietal cortex. From a neurocognitive systems perspective, there are additional reasons to suspect greater vulnerability within dorsal stream processing. As summarized, recent models consider the primary role for dorsal stream function to be in the service of behavioral and cognitive 'action,' and there is compelling evidence that typical visuospatial functions depend on the tightly integrated activity between the parietal and frontal cortex networks. Recent neuroimaging findings investigating structural (DTI) and functional connectivity (Fair et al., 2007, 2008, 2009) converge to suggest that the parietal–frontal networks have a protracted development period that does not reach maturity until adolescence. Thus, disruption of typical visual development that impacts parietal lobe-related visuospatial functions would be compounded later in childhood when advanced visuospatial abilities require the contributions from frontal lobe-dependent processes in addition to the posterior visuospatial abilities in the ventral occipital–temporal and parietal networks.

As this chapter suggests, the present state of the field requires a much greater emphasis on coordinated studies of the development of dorsal and ventral stream visual-processing networks. In the real world, there is no dissociation between these important processing systems; they work seamlessly and in concert to guide visual perception and action. Across development, it is likely that change in one system affects change in the other. The challenge is to better define the emergence in developmental time of each of these systems and to understand how their separate activities become coordinated. Studies of functional connectivity across development hold considerable promise for defining the emergence and integration of these systems at the neural level. At the behavioral level, studies designed to directly compare and contrast the developmental trajectories can inform our understanding. It is essential that studies link spatial perception and cognition to address the understudied problem of how spatial action systems emerge.

Memory Development

P.J. Bauer

Emory University, Atlanta, GA, USA

16.1 INTRODUCTION

The title of this chapter – *Memory Development* – creates the impression that a single entity – *memory* – has a single course of development. Instead, there are several different types of memory, each with its own characteristics and course of development. For example, one type of memory is short-term, lasting only seconds or minutes before fading away, whereas another type is long-term, lasting as long as a lifetime. Some types of memory have a limited capacity, whereas others are, for all practical purposes, limitless. Memory sometimes is context-specific and other times highly flexible. In fact, it sometimes seems that the only thing all memories have in common

is that they are about the past. Yet even this characterization is not universally true, in that remembering to do something *in the future* also qualifies as 'memory' of the prospective type.

One primary goal of this chapter is to characterize the major forms of memory. This step is necessary in order to accomplish the second goal, which is to describe the course of development of different types of memory over the first years of life. As will become apparent, different types of memory have different courses of development. Differences in the timing and course of development shed light on some of the mechanisms of age-related change, consideration of which is the third major goal of the chapter.

16.2 DIFFERENT FORMS OF MEMORY

The suggestion that memory is not a unitary construct is an old one. Maine de Biran (1804/1929) is credited as the first to suggest that there might be different forms of memory (Schacter et al., 2000). The notion was furthered at the beginning of the twentieth century with studies of wounded veterans from World War I. Kleist (1934), a German physician, examined veterans who had received head wounds from gun shots or shrapnel and the behavioral patterns that seemed to result from them. He observed that there were systematic relations between the site of the wound (and resulting brain lesion) and the type of mental impairment experienced by the veteran. The notion that different parts of the brain subserve different cognitive functions, including different types of memory, received especially strong impetus from the famous case of H. M. who, at the age of 27, underwent experimental surgery to treat intractable seizures. To treat the seizures, his surgeon removed large portions of the temporal lobes on both sides of the brain (Scoville and Milner, 1957). Subsequent to the surgery, H. M. suffered impairment of some forms of memory, yet not all of his memory capacities were disrupted. His case in particular led to the notion that there are different types or forms of memory. Whereas some distinctions within the domain are readily accepted, others are sources of debate.

16.2.1 Short- and Long-Term Memory

Characterizing memory along a temporal dimension is relatively uncontroversial. Whereas some memories are short-term, lasting only seconds, others last much longer, on the order of days, months, and even years. Short-term memory generally is recognized as capacity-limited. It is commonly thought to hold 7 'units' of information – such as digits in a phone number – plus or minus 2 (Miller, 1956), though estimates of capacity vary. In contrast, long-term memory is virtually limitless in its capacity. There seemingly is no upper limit on the number of items, pieces of information, or personal experiences that one can maintain in long-term memory stores (more on the temporal dimension and capacity limitations of memory below).

16.2.2 Declarative and Nondeclarative Memory

Within long-term memory, many recognize a division based on the contents of memory, its function, its rules of operation, and the neural substrates that support it. Although the precise distinctions captured by the different labels given to the divisions are not identical, there is substantial overlap in contemporary conceptualizations of declarative or explicit memory versus nondeclarative, procedural, or implicit memory. Each is discussed in turn.

16.2.3 Declarative or Explicit Memory

Declarative or explicit memory is devoted to processing of names, dates, places, facts, events, and so forth. These are entities that are thought of as being encoded symbolically and that thus can be described with language. In terms of function, declarative memory is specialized for fast processing and learning. New information can be entered into the declarative memory system on the basis of a single trial or experience. In terms of rules of operation, declarative is fallible: one forgets names, dates, places, and so forth. Although there are compelling demonstrations of long-term remembering of lessons learned in high school and college (e.g., foreign language vocabulary: Bahrick, 2000), a great deal of forgetting from declarative memory occurs literally minutes, hours, and days after an experience. Declarative memory also has a specific neural substrate. Current conceptualizations suggest that the formation, maintenance, and subsequent retrieval of declarative or explicit memories depend on a multicomponent network involving cortical structures (including posterior–parietal, anterior–prefrontal, and limbic–temporal association areas) as well as medial temporal structures (including the hippocampus and entorhinal, perirhinal, and parahippocampal cortices: e.g., Eichenbaum and Cohen, 2001; Murray and Mishkin, 1998; Zola and Squire, 2000). The medial temporal structures may be considered 'primary' in the sense that without them, whether measured by recall or recognition, declarative memory is impaired (Moscovitch, 2000).

Declarative memory is itself subdivided into the categories of semantic and episodic memory (e.g., Schacter and Tulving, 1994), with a finer distinction between episodic and autobiographical memory. Semantic memory supports general knowledge about the world (Tulving, 1972, 1983). People are consulting semantic memory when they retrieve the facts that the capital of the United States is Washington, DC, that the United States has 50 states, and that with over 660 000 square miles, Alaska is the largest state in terms of land mass. For practical purposes, both the capacity of semantic memory and the longevity of the information stored in it seem infinite. Semantic memory also is not tied to a particular time or place. That is, people know facts and figures, names and dates, yet in most cases, they do not know when and where they learned this information. People might be able to reconstruct how old they were or what grade they were in when they learned some tidbits of information, but unless there was something unique about the experience surrounding the acquisition of this information, they carry it around without address or reference to a specific episode.

In contrast to semantic memory, episodic memory supports retention of information about unique events (Tulving, 1972, 1983), such as a specific visit to

Washington, DC, or the fact that Alaska was one of the states on a list of state names studied in a memory experiment. Some episodic memories, such as whether a specific state was included in a word list, may not stay with one for very long and are not especially personally relevant or significant. Yet other episodic memories are personally significant and even self-defining. These so-called *autobiographical* memories are episodic memories that are infused with a sense of personal involvement or ownership (Bauer, 2007). They are the episodes on which people reflect when they consider who they are and how their previous experiences have shaped them.

16.2.4 Nondeclarative, Procedural, or Implicit Memory

Nondeclarative, procedural, or implicit memory is devoted to perceptual and motor skills and procedures. Skilled motor behavior, such as dancing or swinging a tennis racket, is not a name, date, place, fact, or event but a collection of finely tuned motor patterns, behaviors, and perceptual skills that one cannot verbally describe. Most types of nondeclarative memory function to support gradual, incremental learning. That is, behavior is modified through practice, experience, or multiple trials. Perhaps as a result of its slow function, a rule of the operation of nondeclarative memory is that the learning is relatively infallible (see next paragraph). A typical example is riding a bicycle – one may not have ridden a bicycle in many years but when he or she rides one again, he or she 'just knows how.' Indeed, breaking an old nondeclarative pattern can be quite difficult, as exemplified by the tendency to, in a moment of panic, slam the pedals backward (as one does on his or her old 1-speed bike) instead of squeezing the hand brakes (as one should on his or her adult, multi-speed bike). As might be expected, given the diversity of behaviors supported by nondeclarative memory, different types of nondeclarative memory depend on different neural structures. For example, motor skill learning and many types of conditioning seemingly are dependent on cerebellum and subcortical structures such as the basal ganglia and priming seems dependent on extrastriate cortex.

Just as declarative memory is subdivided, so too is nondeclarative memory. The most common categories of nondeclarative memory are (1) motor skill learning and (2) priming, and (3) classical conditioning. The range of motor skills that people acquire is limitless. What they have in common is that although there might be a declarative component to them (to stop the bike, put on the brakes), their fluid execution is not accomplished via learning and frequent repetition of the declarative 'rules,' but motor practice. Hours and hours and hours of practice lie behind the fluid swish of a tennis

champion's racket or the dance steps of Ginger Rogers and Fred Astaire. A tennis or dance instructor can tell one how to hold the racket or how to position one's foot to produce certain steps, but it is not this knowledge on which accomplished athletes depend. Closer to home, people all know that to stop cars that they are driving, they put their feet on the brakes. Yet few if any people know how many pounds of pressure they must put on the brake pedal to stop quickly versus more gradually. The information is encoded in their muscles and joints; it is not accessible to conscious access or description.

Another form of nondeclarative memory is priming, which is facilitated processing of a stimulus following prior exposure to the stimulus. Perceptual priming occurs when subsequent processing of a stimulus is facilitated by prior perceptual exposure to it. Conceptual priming occurs when there is overlap between related concepts in memory. A person who had recently studied a list that included the word 'Alaska' would be more likely to include it in a list of states than an individual who had not studied the item. With regard to the distinction between conscious (declarative) and unconscious (nondeclarative) memory, an important point to remember about priming is that it can occur without conscious awareness that the item had been studied earlier, or that subsequent processing was facilitated by earlier processing. That is, facilitated processing occurs even in the absence of recognition or recall of the originally studied item (see Lloyd and Newcombe, 2009 and Roediger and McDermott, 1993, for discussions).

Finally, classical conditioning occurs when two stimuli that naturally do not co-occur become associated with one another through repeated pairing. Typically, one of the stimuli – the unconditioned stimulus – evokes a high-probability or even reflexive response termed the unconditioned response. For example, a puff of air to the eye (unconditioned stimulus) produces a blink (unconditioned response). The other stimulus – the conditioned stimulus – is behaviorally neutral, such as a tone. Classical conditioning occurs when, over time and repeated pairing of the two stimuli, the conditioned stimulus (the tone) takes on the same significance as the unconditioned stimulus, such that it alone is sufficient to produce the response: anticipatory eye closure at the sound of the tone (see Woodruff-Pak and Disterhoft, 2008, for a review). This simple form of learning occurs across phyla (e.g., rodents, nonhuman primates, and humans), making it one of the clearest examples of learning and memory without awareness.

16.2.5 Relations Between Different Forms of Memory

An important point to keep in mind with regard to the distinction between declarative and nondeclarative forms of memory is that, in most cases, one derives both

declarative and nondeclarative memories from the same experience. Learning to drive a car is a good example. In driver's education class, students learn that to go, they step on the accelerator and to stop, they step on the brake. Tests to obtain a license to drive probe the student's memory of appropriate following and stopping distance and the steps involved in parallel parking, for example. But one would never become an expert driver based on this type of memory alone. To become a good driver, one must practice executing the motor movements. Although one may be consciously aware that vehicle stopping distance is 15 feet per second, it is not this knowledge that permits him or her to bring the vehicle to a gentle stop at a stop sign. That skill is acquired through practice, practice, and more practice at driving and braking.

Another important point is that, in most cases, declarative and nondeclarative memories not only are acquired in parallel but also continue to coexist, even after execution of the behavior no longer seems to require conscious awareness. Many skills, such as driving, start out very demanding of attentional resources yet eventually can be performed almost 'automatically,' that is, without conscious attention paid to them. Such changes tempt the conclusion that once these skills no longer require conscious attention to execute, they no longer are declarative. Yet such a conclusion is not valid: If declarative memories were to become nondeclarative, that would mean that they were no longer accessible to consciousness or declaration. The fact that one can tell that vehicle stopping distance is 15 feet per second proves that memory of the procedure is accessible to consciousness, even though one does not have to think about feet per second in order to brake. In other words, one still has the declarative memory, even though it is not that memory on which he or she depends to execute the behavior. In the intact organism, declarative and nondeclarative memory coexist. Many behaviors are executed based on nondeclarative memory alone, but that does not mean that one type of memory has 'turned into' another. Rather, at the time of learning, both types of memory were acquired; skilled performance of the motor behavior may be supported by one (nondeclarative), yet the other (declarative) continues to exist.

The observations that different forms of memory are acquired in parallel and coexist, possibly throughout the life of the memory, beg the question of why organisms would have multiple types of memory. It is likely that either these different forms of memory evolved in order to deal with competing demands for different kinds of information storage or nature took fair advantage of structures that had evolved for other reasons, in order to deal with the demands. Either way, one memory system seems specialized for rapid encoding of information that is subject to equally rapid forgetting whereas the other seems specialized for acquisition of information at a slower rate yet seemingly permits more robust retention. Why could not a single system accomplish both tasks? Although this question cannot be answered definitively, computer simulations have revealed that a system that can change rapidly to accept new inputs has difficulty maintaining old inputs. Conversely, a system that is good at maintaining old inputs has difficulty 'learning' new things (e.g., McClelland et al., 1995). This analysis suggests that complementary memory systems work in concert in order to avoid interference with existing knowledge yet still maintain flexibility.

16.3 DEVELOPMENTAL CHANGES IN NONDECLARATIVE AND DECLARATIVE MEMORY

Discussion of developmental changes in all of the different forms of memory is well beyond the scope of this chapter. Instead, exemplars of each major type of memory are discussed as follows: priming, as an exemplar of nondeclarative memory, and episodic and autobiographical memory, as exemplars of declarative memory.

16.3.1 Priming

In the modern cognitive science and neuroscience literatures, priming is perhaps the most thoroughly studied form of nondeclarative memory. As defined above, priming involves facilitated processing of a stimulus as a result of prior exposure to it. Perceptual priming occurs when facilitated processing is based on the surface features of the stimulus; conceptual priming occurs when the facilitation is based on the meaning of the stimuli. In both cases, the facilitation is observed independent of explicit recognition of the stimuli as having been seen before (thus leading to characterization of the effect as nondeclarative).

Perceptual priming is apparent from an early age and is thought to show only small developmental changes. In a typical paradigm, subjects encounter pictures of common objects early in an experimental session. Later in the session they are shown degraded pictures that are slowly made sharper and clearer. Some of the pictures are of the objects studied earlier whereas others are of new objects. Children as young as 3 are faster to name the pictures (i.e., they name them at lower levels of clarity) when they have seen them previously than when they have not. Age-related differences in performance on these types of tasks are not pronounced (e.g., Hayes and Hennessey, 1996; Parkin and Streete, 1988), even when children are compared with adults

(e.g., Drummey and Newcombe, 1995). For this reason, perceptual priming is thought to be relatively developmentally invariant (see Lloyd and Newcombe, 2009, and Parkin, 1998 for reviews).

Age-related differences are apparent in conceptual priming paradigms. In a representative conceptual priming paradigm, subjects are presented with words early in a session. Later they are challenged to list members of target categories. For example, in response to the instruction to list as many states as they can, subjects are more likely to nominate 'Alaska' if they saw the word earlier in the session than if they did not. Effects of this nature – effects that seemingly depend on activation of related concepts in memory – are more robust in older relative to younger children (e.g., Perez et al., 1998). Data such as these have been used to argue that conceptual priming shows salient improvements with age. Lloyd and Newcombe (2009) sounded a cautionary note in their review of this literature, however. They noted the distinct possibility that rather than differences in priming, these paradigms may reflect age-related improvements in conceptual knowledge. That is, the mechanism of priming may be age-invariant, and what accounts for improvements with age is category knowledge. Testing of this possibility is an area for future research.

16.3.2 Episodic and Autobiographical Memory

Episodic and autobiographical memory have a protracted course of development, beginning in the first year of life and extending into early adulthood. As discussed above, episodic memory supports retention of information about unique events that can be located in a particular place and time (Tulving, 1972, 1983). Autobiographical memories are episodic memories that are especially personally relevant. They are what is thought to make up the life story or personal past.

16.3.3 Questioning the Existence of Episodic Memory in Young Children

Until the middle 1980s, it was widely believed that infants and young children were incapable of remembering specific episodes and thus of forming autobiographical memories. As discussed in Bauer (2006b, 2007), the pessimism as to children's mnemonic abilities stemmed from a number of sources. One salient source of the perspective was the literature on *infantile* or *childhood amnesia*. Most adults remember few if any memories from the first 3–4 years of life, and from the ages of 3.5–7, they have a smaller number of memories than would be expected based on forgetting alone. As reviewed in Bauer (2007, 2008), the phenomenon is strikingly robust and consistent across time, population, and method (e.g., free recall,

response to cue words, and questionnaire). Although a variety of explanations for the amnesia have been advanced (see Bauer, 2007, 2008, for reviews), one of the most common was also the simplest: adults lacked memories from early in life because children failed to create them.

The suggestion that children younger than age 3 years did not form episodic memories was consistent with the dominant theoretical perspective at the time. A central tenant of Jean Piaget's *genetic epistemology* (see Flavell, 1963, for an introduction to the perspective) was that for the first 18–24 months of life, infants lacked symbolic capacity and, thus, the ability to mentally represent objects and events (e.g., Piaget, 1952). Instead, they were thought to live in a 'here and now' world that included physically present entities, yet the entities had no past and no future. In other words, infants were described as living an 'out of sight, out of mind' existence. Piaget hypothesized that by 18–24 months of age, children had constructed the capacity for mental representation. However, even then, they were thought to be without the cognitive structures that would permit them to organize events along coherent dimensions that would make the events memorable. Consistent with this suggestion, in retelling fairy tales, children as old as 7 years made errors in temporal sequencing (Piaget, 1926, 1969). Piaget attributed their poor performance to the lack of reversible thought. Without it, children could not organize information temporally and thus could not tell a story from beginning, to middle, to end. Without this ability, they could not be expected to retain coherent episodic memories.

16.3.4 A New Perspective on Young Children's Memory Abilities

The perspective on infants' and young children's mnemonic abilities began to change in the middle 1980s as a result of recognition of the importance to memory of meaningful and familiar stimuli and development of a means of assessing event memory in pre- and early-verbal children. In an influential series of studies, Mandler and her colleagues (e.g., Mandler and DeForest, 1979; Mandler and Johnson, 1977) demonstrated that even young children are sensitive to the structure inherent in story materials. When the stories were well-organized, children had high levels of recall. They also tended to 'correct' poorly organized stories, to conform to the hierarchical structure (see Mandler, 1984, for a review). At roughly the same time, Nelson and her colleageus (e.g., Nelson, 1986) demonstrated that when children were asked to recall 'what happens' in the context of everyday events and routines, such as going to McDonald's, their performance was qualitatively similar to that of older children and even adults. Moreover, it

became apparent that children did not require multiple experiences of events in order to remember them. For example, Fivush (1984) interviewed kindergarten children after only a single day of school. Although the children had experienced the school-day routine just once, they nevertheless provided well-organized reports of the experience.

The change in perspective on memory ability extended to infants as well, with the development of nonverbal means of assessing memories for specific episodes, namely, elicited and deferred imitation. Elicited and deferred imitation entail use of objects to demonstrate an action or sequence of actions that, either immediately (elicited imitation), after some delay (deferred imitation), or both, infants are invited to imitate. Piaget (1952) himself had identified deferred imitation as one of the hallmarks of the development of symbolic thought. Meltzoff (1985) and Bauer and her colleagues (Bauer and Mandler, 1989 and Bauer and Shore, 1987) brought the technique under experimental control. Meltzoff (1988) demonstrated that infants as young as 9 months of age were able to defer imitation of an action for 24 hours. Bauer and Shore (1987) published findings that over a 6-week delay, infants 17–23 months of age remembered not only individual actions but temporally ordered sequences of action. That is, even after 6 weeks, they were able to reproduce in the correct temporal order the steps of putting a ball into a cup, covering it with another cup, and shaking the cups to make a rattle.

Whereas originally, the argument that imitation-based paradigms provide a means of testing declarative memory was based in Piaget's (1952) observations, there are a number of characteristics that support the claim. Because the argument has been developed in detail elsewhere (e.g., Bauer, 2006b, 2007 and Carver and Bauer, 2001), only two components of it are presented. First, once children acquire the requisite language, they talk about events that they experienced as preverbal infants, in the context of imitation tasks (e.g., Bauer et al., 2002b; Cheatham and Bauer, 2005). This is strong evidence that the format in which the memories are encoded is declarative, as opposed to nondeclarative or implicit (formats inaccessible to language). Second, the paradigm passes the 'amnesia test.' Whereas intact adults accurately imitate sequences after a delay, patients with amnesia due to hippocampal lesions perform no better than naïve controls (McDonough et al., 1995). Adolescents and young adults who sustained hippocampal damage early in life also exhibit deficits in performance on the task (Adlam et al., 2005). This suggests that the paradigm taps the type of memory that gives rise to verbal report. For these reasons, the task has come to be widely accepted as a nonverbal analogue to verbal report (e.g., Bauer, 2002; Mandler, 1990; Meltzoff, 1990; Nelson and Fivush, 2000; Rovee-Collier and Hayne, 2000; Schneider and Bjorklund, 1998; Squire et al., 1993) and is widely used to examine developments in memory for specific episodes in the first two years of life.

16.3.5 Memory for Specific Episodes in the First Two Years of Life

Over the first two years of life, there are developmental changes in memory for specific episodes along a number of dimensions. Perhaps the most salient change is in the length of time over which memory is apparent. Importantly, because like any complex behavior, the length of time an episode is remembered is multiply-determined, there is no 'growth chart' function that specifies that children of X age should remember for Y long. Nonetheless, across numerous studies, there has emerged evidence that with increasing age, infants tolerate lengthier retention intervals. For example, at 6 months of age, infants remember an average of one action of a three-step sequence for 24 hours (Barr et al., 1996; see also Collie and Hayne, 1999). Nine-month-olds remember individual actions over delays from 24 hours (Meltzoff, 1988) to 5 weeks (Carver and Bauer, 1999, 2001). By 10–11 months of age, infants remember over delays as long as 3 months (Carver and Bauer, 2001 and Mandler and McDonough, 1995). Thirteen- to fourteen-month-olds remember actions over delays of 4–6 months (Bauer et al., 2000 and Meltzoff, 1995). By 20 months of age, children remember the actions of event sequences over as many as 12 months (Bauer et al., 2000).

Infants also recall the temporal order of actions in multistep sequences, though retaining order information presents a cognitive challenge to young infants, in particular, as evidenced by low levels of ordered recall and substantial within-age-group variability in the first year. Although 67% of Barr et al.'s (1996) 6-month-olds remembered individual actions over 24 hours, only 25% of them remembered actions in the correct temporal order. Among 9-month-olds, approximately 50% of infants exhibit ordered reproduction of sequences after a 5-week delay (Bauer et al., 2001, 2003; Carver and Bauer, 1999). By 13 months of age, the substantial individual variability in ordered recall has resolved: 78% of 13-month-olds exhibit ordered recall after 1 month. Nevertheless, throughout the second year of life, there are age-related differences in children's recall of the order in which actions of multistep sequences unfolded. The differences are especially apparent under conditions of greater cognitive demand, such as when less support for recall is provided, and after longer delays (Bauer et al., 2000).

The first two years of life also are marked by changes in the robustness of memory for specific episodes. For instance, there are changes in the number of experiences

that seem to be required in order for infants to remember. In Barr et al. (1996), at 6 months, infants required six exposures to events in order to remember them 24 hours later. If instead they saw the actions demonstrated only three times, they showed no memory after 24 hours (i.e., performance of infants who had experienced the puppet sequence did not differ from that of naïve control infants). By 9 months of age, the number of times actions need to be demonstrated to support recall after 24 hours has reduced to three (e.g., Meltzoff, 1988). Indeed, 9-month-olds who see sequences modeled as few as two times within a single session recall individual actions of them 1 week later (Bauer et al., 2001). However, over the same delay, ordered recall was observed only among infants who had seen the sequences modeled a total of six times, distributed over three exposure sessions. Three exposure sessions also support ordered recall over the longer delay of 1 month. By the time infants are 14 months of age, a single exposure session is all that is necessary to support recall of multiple different single actions over 4 months (Meltzoff, 1995). Ordered recall of multistep sequences is apparent after as many as 6 months for infants who received a single exposure to the events at the age of 20 months (Bauer and Leventon, in press).

Another index of the robustness of memory is the extent to which it is disrupted by interference. One form of interference that has been studied in infancy is changes in context between encoding and retrieval. Reports on infants' sensitivity to contextual changes are mixed. There are some suggestions that recall is disrupted if between exposure and test, the appearance of the test materials is changed (e.g., Hayne et al., 1997, 2000; and Herbert and Hayne, 2000). However, there also are reports of robust generalization from encoding to test by infants across a wide age range. Infants have been shown to generalize imitative responses across changes in (1) the size, shape, color, and/or material composition of the objects used in demonstration versus test (e.g., Bauer and Dow, 1994; Bauer and Fivush, 1992; Bauer and Lukowski, 2010; and Lechuga et al., 2001), (2) the appearance of the room at the time of the demonstration of modeled actions and at the time of the memory test (e.g., Barnat et al., 1996 and Klein and Meltzoff, 1999), (3) the setting for the demonstration of the modeled actions and the test of memory for them (e.g., Hanna and Meltzoff, 1993; Klein and Meltzoff, 1999), and (4) the individual who demonstrated the actions and the individual who tested for memory of the actions (e.g., Hanna and Meltzoff, 1993). Evidence of flexible memory extends to infants as young as 9–11 months of age (e.g., Baldwin et al., 1993; Lukowski et al., 2009; McDonough and Mandler, 1998). In summary, whereas there is evidence that with age, infants' memories as tested in imitation-based paradigms become more generalizable

(e.g., Herbert and Hayne, 2000), there is substantial evidence that from an early age, infants' memories survive changes in context and stimuli.

16.3.6 Developments in the Preschool Years and Beyond

Beginning in the third year of life, verbal assessments become a viable means for testing episodic memory. This opens up new possibilities: children can be tested not only for memory for controlled laboratory events but for events from their lives outside the laboratory as well. This combination of approaches has yielded a wealth of data about children's memories for the routine events that make up their everyday lives, and about their memories for unique events. Some of the events are highly personally significant and contribute to an emerging autobiography or personal past. Major findings from each of these categories are reviewed.

Early studies of young children's memories for the events of their own lives focused on everyday, routine events. The children's reports included actions common to the activities, and almost invariably, the actions were mentioned in the temporal order in which they typically occurred. Representative of the findings was the answer provided by a 3-year-old child to the question, "What happens when you have a birthday party?": "You cook a cake and eat it" (K. Nelson and Gruendel, 1986, p. 27). This early research revealed 'minimalist,' yet nevertheless accurate, reports by children as young as 3 years of age (see also K. Nelson, 1986, 1997). Subsequent studies revealed that with development, children's reports included more information. For example, in addition to mention of cooking a cake and then eating it, 6- and 8-year-old children told of putting up balloons, receiving and then opening presents from party guests, eating birthday cake, and playing games. Second, relative to younger children, older children more frequently mentioned alternative actions: "...and then you have lunch *or whatever you have*." Third, with age, children include in their reports more optional activities, such as "*Sometimes* then they have three games...then *sometimes* they open up the other presents...." Finally, with increasing age, children mentioned more conditional activities, such as "*If* you're like at Foote Park or something, *then* it's time to go home...." (Nelson and Gruendel, 1986, p. 27). Whereas some of the differences in younger and older children's reports might be due to the greater number of experiences of events such as birthday parties that older children have, relative to younger children, experience alone does not account for the developmental differences. In laboratory research in which children of different ages are given the same amount of experience with a novel event, older children produce more elaborate reports relative to younger children (e.g., Fivush et al., 1992; Price and Goodman, 1990).

Young children also form memories of unique events. In an early study, Fivush et al. (1987) found that all of the children in a sample of 2.5–3-year-olds recalled at least one event that had happened 6 or more months in the past. The children reported the same amount of information about events that had taken place more than 3 months ago as they did about events that had taken place within 3 months. In Hamond and Fivush (1991), 3- and 4-year-old children recalled a trip to Disney World they had taken either 6 months previously or 18 months previously. The amount they remembered did not differ as a function of the delay. Moreover, the older and younger children did not differ in the amount of information they reported about the event. Yet the age groups did differ in how elaborate their reports were. Whereas the younger children tended to provide the minimum required response to a question, the older children tended to provide more elaborate responses.

With development, there are changes in what children include in their reports about events. For example, young children seemingly focus on what is common or routine across experiences whereas older children and adults focus on what is unique or distinctive. This trend is illustrated in Fivush and Hamond (1990). In response to an interviewer's invitation to talk about going camping, after providing the interviewer with the distinctive information that the family had slept in a tent, a 2.5-year-old child went on to report on the more typical features of the camping experience. In total, 48% of the information that the children reported was judged to be distinctive, implying that 52% of it was not. By 4 years of age, children report about three times more distinctive information than typical information (Fivush and Hamond, 1990). One consequence of focus on what is common across experience is that a unique event such as camping gets 'fused' into the daily routine of eating and sleeping. In the process, the features that distinguish events from one another may fade into the background and be lost. The result would be fewer memories of episodes that are truly unique. Conversely, with increasing focus on the more distinctive features of events, there is a resulting increase in the number of memories that are truly unique.

With age, children not only include different types of information in their narratives but also include more information. For example, in research by Fivush and Haden (1997), from 3.5 to 6 years of age, the number of propositions children included in the average narrative increased more than twofold, from 10 to 23. Young children's narratives include basic information about what actions occurred in the event; they feature intensifiers, qualifiers, and internal evaluations, and the actions in the narrative are joined by simple temporal and causal connections (e.g., *then*, *before*, and *after*, and *because*, *so*, *in order to*, respectively). What accounts for the increase in narrative length over this age period is that with age, children provide (1) more information about who was involved and when and where the event occurred, (2) more information about optional or variable actions (e.g., "*When it turned red light*, we stopped"; Fivush and Haden, 1997, p. 186), and (3) more elaborations (Fivush and Haden, 1997). As a result, relative to younger children's, older children's stories are more complete, easier to follow, and engaging.

The dramatic increases with age in the amount of information that children *report* tempt the conclusion that there also are age-related increases in the amount of information that children *remember* about events. This is not a 'safe' conclusion, however, in light of evidence that perhaps especially for younger children, verbal reports underestimate the richness of memories (e.g., Fivush et al., 2004; see Bauer, 1993, in press and Mandler, 1990, for discussions). Indeed, because of the inevitable confounding between increases in age and increases in narrative skills, whereas it is clear that children report more with age, it is not clear whether they also remember more.

16.3.7 Autobiographical Memory

Over the course of the preschool years, autobiographical or personal memory becomes increasingly apparent. Autobiographical memories are the memories of events and experiences that make up one's life story or personal past. They are the stories that people tell about themselves that reveal who they are and how their experiences have shaped their characters. As implied by this description, autobiographical memories differ from 'run-of-the-mill' episodic memories in that autobiographical memories are infused with a sense of personal involvement or ownership in the event. They are memories of events that happened to one's self, in which one participated, and about which one had emotions, thoughts, reactions, and reflections. It is this feature that puts the 'auto' in '*auto*biographical.'

Throughout the preschool years, children's memories take on more and more autobiographical features (see Bauer, 2007, for discussion). From a very young age, children include references to themselves in their narratives: "*I* fell down." With age, they increasingly pepper their narratives with the subjective perspective that indicates the significance of the event for the child (Fivush, 2001). For example, they go beyond comment on the objective reality of 'falling down' to convey how they felt about the fall: "I fell down and *was so embarrassed* because everybody was watching!" It is this subjective perspective that provides the explanation for why events are funny, or sad, for instance, and thus of significance to one's self.

There also are changes in the marking of events as having taken place at a specific place and time.

For instance, children increasingly include specific references to time, such as "on my birthday," "at Christmas," or "last summer" (Nelson and Fivush, 2004). Markings such as these not only establish that an event happened at a time different from the present but also begin to establish a time line along which an organized historical record of when events occurred can be constructed. Children also include in their narratives more orienting information, including where events took place and who participated in them (e.g., Fivush and Haden, 1997). These changes serve to distinguish events from one another, thereby making them more distinctive. Children also include more descriptive detail in their reports, suggestive of a sense of reliving the experience. For example, they include more intensifiers ("Cause she was *very* naughty"), qualifiers ("I *didn't like* her video tape"), elements of suspense ("And *you know what*?"; examples from Fivush and Haden, 1997), and even repetition of the dialogue spoken in the event ("...I said, 'I hope my Nintendo my Super Nintendo is still here'.", from Ackil et al., 2003). The result is a much more elaborate narrative that brings both the storyteller and the listener to the brink of reliving the experience. It is tempting to conclude that these changes account for the finding among adults of a steadily increasing number of memories of events that took place from the ages of 3–7 years (Bauer, 2007).

Relative to those in the preschool years, developments in autobiographical or personal memory in later childhood and adolescence have been relatively neglected. Yet age-related changes in autobiographical reports continue throughout the elementary school years and beyond. An illustration of the types of changes that occur during this period is the breadth or completeness of children's narratives. Like a good newspaper story, a 'good' autobiographical narrative includes a number of elements, including information about the *who, what, where, when, why,* and *how* of the experience. The average 7-year-old includes only half the number of these narrative elements than the average 11-year-old (see Bauer et al., 2007).

16.4 MECHANISMS OF DEVELOPMENTAL CHANGE

Given that memory is not a single entity or unity construct, it is not surprising that there is not a single answer to the question of 'what develops' in the development of memory. Rather, like all complex behaviors, memory is multiply-determined. An adequate explanation of why it develops as it does will entail multiple levels of analysis, ranging from the cellular and molecular events that allow for the storage of information to the cultural influences that shape the expression of memory (see Bauer, 2007, for discussion). Because the focus of this volume is on basic neural and cognitive processes, the author focuses on these two categories of explanation. The reader is referred to other sources (e.g., Bauer, 2007, in press and Nelson and Fivush, 2004) for elaboration of the roles of other aspects of development, including conceptual change and social influences on remembering.

16.4.1 Neural Structures and Processes

A thorough review of the neural substrates that support the different types of memory, and the courses of development of each, is well beyond the scope of this chapter (see Bauer, 2007, 2009 and Nelson et al., 2006 for reviews of subsets of this large literature). Yet a brief review is essential to the goal of identifying possible mechanisms of developmental change. Studies of patients with specific types of lesions and disease and animal models thereof, as well as neuroimaging studies, have made clear that registration of experience and formation of memory traces to represent it involve multistage processes that depend on networks of neural structures. For example, encoding, storage, and later retrieval of declarative memories depend on a multicomponent network involving temporal (hippocampus, and entorhinal, parahippocampal, and perirhinal cortices) and cortical (including prefrontal and other association areas) structures (e.g., Eichenbaum and Cohen, 2001; Markowitsch, 2000; Zola and Squire, 2000). In the review to follow, the author focuses primarily on this network in large part because its course of development is better worked out, relative to the networks supporting nondeclarative memory.

16.4.2 The Neural Substrate of Declarative Memory

Formation of a declarative memory begins as the elements that constitute an experience register across primary sensory areas (e.g., visual and auditory). Inputs from primary cortices are projected to unimodal association areas where they are integrated into whole percepts of what objects look, feel, and sound like. Unimodal association areas in turn project to polymodal prefrontal, posterior, and limbic association cortices where inputs from the different sense modalities are integrated and maintained over brief delays (see, e.g., Petrides, 1995). Prefrontal structures not only are involved in the initial processing or *encoding* of experiences into long-term traces but also are implicated in the temporary maintenance of material in short-term and working memory. As well, the neocortical regions involved in the initial perception and registration of experience are thought to be responsible for both perceptual and

conceptual priming (e.g., Gabrieli, 1998; see Toth, 2000 for a review).

For maintenance of traces of experience over delays of longer than a few seconds or minutes, the inputs to the association areas must be stabilized or *consolidated*, a task attributed to medial–temporal structures, in concert with cortical areas (McGaugh, 2000). Specifically, information from association areas converges on perirhinal and para-hippocampal structures from which it is projected to the entorhinal cortex and in turn to the hippocampus. Within the hippocampus, conjunctions and relations among the elements of experience are linked into a single event. Association areas share the burden of consolidation by relating new memories to episodes already in storage: information processed in the hippocampus is projected back through the temporal cortices which in turn project to the association areas that gave rise to their inputs. Eventually, traces are stabilized such that the hippocampus is no longer required to maintain them; consolidated traces are *stored* in neocortex (although, whether memories are ever wholly independent of the hippocampus is debated: see, e.g., Moscovitch and Nadel, 1998 and Reed and Squire, 1998, for opposing views).

Finally, behavioral and neuroimaging data implicate prefrontal cortex in the *retrieval* of memories from long-term storage (e.g., Cabeza et al., 1997, 2004; Maguire, 2001; Markowitsch, 1995). For example, damage to prefrontal cortex disrupts retrieval of facts and episodes. Deficits are especially apparent (1) in free recall versus recognition, (2) for temporal information versus items, (3) for specific event features, and (4) for source of information. Imaging studies have revealed high levels of activation in prefrontal cortex during retrieval of episodic memories from long-term stores (reviewed in Gilboa, 2004). Activations in medial prefrontal cortex are observed during retrieval of internally generated information, such as the thoughts and feelings that put the *auto* in autobiographical memories (Cabeza et al., 2004). Lateral posterior parietal and precuneus also are implicated in retrieval of autobiographical memories. The activations are greater when subjects report retrieving more details about the memory (reviewed in Gilboa, 2004).

16.4.3 Development of the Neural-Substrate-Supporting Declarative Memory

Developments in the neural-substrate-supporting declarative memory are summarized in a number of sources (e.g., Bauer, 2007, 2009, in press; Nelson, 2000; Nelson et al., 2006; Richman and Nelson, 2008). In terms of brain development in general, there are changes in both gray and white matter from infancy well into adolescence (e.g., Caviness et al., 1996; Giedd et al., 1999; Gogtay et al., 2004; and Sowell et al., 2004). Reflecting changes in vasculature, glia, neurons, and neuronal processes, gray matter increases until puberty. Beyond puberty, as a result of pruning and other regressive events (i.e., loss of neurons and axonal branches), the thickness of the cortical mantle actually declines (e.g., Giedd et al., 1999; Gogtay et al., 2004; Sowell et al., 2001; Van Petten, 2004). In contrast to curvilinear change in gray matter volume, white matter volume increases linearly with age (Giedd et al., 1999). Increases in white matter are associated with greater connectivity between brain regions and with myelination processes that continue into young adulthood (e.g., Johnson, 1997; Klingberg, 2008; Schneider et al., 2004).

In terms of the temporal–cortical episodic-memory network, there are a number of indicators that in the human, many components of the medial temporal lobe develop early. For instance, as reviewed by Seress and Abraham (2008), the cells that make up most of the hippocampus are formed in the first half of gestation and virtually all are in their adult locations by the end of the prenatal period. The neurons in most of the hippocampus also begin to connect early in development: synapses are present as early as 15 weeks gestational age. The number and density of synapses both increase rapidly after birth and reach adult levels by approximately 6 postnatal months. Perhaps as a consequence, glucose utilization in the temporal cortex reaches adult levels at the same time (i.e., by about 6 months: Chugani, 1994; Chugani and Phelps, 1986). Thus, there are numerous indices of early maturity of major portions of the medial temporal components of the network.

In contrast to early maturation of most of the hippocampus, development of the dentate gyrus of the hippocampus is protracted (Seress and Abraham, 2008). At birth, the dentate gyrus includes only about 70% of the adult number of cells. Thus, roughly 30% of the cells are produced postnatally. Indeed, neurogenesis in the dentate gyrus of the hippocampus continues throughout childhood and adulthood (Tanapat et al., 2001). It is not until 12–15 postnatal months that the morphology of the structure appears adultlike. Maximum density of synaptic connections in the dentate gyrus also is delayed, relative to that in the other regions of the hippocampus. In humans, synaptic density increases dramatically (to well above adult levels) beginning at 8–12 postnatal months and reaches its peak at 16–20 months. After a period of relative stability, excess synapses are pruned until adult levels are reached at about 4–5 years of age (Eckenhoff and Rakic, 1991).

Although the functional significance of later development of the dentate gyrus is not clear, there is reason to speculate that it impacts behavior. As already noted, upon experience of an event, information from

distributed regions of cortex converges on the entorhinal cortex. From there, it makes its way into the hippocampus in one of two ways: via a 'long route' or a 'short route.' The long route involves projections from entorhinal cortex into the hippocampus, by way of the dentate gyrus; the short route bypasses the dentate gyrus. Whereas the short route may support some forms of memory (Nelson, 1995, 1997a,b), based on data from rodents, it seems that adultlike memory behavior depends on passage of information through the dentate gyrus (Czurkó et al., 1997; Nadel and Willner, 1989). This implies that maturation of the dentate gyrus of the hippocampus may be a rate-limiting variable in the development of episodic memory early in life (e.g., Bauer, 2007, 2009; Nelson, 1995, 1997a,b, 2000). Finally, hippocampal volume continues to increase gradually throughout childhood and into adolescence (e.g., Gogtay et al., 2004; Pfluger et al., 1999; Utsunomiya et al., 1999). Myelination in the hippocampal region continues throughout adolescence (Arnold and Trojanowski, 1996; Benes et al., 1994; Schneider et al., 2004).

The association areas also undergo a protracted course of development (Bachevalier, 2001). For example, it is not until the seventh prenatal month that all six cortical layers are apparent. The density of synapses in the prefrontal cortex increases dramatically at 8 postnatal months and peaks between 15 and 24 months. Pruning to adult levels does not begin until late childhood; adult levels are not reached until late adolescence or early adulthood (Huttenlocher, 1979; Huttenlocher and Dabholkar, 1997; see Bourgeois, 2001, for discussion). In the years between, in some cortical layers, there are changes in the size of cells and the lengths and branching of dendrites (Benes, 2001). Although the maximum density of synapses may be reached as early as 15 postnatal months, it is not until 24 months that synapses develop adult morphology (Huttenlocher, 1979). There also are changes in glucose utilization and blood flow over the second half of the first year and into the second year: blood flow and glucose utilization increase above adult levels by 8–12 and 13–14 months of age, respectively (Chugani et al., 1987). Other maturational changes in prefrontal cortex, such as myelination, continue into adolescence, and adult levels of some neurotransmitters are not seen until the second and third decades of life (Benes, 2001). It is not until adolescence that neurotransmitters such as acetylcholine reach adult levels (discussed in Benes, 2001).

Although much of the attention to developmental changes has focused on the medial–temporal and prefrontal regions, there also are age-related changes in the lateral temporal and parietal cortices. Cortical gray-matter changes occur earlier in the frontal and occipital poles, relative to the rest of the cortex, which matures in a parietal-to-frontal direction. The superior temporal cortex is last to mature (though the temporal poles mature early; Gogtay et al., 2004). The late development of this portion of the cortex is potentially significant for memory as it is one of the polymodal association areas that plays a role in integration of information across sense modalities.

16.4.4 Functional Consequences of Development of the Temporal–Cortical Network

What are the consequences for behavior of the slow course of development of the neural network that supports declarative memory? At a general level, one may expect concomitant behavioral development: As the neural substrate develops, so does behavior (and vice versa, of course). But precisely how do changes in the medial temporal and cortical structures, and their interconnections, produce changes in behavior? In other words, how do they affect memory representations? To address this question, one must consider the basic processes involved in memory-trace formation, storage, and retrieval and how the 'recipe' for a memory might be affected by changes in the underlying neural substrate. In other words, one must consider how developmental changes in the substrate for memory relate to changes in the efficacy and efficiency with which information is maintained over the short-term, encoded and stabilized for long-term storage, in the reliability and ease with which it is retrieved.

16.4.5 Basic Cognitive and Mnemonic Processes

With developmental changes in the temporal–cortical network, one may expect changes in basic cognitive processes and in behavior. The basic processes involved in memory are encoding, consolidation, and retrieval of memory traces. Although the processes are difficult to cleanly separate from one another (e.g., when the encoding ends and the consolidation begins is a challenging question to address), they do build on one another and thus are described in the nominal order in which they occur: short-term maintenance and encoding, consolidation and storage, and retrieval.

16.4.6 Encoding

Association cortices are involved in the initial registration and temporary maintenance of experience. Because prefrontal cortex in particular undergoes considerable postnatal development, it is reasonable to expect that neurodevelopmental changes in it relate to age-related changes in the speed and efficiency with which information is encoded into long-term storage. Consistent with this suggestion, in a longitudinal study,

Bauer and her colleagues (Bauer et al., 2006) found differences in the amplitudes of event-related potential (ERP) responses to familiar stimuli between 9 and 10 months of age that correlated with age-related improvements in recall after a 1-month delay. Behavioral data also indicate developments in encoding throughout the second year of life. For example, relative to 15-month-olds, 12-month-olds require more trials to learn multistep events to a criterion (learning to a criterion indicates that the material was fully encoded). In turn, 15-month-olds are slower to achieve criterion, relative to 18-month-olds (Howe and Courage, 1997). Indeed, across development, older children learn more rapidly than younger children (Howe and Brainerd, 1989). Changes in the temporary registration of information are apparent throughout the preschool years and school years (e.g., Cowan and Alloway, 2009). The net result of these changes is that children become increasingly adept not only at maintaining information in temporary registration but also in initiating the type of organizational processing that promotes consolidation of it.

16.4.7 Consolidation and Storage

As reviewed earlier, medial temporal structures are implicated in the processes by which new memories become 'fixed' for long-term storage; cortical association areas are the presumed repositories for long-term memories. In a fully mature, intact adult, the changes in synaptic connectivity associated with memory-trace consolidation continue for hours, weeks, and even months, after an event. Memory traces are vulnerable throughout this time, as evidenced by the fact that lesions inflicted during the period of consolidation result in deficits in memory whereas lesions inflicted after a trace has been consolidated do not (e.g., Kim and Fanselow, 1992; Takehara et al., 2003). For the developing organism, the period of consolidation may be one of greater vulnerability for a memory trace, relative to the adult. Not only are some of the implicated neural structures relatively undeveloped (i.e., the dentate gyrus and prefrontal cortex) but also the connections between them are still being sculpted and thus are less than fully effective and efficient. As a consequence, even once children have successfully encoded an event, they remain vulnerable to forgetting. Younger children may be more vulnerable to forgetting, relative to older children (Bauer, 2004, 2006a).

To examine the role of consolidation and storage processes in long-term memory in 9-month-old infants, Bauer et al. (2003) combined ERP measures of immediate recognition (as an index of encoding), ERP measures of 1-week delayed recognition (as an index of consolidation and storage), and deferred imitation measures of recall

after 1 month. After the delay, 46% of the infants evidenced ordered recall of the sequences, and 54% did not. At the immediate ERP test, regardless of whether they subsequently recalled the events, the infants evidenced recognition: Their ERP responses were different to the old and new stimuli. This strongly implies that the infants had encoded the events. Nevertheless, 1 week later, at the delayed-recognition test, the infants who would go on to recall the events recognized the props, whereas infants who would not evidence ordered recall did not. Thus, in spite of having encoded the events, a subset of 9-month-olds failed to recognize them after 1 week and subsequently failed to recall them after 1 month. Moreover, the size of the difference in delayed-recognition response predicted recall performance 1 month later. Thus, infants who had stronger memory representations after a 1-week delay exhibited higher levels of recall 1 month later (see also Carver et al., 2000). These data strongly imply that at 9 months of age, consolidation and/or storage processes are a source of individual differences in mnemonic performance.

In the second year of life, there are behavioral suggestions of between-age group differences in consolidation and/or storage processes as well as a replication of the finding among 9-month-olds that intermediate-term consolidation and/or storage failure relates to recall over the long-term. In Bauer et al. (2002a), 16- and 20-month-olds were exposed to multistep events and tested for recall immediately (as a measure of encoding) and after 24 hours. Over the delay, the younger children forgot a substantial amount of the information they had encoded: they produced only 65% of the target actions and only 57% of the ordered pairs of actions that they had learned just 24 hours earlier. For the older children, the amount of forgetting over the delay was not statistically reliable. It is not until 48 hours that children 20 months of age exhibit significant forgetting (Bauer et al., 1999). These observations suggest age-related differences in the vulnerability of memory traces during the initial period of consolidation.

The vulnerability of memory traces during the initial period of consolidation is related to the robustness of recall after 1 month. This is apparent from another of the experiments in Bauer et al. (2002a), this one involving 20-month-olds only. The children were exposed to multistep events and then tested for memory for some of the events immediately, some of the events after 48 hours (a delay after which, based on Bauer et al., 1999, some forgetting was expected), and some of the events after 1 month. Although the children exhibited high levels of initial encoding (as measured by immediate recall), they nevertheless exhibited significant forgetting after both 48 hours and 1 month. The robustness of memory after 48 hours predicted 25% of the variance in recall

1 month later; variability in level of encoding did not predict significant variance. This effect is a conceptual replication of that observed with 9-month-olds in Bauer et al. (2003) (see Bauer, 2005 and Howe and Courage, 1997, for additional evidence of a role for post-encoding processes in long-term recall). The findings that infants who are 'good consolidators' have high levels of long-term recall are reminiscent of Bosshardt et al. (2005) with adults: fMRI activations 1 day after learning were predictive of forgetting 1 month later.

Changes in the processes by which memory representations are consolidated and stored can be expected to continue throughout the preschool years. However, although neuroimaging techniques such as ERPs could be brought to bear on the question, as they are in the infancy period, such studies have not been conducted with preschool-age children. Neither is there a plethora of behavioral studies to address the question. A major reason is that few studies include the requisite type or number of tests. Frequently, studies of long-term memory fail to include a measure of initial encoding (e.g., Liston and Kagan, 2002), thus making it impossible to determine the variance associated with encoding processes. They also tend to measure recall only once, at the end of the retention interval, thus making it impossible to determine the variance associated with post-encoding processes during the period of consolidation. An exception to this approach is described in the next section.

16.4.8 Retrieval

Prefrontal cortex is implicated in retrieval of memories from long-term storage sites. Prefrontal cortex undergoes a long period of postnatal development, making it a likely candidate source of age-related differences in long-term recall. Surprisingly, although retrieval processes are a compelling candidate source of developmental differences in long-term recall, there are few data with which to evaluate their contribution. A major reason is that most studies do not allow for assignment of relative roles of the processes that take place before retrieval, namely, encoding and consolidation. As discussed in the section on encoding, older children learn more rapidly than younger children. Yet age-related differences in encoding effectiveness rarely are taken into account. In fact, as just noted, in many studies, no measures of encoding or initial learning are obtained. In addition, with standard testing procedures, it is difficult to know whether a memory representation has lost its integrity and become unavailable (consolidation or storage failure) or whether the memory trace remains intact but has become inaccessible with the cues provided (retrieval failure). Implication of retrieval processes as a source of developmental change requires that encoding

be controlled and that memory be tested under conditions of high support for retrieval.

In the infancy period, one of the studies that permits assessment of the contributions of consolidation and/or storage relative to retrieval processes is Bauer et al. (2000) (see also Bauer et al., 2003, described earlier). The study provided data on children of multiple ages (13, 16, and 20 months) tested over delays of 1–12 months. Immediate recall of half of the events was tested, thus providing a measure of encoding. Because the children were given what amounted to multiple test trials, without intervening study trials, there were multiple opportunities for retrieval. As discussed by Howe and his colleagues (e.g., Howe and Brainerd, 1989; Howe and O'Sullivan, 1997), for intact memory traces, retrieval attempts strengthen the trace and route to retrieval of it, thereby increasing accessibility on each test trial. Conversely, lack of improvement across test trials implies that the trace was no longer available (although see Howe and O'Sullivan, 1997, for multiple nuances of this argument). Third, immediately after the recall tests, relearning was tested. That is, after the second test trial, the experimenter demonstrated each event once and allowed the children to imitate. Since Ebbinghaus (1885), relearning has been used to distinguish between an intact but inaccessible memory trace and a trace that has disintegrated. Specifically, if the number of trials required to relearn a stimulus was smaller than the number required to learn it initially, savings in relearning were said to have occurred. Savings presumably accrue because the products of relearning are integrated with an existing (though not necessarily accessible) memory trace. Conversely, the absence of savings is attributed to storage failure: there is no residual trace upon which to build. In developmental studies, age-related differences in relearning would suggest that the residual memory traces available to children of different ages are differentially intact.

To eliminate encoding processes as a potential source of developmental differences in long-term recall, in a reanalysis of the data from Bauer et al. (2000), subsets of 13- and 16-month-olds and subsets of 16- and 20-month-olds were matched for levels of encoding (as measured by immediate recall; Bauer, 2005). The amount of information the children forgot over the delays then was examined. For both comparisons, even though they were matched for levels of encoding, younger children exhibited more forgetting relative to older children. The age effect was apparent on both test trials. Moreover, in both cases, for older children, levels of performance after the single relearning trial were as high as those at initial learning. In contrast, for younger children, performance after the relearning trial was lower than at initial learning. Together, the findings of age-related differential loss of information over time and of age effects in

relearning strongly implicate storage processes, as opposed to retrieval processes, as the major source of age-related differences in long-term recall.

The conclusions from the infancy literature are consistent with the results of research with older children conducted within the trace-integrity framework (Brainerd et al., 1990) and conceptually related fuzzy-trace theory (Brainerd and Reyna, 1990). In this tradition, to eliminate encoding differences as a source of age-related effects, participants are brought to a criterion level of learning prior to imposition of a delay. To permit evaluation of the contributions of storage processes versus retrieval processes, participants are provided multiple test trials, without intervening study trials. In one such study, 4- and 6-year-old children learned and then recalled eight-item picture lists (Howe, 1995). In this study, as in virtually every other study conducted within this tradition (reviewed in Howe and O'Sullivan, 1997), the largest proportion of age-related variance in children's recall was accounted for by memory failure at the level of consolidation and/or storage, as opposed to retrieval. Whereas consolidation and/or storage failure rates decline throughout childhood, retrieval failure rates remain at relatively constant levels (Howe and O'Sullivan, 1997). The apparent lack of change in retrieval failure rates throughout childhood undermines the suggestion that retrieval processes are a major source of developmental change during this period.

If not by affecting retrieval, by what means do developmental changes in prefrontal cortex influence memory development in infancy and childhood? As discussed in Bauer (2006a, 2007), rather than on retrieval processes, a major effect of developments in prefrontal structures may be on consolidation and/or storage processes. Consolidation is an interactive process between medial temporal and cortical structures. As such, changes in cortical structures may be as important to developments in consolidation processes as are changes in medial temporal structures. Moreover, the ultimate storage sites for long-term memories are the association cortices. Thus, developmental changes in prefrontal cortex may play their primary role in supporting more efficient consolidation and more effective storage.

16.5 CONCLUSION

The title of this chapter – *Memory Development* – gives the impression that its subject will be singular: a singular system with a singular course of development. On the contrary, there are many different forms of memory, each with its own characteristics and developmental course. Although some broad generalizations apply, most of what one can be said to know about memory is relevant within a limited frame and for a subset of the types of memory. Continued progress in understanding memory and its development requires that appropriate distinctions be maintained.

Historically, most types of memory were thought to be relatively late to develop. This expectation was perhaps nowhere more apparent than in reference to episodic and autobiographical memory. Research in the last decades of the twentieth century made clear that the assumption was unwarranted. When they are tested with structured stimuli and personally relevant events and materials, even young children show evidence of mnemonic competence. Thus, in sharp contrast to expectations of developmental discontinuities in event memory, there is ample evidence that the capacity to remember past events develops early. The research also made clear, however, that development is a protracted event, beginning in infancy and continuing into late adolescence. A full accounting of the development of 'memory' thus requires a long-term perspective.

Finally, it is a truism to say that complex behaviors are multiply determined. In the field of the development of memory, this dictum must be embraced wholeheartedly. Within the same space of time as the mnemonic capabilities of even young children were chronicled, progress in explaining the timing and course of development was made at a variety of different levels. Although much remains to be discovered, understanding of the cellular and molecular events that permit the storage and later retrieval of information is now within reach. Similarly, people are on the verge of understanding how basic memory processes determine the life course of a memory at different points in developmental time. People may look forward to the day when multiple levels of explanation come together into a comprehensive account of the processes and determinants of the capacities called *memory*.

Early Development of Speech and Language
Cognitive, Behavioral, and Neural Systems

H. Tager-Flusberg, A.M. Seery

Boston University, Boston, MA, USA

17.1 INTRODUCTION

The acquisition of spoken language is one of the most remarkable and uniquely human accomplishments. At birth, newborns are capable of producing only cries and other vegetative sounds, have no control over their oral-vocal tract, and understand no meaningful speech. Within 3 years, without overt instruction, children have mastered the complex speech sound system of their language and acquired a rich and varied vocabulary. They have sufficient grammatical knowledge to allow them to talk about a wide range of topics, referring to events, people, and abstract ideas that are not immediately present in their environment and may exist only in their imaginations, thus going well beyond the communicative abilities of any other species. Human languages are highly complex, hierarchically organized abstract systems, composed of a phonological rule system specifying how speech sounds are combined, lexicon, syntax, morphology, and pragmatic and discourse rules. These systems depend on the development of a range of domain-specific and domain-general cognitive and

neural mechanisms that interact and become integrated into organized functional networks over the course of the first few years of life. This chapter summarizes what is currently known about the early development of speech and language skills in typically developing children, beginning with the prenatal period and then addresses how these developmental processes may go awry in children with language disorders.

17.1.1 What Is Language?

Spoken languages are composed of sounds; phonemes are the minimal linguistic units of a language and include vowels and consonants. The rapidly changing acoustic properties of phonemes are free to vary across speakers, time, and context, which makes the problem of speech perception particularly challenging. On the production side, speech sounds involve highly complex and intricately timed sequences of movements from the lower to the upper respiratory tract, through the larynx and oral and nasal cavities, and involving the lips, tongue, teeth, and glottis to produce phonemes. Within each language, there are constraints, or rules, which specify the permissible sequences of phonemes, referred to as phonotactic constraints. In addition, speech involves prosodic features that characterize the stress patterns of words and sentences that may be influenced by lexical, grammatical, or pragmatic factors.

Phonemes are combined to create the minimal unit of a language that carries meaning (semantic function), referred to as morphemes. Words (or lexical items) make up the vast majority of a language's morphemes. Most languages also include a smaller set of morphemes called 'bound morphemes' because they are affixed to other morphemes but still carry meaning such as tense, mood, number, and gender. Examples in English include past tense (-ed), the negative un-, or the plural -s. In turn, words and morphemes are combined to create sentences. The rules governing the order and hierarchical organization of sentence structure make up the syntax of a language. Together, the phonology, morphology, semantics, and syntax form the structural components of language. The functional uses of language, or pragmatics, include a variety of speech acts (e.g., directive, question) as well as the social rules governing the use of language in a range of discourse contexts (e.g., conversation, narrative).

The neural bases of language perception and production are relatively well known (e.g., Hickock, 2009). Large networks of cortical and subcortical regions are involved, spanning basic sensory and motor systems to higher-order, relatively specialized cortical areas. In the majority of adults, in whom most *in vivo* studies have been carried out, these specialized areas, devoted primarily to linguistic processing, are functionally organized asymmetrically in the left hemisphere of the brain; the two most significant areas include Broca's area in the inferior frontal cortex and Wernicke's area in the temporal lobe. These regions are connected via white matter fiber bundles, including the primary dorsal pathway, the *arcuate fasciculus*, as well as secondary dorsal and ventral pathways (Friederici, 2009). Although less is known about the development of these neural systems because of limitations to the use of neuroimaging methods in infants and young children, there is now an emerging body of research focusing primarily on perceptual and language processing using electrophysiological methods, which are the most easily adapted for use with infants (Kuhl, 2010).

17.2 SPEECH PERCEPTION

Speech perception and language comprehension rely on complex neural networks that, in most adults, heavily involve the perisylvian region of the left hemisphere. Research has explored the early behavioral responses and neural correlates of exposure to language in neonates and infants to investigate the development of the language networks.

17.2.1 Prenatal Responses to Speech and Language

The auditory system is almost fully developed by the third trimester of pregnancy, so the developing fetus can process auditory and speech stimuli, although the rapid temporal features of phonemic stimuli are, for the most part, filtered out by the mother's body and uterine environment. Near-term fetuses show a more sustained heart rate deceleration to sentences than to music but do not differ in their response to sentences and chimeras of these sentences with all phonetic information removed (Granier-Deferre et al., 2010). Most prenatal exposure to phonemic stimuli is provided by the mother's voice, the vibrations of which are transmitted directly to the fetus.

Infants learn about many aspects of language during the last weeks of the prenatal period, including the identity of their mother's voice, stress patterns of the language, as well as specific segments of language (such as repeated passages from storybooks) to which they have been exposed. Beginning around 32 weeks' gestation, fetuses exhibit heart rate deceleration in response to recordings of their mother's voice (Kisilevsky and Hains, 2011), and near-term infants show differential patterns of heart rate response to recordings of the mother's voice and a stranger's voice (Kisilevsky et al.,

2003). At birth, infants distinguish and prefer their own mother's voice over the voice of a female stranger (DeCasper and Fifer, 1980), speech passages they were exposed to prenatally over novel passages (DeCasper and Spence, 1986), and their native language over other rhythmically dissimilar languages (Byers-Heinlein et al., 2010; Mehler et al., 1988; Nazzi et al., 1998).

17.2.2 Newborn Speech Perception

From birth onward, infants display a strong preference for listening to speech over other auditory stimuli. Neonates exhibit more nonnutritive, high-amplitude sucking when rewarded with linguistic stimuli than with white noise (Butterfield and Siperstein, 1970), tones, or scrambled speech sounds (Vouloumanos and Werker, 2007). Even very young infants possess sophisticated speech perception abilities, which is similar to adults in a variety of ways.

Adults perceive phonetic information categorically. For instance, the speech sounds /da/ and /ta/ differ with respect to the phonetic feature of voice onset time (VOT), and when presented with syllables with VOTs varying continuously, adults perceive only two sounds: /da/ or /ta/. Furthermore, adults are easily able to extract phonetic information despite the fact that the acoustic properties of speech vary drastically depending on the individual speaker's voice. Behavioral studies have found that 2-month-old infants detect phonetic changes regardless of whether this change is accompanied by a change in pitch (Kuhl and Miller, 1982) or speaker (Jusczyk et al., 1992). In newborns, electrophysiological studies have shown that the neonatal brain responds as quickly to a change in phonemic category whether or not this is accompanied by a change of speaker (Dehaene-Lambertz and Pena, 2001). Neonates extract linguistically relevant phonemic information from the extraneous acoustic information related to specific voices and thus normalize across speakers. Notably, however, this is not due to an inability of infants to discern the different voices as neonates have been shown to discriminate at least between male and female voices (Floccia et al., 2000). In addition to normalizing across speakers, very young infants, like adults, perceive speech sounds categorically rather than continuously. Infants will dishabituate more to a change in syllable when this change crosses adult categorical boundaries than when the change occurs within a given phonetic category (Eimas et al., 1971). Newborns are sensitive to linguistic or auditory 'gestalts,' such as syllable repetition. Specifically, they show increased response over the temporal and left frontal areas to grammars containing a consecutive repetition (ABB sequences, e.g., 'mubaba'), suggesting the possibility of automatic

perceptual detection of auditory repetition (Gervain et al., 2008).

17.2.3 Development of Speech Perception

After birth, infants continue to learn about the language that they are exposed to, and by 4 months, infants discriminate their own language even from other very similar languages, such as Spanish and Catalan (Bosch and Sebastián-Gallés, 2001). Infants also undergo a drastic transition where their perception of speech becomes shaped by exposure to a specific language. Each language contrastively uses only subsets of the available universal phonetic categories, and adults cannot easily discriminate between phonetic categories not used in their native language.

Infants are prepared to perceive any language they might encounter but gradually restrict this ability to their own language over the first year of life through a process of perceptual narrowing. Infants stop discriminating consonant contrasts not used in their native language by around 10 months of age (Werker and Tees, 1984). Measuring electrophysiological response to a phonetic change after a repeated syllable has shown that this perceptual narrowing involves decreased response when the change involves nonnative phonemes (Cheour et al., 1998; Rivera-Gaxiola et al., 2005) coupled with increased response when the change involves native-language phonemes (Rivera-Gaxiola et al., 2005), suggesting a process of neural commitment to native-language phonemes (Kuhl, 2004). A similar study using near-infrared spectroscopy, which is more sensitive than electrophysiology to spatial localization of neural processing, found that increased response to native phoneme changes did not stabilize until around 10 months of age, and a left-lateralized response to native-language phonemes emerged around 13 months of age (Minagawa-Kawai et al., 2007).

Using magnetoencephalography, Imada and colleagues found that a wide range of sounds, including speech, elicited responses in left hemisphere superior temporal areas in infants from birth through 12 months of age (Imada et al., 2006). In contrast, inferior frontal areas of the left hemisphere were not responsive to speech until after age 6 months; this response was correlated with temporal region responses to speech by 12 months of age, suggesting the basic neural network for processing language is in place by the end of the first year. It may be that there are structural predispositions for these functional networks to develop in the left hemisphere (Dubois et al., 2009).

In sum, it is evident that the infant brain possesses some degree of functional organization of the language networks present in human adults. The superior

temporal region, in particular, responds to language at birth, although this response is not specific to speech. To some extent, left-lateralized responses may be driven by acoustic characteristics of the auditory stimulus in addition to truly linguistic properties. Although there are some inconsistencies in the current infant literature, which may be the result of different experimental paradigms and stimuli as well as imaging modality, by the end of the first year, the neural and cognitive bases for speech perception appear to be firmly in place in perisylvian regions of the left hemisphere.

17.3 SPEECH PRODUCTION

In contrast to the perception of speech, at birth, infants are not able to produce any speech-like sounds. This capacity develops over the course of the first year of life and continues as the child's developing phonological system is acquired alongside other aspects of language development.

17.3.1 Infant Speech Production

The developmental progression in speech production follows universal pathways. During the first 2 months of life, infants produce a range of reflexive vocalizations that appear to be automatic responses to their physical state. These include crying, fussing, and vegetative sounds. The range of sounds produced by very young infants is constrained by the size of their oral cavity and the position of the larynx (Lieberman et al., 1972). Between 2 and 4 months, there are still significant limitations to the infant's ability to articulate, but the vocal repertoire expands to include pleasure-related cooing sounds. These sounds, which may include some vowels or consonants, are produced in the back of the mouth with articulation limited to movements of the jaw (Kent, 1999).

Beginning at around 4 months, as developmental changes take place in the morphology of the vocal tract, infants engage in more vocal play that includes both nonspeech and speech sounds such as rudimentary vowels and consonants. At 6 months, babbling begins, with the infant producing well-formed consonant–vowel (CV) syllables that now extend to those involving movements of the lips and tongue. Canonical babbling (repeated sequences of CV syllables) is viewed as the most significant milestone in speech production (Oller, 2000). During the latter half of the first year, the infant's sound combinations become increasingly more variable and frequent, though there appears to be a relatively small set of consonants produced across infants acquiring many different languages (Locke, 1983). As infants move closer to the onset of meaningful speech, their babbles increase in length and incorporate varied stress and intonation patterns, often referred to as 'jargon' or conversational babble.

The development of speech motor control plays an important role in speech sound production. A computational model of this process was introduced by Guenther (1995). According to this self-organizing model, the initiation of speech is the product of the perception of intended target sounds. Thus, auditory feedback from both adult and self-produced speech is critical in developing the mapping between target sounds and developmental changes in the vocal tract. On this view, there is a close link between the development of speech perception and production, which is consistent with the finding that although deaf infants produce early vocalizations, they rarely engage in canonical babbling and their sound production lessens over time (Stoel-Gammon, 1998).

17.3.2 Relationship Between Speech and Motor Developments

During the first year of life, infants not only develop the ability to articulate complex speech sounds, they also make significant advances in other aspects of motor development. While there are parallels between speech and motor developments, the relationship between them is both complex and quite specific. Gross motor milestones are not closely tied to developmental stages in babbling; however, it has been found that rhythmic arm banging, with or without objects, consistently emerges just prior to the onset of canonical babbling (Iverson and Thelen, 1999). Iverson (2010) argues that these repetitive hand movements provide opportunities for practicing skills required for canonical babbling as they both involve rhythmically organized motor stereotypies.

Babbling begins as a behavior tied closely to the speech motor system, offering the opportunity to practice complex articulatory movements in the context of proprioceptive and auditory feedback. Over time, babbling rapidly becomes integrated with other developmental changes and events in the environment to emerge as an early linguistic skill (Iverson, 2010). The close neural links between brain regions involved in language and motor behavior provide support for the view that there are reciprocal influences between these systems over the course of development, with the onset of intentional communication in infants evident in manual and other body gestures (Iverson et al., 2007).

17.3.3 Phonological Development

It is generally agreed that there is essential continuity between prelinguistic babbling and the earliest stages of phonological development evidenced in the child's first

words (Stoel-Gammon, 1998). The majority of sounds produced in the earliest words of children are the same as those preferred in their babbles. Initially, children's words are composed of simple CV syllable structures, using a relatively small inventory of sounds. Gradually, over time and with growth in vocabulary, there is an expansion in the range of sounds produced by children. Although there is no universal order in the acquisition of phonological features, certain regularities have been found in the phonological sounds that are used across children, reflecting developmental changes in the vocal tract (Stoel-Gammon and Sosa, 2007). Mastery over vowels occurs before that over consonants. The main consonant classes that are used earlier in development include stops (e.g., *b*, *d*), nasals (e.g., *m*, *n*), and glides (e.g., *w*). Later developing consonants include fricatives (e.g., *v*) and liquids (e.g., *l*, *r*).

As children begin producing more elaborate syllable structures and a wider range of sounds in words, they begin making speech sound errors. The most striking feature of these errors is that while there are individual differences in the particular kinds of errors made, the errors are not random, but instead fall into common patterns, reflecting developmental changes in the child's representation of the speech sound system (Grunwell, 1981; Ingram, 1976). In children with more severe articulation difficulties, words may be produced that involve combinations of different error patterns, but in most children, speech sound errors do not persist beyond the preschool years.

Young children will often omit syllables or specific sounds as they attempt to reproduce more complex adult words (Menn and Stoel-Gammon, 2009). Typically, unstressed syllables will be omitted; those occurring at the beginning of words (e.g., *mato* for *tomato*) or in the unstressed medial position (e.g., *e'phant* for *elephant*), and consonant clusters often lead to omissions (e.g., *top* for *stop*). Another class of error patterns is to change sounds at the level of individual articulatory features. For example, voiced consonants may be changed to unvoiced consonants (e.g., *bot* for *pot*). Place changes also may be found in some children, with back consonants becoming more frontal (e.g., *dame* for *game*). These kinds of errors demonstrate the significance of features in children's phonological representations. A third class of errors illustrates how the child's representation of the target word may influence the kinds of sound substitutions that are made. Assimilation errors entail the change in one sound in the target word to make it more similar to another sound in that word. Such errors may involve assimilation in different feature classes such as voicing (e.g., *doad* for *toad*) or place (*gog* for *dog*).

Several theoretical frameworks have been proposed to account for the acquisition of phonology, but the most promising current formal model is optimality theory (Archangeli and Langendoen, 1997). On this model, representations of phonological inputs are evaluated against a set of finite and universal constraints to determine an optimal output phonological form. Here, the notion of constraints replaces earlier theories that defined absolute, serially applied abstract rules. Within optimality theory, constraints are not absolute but operate in parallel in a language-specific order. Optimality theory has been shown to be highly successful in capturing children's phonological error patterns as well as variation found between, and within, individual children acquiring different languages (Barlow and Geirut, 1999).

17.4 SOCIAL–COGNITIVE FOUNDATIONS OF LANGUAGE

Language is a cultural system, acquired within the context of specific environments and embedded in the emergence of developments in the child's cognitive, emotional, and social capacities. Thus, language is the vehicle that satisfies the child's motivation to engage and communicate with social partners. In the absence of any social partners, for example, in children raised in complete isolation, language is not acquired (cf. Curtiss, 1977).

17.4.1 Social Engagement

From birth, the social niche for language is clearly established in the infant's preference for human voices and faces. Over the first few months of life, rapid changes take place. Mothers and their infants begin to interact in finely tuned ways with one another. They synchronize their eye gaze, movements, and facial expressions of affect in patterns that resemble turn-taking patterns in conversations (Snow, 1977). By the age of 4 months, there is a marked increase in vocal turn-taking during these rich interactions between infants and their caretakers (Ratner and Bruner, 1978). Thus, engagement with other people provides the context that lays the groundwork for infants' motivation to communicate. Interestingly, the neural foundations for these social capacities are available very early in the first year of life (Grossmann and Farroni, 2009).

17.4.2 Infant-Directed Talk

In their interactions with infants, adults in most cultures speak in a special register, including a higher pitch, more variable intonation patterns, and shorter utterances that focus on objects and people in the immediate environment (Fernald, 1989). This register, now referred

to as 'infant-directed talk' (IDT), is strongly preferred by infants (e.g., Werker and McLeod, 1989). Its properties capture infants' attention and facilitate the analysis of the phonological properties and statistical regularities of their native language (Burnham et al., 2002; Thiessen et al., 2005). Together, these features serve to facilitate the acquisition of the formal features of language as well as the child's ability to learn the meanings of words toward the end of the first year (Waxman, 2003).

IDT also incorporates rich emotional content captured in the prosodic contours that convey different emotional states. Younger infants are very sensitive to this component of IDT and respond to IDT statements of approval and praise with higher rates of smiling and attention even when they hear adults speaking in a different language (Fernald, 1989). Together, the features of IDT ensure that infants attend to the speech and language in their environment and facilitate the processing of its essential features and characteristics.

17.4.3 Intentional Communication

Toward the end of the first year of life, vocalizations as well as other nonvocal behaviors become genuinely integrated into social interaction as infants' developing social–cognitive capacities lead to the onset of intentional communication (Carpenter et al., 1998). At this point, infants become capable of coordinating their attention to objects or events with other people through eye gaze patterns (joint attention), gestures, and vocalizations. This developmental achievement is generally viewed as a critical step in language acquisition, with the onset of communicative intent. Infants at this stage are able to communicate a variety of meanings, including *protodeclaratives*, which involve pointing or other gestures to draw another person's attention to objects of interest, and *protoimperatives*, gestures or vocalizations to express requests for objects or actions. The significance of these communicative attempts is that they indicate the infant's capacity to understand the intentions of others (the beginning of a theory of mind), at least in a rudimentary or implicit form (Tomasello, 1999).

Infants' preverbal communications go beyond pointing to encompass other conventional gestures such as nodding or shaking their head to signify acceptance or rejection, waving as a salutation, or invented gestures that may incorporate symbolic features of an object or event, such as wiggling a finger to refer to a dog (Carter, 1979). Gestural communication is an important predictor of spoken language development in children and is another example of the close developmental links between the motor and linguistic systems (Rowe and Goldin-Meadow, 2009).

17.4.4 Pragmatic Development

As children begin to speak, their utterances express the same functions as their early preverbal gestural forms. By the time children are three, new functions emerge, including the use of language to describe objects or events, or to assert an opinion, for example, and they employ a range of conversational devices. At this point, children are able to express each of these functions using a variety of linguistic forms. The development of functional and communicative aspects of language is closely tied to developments in theory of mind and related social–cognitive achievements (Bartsch and Wellman, 1995).

There is a more protracted period of development for expressing functions using more indirect forms, such as indirect requests. Although 2-year-olds use terms such as *want* or *need* as a way of asking for something (e.g., *I need new ball*), genuine indirect requests do not emerge until around the age of three (e.g., *Where is the truck?*). By three years of age, children can use polite forms to make their request (e.g., *Would you give me a cookie?*), but hints or oblique indirect requests are not used until the early school years (Bryant, 2009).

Research has focused on children's developing awareness of the effect of their speech on a listener by taking into account the listener's knowledge. For example, 4-year-olds change the way they speak depending on their audience; thus, they use simpler language if they are talking to 2-year-olds compared to their language addressed to older children or adults. These modifications in children's discourse show some awareness of the distinct needs of a very young conversational partner (Shatz and Gelman, 1973).

Communicative competence entails knowing how to engage in conversations in appropriate and informative ways. Ultimately, this depends on appreciating both literal and nonliteral uses of language (e.g., metaphor, irony, and white lies), but these developments continue well into middle childhood (Siegal and Surian, 2007). Children also must master a range of different forms of discourse from conversation, to personal narratives to storytelling. The use of language in various contexts provides the interactive, communicative framework within which children acquire knowledge of the linguistic structures available in their native language so that they can express more fully the ideas that are generated by their developing cognitive and social systems.

17.5 LEXICAL DEVELOPMENT

By the end of the first year, infants already understand a number of words and phrases and soon begin to produce words. This is a critical milestone that is often used

as an objective proxy for the onset of language. Long before this milestone is reached, infants have acquired the skill of segmenting words within streams of continuous speech where there are often no clear boundaries, using a variety of cues, including sequential statistical information (Saffran et al., 1996) and consistent stress patterns (Jusczyk et al., 1999).

17.5.1 Stages of Lexical Development

Lexical development can be divided into three broad periods. The first covers the acquisition of the initial 50 words or so, during which children are learning what words do. At this stage, some words appear to be tied to particular contexts and serve primarily social or pragmatic purposes. Word learning during this initial phase is relatively slow and uneven (Nelson, 1981). The child's vocabulary at this stage, especially in Western middle-class children, is dominated by names for objects, including animals, people, toys, and familiar household things. Other early words include social terms (e.g., *hi*, *bye*), modifiers (e.g., *more*, *wet*), and relational terms that express success, failure, recurrence, direction, and so forth (Bates et al., 1994).

By the middle of the second year, there is a significant increase in the rate at which children acquire new words. This new period is usually referred to as the vocabulary spurt and may be punctuated by requests from children for adults to label things in the world around them. Words are learned very quickly, often after only a single exposure that may take place without any explicit instruction (Tomasello, 2003). This process of rapid word learning is referred to as *fast mapping* (Houston-Price et al., 2005).

By the time children reach their third birthday, they begin to develop a more organized lexicon, in which the meaning relations among groups of words are discovered. For example, at this time, children begin to learn words from a semantic domain, such as kinship, and they are able to organize the words according to their similarities and differences in dimensions of meanings (Nagy and Scott, 2000). For nouns labeling concrete objects, children begin to organize taxonomies, now also learning words at the superordinate and subordinate levels and understanding the hierarchical relations among terms such as dachshund, dog, and animal. Semantic developments at this stage will often lead to reorganizational processes as these kinds of relationships among words are realized by the child (Bowerman, 1978). The rate of word learning continues to be very rapid with estimates suggesting that children acquire about 15–20 new words a day during the preschool years and beyond (Bloom, 2000).

17.5.2 Developmental Processes

How do children accomplish the challenge of acquiring arbitrary symbols and their associated sound forms (words) to communicate concepts so rapidly? Research has identified several factors that facilitate the task of word learning in young children. At the most transparent level, the input to children provides one critical constraint on the words they acquire. The number and frequency of specific words in parents' speech to children correlates significantly with the frequency of those words in the children's vocabulary (Huttenlocher et al., 1991), and these variables correlate with socioeconomic status, reflecting the fact that more highly educated mothers speak far more to their children than mothers with little education (Hoff, 2006). The social context of word learning also helps young children who, because of their ability to infer intentions, can map word meanings by observing where their mother is looking or what she is pointing at when she labels objects (Baldwin and Meyer, 2007).

The child's developing conceptual knowledge influences the meanings they map onto words (Bloom, 2000). The relationship between language and conceptual development, or more generally between language and thought, is highly complex with each system placing constraints on the other, and with both being dependent on the social environment for their elaboration in development. Other general cognitive processes, including attention and memory, are also clearly important in word learning (Samuelson and Smith, 2000).

Children bring to the task of word learning several constraints that guide their hypotheses about the possible meanings of words. Markman (1989) has proposed that young children rely on three primary constraints including the *mutual exclusivity constraint*, which leads the child to assume that each object only has a single name and that a name can only refer to one category of objects; the *whole-object constraint*, which states that new words refer to whole objects rather than parts of objects; and the *taxonomic constraint*, which states that words refer to categories of objects (not specific exemplars). While some view these kinds of constraints as principles that are specific to lexical development, others view them as more general biases that may be an aspect of broader pragmatic or cognitive processes (Diesendruck, 2007).

Lexical development takes place in parallel with other aspects of language, particularly the acquisition of syntactic knowledge. Children use syntactic information to facilitate word learning, especially when other cues are not available, as is often the case for learning the meanings of related verbs such as *look* and *see*. In cases such as this, children can use information about the number and kind of arguments that occur with particular verbs to work out their meanings (Naigles and

Swensen, 2007). Thus, transitive verbs take object arguments while intransitive verbs do not. Syntactic information is also useful for figuring out the distinction between mass nouns (e.g., *spaghetti*) from count nouns (e.g., *a potato*), or between common nouns and proper names, and very young children have been shown to use this information when they hear new words in ambiguous contexts (Hall and Waxman, 2004).

Children depend on a wide range of cognitive, social, and linguistic mechanisms to learn the meanings of new words, and the input provided by their conversational partners helps to guide and constrain the learning process. Several integrative theoretical models have been proposed to account for how children might attend to different types of cues at different developmental stages and weigh the information carried by competing cues to lexical meaning (Bloom, 2000; Hollich et al., 2000). Such models have the potential to account for individual differences in, for example, children learning different languages or raised in different kinds of learning environments. A number of computational models of early word learning have been developed (e.g., Frank et al., 2009), though thus far, none has incorporated the full range of processes or constraints that are central to these integrative developmental models.

17.5.3 Neural Bases of Word Learning

By 5 months of age, infants' neural response shows sensitivity to the word stress patterns used in their language and will show a mismatch event related potential (ERP) response to deviations from this stress pattern (Weber et al., 2004). By 10 months, infants show distinct patterns of brain activity in response to familiar two-syllable words embedded in continuous speech, even when they have previously heard the word only in isolation (Kooijman et al., 2005).

As infants become more verbal, experience with language influences the organization of their neural response, resulting in distinct patterns of brain activity in response to words that an infant understands by 11 months (Thierry et al., 2003). Between 13 and 17 months, infants exhibit a broadly distributed bilateral response to words in general and a stronger N200 response to words that are understood than to words that are not (Mills et al., 1997). By 20 months, this pattern of response is localized to temporal and parietal electrode sites over the left hemisphere (Mills et al., 1993). The lateralized and focal response to known versus unknown words is linked more closely to linguistic ability rather than simply developmental maturation of the brain or brain connectivity. Thus, 13- to 17-month-old infants with more advanced receptive language skills showed a more localized neural response, whereas infants with low receptive language showed a less mature broader response pattern. One study with 20-month-old infants used a training paradigm to teach new words to label pictures of objects. After the training, there was an increased N200 response to the trained words over anterior electrode sites. This change in N200 response was independent of expressive vocabulary size, highlighting the influence of experience with a particular word and its meaning, not simply the infants' maturational level or overall language ability (Mills et al., 2005). Still, developmental maturation of language areas may influence the latency of response to new words as it decreases with age independent of language level (Mills et al., 1997).

In infants, semantic knowledge of word meaning is captured by a later negative response similar to the adult N400, which processes the integration of word meaning in context and involves the middle and superior temporal gyri (Kutas and Federmeier, 2011). In 19-month-old infants, the N400 response is elicited when shown pictures of objects paired with incongruent verbal labels (Friedrich and Friederici, 2004). Response to incongruent picture–word pairings is present early in the waveform over lateral frontal electrode sites, but is largest later in the waveform over both posterior and frontal sites. This later N400 was stronger, earlier, and more similar to that of adults in infants with more advanced receptive vocabularies. At 19 months, robust N400 responses are also elicited in priming contexts in the majority of infants. At 12 months, infants with advanced productive vocabularies also show an N400 response to priming, though at this early age, it is slightly delayed in onset and smaller in duration than in older children or adults (Friedrich and Friederici, 2010). The early functioning of N400 neural mechanisms highlights their significance for word learning, though the precise nature of this relationship is not yet known.

17.6 SYNTACTIC DEVELOPMENT

By the time they are 2 years old, toddlers begin combining words to form two or three word phrases or primitive sentences. From the earliest stages, children demonstrate their sensitivity to some of the basic rule-governed properties of their target language, for example, word order rules in English, though the precise nature of the knowledge this represents is still hotly debated.

17.6.1 Stages of Syntactic Development

Children must segment the sound stream they hear into morphemes, phrases, and sentences (Morgan, 1986) and discover word classes (nouns, verbs,

determiners, etc.) because grammatical rules operate on these more abstract categories to create hierarchically organized sentences. They must also figure out if their target language encodes tense, person, number, etc., and if so, whether these are marked by grammatical morphemes or other linguistic means. Different theories have been proposed for how children acquire this knowledge, ranging from distributional statistical (e.g., Mintz et al., 2002), to functional (Tomasello, 2002), to semantic bootstrapping (Pinker, 1984), to linguistic nativist approaches (Chomsky, 1995).

Across different languages, children begin by building phrasal units (e.g., noun phrase), move on to simple sentence structures and different sentence modalities (e.g., statements, questions), and finally master complex sentences such as coordinations and embeddings. As children's grammatical development proceeds, the length of their utterances increases, reflecting both the acquisition of linguistic knowledge (Brown, 1973) and growth in general cognitive capacities, particularly verbal working memory.

17.6.2 Early Sentences

As early as 18 months of age, the hierarchical nature of phrasal structures (e.g., *the red barn*) is available to children (Lidz et al., 2003). At this stage, English-speaking children adhere closely to using word order in their productive speech but omit most grammatical morphemes that mark, for example, tense or number. In contrast, children acquiring inflectionally rich languages such as Italian or Hebrew use the morphemes marking these features even in their very early productions (Caselli et al., 1999; Levy, 1988).

Children's early 'sentences' express a universal set of meanings: they talk about objects and people present in the environment, their locations, attributes, and interrelationships (Brown, 1973). Often their sentences will omit the subject, and while children acquiring languages where subjects are obligatory do so less than children acquiring languages in which so-called null subjects can be grammatical (Valian, 1990), these omissions reflect the limited cognitive capacity of young children and the fact that sentence subjects may be inferred from the context and are therefore pragmatically not necessary (O'Grady et al., 1989).

17.6.3 Grammatical Morphology

In contrast to many other languages, English has a relatively impoverished set of affixes and lexical terms that comprise its grammatical morphology to mark tense, number, person, etc. The course of development is thus a gradual process that is quite protracted, though across children, there is a similar order in which different morphemes are acquired reflecting their linguistic complexity. The developmental process is more rapid in languages such as Italian, though within each language, there is still a constrained order in which different morphemes are mastered (Brown, 1973).

In English, there are both regular and irregular forms to mark, for example, tense (e.g., *walk–walked*; *run–ran*) or number (e.g., *boy–boys*; *mouse–mice*). As children acquire these morphemes, they go through a stage of making errors, particularly by providing regular affixes to irregular verbs or nouns (e.g., *runned*; *mouses*). Pinker and his colleagues (Pinker, 1999; Ullman, 2001) argue that the acquisition and use of these different forms reflect two distinct mechanisms: a rule-learning system for regular forms and a lexical-memory system for irregular forms. In contrast, some computational models have been developed that can acquire the different forms based on a unitary mechanism that operates on the distributional properties of lexical items in the input (McClelland and Patterson, 2002).

17.6.4 Later Grammatical Development

Children's early utterances may be used to express a range of functions including statements, questions, and negations; however, they rely on single words or intonation to do so. By the preschool years, children acquire auxiliary verbs (do, be), and their negations and questions include the requisite verb morphology and inversion needed for questions (de Villiers et al., 1990). Sentences are now combined to create longer and more complex coordinated structures using '*and*' and later, '*if*,' '*because*,' and other coordinating conjunctions. Rarer complex linguistic constructions, for example, relative clauses, or the passive form are not mastered until the early school-age years. The order and speed of syntactic development reflect both the frequency of forms in the input and the complexity of the abstract rules that underlie them (Tager-Flusberg and Zukowski, 2009).

17.6.5 Neural Bases of Grammatical Development

In comparison to research on the neural bases of speech perception and word learning, few studies have been conducted on early grammatical development, perhaps reflecting the relative difficulty of obtaining reliable data from preschoolers who are less tolerant of electrode caps or sitting still. In adults, the most widely studied ERP components are an early left anterior negativity (ELAN), which is related to automatic sentence parsing based on word-category information or morphological violations and is thought to be generated in the left inferior frontal

gyrus and anterior superior temporal gyrus (STG; Friederici et al., 2000). Later, and more controlled, syntactic processing occurs with a later positivity, the P600, during which syntax is integrated with other information and sentence reanalysis occurs in the context of syntactic anomalies or ambiguities (Kaan and Swaab, 2003).

By around 30 months, the ERP responses of toddlers to syntactic violations show a large, late positivity similar to the P600 (Bernal et al., 2010; Silva Pereyra et al., 2005) and, in some cases, display an earlier left-lateralized negativity similar to the adult ELAN (Bernal, et al., 2010). This similarity in waveform topography and morphology suggests that toddlers have already developed or constructed a relatively adult-like system for processing the syntax of simple sentences, including to some extent a system of automatic processing. Passive sentences, on the other hand, involve higher processing demands than do active sentences and do not evoke adult-like automatic components until late childhood or adolescence (Hahne et al., 2004).

Nevertheless, the neural response to syntactic violations is immature in children in that it is not yet functionally specified the way it is in adults. For example, functional magnetic resonance imaging (MRI) studies in adults show that distinct areas of the inferior frontal gyrus and STG are activated in response to syntactic violations versus semantic violations, particularly as processing demands increase. At the age of five or six, children still show substantial overlap in their fMRI activation to syntactic and semantic violations, particularly in the STG (Brauer and Friederici, 2007). These findings provide some support for the view that the acquisition of syntactic structure may be closely linked to semantics in young children.

17.7 LANGUAGE DISORDERS

The vast majority of children follow the developmental pathway to language described in the previous sections. But for some children, the onset of language is quite delayed; thereafter, the rate of development may be slowed, and the normal synchrony between the structural and pragmatic components of language may not hold. Children whose language is significantly delayed may never reach the same endpoints as typically developing children; this is especially true for those who also have intellectual disability, for example, children with known genetic syndromes including Down syndrome or fragile X syndrome (Tager-Flusberg, 2007). Limits in the acquisition of language beyond the early school years, specifically in the domains of syntax and morphology, have been taken as evidence for a critical period (e.g., Lenneberg, 1967).

Two complex neurodevelopmental disorders are defined, in part, on the basis of primary impairments in language and communication: specific language impairment (SLI) and autism spectrum disorder (ASD). SLI is diagnosed on the basis of delays and slowed rate of development of language in the absence of hearing impairment, frank neurological damage, social deprivation, or other neurodevelopmental disorders. ASD is diagnosed on the basis of impairments in communication, social reciprocity, and restricted or repetitive behaviors and interests. The majority of children with ASD also have co-morbid impairments in structural aspects of language, and there is a growing interest in the overlap between ASD and SLI in their language phenotypes as well as genetic risk factors (e.g., Abrahams and Geschwind, 2008; Tager-Flusberg, 2004; Tager-Flusberg et al., 2008). A selective review of what is currently known about the developmental course and neurocognitive bases of language impairment in young children with these disorders, both of which are marked by significant heterogeneity in the severity and characterization of core and associated symptoms, is presented here.

17.7.1 Speech Perception

SLI and ASD are not diagnosed until the preschool years; however, in recent years, research has focused on infants at risk for these disorders, defined usually on the basis of family risk (e.g., presence of older sibling or other first-degree relative with the disorder), in order to capture the earliest emergence of deviations from patterns of normal development. Studies of 2-month-old infants at risk for SLI show significant differences in ERP responses for discriminating between long versus short syllable lengths (Friederici, 2006), and by 4–5 months, they show a reduced ERP response for discriminating the stress pattern of two-syllable words (Weber et al., 2004), suggesting that deficits in processing speech duration very early in life may be a marker for later language impairment. At 6 months of age, infants at risk for SLI are less able to discriminate tones presented in rapid succession, and the amplitude of the N250 mismatch ERP response is smaller and delayed in onset when listening to tones with brief interstimulus intervals (Benasich et al., 2006). These ERP measures predicted to language outcomes at the age of two. Taken together, these studies suggest that differences, which may affect auditory as well as speech perception, are present very early in life for infants at risk for SLI. Similar studies have not yet been carried out with infants at risk for ASD.

17.7.2 Speech Production

Retrospective reports highlight delays in the onset of babbling in children with SLI and ASD (Norbury et al., 2008; Tager-Flusberg et al., 2005). Children with ASD

who have more severe deficits in acquiring spoken language also have a history of deficits in a range of other oral-motor skills (Gernsbacher et al., 2008). Prospective studies of infants at risk for ASD have confirmed that babbling is delayed in this group: between 6 and 12 months, infants at risk have fewer speech vocalizations and produce fewer consonants and less canonical babble (Paul et al., 2010). In addition, there is not as close a connection between the onset of babbling and rhythmic arm banging in high-risk infants as in typical infants (Iverson and Wozniak, 2007).

When children with SLI begin speaking, they are at higher risk for articulation disorders: though these are distinct syndromes, there is some overlap between SLI and speech sound disorders (Sices et al., 2007). Most children with ASD do not have impaired articulation (Kjelgaard and Tager-Flusberg, 2001), and their order of acquiring consonants follows the normal pattern (McCleery et al., 2006). Nevertheless, there is a group of children with more severe ASD (and often comorbid intellectual disability) who remain without spoken language and minimal vocal and speech repertoires despite years of intervention. It is not known what mechanisms are impaired in these children.

17.7.3 Social–Cognitive Foundations of Language

Relatively little research has focused on the early social development of children with SLI. Given that these children do not have primary social impairments, communicative and pragmatic aspects of language are less likely to be affected. There is some evidence that children with SLI may use more nonverbal communicative signals, particularly gestures, to compensate for their limited expressive language skills (Iverson and Braddock, 2011).

In contrast, given their primary impairments in social reciprocity, children with ASD have been extensively studied for the social–cognitive foundations of language. Infants at risk for ASD who later receive a diagnosis show significant declines in social engagement (eye contact, social smiling) beginning around 12 months (Ozonoff et al., 2010); they also produce significantly fewer gestures and do not respond to their name (Landa et al., 2007; Nadig et al., 2007). Early indicators of social cognition, including joint attention, imitation, and gestural communication, are all strongly correlated with language development in toddlers with ASD (Luyster et al., 2008), highlighting the ties between these domains.

Unlike typically developing children, most preschoolers with ASD show no preference for IDT, even their own mothers' IDT, over nonspeech analogs or other environmental sounds (Klin, 1991; Kuhl et al., 2005).

A stronger preference for nonspeech sounds was associated with a lack of ERP response to differentiating speech sounds in a mismatch negativity paradigm and with more severe impairments in language development (Kuhl et al., 2005).

When they do begin speaking, children with ASD use a restricted range of functions, failing to use language in prosocial ways, such as directing attention to an object of interest, or exchanging thoughts and experiences (Wetherby et al., 2007). They have poor conversational skills, which is associated with deficits in theory of mind (Hale and Tager-Flusberg, 2005), and other discourse genres, including narration and storytelling, are also impaired when compared to children at the same language level (e.g., Diehl et al., 2006; Losh and Capps, 2003). Even children with ASD who have intact structural language skills continue to struggle with interpreting nonliteral uses of language, such as lies or metaphors, and show subtle deficits in integrating verbal and nonverbal (prosody, gesture, and eye gaze) modalities when communicating in face-to-face interactions (Tager-Flusberg et al., 2011).

17.7.4 Lexical Development

Children with SLI and ASD do acquire words, though usually at a slower rate. Among children with SLI, vocabulary size has been linked to the ability to accurately repeat multisyllabic nonsense words (e.g., Ellis Weismer et al., 2000). Nonword repetition provides a sensitive measure of phonological working memory, which is an important component of learning to map novel sound sequences to meaning. Children with ASD and comorbid language impairment also show impairments in nonword repetition (Kjelgaard and Tager-Flusberg, 2001).

Researchers have investigated whether children with language disorders are able to use the full range of processes and constraints to guide their acquisition of new words. Young children with SLI are less able to acquire new words using fast mapping (Rice et al., 1994) and are especially vulnerable when using syntactic cues (Rice et al., 2000). Studies of children with ASD have shown that they are able to use the mutual exclusivity constraint (e.g., Preissler and Carey, 2005), but they are less sensitive to social cues for word learning such as direction of eye gaze that signals a speaker's intention (Parish-Morris et al., 2007).

Toddlers who were later significantly delayed in language milestones showing signs of SLI did not exhibit the expected N400 ERP response for lexical-semantic processing in a picture–word matching paradigm at either 14 or 19 months (Friedrich and Friederici, 2005). Even older children with SLI only show a P600 response (but no N400) in response to semantic violations in sentence contexts. These differences in neural

response suggest weaker lexical-semantic representations (Friederici, 2006).

17.7.5 Syntactic Development

There is general agreement that language disorders involve more serious impairments in syntax and morphology, compared to phonological or lexical development (e.g., Tager-Flusberg, 2007; Tomblin and Zhang, 1999). Children with SLI begin combining words to form simple utterances at least 2 years later than typical children, though they show the same general developmental trajectory in the growth of sentences over time (Rice, 2007). Children with ASD are also delayed, though there is far greater heterogeneity in both the onset of word combinations and rate of development in this population (Tager-Flusberg et al., 1990).

Rice (2007) has argued that SLI is characterized by primary deficits in the acquisition of particular aspects of grammar: those related to the morphology and syntax of tense, agreement, and case marking. For example, children with SLI go through a more protracted developmental period of omitting past or present tense morphemes (Rice et al., 1998). Children with ASD who have impairments in structural language also omit tense morphemes (Roberts et al., 2004), underscoring the parallels between these disorders. While Rice and her colleagues argue that these tense-marking deficits can be explained on the basis of disruptions in the acquisition of linguistic knowledge, others argue that they reflect domain-general processing limitations (e.g., Leonard et al., 1997).

A number of studies have investigated neural responses to different aspects of syntax in children with SLI. An early study found that lexicalized grammatical morphemes (function words), but not content words, elicited a more bilateral or even right-lateralized negativity, in contrast to the LAN evoked in typical children (Neville et al., 1993). Van der Leley (2005) investigated ELAN responses in SLI children with severe grammatical deficits. In this subgroup of children with SLI, syntactic violations did not elicit any ELAN response. Similar studies have not been conducted on children with ASD. While these preliminary findings are interesting, there are still only limited investigations of the mechanisms that underlie impairments in syntactic development in children with language disorders.

17.7.6 Neural Bases of Language Disorders

As noted earlier, in most individuals, regions that comprise the language network are asymmetric and larger in the left hemisphere. Functionally, the left hemisphere assumes a primary role in processing phonological, semantic, and grammatical aspects of language. Developmental studies have found that while the left hemisphere assumes language processing functions by the end of the first year, there is continuing developmental growth in the structure and asymmetry of language-related cortices into late adolescence (e.g., Sowell et al., 2004).

In children with SLI, both structural and functional differences have been found in studies using MRI. In general, these children have reduced volumes in the primary cortical language areas and reduced asymmetry in the frontal areas, and they are functionally less left lateralized (Tager-Flusberg et al., 2008). In ASD, similar atypical structural patterns have been found, although findings across different studies vary, depending on the methods used, and the age and characteristics of the participants. The majority of studies, which almost always include only boys with ASD, report reduced volumes of the pars triangularis in Broca's area and posterior language regions (e.g., McAlonan et al., 2005; but see also, Knaus et al., 2009). Interestingly, a recent study suggested that reduced volumes in these regions may be associated with later onset of language (McAlonan et al., 2008). Reduction in left hemisphere asymmetry of frontal language regions has also been found in several studies and is associated with greater impairment in language abilities (de Fossé et al., 2004). Almost all functional studies have been conducted with older children or adults. The most consistent findings are reduced left hemisphere asymmetry of language processing, especially in frontal areas, and reduced correlations in activation patterns across language regions (see Tager-Flusberg et al., 2008). One study found atypical activation to speech in toddlers with ASD (Redcay and Courchesne, 2008). In contrast to the control children, who activated the left hemisphere language network, toddlers with ASD primarily activated corresponding regions in the right hemisphere, suggesting that these atypical patterns begin early in development. It is not known, however, the extent to which these differences in functional organization of language in ASD are related to fundamental differences in neuroanatomy that are present at birth, to developing language skills, or to compensatory mechanisms. Nevertheless, the consistent pattern across a range of neuroimaging studies is that children with SLI or ASD are less likely than nondisordered children to depend on language areas in the left hemisphere for processing language.

17.8 CONCLUSIONS

The development of language is a remarkable accomplishment that depends on critical interactions between infants and their environment. Already at birth, attention and motivation bias newborns toward social

stimuli, especially human language, and their brains seem tuned to selectively respond to linguistic stimuli. Over the first year of life, experience with language embedded in supportive social contexts leads to greater neural specialization and behavioral changes, and by their first birthday, most infants are already well on their way to acquiring the phonology, lexicon, and grammar of their target language. The course of development involves complex interactions between language-specific and other general cognitive, social, and physiological mechanisms, and the normal pathway depends on exquisite timing and synchrony across multiple domains. Future research will unravel further the neurocognitive systems that contribute to successful language acquisition, and as progress is made in discovering the genetic bases of language-related neurodevelopmental disorders, we will begin to understand how genes help to build a brain that is capable of learning how to speak and understand an abstract symbolic system in just a few short years (see Rubenstein and Rakic, 2013).

CHAPTER

18

The Neural Architecture and Developmental Course of Face Processing

G. Righi[1], C.A. Nelson III[2]

[1]Boston Children's Hospital, Boston, MA, USA; [2]Harvard Medical School, Boston, MA, USA

18.1 INTRODUCTION

Faces are ubiquitous in our environment and convey information that is used extensively in all social interactions. For example, human adults can easily classify faces on the bases of their gender, race, and identity and thus recognize quickly whether they have come across a friend or a foe (Bruce and Young, 1986). Moreover, faces also convey information that can assist an observer in gaining insight into the internal state of another person; for example, slight changes in facial features are related to different emotional states, from happiness to sadness, from anger to fear, from surprise to disgust (Ekman, 1993). Even though for most adult

observers, gathering information from a face is a relatively seamless process, this skill undergoes a lengthy developmental trajectory that has its origins in infancy and continues well into adolescence. Throughout development, both the behaviors that accompany face processing and the neural underpinning of these behaviors undergo substantial modification. The bias brought to this chapter is that we cannot fully understand the mature face-processing system unless we make a parallel effort to understand the development of this system. The goal of this chapter is to provide an extensive overview of the research on face processing from infancy to adulthood. In each of the sections, the results of both behavioral and neurophysiological research that examines different aspects of face processing, including facial identity, facial categorization (e.g., of gender, race), and the discrimination and recognition of facial expressions are reviewed. The various sections that follow are organized chronologically with the exception of the first section. In the first section, face processing in adults is discussed in order to provide the reader with a framework on which to understand the results of the developmental work, which is presented in chronological order from infancy through adolescence. The last section of this chapter discusses impairments in face development that result from either traumatic brain injury or neurological syndromes.

18.2 FACE PROCESSING IN ADULTS

Despite the chronological organization of the majority of this chapter, the discussion of face processing in adults is dealt with first. This will provide the reader with an illustration of the mature face-processing system, including its neural architecture, which in turn will serve as a template against which to compare the development of this system. In this first section, primarily experimental evidence is reviewed, but the methodological tasks most commonly used to measure face processing are also discussed, as they apply to both the study of adults and the study of developmental populations.

18.2.1 How Adults Process Faces

Most people can recognize hundreds of individual faces by the time they reach adulthood, and their ability to memorize facial identities remains more or less intact throughout their lifespan. Moreover, face recognition is surprisingly robust. For example, it has been shown that recognition performance is relatively impervious to physical transformations including blurring (Harmon, 1973; Yip and Sinha, 2002), changes in lighting conditions (Braje, 2003; Braje et al., 1998), and changes in

viewing angle (Hill et al., 1997; O'Toole et al., 1998). The resilience to these transformations is something that any observer has experienced as these variations make the recognition of identity more challenging but nevertheless successful. One of the reasons behind the robustness of face processing is that faces are not identified by focusing on specific features in isolation; rather, human observers rely on both specific facial features and on the relations among them and perform what has been termed 'holistic processing' (Tanaka and Farah, 1993; Young et al., 1987). More recently, several authors have suggested that there are three different types of holistic processing that all come into play during face processing but that can be specifically tested using different experimental manipulations (Gauthier and Tarr, 2002; Maurer et al., 2002). Aside from differences in terminology, both Gauthier and Tarr (2002) and Maurer and colleagues (2002) suggest that when viewing faces, observers process (1) the specific special arrangement of features in a face (i.e., two eyes above nose and mouth), (2) the specific spatial relations among features in a face (i.e., distance between the eyes, length of the forehead, etc.), and (3) a face gestalt in which all facial features are integrated into a representation. Healthy adults are also very proficient at detecting facial expressions, regardless of whether they are familiar or unfamiliar with a specific face. There are several well-established behavioral demonstrations of these specific types of processing strategies. The sensitivity to facelike configurations is such that adults excel at detecting the presence of faces even in very degraded situations such as in extremely blurred images or even when they are presented with highly schematic faces (Diamond and Carey, 1986). Adults are also very good at detecting variations in the spacing of features within a face, such that they can recognize different identities even when they vary only in spacing among facial features (Le Grand et al., 2001). This sensitivity to the 'configural' properties of a face has also been shown by using the 'face inversion' paradigm (Yin, 1969), which has revealed that the ability to recognize faces is greatly hindered by picture plane inversions and even more so when the distinctions between the experimental stimuli are created by spacing manipulations (Goffaux and Rossion, 2007). Lastly, the bias to produce 'holistic' face representations has been shown using the 'face composite' paradigm (Young et al., 1987). In this paradigm, subjects are presented with a face created by combining tops and bottoms of different individuals, and they are asked to pay attention to only one of the two specific parts; what has been shown is that when the two parts are presented in alignment with one another, subjects make more errors because they get distracted by the irrelevant face part. These experimental effects have been extensively replicated in the adult literature and are considered the hallmarks of expert face processing.

18.2.2 Models of Face Processing

Going beyond face recognition, adults are also very quick at determining many other different types of information from faces, including gender, race, direction of gaze, and emotional expressions. In order to understand fully the nuances of face processing, it is worth discussing in brief theoretical models that have been proposed in the literature. The most influential model of face perception remains Bruce and Young's dual-route model (1986) formulated to provide a theoretical framework that can explain how perceivers extrapolate and process different types of information from faces, such as identity, emotional expression, and facial speech. The core assumption of this model is that independent modules and processing streams support these different tasks and they work in parallel with no cross talk of information between them. Face processing begins with 'structural encoding,' which produces a number of descriptions of a face, some of which are dependent on the specific instance of the face that is presented (view-centered), while others can be more general and contain knowledge about the global structure of that face in a more invariant manner (expression-independent), meaning that they are not related to a specific expression or viewing condition. The segregation of the processing streams takes place after the initial structural encoding phase.

Regardless of whether the face is novel or familiar, expression and facial speech-processing modules receive only the information contained in the view-centered descriptions, while expression-independent descriptions are connected to a processing module that works exclusively for identity recognition. A module separate from the recognition module, which receives both the view-centered and the expression-independent information, processes the physical structure of a novel face. This module is also responsible for extracting information about the physical configurations that can be used to judge gender, race, age, etc. To summarize, after a common initial visual analysis, the information is sent to one or more of the four different modules depending on the objective of the task at hand. In turn, the outputs of each of the modules are sent to a common 'cognitive system.' This system is responsible for directing attention and decision processes, but most importantly it contains memory information about all the semantic knowledge that can be associated with a face. Bruce and Young (1986) divide the stored semantic information on the basis of which processing module provides the physical analysis needed to retrieve it. They suggest four different types of codes: expression codes, facial speech codes, visually derived semantic codes, and identity-derived semantic codes. Expression codes contain the labels for facial expressions. Facial speech codes contain representations for mouth movements connected to speech. Visually derived semantic codes contain the information relative to judgments that can be based on the physical structure alone and are independent of identity, emotional expression, and facial speech, such as gender, race, age, and some social attributions. Identity-derived semantic codes contain all the information one has acquired about a specific person that one knows.

Another class of face-processing models is represented by the prototype-based or face space model (Valentine, 1991, 1999). This type of model has been formulated with the goal of providing a unitary account of various phenomena of face processing including recognition and identification of race and gender. The basic assumption that these models make is that any face can be represented within a multidimensional space. The number of variables needed to discriminate between faces determines the dimensions of the space. The center of the space is assumed to represent the average value of a population on that specific dimension. What makes a face more or less recognizable among other faces is the distance between the target face and neighboring faces in the space. The creation of average faces gives rise to prototypes, which are presumably stored in memory. It has been suggested that observers have prototypes not only for identity but also for gender, race, and possibly even age because despite sharing the basic shape and features, individuals classified in these categories differ on the basis of specific featural and configural information (O'Toole et al., 1997).

18.2.3 Neural Substrates of Face Processing

The neural substrates of adult face processing have been extensively studied over the last decade. The advent of functional magnetic resonance imaging (fMRI) has opened the way to look at the neural networks recruited by face processing. One of the most significant findings of this literature is the identification of a portion of the cortex located within the medial fusiform gyrus that is found to be primarily responsive to faces, compared to most common objects; this functional area has been termed the fusiform face area or FFA (Figure 18.1; Kanwisher et al., 1997).

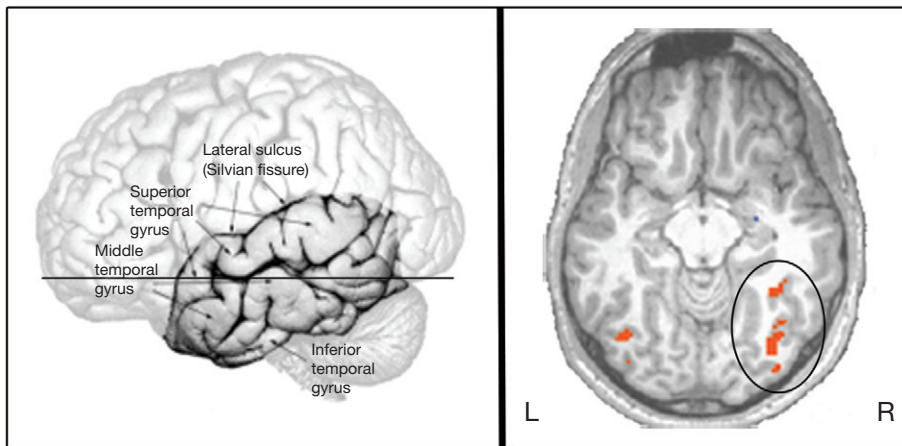
Subsequent to Kanwisher's important contribution regarding the role of the fusiform gyrus in face processing, other researchers have identified a rich network of areas that are recruited by a variety of face-processing tasks (Haxby et al., 2000; Ishai et al., 2005; Tsao et al., 2008). For example, the findings from a variety of neuroimaging studies have been integrated by Haxby and colleagues (Haxby et al., 2002) into a model of the brain network of face perception. Their proposal is strongly influenced by Bruce and Young's (1986) dual-route model, as they suggest that the recognition of identity


FIGURE 18.1	The fusiform face area in adult subjects.

and the processing of social information from a face are dependent on different variables that give rise to independent cognitive representations, which in turn produce distinct neural representations (Haxby et al., 2002). In line with Bruce and Young's model (1986), they suggest that while face identification is based on those features that remain invariant over time, other tasks, such as eye gaze perception, expression identification, and lip movement recognition, are derived from the analysis of the changeable features of a face. After an initial visual analysis carried out in the inferior occipital gyri, the two classes of features mentioned above are directed to either the superior temporal sulcus (STS) (changeable features) or to the lateral fusiform gyrus (invariant features). These two areas are in agreement with studies that have reported the STS to be activated by different types of biological movement including those of the eyes and mouth, while the fusiform gyrus has been consistently found to be activated when subjects are asked to judge facial identity, but less so when subjects are asked to detect eye gaze direction. From the STS, information is segregated further such that eye gaze processing is directed to the intraparietal sulcus, lip reading information is directed to auditory cortex, and emotion-related information is directed to the amygdala, insula, and other limbic system structures. The identification of the neural substrates for these three different processes is inspired by considering each process a face-specific instance of a more generic cognitive process. That is, these specific tasks recruit areas that perform the more general operations and become part of this network only when face stimuli are the input of the system. The direction of gaze can be used to direct the subject's attention toward what another individual might be looking at and as such can be considered a special case of attentional mechanisms. Emotional expressions provide information about the emotion that an individual might be experiencing and as such are processed by the same areas that are involved in the experiencing of emotions. Lip movements are the face-specific component of the multimodal speech signal and as such are processed by areas involved in speech perception. The information that reaches the fusiform gyrus is used for judgments of identity and other types of classifications that are independent of dynamic changes in facial structure (possibly gender, race, age, etc.) and as such is suggested to be relayed to areas that contain task-relevant stored knowledge, such as biographical or semantic information. In support of this idea, studies have shown that the recognition of a face is associated with activity in the anterior temporal cortex (Gobbini and Haxby, 2007; Leveroni et al., 2000), suggesting that these areas might contain semantic knowledge that is associated with known faces.

Beyond the individuation of anatomical substrates involved in face processing, many researchers have been interested in identifying functional signatures using methods such as event-related potentials (ERPs) in order to shed light on the time course of different aspects of face processing. A review of the findings using this methodology is also important in the context of development because ERPs are the most widely used technique to study the brain's response to faces in infants, toddlers, and children. Studies using ERP have identified a series of electrical potentials that respond to different aspects of face processing. The most widely studied of these components is the N170, a negative deflection in the ongoing electroencephalography (EEG) that occurs on average around 170 ms after the presentation of a face and is measured over posterior scalp electrodes, which is suggested to reflect the activity of the occipitotemporal face-selective neurons and is specifically responsive to the structural encoding of faces (Bentin et al., 1996; Carmel and Bentin, 2002; Eimer, 2000; Rossion et al., 1999). Moreover, the N170 has also been associated with configural processing as it shows both amplitude and

latency modulations in response to inverted faces, when compared to upright faces (Bentin et al., 1999; Jacques and Rossion, 2007). The recognition of facial identity has been suggested to take place later in the processing stream and has been associated with other components such as the N250 (Rossion et al., 1999; Rossion and Gauthier, 2002), the N400, and the P600 (Eimer, 2000).

18.2.4 Conclusions

In summary, with a few exceptions, adults are very good at recognizing and processing the information present in faces. However, it should be evident from the data reviewed in this section that these abilities are dependent on complex processing strategies and rely on the interactions of a rich network of brain regions. Moreover, adult expertise is also dependent on the constant interactions with faces that we all experience in everyday life. The next sections in this chapter will examine how face expertise arises throughout development, with the hope to provide the reader with an understanding on both the behavioral and neural specialization for face processing.

18.3 FACE PROCESSING IN THE FIRST YEAR OF LIFE

18.3.1 How Infants Learn to See Faces

Despite a very immature visual system, infants develop the ability to process facial identities and facial expressions surprisingly quickly over the first year of life (Figure 18.2) (see Chapter 14).

FIGURE 18.2   Development of the infant visual system within the first year of life.

Their experience with faces begins at birth, and one of the most striking findings of the literature looking at face processing in infants is that since birth they show a preference to pay attention to faces and facelike stimuli, compared to other visual objects (Johnson and Morton, 1991; Maurer, 1983; Mondloch, et al., 1999; Valenza et al., 1996). The ontogeny of their face preference is still under debate. On one hand, it has been hypothesized that infants are 'innately' attracted to stimuli that resemble faces (e.g., an oval with three dots in it) and that from birth there is a subcortical brain system, possibly including the superior colliculus and the pulvinar, that causes infants to orient toward facelike patterns (Johnson, 2005). This mechanism is supposed to be replaced at around 2 months of age by a cortical mechanism (Conlearn) that is already somewhat specialized for faces (Johnson, 2005). On the other hand, it has been hypothesized that faces happen to be optimal stimuli for a developing visual system in terms of their physical characteristics (Banks and Salapatek, 1976; Kleiner, 1987). Following this initial orienting toward faces, it is through exposure and active experience that the infant brain starts to develop what become face-sensitive processes and neural structures (Nelson, 2001).

Over the first months of life, infants rapidly learn to perform several types of facial discriminations. Several studies have shown that infants as young as 4 days old show signs of discriminating their mother's face from that of a stranger, although this ability is not yet robust enough to withstand, for example, the presence of a headscarf (Pascalis et al., 1995). However, infants rapidly progress in their ability to recognize their mother's faces such that at 3 months of age, they are able to do so even across variations in viewpoint (Pascalis et al., 1998). It is around 3 months that infants also show the ability to discriminate between male and female faces (Quinn et al., 2002) and also between faces of different races (Bar-Haim et al., 2006; Kelly et al., 2005; Quinn et al., 2008).

Related to the development of the ability to discriminate between faces of different identities, different gender, and different races is a phenomenon called perceptual narrowing (see Nelson, 2001 for discussion). While at 3 months infants seem to be learning to differentiate between different categories of faces, it has been suggested that by 9 months they develop the ability to distinguish between exemplars within a category but only if they have experience with that specific category. Perceptual narrowing refers to the fact that between 3 and 9 months, on average around 6 months, infants are able to discriminate between individual exemplars of many different visual categories. However, by 9 months, this flexibility appears lost in most categories, except for the ones with which the infant has the most experience.

In behavioral studies, it has been shown that 9-month-olds do not successfully differentiate between different individuals of a race other than their own (Kelly et al., 2007). Moreover, by 9 months of age, infants are not discriminating among a pair of monkey faces, something that 6-month-olds are capable of doing, while successfully differentiating between human faces (Pascalis et al., 2002, 2005).

During the first year of life, infants also experience changes in the strategies they use when they process faces. One of the hallmarks of face processing in adults is their reliance on the configural properties of a face, which is at the root of their expertise with faces. Infants do not seem to show the ability to use configural cues at birth, but some investigators have suggested that this ability emerges within the first year of life, even though it may not be reaching adultlike levels until later in development. Recent studies have shown that by 7 months of age, infants are sensitive to prototypical face configurations (Thompson et al., 2001), such that they can discriminate between faces that contain atypical distances between their features and more prototypical exemplars. A recent study has suggested that infants as young as 5 months are able to discriminate between faces that differ only in spacing between the eyes and spacing between the nose and mouth while maintaining identical features (Bhatt et al., 2005).

18.3.2 How Infants Process Facial Expressions

Within the first year of life, infants are also able to discriminate some facial expressions (Barrera and Maurer, 1981; de Haan et al., 1998; Nelson and Dolgin, 1985; Nelson and Salapatek, 1986; Nelson et al., 1979; Young-Browne et al., 1977), and within their first 12 months, they undergo a series of developmental changes. Starting as early as 36 h after birth, infants show evidence of being able to discriminate among happy, sad, and surprised faces (Field et al., 1982). Experimental evidence from infants in their first 6 months of life shows that they continue to be able to discriminate at least some facial expressions from one another, with some variability depending on the intensity of the exemplars used on their specific characteristics. Overall, it seems that happy faces are successfully differentiated from other expressions and neutral faces (Farroni et al., 2007; LaBarbera et al., 1976; Young-Browne et al., 1977), while negative expressions are more difficult to differentiate for young infants (LaBarbera et al., 1976; Nelson and Dolgin, 1985; Young-Browne et al., 1977). It has been hypothesized that during the first few months of life, infants may learn to discriminate the expressions that they are most often exposed to, which are usually positive, and are not yet capable of discriminating among ones that they do not

see often. It is between 7 and 12 months that, perhaps, emotion processing experiences the most dramatic changes and infants start showing the ability to discriminate expression with which they do not have much experience. For example, it is around 7 months that infants first show the ability to consistently discriminate fearful faces (Nelson and Dolgin, 1985) and start showing longer fixations toward this expression (Leppänen et al., 2007; Peltola et al., 2009). Another important shift that takes place starting at around 7 months is the perception of facial expression in a categorical manner, which is a signature of emotion processing present in adults. Thus, it is around this age that infants demonstrate the ability to (a) generalize their discrimination of facial expressions across multiple exemplars (e.g., Nelson et al., 1979) and (b) discriminate qualitatively between two facial expressions even though the stimuli used are created using a quantitative morph continuum. This effect has been using faces that are morphed in a continuous way between happiness to sadness (Leppänen et al., 2009) and fear and happiness (Kotsoni et al., 2001).

18.3.3 Neural Substrates of Face Processing in Infants

The study of the neural substrates of face processing in infants has received much attention in recent years. One of the questions that is still debated is whether faces are processed by specialized neural structures since birth (Johnson, 2005; Johnson and Morton, 1991) or whether the neural structures that are found to be face-selective in the adult brain become specialized for face processing through active experience over the course of development (Gauthier and Nelson, 2001; Nelson, 2001). Because of obvious methodological difficulties, there are very few studies that have used functional brain imaging methods to test whether infants show face-selective brain activations. To our knowledge, the only investigation of this type used PET scanning in six 2-month-old infants, who at birth had experienced hypoxic–ischemic encephalopathy (Tzourio-Mazoyer et al., 2002). In this study, infants were presented with faces of adult females and schematic dot patterns. The infants' brain showed a surprisingly rich network of clusters of activation in response to faces akin to what is found in the adult brain in the inferior occipital cortex, but it also showed activation for faces in parietal and frontal regions (Tzourio-Mazoyer et al., 2002). These results are important as they confirm the presence of a neural system sensitive to faces as early as 2 months of age. However, there are two issues to consider with this study. First of all, the infants tested were not neurologically normal. Second, the comparison stimulus used was far less attractive and complex compared to faces, and as such it is difficult to

determine whether any complex object would have elicited similar patterns of activation.

18.3.4 Neural Signatures of Face Processing in Infants

The most widely used method to assess infants' brain responses to faces is ERPs, and the adaptability of this methodology to infant studies has given rise to an extensive literature that has investigated the functional signatures of face processing in infants. ERP components that are sensitive to faces have been shown to emerge as early as 3 months of age (Halit et al., 2004). There are two components that are considered to be the antecedents of the adult N170: the N290 and the P400. The N290 shows an adultlike effect of inversion starting around 6 months of age (Halit et al., 2004), but as pointed out by de Haan and colleagues (de Haan et al., 2003), the selectivity for faces of this component has yet to be tested in infants. The P400 shows an adultlike latency difference between faces and objects and by 12 months also shows an effect of inversion (Halit et al., 2004). Similar to the adult literature, these two components have been linked to the structural analysis of faces, while another set of components has been linked to the recognition of familiar faces: the Nc and the positive slow wave. The Nc appears to show a difference between the mother's face and a stranger's face starting at 6 months of age as long as the two faces are different enough from one another (Figure 18.3; de Haan and Nelson, 1997).

ERP components elicited in response to faces have also been shown to be modulated by the presence of emotional expressions. Among face-sensitive components, the Nc component appears to be sensitive to several facial expressions in infants. In one of the first studies using ERP to look at facial expression processing, Nelson and de Haan (1996) showed that fearful faces elicited an increased amplitude of the Nc component, compared to happy faces. Leppänen and colleagues (Leppänen et al., 2009) also found differential sensitivity to happy and sad faces in the Nc component in 7-month-olds, but no differences were found in the N290 and P400. Grossman and colleagues found amplitude modulations in this component in response to angry and happy faces in 7-month-olds (Grossmann et al., 2007). Interestingly, it is only around 12 months that infants start showing modulations of emotional expressions on more posterior components (Grossmann et al., 2007).

18.3.5 Conclusions

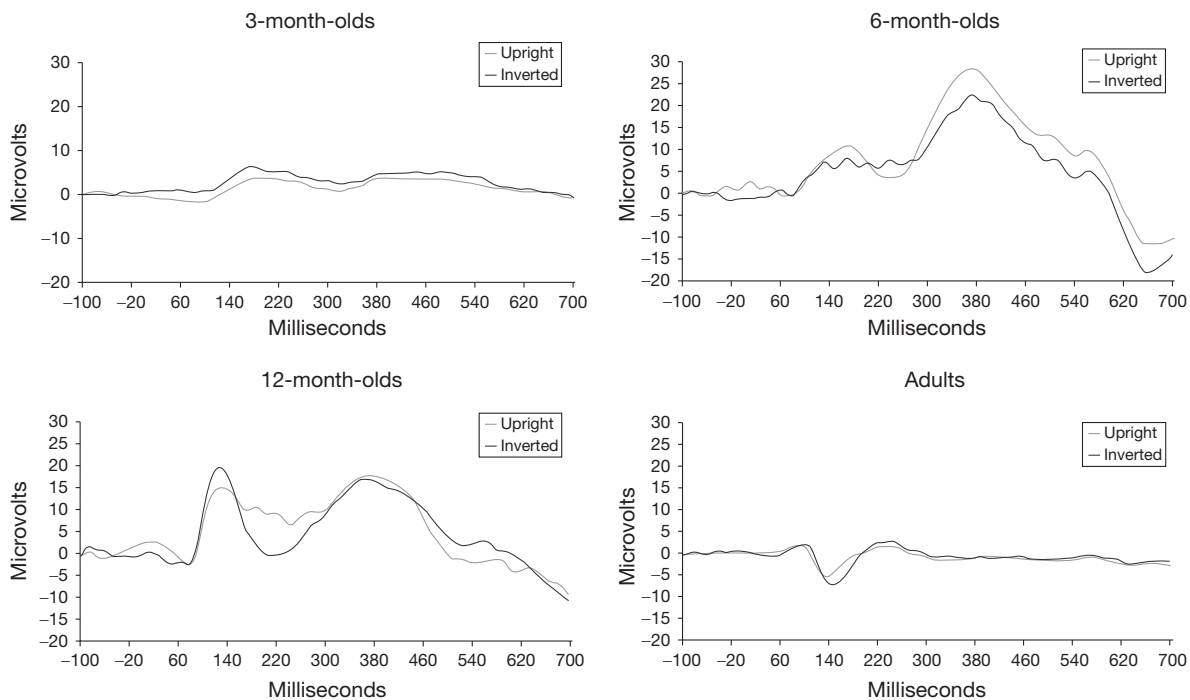
During the first year of life, face processing undergoes rapid development both behaviorally and neurally. In the first 12 months of life, infants start to show many of the face-processing skills that will gain strength throughout development and will reach full maturity in adolescence and adulthood. Moreover, their neural responses to faces also start to show signs of face specialization, although it is apparent that much anatomical and functional maturation will take place with


FIGURE 18.3   Functional signatures of face processing as measured using ERPs in the first year of life and adulthood.

development in order to reach adultlike neural signatures of face processing. Even though issues regarding the ontogeny of face processing have yet to be resolved in the literature, it is clear that experience with faces since birth is very important for infants in order to lay the groundwork to develop expert face processing.

18.4 FACE PROCESSING IN TODDLERS AND PRESCHOOLERS

18.4.1 How Young Children Process Faces

Even though infants make incredible strides in the first year of life, their face-processing abilities are far from fully developed by the time they turn one. As discussed below, a great deal of development takes place after a child's first birthday. However, while infants' face-processing abilities are studied extensively, there are fewer investigations available of toddlers and preschoolers, with very few studies documenting the performance of 2- and 3-year-olds and relatively more data available for 4- and 5-year-olds.

There are few studies that have quantified the behavioral performance of toddlers and preschoolers in facial recognition and facial expression recognition. Bruce and colleagues (Bruce et al., 2000) have carried out an extensive behavioral investigation of how children as young as 4 and 5 perform on a variety of measures of face processing including the processing of facial identity, the processing of direction of gaze, and the processing of facial expressions. In this investigation, young children's performance was above chance across all tasks but still significantly below the proficiency attained by adults. Preschoolers also had trouble matching facial expression and direction of gaze with a specific target face, while they were easily able to discriminate along these dimensions (Bruce et al., 2000).

The results of Bruce and colleagues' investigation of face processing in young children suggest that they have yet to reach adultlike face-processing proficiency. There are two main hypotheses as to how these children differ from adults. On one hand, these differences have been hypothesized to be due to the fact that toddlers and preschoolers have yet to develop the face-specific processing strategies found in adults, namely, configural and holistic processing, and rely more heavily on feature-based strategies (see Mondloch et al., 2003a,b for a review). This hypothesis has been supported by studies showing that preschoolers experience difficulty in recognition when faces are 'disguised' (i.e., presented with a hat) between the original presentation and the subsequent ones, suggesting that perhaps they are not encoding faces using their configural properties but rather rely on specific isolated features (Carey and Diamond, 1977; Freire and Lee, 2001). Further support for this hypothesis

has come from studies using artificial face sets that are created such that different faces can vary exclusively either in terms of individual facial features, in terms of the spacing between facial features, or in terms of the facial contours (Mondloch et al., 2002). These studies have shown that toddlers and preschoolers fail to discriminate different identities when they have to rely exclusively on configural information but perform above chance when they can use featural and contour information (Mondloch et al., 2002, 2003a,b, 2006).

Alternatively, some researchers have proposed that the differences found in performance between young children, older children, and adults are produced by the protracted development of generic cognitive functions that can support the employment of more complex processing strategies (i.e., configural and holistic processing) more effectively (see McKone and Boyer, 2006 for a review). That is, it has been suggested that toddlers and preschoolers show a quantitative shift in their processing strategies and not a qualitative one. In support of this hypothesis, several researchers have used tasks such as the classic inversion effect task (Yin, 1969) and the composite effect task (Young et al., 1987) and measured young children's performance using faces and nonface objects such as cars or shoes. These investigators have found positive evidence of a difference in performance between upright and inverted faces in children as young as 3 (Macchi Cassia et al., 2006; Picozzi et al., 2009; Sangrigoli and de Schonen, 2004) and of holistic processing in children as young as 3½ years of age (de Heering et al., 2007; Macchi Cassia et al., 2009; Pellicano and Rhodes, 2003), even though across all these studies, overall performance in young children was usually worse compared to older children and adults.

Even though these two hypotheses point to diverging developmental trajectories, it may also be the case that their findings are not diametrically opposed. First of all, there are marked methodological differences among these studies, and different types of stimulus manipulations are used to measure configural and holistic processing, which could in part lead to diverging behavioral effects. Moreover, the tasks used vary in the relative difficulty of the different manipulations, and as such it is difficult to compare their findings objectively. Perhaps, results from electrophysiological investigations, which will be discussed below in this section, may shed more light on this controversy (Box 18.1).

18.4.2 How Young Children Process Facial Expressions

The ability to recognize facial expression has also not reached adultlike levels of performance in toddlers and preschoolers. Interestingly, there appear to be different developmental trajectories for different facial expressions

Electrophysiological and neuroimaging methods used in face processing

There are two primary techniques that are most widely used in the study of face perception: related potentials (ERP) and functional magnetic resonance imaging (fMRI). Traditionally, ERP has been used to study face processing in developmental populations, while both techniques have been used with adults. However, in recent years, fMRI has been used successfully with children as young as 7 years of age.

Event-related potentials measure the synchronous activity of large populations of neurons in response to a specific event. In a typical ERP experiment, stimuli of various types will be repeated many times, in order to be able to compute an average response by collapsing across repeated presentations of the same stimulus or category of stimuli. ERPs are collected using arrays of electrodes. In recent years, the number of recording electrodes has grown from 32 to 64, 128, and even 256, available in caps or nets that can be used with infants, children, and adults. Researchers use several characteristics of the ERP signal in a diagnostic manner: latency of a specific waveform, amplitude of a specific waveform, and the location of potentials across the scalp at specific time points (scalp topography).

fMRI measures the hemodynamic response in the brain related to the presentation of specific experimental stimuli. It has been shown that when nerve cells are active, they increase their oxygen consumption. In response to the increased need for oxygen, there is an increase in blood flow in local capillaries. As a consequence, there will be an imbalance in the relative concentration of oxyhemoglobin and deoxyhemoglobin. Because the magnetic properties of blood vary depending on the level of oxygenation, pulse sequences can be used to detect these imbalances and measure the blood oxygen level-dependent (BOLD) contrast. In turn, the BOLD response can be used as an indirect measure of localized brain activity. Studies of face processing using fMRI will present subjects with faces and other types of objects and then measure the BOLD response to the different stimuli across the entire brain, in order to understand whether there are specific regions that modulate their response on the basis of the stimuli that they see.

---

with happiness being the most readily recognized expression followed by sadness, anger, and fear (see Herba and Phillips, 2004 for a review). Moreover, it has also been shown that preschoolers need more intense expressions in order to successfully recognize emotions, compared to older children (Gao and Maurer, 2009). These findings may initially seem at odds with those described in the previous section suggesting that infants are already capable of discriminating basic facial expression. However, it is important to point out that the nature of the tasks used between infants and toddlers can be very different and, as such, it is difficult to compare directly the results across age groups (McClure, 2000), and as a consequence researchers have wondered whether the different tasks are measuring similar processing abilities. Moreover, given that the neural substrates supporting emotion recognition are far from fully mature at these ages, it is not surprising that young children show behavioral differences in emotion processing compared to older children and adults.

18.4.3 Functional Signatures of Face Processing in Young Children

If infants present a challenge for the study of the neural underpinnings of face processing, toddlers and preschoolers may be even more difficult to test. Thus, there are relatively few studies investigating how the brain of young children responds to faces, and for the most part, these studies employed ERPs. Nevertheless, these investigations can be particularly informative to help us understand the ability of young children to discriminate among different faces and different facial expressions, as the behavioral investigations alone have produced somewhat conflicting evidence. Overall, one would not expect major changes in the types of components elicited by faces, such as the P1 and the N170, and the nature of the changes is expected to be primarily in terms of latency (i.e., decreased latencies), morphology (i.e., more defined waveforms), and topography (i.e., hemispheric specialization) of these components, as toddlers' and preschoolers' brains undergo structural changes such as increased myelination, increased functional specialization, and changes in the underlying neural generators (de Haan et al., 2003; Gauthier and Nelson, 2001). There are, however, other changes that are taking place in these components that are more specific to the stimuli used, as the specific faces used acquire different significance with age. For example, Carver and colleagues (Carver et al., 2003) found that relative amplitude differences in the Nc and P400 components in the mother's face and a stranger's face switched between 2–3-year-olds and 4–5-year-olds with the younger children showing increased amplitude to the mother's face and the older children showing the opposite pattern.

Overall, while the morphology and topography of face-sensitive ERP components is changing toward adultlike brain signatures, their development is far from over within this age group (Taylor et al., 1999, 2004), possibly suggesting that even though young children show some evidence of adultlike face processing, they are still undergoing maturational changes both behaviorally and neurally.

Components reflecting differences in responding to emotional faces also show developmental changes, and these studies can further the understanding of how young children perceive facial expressions. Despite the fact that from a behavioral perspective, toddlers and preschoolers have difficulty recognizing fear in a face, Dawson and colleagues have shown that fearful faces elicit faster and larger P200 and N300 components, compared to neutral faces (Dawson et al., 2004). Batty and Taylor (2006) found that facial expressions also affected early components such as the P1. Toddlers and preschoolers had faster P1 latencies across all six emotions compared to neutral faces and more specifically showed the fastest latencies for positive emotions and, in particular, for happiness (Batty and Taylor 2006).

18.4.4 Conclusions

Taken together, the results of behavioral investigations and ERP studies looking at various aspects of face processing and face-processing strategies have led the majority of investigators to believe that toddlers and preschoolers are still on a developmental trajectory toward adultlike face processing. Nevertheless, it is important to point out that in very few years of life, young children demonstrate an uncanny proficiency in extracting information from faces.

18.5 FACE PROCESSING IN SCHOOL-AGE CHILDREN AND ADOLESCENTS

18.5.1 How Children and Adolescents Process Faces

The behavioral performance of school-age children and adolescents is relatively well documented, compared to that of toddlers and preschoolers. The majority of studies performed with these age groups have used experimental paradigms that are commonly used with adults (i.e., recognition memory paradigms, inversion face task, composite face task, etc.) in order to examine when and how children achieve adultlike levels of performance in face recognition and also when they show evidence of using configural and holistic processing strategies.

It is primarily within this age group that the scientific debate over children experiencing quantitative or qualitative changes in face-processing strategies is contested. This debate ensues because experimental results are heterogeneous. On the one hand, there are several studies pointing to the fact that school-age children, and in some cases even adolescents, differ in the type of information they use within a face (see Mondloch et al., 2003a,b for a review). For example, it has been demonstrated that children up to the age of 15 are not yet able to rely on the internal facial features of a face without contour information in order to successfully identify unfamiliar faces but rather perform better when they are provided only with the external contour information, compared to the internal features alone (Campbell and Tuck, 1995; Campbell et al., 1999; Want et al., 2003), which is opposite to the pattern that is observed in adults. Using a set of faces created in the laboratory that can differ only in terms of the external contour, or internal features, or the spacing among the internal features, Mondloch and colleagues found that, unlike adults, 6-, 8-, and 10-year-olds produced the most errors when discriminating faces differing in feature spacing (Mondloch et al., 2002). Moreover, Mondloch and colleagues have shown that 6-, 8-, and 10-year-olds failed to show an increased cost of face inversion in the feature-spacing set, compared to the other two stimuli manipulations, which is also different from how adult subjects perform (Mondloch et al., 2002).

Although these studies and others (Freire and Lee, 2001; Mondloch et al., 2006) suggest that children are less sensitive than adults to configural information, other researchers have produced results providing support for the hypothesis that children apply adultlike processing strategies from a young age. Children as young as 4 have demonstrated evidence of holistic processing as demonstrated using the composite face task (Mondloch et al., 2007; Pellicano and Rhodes, 2003), and Tanaka and colleagues (Tanaka et al., 1998) have found an adultlike whole-part advantage in 6-year-olds. Moreover, children as young as 6 have performed in a manner similar to that of adults on an inversion effect task, producing comparable differences between performance on upright and inverted faces (Mondloch et al., 2002).

In order to examine the controversy mentioned in the previous paragraphs regarding the nature of the development of face-processing strategies, there are some methodological considerations to be made. First, one possible explanation for the divergent results is the methodological differences employed across studies. For example, in some cases, memory-encoding paradigms are used, which require children to learn a specific set of faces prior to the testing phase, while in other cases the children are presented with simultaneous matching paradigms, in which there is very little memory load. Second, depending on the specific nuances of each study, the children are sometimes compared to the

adults in terms of their quantitative performance, while in other cases their behavioral trends are compared to those found in adults. Thus, this makes it difficult to examine directly all these results and draw unified conclusions. In order to aid the resolution of this debate, it may be useful to consider it in the context of neurophysiological findings, which will be discussed below in this section.

Identity recognition, however, appears to be a process that does not reach full maturation until adolescence. In an extensive study looking at performance both on face and emotion recognition, Bruce and colleagues (Bruce et al., 2000) showed that performance on face recognition and emotion recognition increased steadily from 5 years of age until about 11 years of age. Moreover, they showed that when the experimental faces used were highly dissimilar, 11-years-olds performed as well as adolescents, but this was not the case when more similar faces were used, suggesting that more challenging face recognition follows a slow progression. Similarly, using a recognition memory paradigm, Golarai and colleagues have shown that adultlike levels of recognition memory performance for faces are not reached until at least 14 years of age (Golarai et al., 2007), while these authors did not find any age effects in the recognition memory performance for common objects. Moreover, school-age children tend to make more errors than adults when asked to recognize faces across viewpoints, lighting conditions, and changes in facial expression (Bruce et al., 2000; Mondloch et al., 2002, 2003a,b). While in the majority of studies it has been found that children perform worse than adolescents in recognition memory tasks, it is important to acknowledge that this may not be specific to faces, but it may be an issue of task difficulty. Why this issue is not easily solved is because, to our knowledge, there are no extensive studies comparing face processing to the processing of other complex visual objects.

18.5.2 How Children and Adolescents Process Facial Expressions

The recognition of emotional facial expression is also still undergoing development from childhood through adolescence, and the specific pattern of improvement appears dependent on the types of emotional faces used, on the intensity of the facial expression, and on the specific expression itself (Durand et al., 2007; Gao and Maurer, 2009; Herba et al., 2006; Kolb et al., 1992; Thomas et al., 2007; Vicari et al., 2000). Overall, behavioral studies of emotion recognition with children and adolescents show that children as young as 5 recognize happy faces accurately (Gao and Maurer, 2009; Vicari et al., 2000) but also show that sad and fearful faces remain more difficult to recognize especially if the face

stimuli used depict less intense emotion (Gao and Maurer, 2009; Thomas et al., 2007; Vicari et al., 2000). The speed of processing of facial expression also undergoes a maturation change between the ages of 7 and 10 (De Sonneville et al., 2002). There are nevertheless some differences in studies, in terms of the specific age ranges and their performance, and these differences are likely due to the different methodologies employed and the types of stimuli used. However, a protracted pattern of development for the recognition of facial expression makes sense even in the context of the development of the neural regions recruited when children and adolescents look at emotional faces.

The behavioral studies of development provide somewhat heterogeneous evidence, but by and large, they suggest that by 10–11 years of age, children perform in a manner comparable to adults across a variety of tasks that involve facial recognition, the use of face-specific processing strategies (i.e., configural processing, holistic processing), and recognition of emotional expressions. Given the heterogeneity of behavioral findings, it is particularly important to study the neural substrates of face processing in different age groups in order to understand whether by the time performance has reached adultlike levels, the underlying neural substrates and processes have also stabilized to what is found in adults or whether brain and behavior follow two different trajectories.

18.5.3 Neural Substrates of Processing in Children and Adolescents

In contrast to the relatively few studies examining the neural bases of face processing in toddlers and preschoolers, this topic has been more heavily addressed in older children. Of particular interest are recent investigations using fMRI to look not only at the functional signatures of face processing but also at the specificity of the neural substrates recruited. The question of interest in this literature is whether neural selectivity for faces has emerged by the time children are of school-age, that is, whether there are already measurable clusters of neurons that respond more strongly to faces than to most other objects. Several recent studies have been particularly focused on whether category selectivity for faces is present in the brains of children as young as 7 years of age (Aylward et al., 2005; Golarai et al., 2007, 2010; Passarotti et al., 2003; Scherf et al., 2007). Overall, these studies suggest that category selectivity in the right fusiform gyrus emerges around 7 years of age. More specifically, Golarai et al. (2007) have shown that the volume of these regions in the adult brain is larger compared to that in both children and adolescents and that it gets progressively larger between children and adolescents. More evidence of slow maturation is provided also by a recent

study comparing the neural activations in response to upright and inverted faces in fMRI. Pasarrotti and colleagues (Passarotti et al., 2007) found that children ages 8–11 did not show showed increased activation for inverted faces, compared to upright faces, while older children ages 13–15 showed a trend in the opposite direction, which is what is commonly reported in adult studies.

Further evidence of protracted neural face selectivity is also provided by studies using ERP. Investigations using this technique have demonstrated that in children and adolescents, there are still differences in the latency and topography of face-selective neural signatures, compared to adult data. Adultlike characteristics of the latency of N170, for example, are not reached until adolescence (Taylor et al., 1999). Moreover, children do not show an adultlike latency difference between upright and inverted faces in the N170 until about 11 years of age (Itier and Taylor, 2004; Taylor et al., 2004), and the differences in amplitude with the inverted faces eliciting larger amplitudes, compared to upright faces, are observed only in adolescents (Taylor et al., 2004). Moreover, adultlike topography with higher amplitudes in the right hemisphere compared to the left for the N170 does not appear to emerge until adolescence (Taylor et al., 1999).

Although the neural responses to emotional faces are not widely studied within this age group, the few studies available on the topic have shown differences between adults and school-age children, and adolescents have also been reported in the context of emotional face processing. Passarotti and colleagues (Passarotti et al., 2009) tested adolescents with happy and sad faces in fMRI and found that while there were no differences in the areas that were recruited when adolescents and adults looked at emotional faces, there were differences that emerged in the relative activations in different brain regions, such that the adolescents activated paralimbic regions more strongly than the adults, but the adults activated prefrontal regions more strongly than the adolescent subjects. Similarly, Guyer and colleagues found more activation of the amygdala in response to fearful faces in adolescents, compared to adults, who in turn showed stronger functional connectivity between the amygdala and the hippocampus.

Differences in facial expression processing across children, adolescents, and adults are also observed using ERPs. Batty and Taylor (2006) have shown that from the age of 5 to the age of 15, there are changes in the sensitivity of the P1 and the N170 to facial expressions. More specifically, while children show latency modulations in the P1, older children show latency modulations only in the N170. Amplitude changes also vary across components within this age group, showing the same patterns as the latencies. Overall, what does not seem to be changing across development is the fact that positive emotions are processed with shorter latencies compared to negative emotions (Batty and Taylor, 2003, 2006).

18.5.4 Conclusions

Taken together, both the majority of behavioral findings and the results of neurophysiological investigations seem to suggest that face processing is still undergoing maturational changes through childhood and adolescence. Thus, even though children and adolescents already show some of the hallmarks of adultlike face processing, experimental evidence points to the fact that throughout childhood and adolescence, there are quantitative changes that take place in how these observers process faces.

18.6 IMPAIRMENTS IN FACE PROCESSING

While most of us rarely forget a face we have seen before, or have trouble identifying facial expressions, there is a subset of children and adults that experience great difficulties with these seemingly effortless operations. Dysfunctions in different aspects of face processing can arise from structural abnormalities within the brain and visual organs such as brain lesions and cataracts. Difficulties in processing faces can also be found in populations with neurological disorders such as autism spectrum disorder (see Chapter 34) and Williams syndrome (WS).

18.6.1 Prosopagnosia

In the literature, the majority of cases describing face-processing impairments are linked to brain injury to the occipital and temporal cortices, occurring either in the right hemisphere or bilaterally. The impairment that results from this kind of injury and produces primarily a deficit in recognizing familiar people has been termed prosopagnosia (Bodamer, 1947). Prosopagnosics not only show great difficulty in recognizing and learning new faces but also display atypical face-processing strategies (Barton, 2003). More specifically, they appear to be overly dependent on specific facial features, to be insensitive to the configural properties of faces, and to be unable to use holistic processing as reliably as healthy controls (Barton, 2003; Bukach et al., 2006, 2008; Wilkinson et al., 2009). However, prosopagnosics do not typically show difficulty identifying facial expressions (Young, 1992).

While prosopagnosia usually occurs in adults, there are documented cases of prosopagnosia in children following brain injury (Dutton, 2003; Dutton et al., 2006; Young and Ellis, 1989). Similarly to the adults, these children have great difficulty in recognizing individuals by their face, and they also show differences with configural/holistic processing compared to age-matched controls. However, as brain injury in children is rarely localized to the occipitotemporal cortex, these patients manifest neurological and perceptual problems beyond face perception (Dutton et al., 2006). Moreover, in contrast with adult prosopagnosics, children with this type of brain damage also tend to have difficulty recognizing facial expressions (Dutton, 2003).

Prosopagnosia can be also diagnosed in people who have not suffered any brain trauma (Behrmann et al., 2005a; Duchaine and Nakayama, 2006; Kress and Daum, 2003). Recent case studies documenting this type of prosopagnosia have termed it 'congenital,' to distinguish it from the form that follows brain injury ('acquired' prosopagnosia). Congenital prosopagnosics self-report difficulties in recognizing familiar faces that date to childhood and usually have learned to rely on cues other than facial information to recognize people; thus, they appear less impaired than acquired prosopagnosics. In recent years, this population has received much attention, and several studies have been aimed to categorize the nature of these patients' deficits. These patients can reliably detect a face among nonface objects and perform judgments of gender and age on faces successfully. However, they have difficulty in both matching and recognition tasks when they are under time pressure and/or the stimuli used are impoverished (i.e., face ovals with no hair; Behrmann et al., 2005b). Similar to acquired prosopagnosia, congenital prosopagnosics show a different manner of processing of face stimuli, demonstrating a heavier reliance on featural strategy in place of configural and holistic processing (Behrmann et al., 2005b). So far in the literature, this syndrome has primarily been studied in adults. However, a few cases of this syndrome have also been reported in children, and even the adult studies suggest an early onset of these problems (Ariel and Sadeh, 1996; Grueter et al., 2007).

The neural bases of congenital prosopagnosia are yet to be fully understood. Studies using ERPs have shown a reduced brain response to faces in congenital prosopagnosics as measured by the amplitude of face-sensitive components (Bentin et al., 1999). Studies using fMRI have produced discordant results, such that in few instances congenital prosopagnosics did not show brain activation in the right fusiform gyrus in response to faces (Hadjikhani and de Gelder, 2002), while others report typical right fusiform gyrus activation in response to faces (Avidan et al., 2005; Hasson et al., 2003). Brain activations alone have not been a diagnostic measure with these patients, as the relationship between these neural responses and their impairment is not clear. Thus, it has been suggested that congenital prosopagnosia could be caused by anatomical abnormalities in the temporal lobes, the same structures that when damaged produce acquired prosopagnosia. For example, Behrmann and colleagues have measured a reduction in the volume of the anterior fusiform gyrus in congenital prosopagnosics, compared to control subjects (Behrmann et al., 2007). Recent data using diffusion tensor imaging (DTI) have suggested that the recognition impairments may be due to the thinning of white matter fiber tracts connecting the ventral temporal cortex to the anterior temporal and prefrontal cortices (Thomas et al., 2009).

18.6.2 Congenital Cataract Patients

Given how rapidly face processing develops in the first year of life, researchers have wondered whether congenital visual impairments such as cataracts, which are present at birth but are usually surgically repaired within the first 2–6 months of life, have an impact on the ability to process faces later in life. Le Grand and colleagues have conducted a series of studies with children and young adults, aged 9–29, who were congenitally blind at birth because of bilateral cataracts but gained vision between 2 and 6 months of age following corrective surgery. These studies have shown that, despite the extensive experience with faces that these subjects have acquired since their cataracts were removed, they are not able to achieve the same level of performance as age-matched controls on tasks that tap complex face-processing strategies. More specifically, these patients had difficulty recognizing different faces that varied in terms of the distance between internal features (Le Grand et al., 2001), and they also failed to show the traditional 'composite effect' (Le Grand et al., 2004), which is used as an indirect measure of holistic processing (Maurer et al., 2002). Moreover, they experience particular difficulty with recognition when faces change orientation or facial expression across multiple presentations (Geldart et al., 2002). However, these patients are able to recognize faces fairly well in the real world, which is likely due to the fact that they can identify specific faces using the distinctive shape of the internal features and contour information (Mondloch et al., 2003a,b). No studies to date have looked at the functional responses that these patients' brains show when they are viewing faces. However, the dissociation found in this population between featural and configural/holistic processing abilities suggests that their neural network

supporting face processing may have developed differently compared to healthy adults (Mondloch et al., 2003a,b).

18.6.3 Autism and WS

18.6.3.1 How Subjects with Autism Process Faces

Atypical face processing has also been reported in certain populations of individuals diagnosed with autism spectrum disorder (ASD) and WS. ASD is a neurological disorder that is diagnosed early in childhood, usually around the age of 3, and characterized by impairments in social interactions and language development; it is usually accompanied by repetitive behaviors and restricted interests (DSM-IV). In recent years, great interest has been devoted to understanding the nature of face-processing difficulties experienced by children and adults diagnosed with ASD because face-processing deficits are suggested to be strongly related to the social impairments experienced by these individuals. Moreover, some investigators have suggested that face-processing deficits may be one of the earliest indicators for the presence of autism (Dawson et al., 2005; Schultz, 2005; Schultz et al., 2000). The impairments found in ASD individuals since childhood span many different face-processing tasks with studies reporting deficits in recognizing facial identity (Boucher and Lewis, 1992; Boucher et al., 1998; Klin et al., 1999), less reliance on holistic and configurational processing (Behrmann et al., 2006; Gauthier et al., 2009; Joseph and Tanaka, 2003; Schultz et al., 2000; Teunisse and de Gelder, 2003) and reduced visual attention to internal facial features (Chawarska and Shic, 2009; Klin et al., 2002).

18.6.3.2 How Subjects with ASD Process Facial Expressions

Because of the social nature of ASD impairments, much attention has also been devoted to studying whether these patients have difficulties recognizing facial expressions. Overall, the majority of studies conducted on this topic would argue that ASD individuals have difficulty, beginning in childhood, recognizing, identifying, and classifying facial expressions (Braverman et al., 1989; Celani et al., 1999; Gross, 2004; Hobson, 1986). In several studies, it has been reported that these patients experience particular difficulties in recognizing negative emotions (Humphreys et al., 2007; Pelphrey et al., 2002) possibly because of ineffective use of information from the eye region of a face (Baron-Cohen et al., 1997, 2001; Gross, 2004). Moreover, recent studies using facial morphs that vary parametrically in the strength of visible facial expressions have shown that most ASD individuals have difficulty identifying and categorizing more subtle facial expressions (Rump et al., 2009; Teunisse and de Gelder, 2001).

18.6.3.3 Neural Substrates of Face Processing in ASD

The behavioral differences found between ASD individuals and typically developing controls have been connected to a variety of differences found in brain responses to faces between these two subject groups. Studies using ERPs have shown that both children and adults with ASD show shorter latencies for objects compared to faces for the N170 component (Webb et al., 2006). Moreover, the scalp topography of face-sensitive ERP components is different between these two subject groups, suggesting a smaller degree of hemispheric lateralization for face processing in ASD subjects (Dawson et al., 2005). Atypical ERP responses have also been demonstrated when ASD individuals are shown emotional faces (Dawson et al., 2004). Differences between ASD individuals and healthy controls have also been found using fMRI, with several studies showing hypoactivity not only in brain regions associated with processing of facial identity, such as the right fusiform gyrus (Dawson et al., 2002; Grelotti et al., 2002; Pierce et al., 2001; Schultz et al., 2000), but also in brain regions associated with the processing of facial expressions and gaze, such as the STS (Dalton et al., 2005; Pelphrey et al., 2005) and the amygdala (Adolphs et al., 2001; Hadjikhani et al., 2007; Schultz, 2005).

While the majority of studies of face processing in ASD individuals point to atypical development of this skill, this population shows a great deal of variability both in terms of behavioral patterns and neural responses. This heterogeneity of results has produced several debates in the literature regarding the true origins of these deficits. Nevertheless, atypical face processing, both at the behavioral and neural levels, remains one of the hallmarks of ASD.

18.6.3.4 Face Processing in WS

Another neurological disorder that has received attention in association with face processing is WS. WS is a rare genetic disorder characterized by a series of physical deformities, language and motor delays, and atypical cognitive functions in a variety of domains, including atypical social functioning (see Bellugi et al., 2000 for a review). Unlike ASD individuals, children and adults diagnosed with WS show face recognition abilities comparable to healthy controls (Bellugi et al., 1994; Tager-Flusberg, and Joseph, 2003). However, it has been suggested that they do not process faces configurally and holistically but rather rely more heavily on featural processing (Deruelle et al., 1999); but not all researchers agree on this interpretation (Karmiloff-Smith et al., 2004; Tager-Flusberg et al., 2006). Patients with WS are akin to ASD patients in that they also show deficits in emotion recognition from facial expressions (Tager-Flusberg et al., 2003).

These two subject populations also show divergences and similarities in the context of neural responses to faces, which map the dissociations found at the behavioral level. Studies using fMRI in adults diagnosed with WS have found activation in the right fusiform gyrus in response to faces that is comparable to that of healthy controls (Meyer-Lindenberg et al., 2004; Schultz et al., 2000). However, WS patients show hypoactivation in brain regions recruited when processing facial expressions, specifically the amygdala and the orbitofrontal cortex (Meyer-Lindenberg et al., 2005).

18.7 CONCLUSIONS

The goal of this chapter was to provide the reader with a comprehensive overview of the literature concerning face processing and its development from birth to adulthood.

Faces are very important stimuli for humans, as they convey a multitude of information about the people that we encounter in the world. While some debate remains regarding the initial mechanisms that orient infants toward faces, it is most likely that the development of face processing relies on both experience-independent early specificity and an experience-dependent sensitive period (Sugita, 2008). That is, while the initial orienting toward faces may be driven by a genetically specified primitive architecture (Johnson, 2005), the development of the ability to extract information from a face is heavily dependent on experience, and it is through exposure and interactions with specific types of faces that we learn to become 'face experts,' which is a lengthy process that requires the first 10–15 years of life (Nelson, 2001).

Despite the many things that are known in the face-processing literature, it is the authors' wish to conclude this review with some of the questions that are still unanswered. First of all, while it has been demonstrated that experience with faces is very important for one to become an 'expert,' relatively little is known about the specific nature of this experience. Secondly, it is unclear whether the effect of experience is dependent on a sensitive period. Although the data produced by investigations with cataract patients and congenital prosopagnosics would suggest that any derailment from typical development affects face processing, more work will be necessary to establish the precise nature of a sensitive period and its relations to different aspects of face processing. Lastly, we would like to highlight a real conundrum of face processing, which is its apparent lack of plasticity. It has been demonstrated that once a portion of the face-processing system becomes compromised, the ability to recognize faces appears gone for good. This is a very troublesome observation for this literature because it is difficult to reconcile how an operation of such

evolutionary importance that relies on a large network of neural substrates can show so little ability to reorganize itself following an insult, especially given the fact that our brains are overall quite plastic. In our view, this remains an essential issue to resolve in the coming years.

Developmental Neuroscience of Social Perception

A. Voos, C. Cordeaux, J. Tirrell, K. Pelphrey

Yale University, New Haven, CT, USA

19.1 INTRODUCTION

Within adult social psychology, the study of social cognition encompasses a range of phenomena including moral reasoning, attitude formation, stereotyping, and related topics. This definition includes the processes underlying the perception, memory, and judgment of social stimuli; the effects of social, cultural, or affective factors on the processing of information; and even the behavioral and interpersonal consequences of those cognitive processes. Social psychology has provided an arsenal of measurement techniques and theoretical models to inform efforts within social neuroscience to study the mature human brain. However, neuroscience has traditionally defined social cognition more narrowly as the ability to perceive the intentions, actions, and psychological dispositions of others (Brothers, 1990). Within developmental psychology, the study of social cognition and its development has focused most intensely upon 'theory of mind,' or a person's awareness that other individuals maintain thoughts, beliefs, and desires that are different from his or her own, and that the actions of others can be best explained with reference to their

individual mental states (Frith and Frith, 1999; Premack and Woodruff, 1978). Developmental psychologists have characterized the stages of development in theory of mind abilities but have yet to provide a mechanistic account of 'how' theory of mind develops in children. Such questions necessitate studies that bridge the gap between cognitive accounts of theory of mind and the underlying brain mechanisms and, thus, require measurement at both the behavioral and neural system levels. One definition that cuts across disciplines and levels of analysis dictates that *social cognition* refers to the fundamental abilities to perceive, categorize, remember, analyze, reason with, and behave toward conspecifics (Adolphs, 2001; Pelphrey et al., 2004a). Currently, very little is known about the neural correlates of social cognition in children or about the changes in brain structure, function, and connectivity that underlie normative development in this domain. Providing an understanding of brain development in relation to changes in social cognition is important to the field, as it will allow for the construction of normative 'growth charts' for the function of circuits supporting various aspects of social cognition. Additionally, this knowledge

may aid researchers in their search for genetic and environmental factors (and gene × environment interactions) related to suboptimal social cognitive development as observed in autism and related neurodevelopmental disorders.

This chapter focuses on the development of a critical aspect of social cognition – *social perception*. Social perception is the initial stage of evaluating intentions and psychological dispositions of others by analysis of gaze direction, body movement, and other types of biological motion (Allison et al., 2000). It is closely linked to *action understanding*: the ability to appreciate other people's actions in terms of the mental states that drive behavior. It has been argued that social perception is an ontogenetic and phylogenetic prequel to more sophisticated social cognition abilities, particularly theory of mind (e.g., Baron-Cohen et al., 1995; Frith and Frith, 1999; Pelphrey and Morris, 2006; Premack and Woodruff, 1978; Saxe et al., 2004a). A task analysis supports this argument and reveals that successful social perception involves a set of three distinct but interrelated social cognition abilities: (1) individuating and recognizing other people, (2) perceiving their emotional states, and (3) analyzing their intentions and motivations. Successful social perception, in turn, facilitates a fourth and more sophisticated aspect of social cognition: (4) representing another person's perceptions and beliefs, a core component of theory of mind. In this chapter, the five neuroanatomically and functionally dissociable neural circuits that underlie these aspects of social perception are elaborated on and what is known about the functional development of each circuit in infants, children, and adolescents discussed. The focus is on functional magnetic resonance imaging (fMRI) and developmental studies of social perception involving other neuroimaging techniques, for example, electrophysiology are not included. This focus was selected because of the interest in identifying the exact neural systems involved in distinct and dissociable (at the neural systems level) aspects of social perception. It must be noted, however, that fMRI is limited in that it is not yet practical to study awake, behaving infants and toddlers with this method. In contrast, electrophysiology can be readily applied to infants and toddlers. However, in even the best, most controlled conditions with adults, it is a challenge to make precise statements about the neuroanatomical origins of scalp-recorded electrical signals. See, for example, the ongoing debate concerning the origins of the N170 in response to faces (Halgren et al., 2000; Itier and Taylor, 2004). This inferential problem is compounded when one wishes to study the development of a brain system with electrophysiology because then one has to identify a developmental precursor to the well-characterized adult signals and then make inferences about the underlying neural generator. Following the review of the available

literature, a model of social cognitive development has been put forward that aims to explain how an early developing social perception network can give rise to more sophisticated aspects of social cognition, including theory of mind.

19.2 NEUROANATOMICAL SUBSTRATES OF SOCIAL PERCEPTION

19.2.1 Ventral Occipital Temporal Cortex and the Recognition of Other People

Several areas located in the ventral occipitotemporal cortex (VOTC) support the basic representation and recognition of other people. These include the lateral fusiform gyrus (FFG), which contains the 'fusiform face area' (FFA), and the 'extrastriate body area.' The former has a clear role in face perception and recognition (e.g., Kanwisher et al., 1997; Puce et al., 1996), while the latter has been implicated in the visual perception of human bodies (e.g., Downing et al., 2001). These brain regions provide the basic representation of their specific visual category that supports both bottom-up visual processing of social information and top-down imagery of those categories.

In adults, there are well-defined expectations of how brain activity related to visual object processing should be organized (Dehaene and Cohen, 2007; Martin, 2007). Faces and letter strings are two visual categories that have been studied extensively and elicit distinct responses in VOTC. Faces evoke selective activity in the mid-FFG relative to other objects (Allison et al., 1994; Kanwisher, 2000; Kanwisher et al., 1997). In contrast, the lateral mid-fusiform/inferior temporal gyrus shows a bias for processing words, letters, and letter strings over digits and other objects (Allison et al., 1994; Baker et al., 2001; Cohen and Dehaene, 2004; Dehaene et al., 2002; Hashimoto and Sakai, 2004; Polk and Farah, 1998; Polk et al., 2002). Both categories are hypothesized to recruit specialized neural processes that best suit the features that define the category (Kanwisher, 2000; Polk and Farah, 1998). The developmental origins of their specializations, however, are presumably quite different.

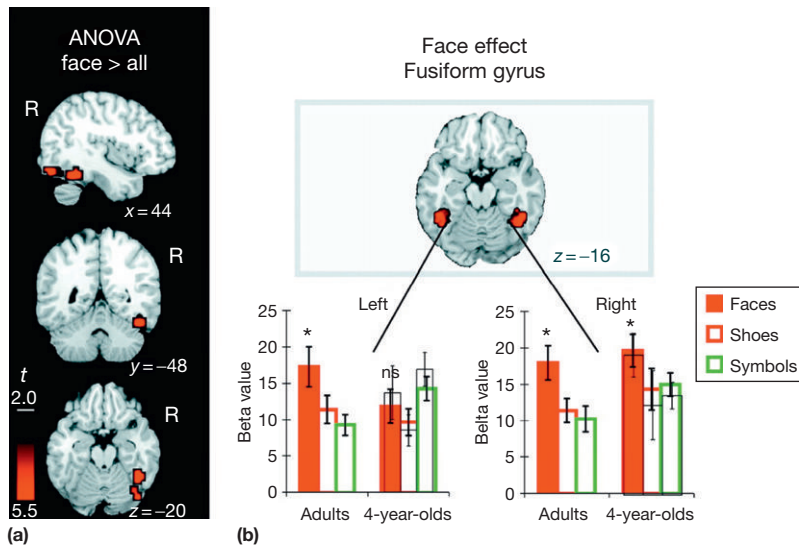
To date, the most is known about the development of the face-sensitive area of the FFG. Current evidence indicates that face-selective neural processing is already present in the FFG by 6 years of age and becomes increasingly robust throughout adolescence (Aylward et al., 2005; Golarai et al., 2007; Grill-Spector et al., 2008; Libertus et al., 2009; Scherf et al., 2007; Tzourio-Mazoyer et al., 2002). Interestingly, the gradual refinement of face-related neural processing over development


FIGURE 19.1 The right fusiform face effect. The right fusiform gyrus face effect for adults and children was evident in (a) a main effect of faces > all categories (shoes, letters, and numbers) in an ANOVA ($p < .05$, corrected) and (b) an ROI analysis in which voxels were selected based on their average response across all categories (faces, shoes, letters, and numbers) > scrambled. The light gray bars within the data from 4-year-olds represent children with motion estimates equal to those of adults (these data are equivalent to the full 4-year-old sample). The asterisks indicate significantly different from all categories at $p < 0.05$, corrected for multiple comparisons.

parallels the well-known changes in children's face recognition abilities (Carey and Diamond, 1994).

In order to differentiate the developmental origins of category-specific areas in VOTC, our group recently used fMRI to examine the organization of the ventral visual pathway for basic processing of symbols, faces, and nonface objects in 4-year-old children (Cantlon et al., 2011). We tested 4-year-old children's and adults' responses to faces, letters, numbers, and shoes in VOTC. As illustrated in Figure 19.1, children and adults exhibited a common pattern of face selectivity in the right mid-FFG at a locus consistent with previously reported face-selective sites in adults. This indicates that certain features of adult brain organization have already taken formed by 4 years of age (Cantlon et al., 2006; Grill-Spector et al., 2008; Mahon et al., 2009; Polk et al., 2007). This biased activity to faces in the right mid-FFG in overlapping regions previously reported as face selective in older children and adults (Grill-Spector et al., 2008) represents an early developing visual specialization for social information in VOTC.

Some evidence indicates that face selectivity in the FFG is related to face recognition memory in children (Golarai et al., 2007), where children who perform better on face recognition tasks exhibit a greater spatial extent of face-related activity. However, it is unknown whether the refinement of face-related processing hinges on 'increases' in the FF response to faces, 'decreases' in the responses to nonfaces, or 'both.' This question is critical for understanding the nature of the developmental process underlying category selectivity in the brain. In fact, a long-standing debate in the developmental literature concerns the question of whether neural development is driven by building up or pruning back representations in the brain (Bourgeois and Rakic, 2003; Changeux, 1985; Changeux and Danchin, 1976; Changeux and Dehaene,

1989; Dehaene-Lambertz and Dehaene, 1997; Purves et al., 1996; Quartz, 1999; Quartz and Sejnowski, 1997).

Faces have an evolutionary significance and spontaneously attract children's attention from birth, with research indicating that infants who are just days old prefer to look at images of faces instead of nonfaces, and familiar rather than novel faces (Johnson et al., 1991; Nelson, 2001). In the constructivist view, experience-dependent input specifies the connectivity and functions of cortical regions and thereby gradually builds up specialized cortical functions (Quartz, 1999). Selectionism, in contrast, postulates that redundant and irrelevant neuronal connections exist from birth and are gradually eliminated on the basis of experience-evoked activity in order to define specialized cortical functions (Changeux and Danchin, 1976). In principle, these two developmental processes can be distinguished in the category-selective brain responses of young children. For instance, in the case of face representation, a constructivist pattern of activity would predict an increase in face-related activity with increasing face recognition ability, whereas a selectionist pattern would predict a decrease in nonface activity with increasing face recognition ability. Naturally, both patterns are nonexclusive and may jointly occur, either simultaneously or at different ages.

In order to test these two theories, the relationship between children's developing category knowledge and their category-related brain activity was examined in the aforementioned study (Cantlon et al., 2011). The children were tested on a series of identification and naming tests with the same stimuli presented in the fMRI session. As illustrated in Figure 19.2, children's accuracy on the face-matching task was not correlated with an increase in the neural response to faces in the right mid-fusiform face-selective region of interest (ROI), as
FIGURE 19.2   Scatterplot illustrating negative correlations between behavioral performance and the magnitude of the brain response to the nonpreferred category. In the brain region that showed the face effect, children's accuracy on a face identification task was correlated with a decrease in activity to the nonpreferred category (shoes) rather than an increase in activity to the preferred category (faces). Chance on the face identification task was 50%.

might be expected. Instead, accuracy on the face-matching task correlated with a decrease in the response to shoes in the face-selective ROI. This finding suggests that as children in this age range become more proficient at recognizing faces, the mid-fusiform face-selective region reduces its response to other visual classes (as opposed to increasing its response to faces). These data suggest that brain regions that will eventually become selective for a particular category already produce a relatively strong response to their preferred category in early childhood, but they gradually decrease their responses to nonpreferred categories as knowledge is acquired. While adult category-selective brain regions show similar types of category biases in early childhood, there are undoubtedly developmental changes in the structure and function of those regions. For example, Golarai et al. (2007) reported that the spatial extent of activation in face-selective fusiform regions expands with increased memory for faces between 7 years of age and adulthood. The degree to which face-selective cortex expands over the course of early childhood (i.e., 0–7 years) remains in question. Our own findings suggest that one catalyst of those functional changes could be a decreasing representation of nonpreferred (i.e., nonface) entities in face-selective regions.

Many questions remain about exactly how the development of face specialization unfolds. One aspect of this process, evident in our fMRI results, is that neural responses in category-selective regions to nonpreferred

categories need to be pruned away. This is supported by the notion that learning proceeds by 'selection,' 'attrition,' or a 'use it or lose it' principle, which has long been proposed at the theoretical level (Bourgeois and Rakic, 2003; Changeux, 1985; Changeux and Danchin, 1976; Changeux and Dehaene, 1989; Dehaene-Lambertz and Dehaene, 1997; Purves et al., 1996) and has received empirical support in domains such as bird song acquisition or speech perception, both of which exhibit perceptual narrowing over development (Kuhl et al., 1992; Werker and Lalonde, 1988). Our data suggest a similar selectionist principle in the development of face-selective VOTC in human children.

It should be noted that our data are not inconsistent with a moderate form of the constructivist view (Sirois et al., 2008), which posits a selection process via lateral inhibition following category learning (for evidence of this phenomenon in adults, see Allison et al., 2002; Pelphrey et al., 2003). Under that hypothesis, however, one might expect preferred and nonpreferred category-related responses in VOTC to become increasingly anti-correlated over development. Although this pattern did not emerge in our data, longitudinal fMRI data on children's category-related visual responses at different points in their acquisition of category knowledge will help to further adjudicate among these hypotheses. Such data could reveal developmental periods during which representations are being constructed (with increasing responses to preferred categories) as well as periods during which a selection mechanism is engaged (with decreasing responses to the nonpreferred category). The degree to which selection or construction is observed at a given point in early childhood likely will depend on children's experience with the specific categories examined. At a single point in development, some categories could exhibit a pattern of increasing responses to preferred stimuli, while other categories exhibit decreasing responses to nonpreferred stimuli. Such a proposal is consistent with our data and with previously reported studies of VOTC activation in older children (Golarai et al., 2007; Grill-Spector et al., 2008; Libertus et al., 2009; Scherf et al., 2007).

A tentative biological mechanism for the reduction in high-level visual activity to nonpreferred categories over development may be the known reduction in synaptic density between 2 and 11 years of age (Chugani et al., 1987; Giedd et al., 1999; Huttenlocher and Dabholkar, 1997; Huttenlocher et al., 1982; Shaw et al. 2008). Synaptic density in visual areas steadily increases between birth and 1–2 years of age, reaches levels that are approximately 50–60% greater than adult levels, and then gradually decreases over the next several years. Some evidence indicates that vascular density parallels synaptic density in primary visual areas and thus blood supply might be related, at least in sensory areas, to neural

plasticity and synapse formation/elimination (Duvernoy et al., 1981; Logothetis and Wandell, 2004).

19.2.2 Limbic Circuitry and the Perception and Experience of Emotions

The limbic system is composed of a set of brain structures that support a variety of functions, including emotion. The amygdala is one such structure, and several fMRI studies have focused on its response to emotional (especially fearful) faces. Baird et al. (1999) first identified amygdala activation to fearful faces in adolescents aged 12–17 years. Thomas et al. (2001) later reported that adults demonstrated greater amygdala activation to fearful facial expressions compared to other expressions, whereas 11-year-old children showed greater amygdala activation to neutral faces compared to other expressions. One explanation offered by the authors is that the neutral faces were seen as more ambiguous than fearful facial expressions, resulting in increases in amygdala activation. In a cross-sectional study, Killgore et al. (2001) reported sex differences in amygdala responses in children and adolescents. They found that the left amygdala responded to fearful facial expressions in all children, although its activity decreased over the adolescent period in females but not in males. In a follow-up study, Killgore and Yurgelun-Todd (2004) compared children, adolescents, and adults during the perception of fearful faces. They reported that males and females differed in the right hemisphere – left hemisphere asymmetry of activation of the amygdala and prefrontal cortex (PFC) and this interacted with age. For boys, activation within the dorsolateral PFC was bilateral in childhood, right lateralized in adolescence, and bilateral in adulthood, whereas females showed a monotonic relationship with age, such that older females showed more bilateral activation than younger ones, but with significant bilateral activation at all ages. In contrast, amygdala activation was similar for both sexes, with bilateral activation in childhood, right-lateralized activation in adolescence, and bilateral activation in adulthood.

Lobaugh et al. (2006) reported that fear, disgust, and sadness recruit distinct neural systems both in 10-year-old children and adults. Two recent cross-sectional studies reported that adolescents display more amygdala activity in response to affective faces than either children or adults (Guyer et al., 2008; Hare et al., 2008). Further, adolescents also show less response to emotions in ventromedial PFC (vmPFC), a region whose functional connectivity with the amygdala is associated with habituation to emotional stimuli (Etkin et al., 2006; Hare et al., 2008). This suggests that teenagers may be more emotionally reactive and also less capable of relying on PFC for affect regulation (see also Grosbras et al., 2007; Lévesque et al., 2004).

In a recent fMRI study, we examined the development of the neural circuitry supporting emotion regulation in school-age children (Pitskel et al., 2011). We focused on the circuitry supporting cognitive reappraisal, a particular approach to emotion regulation frequently utilized in behavioral psychotherapies. Despite a wealth of research on cognitive reappraisal in adults, little is known about the developmental trajectory of brain mechanisms subserving this form of emotion regulation in children. We asked children and adolescents to increase and decrease their emotional response to disgusting images (e.g., a picture of a person with mucus hanging from her nose) by either pretending it was real and right there in front of them (for the increase condition) or by pretending it was just make believe (for the decrease condition). Distinct patterns of brain activation were identified during successful up- and downregulation of emotion, as well as an inverse correlation between activity in vmPFC and limbic structures, particularly the amygdala, during downregulation, indicative of the regulatory role for vmPFC. Further, as illustrated in Figure 19.3, age-related effects on activity in the vmPFC and amygdala were discovered. Of particular interest, during downregulation of emotion, significant negative correlations with age in the amygdala were observed, consistent with more effective emotion regulation.

While this review highlights a number of findings from cross-sectional studies of age-related changes in brain function related to the perception and regulation of emotion, only one study has reported valuable longitudinal data on the neural circuitry underlying emotion processing. In a groundbreaking study, Pfeifer et al. (2011) reported longitudinal data from 38 neurotypical participants who underwent two fMRI sessions across the transition from late childhood (10 years) to early adolescence (13 years). Strikingly, responses to affective facial displays exhibited a combination of general and emotion-specific changes in ventral striatum (VS), vmPFC, amygdala, and temporal pole. Furthermore, VS activity increases correlated with decreases in susceptibility to peer influence and risky behavior. VS and amygdala responses were also significantly more negatively coupled in early adolescence than in late childhood while processing sad and happy versus neutral faces. Together, these results suggest that VS responses to viewing emotions may play a regulatory role that is critical to adolescent interpersonal functioning.

19.2.3 Lateral Temporal Cortex and the Perception of Biological Motion

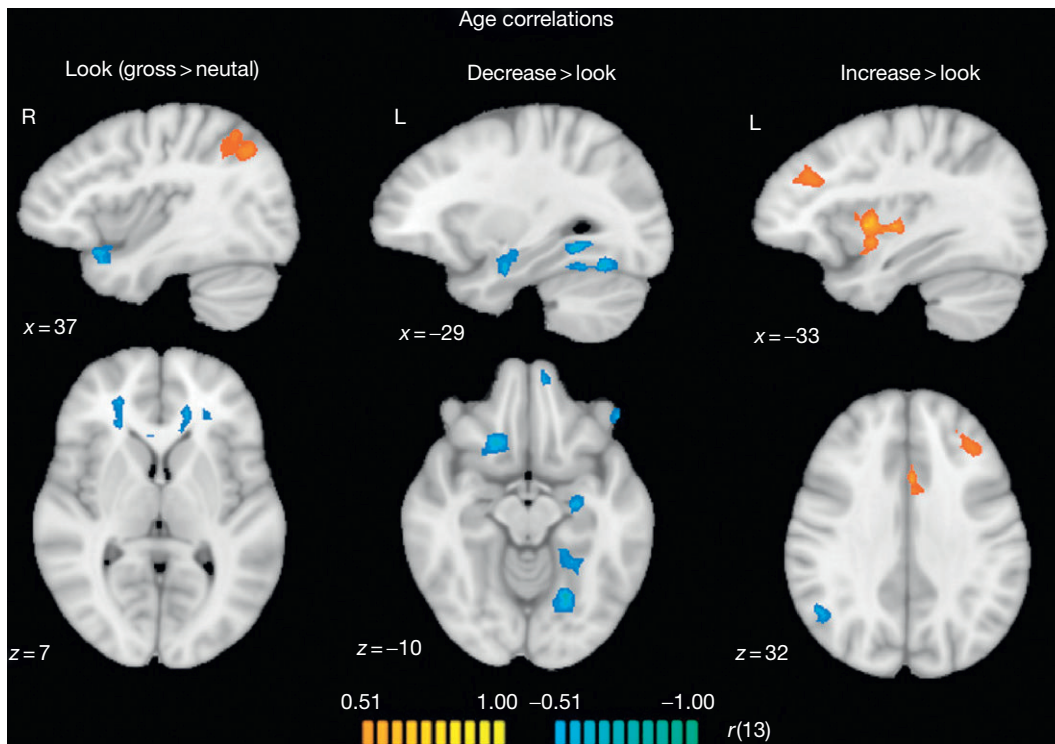
Biological motion perception refers to the visual perception of a biological entity engaged in a recognizable activity. This definition includes the observation of


FIGURE 19.3   Activation correlated with age in each of three key contrasts, look-gross > look-neutral (reflecting the perception of disgust), decrease-gross > look-gross (reflecting efforts to downregulate emotion), and increase-gross > look-gross (reflecting efforts to increase emotion responses). Areas in orange are those that were positively correlated with age; areas in blue exhibited negative correlations with age. All activations are shown at threshold of $p < .05$. Images are displayed in radiologic convention.

humans walking and making eye and mouth movements, but the term can also refer to the visual system's ability to recover information about another's motion from sparse input. The latter is well illustrated by the discovery that point-light displays (moving images created by placing lights on the major joints of a walking person and filming them in the dark), while being relatively impoverished stimuli, contain the information necessary to identify the agent of motion and the kind of motion produced by the agent (Johansson, 1973). Biological motion is integral to social perception. The superior temporal sulcus (STS) region, particularly the posterior STS, has been implicated in the perception of biological motion including eye, hand, and whole-body movements (e.g., Bonda et al., 1996; Pelphrey et al., 2003). Specifically, it exhibits differences in activation to actions that are congruent with contextual factors relative to actions that are incongruent with the context. It is hypothesized that the STS plays such a role because intentions are used, chiefly, for predicting what people will do in the future. Since future actions are intrinsically dynamic biological motion, it seems reasonable that the STS, whose job it is to represent such motion, could be used for this role. However, it is currently unknown whether regions that represent intention for anticipation and prediction

are distinct from areas that simply represent the current state of perceived biological motion.

Frith and Frith (1999) first suggested that the ability to distinguish between biological and nonbiological figures and their actions is one of the likely evolutionary and developmental precursors to theory of mind. They also noted that the STS region previously implicated in biological motion processing is adjacent to regions of the brain used for other, higher level aspects of 'mentalizing,' a concept closely related to theory of mind. The ability to infer goal states using the actions of an agent has been called an 'intentionality detector' and proposed as a component of the human mentalizing system (Baron-Cohen et al., 1994). By the age of 4 months, infants can detect biological motion from impoverished stimuli, 'point-light walkers,' and prefer these movies to those of nonbiological motion (Fox and McDaniel, 1982). A study of 8-month-old infants using ERPs suggested that there was activity in the right hemisphere in response to biological motion (Hirai and Hiraki, 2005). Lloyd-Fox et al. (2011) recently identified a more precise neurobiological basis for this very early developing social perception ability using functional near-infrared spectroscopy. In their pioneering study, 5-month-old infants watched videos of adult actors moving their hands, their

mouth, or their eyes, all in contrast to nonbiological mechanical movements. They observed that different regions of the frontal and temporal cortex responded to these biological movements and that different patterns of cortical activation emerged according to the type of movement watched. These findings demonstrate that from an early age, our brains selectively respond to biologically relevant movements, and further, selective patterns of regional specification to different cues occur within the lateral temporal cortex, including the STS region.

Only a handful of fMRI studies have examined the brain mechanisms for the perception of biological motion compared to nonbiological motion in children. In one fMRI study (Carter and Pelphrey, 2006), the functional development of the STS region was explored using a paradigm that was previously employed with a sample of adults (Pelphrey et al., 2003). In order to determine whether the STS region responded to biological motion more than to other types of complex, meaningful motion or to random motion, adult participants viewed a virtual scene that included four types of carefully matched, animated stimuli: a walking human (human), a walking robot (robot), a grandfather clock (clock), and a disjointed mechanical figure (mechanical) (see Figure 19.4). While the figures differed markedly in form, their movements were nearly identical. These figures allowed for the exploration of whether a biological motion pattern (walking) would be processed differently if made by a biological (human) versus nonbiological (robot) figure and whether there were differences in brain activation patterns for organized versus disorganized mechanical motion.

In adults, there were no significant differences between the human and the robot or between the clock and the disjointed mechanical figure in the posterior STS region. The posterior STS (right hemisphere > left hemisphere) responded more strongly to biological

motion (robot and human) than to nonmeaningful but complex nonbiological motion (mechanical) or complex and meaningful nonbiological motion (clock) (Pelphrey et al., 2003). Importantly, not every brain region showed this pattern of effects. We observed a dissociation of function between the STS region and an area posterior and inferior to the posterior STS region corresponding to the motion-sensitive visual area MT or V5 (MT/V5, e.g., McCarthy et al., 1995; Tootell et al., 1995; Zeki et al., 1991). The STS region responded selectively to biological motion, whereas MT/V5 responded equally to all four types of motion.

As illustrated in Figure 19.5, 7- to 10-year-old children exhibited robust biological > nonbiological activity in the middle and posterior portions of the STS region. To examine possible age-related changes in these responses, it was assumed that higher levels of biological > nonbiological activity (i.e., greater biological−nonbiological difference scores) were indicative of a more maturely functioning system. Consequently, a positive correlation between the specificity of the STS region for biological motion and age was anticipated. Consistent with this prediction, the magnitude of the biological−nonbiological difference score was positively correlated with age in the right posterior STS region ($r = 0.64$, $p = 0.03$, two-tailed), with age accounting for approximately 41% of the variance in the biological−nonbiological difference scores. This finding highlights developmental changes in the functioning of the STS region during biological motion perception across middle childhood.

Much of what develops in regard to social cognitive abilities in childhood likely involves changes in connections among the various brain regions involved in social information processing. Increasing connections allow for increasingly sophisticated social perception and mentalizing abilities. Given the available research on the STS region, future research should aim to explore the development of structural and functional connectivity to and from this area. It could be the case that what appears to be a relative increase in differentiation in the STS region could represent changes in its inputs and outputs and
FIGURE 19.4 Biological (robot and human) and nonbiological (clock and mechanical) motion stimuli.
FIGURE 19.5 The red-colored map indicates regions of significant biological > nonbiological motion activity in school-age children.

could thus either be a function of tuning of the STS response *per se*, or a development in the input by top-down regions to the STS. This could be examined using functional connectivity (to explore when regions work together) and diffusion tensor imaging (to determine the structural connections between these regions).

19.2.4 Medial PFC and the Representation of the Self and the Other

In adults, the medial PFC (mPFC) has been implicated in a wide range of social cognitive tasks, including making inferences about other people's intentions and mental states (Castelli et al., 2002; Gregory et al., 2002), the attribution of emotion to the self and others (Ochsner et al., 2004), self-reflection (Heatherton et al., 2006; Kelley et al., 2002; Northoff et al., 2006), and representing semantic knowledge about the psychological aspects of other people (e.g., Mitchell et al., 2005a,b). Additionally, the precuneus and posterior cingulate in the medial posterior parietal cortex (mPPC) are more active during self-knowledge retrieval than during other types of social or semantic tasks (e.g., D'Argembeau et al., 2010; Kelley et al., 2002). The capacity to perceive and reflect upon oneself as an individuated, unified, and stable entity with lasting qualities and traits (e.g., shy, intelligent, and kind) is a critically important and perhaps unique aspect of the human experience.

Many theoretical accounts of social cognition make self-referential processing a central component of processing others (Mitchell et al., 2005a,b; Spengler et al., 2009; Uddin et al., 2007), positing that one strategy for predicting the mental states of others is by referencing one's own thoughts, feelings, or behaviors in a similar situation. Recent studies have shown developmental changes from childhood to adulthood in activity in the frontoparietal network during self-perception tasks. To illustrate, Pfeifer et al. (2011) studied a sample of 12 children and 12 adults (average age = 10.2 and 26.1 years, respectively) using fMRI. The participants reported whether short phrases described themselves or a highly familiar other (Harry Potter). In both children and adults, the mPFC was relatively more active during self – than social – knowledge retrieval, and the mPPC was relatively more active during social – than self-knowledge retrieval. Direct comparisons between children and adults indicated that children activated the mPFC during self-knowledge retrieval to a much greater extent than adults. The particular regions of the mPPC involved varied between the two groups, with the posterior precuneus engaged by adults, but the anterior precuneus and posterior cingulate engaged by children. Only children activated the mPFC significantly above baseline during self-knowledge retrieval. This last finding suggests that the presence of a cortical, prefrontal-mediated, neural system supporting self-referential processing in children, is perhaps no longer needed in adults. Longitudinal data will be needed to more fully understand this pattern.

19.2.5 Posterior Parietal Cortex and Thinking About the Thoughts of Others

Thinking about the thoughts of others, or 'theory of mind,' has been studied most intensely using false belief tasks. In the typical design, a child watches while a puppet places an object in location A. The puppet leaves the scene and the object is transferred to location B. The puppet returns and the child is asked to predict where the puppet will look for the object. Three-year-olds think the puppet will look in location B, where the object actually is; older children think the puppet will look in location A, where the puppet last saw the object (Wellman et al., 2001). The 3-year-olds who fail the false belief task are not performing at chance, nor are they confused by the questions, but instead make systematically below-chance predictions with high confidence (Ruffman et al., 2001). The standard interpretation of these results is that 3-year-olds lack a representational theory of mind. That is, 3-year-olds fail to understand how the contents of thoughts can differ from reality (Gopnik and Astington, 1988; Wellman et al., 2001).

Although the false belief task has been used in literally hundreds of studies, it remains controversial whether success on this task depends on the deployment of a 'special' domain-specific mechanism for reasoning about other minds. As many researchers have noted (Bloom and German, 2000; Leslie, 2000; Roth and Leslie, 1998), children might pass or fail the false belief task for reasons having nothing to do with deficits in understanding other minds. In particular, the false belief task requires a high level of executive control – that is, the ability to plan and carry out a sequence of thoughts or actions, while inhibiting distracting alternatives. Thus, researchers have suggested that the false belief task underestimates children's ability to think about mental states (Bloom and German, 2000). Alleged shifts in children's theory of mind might reflect changes only in children's executive function – especially the abilities to select from among competing responses and to inhibit the tendency to respond based on reality (Carlson et al., 2004). Recently, an even bigger obstacle has arisen for the standard view: multiple reports that infants can make correct predictions on false belief tasks, when measured by violation-of-expectation looking time measured at 12–15 months (Onishi and Baillargeon, 2005; Surian et al., 2007) or predictive looking at 24 months (Southgate et al., 2007). These results have been taken as evidence for very early emerging, or even innate, cognitive mechanisms for theory of mind (Leslie, 2005).

Cognitive neuroscience provides a complementary route to address the same theoretical concerns. Are there cognitive and neural mechanisms selectively implicated in theory of mind, independent of executive demands? If so, do these brain regions' response profiles mature around age 4, the age when children reliably pass explicit false belief tasks, or early in childhood or even infancy?

Recent neuroimaging of adult brains has revealed a small but remarkably consistent set of cortical regions associated with thinking about other people's thoughts, or 'theory of mind' (Frith and Frith, 2003; Gallagher et al., 2000; Saxe and Kanwisher, 2003): bilateral temporoparietal junction (TPJ), mPFC, and posterior cingulate. The mPFC is recruited when processing many kinds of information about people (Amodio and Frith, 2006; Mitchell et al., 2005a; Ochsner et al., 2005), whereas the right TPJ is recruited selectively for thinking about thoughts (Saxe and Kanwisher, 2003; Saxe and Powell, 2006). Many functional neuroimaging studies have borrowed paradigms from the rich, older tradition of studying theory of mind in children, though few have directly investigated the development of these neural mechanisms in childhood (Kobayashi et al., 2006, 2007). In two initial studies, Kobayashi et al. (2006, 2007) reported that unlike adults, 9-year-old children did not show activation in the right or left TPJ during belief-reasoning tasks. These results suggested the tantalizing possibility of surprisingly late developmental changes in the neural mechanisms for theory of mind. However, many important questions remain opened. For example, if the TPJ, bilaterally, is not recruited for theory of mind in 9-year-olds, when do these regions develop adult-like selectivity? Are these brain regions involved in some other social cognitive function in the younger children? Or are these brain regions perhaps involved in domain-general functions in younger children and acquire a social role only later in life?

Another important question concerned the developmental relation between theory of mind and the perception of human body actions. Basic perception and understanding of human action are very early emerging, with preverbal infants demonstrating their ability to attend to human action and interpret human body movements in terms of pursuit of goals (Gergely et al., 1995; Johnson, 2003; Meltzoff and Brooks, 2001; Woodward, 1998; Woodward et al., 2001). A longitudinal study found that infants' early action understanding predicts their later success at age 4 years on explicit false belief tasks, suggesting that early perceiving and later reasoning about other people may rely on common cognitive mechanisms (Wellman et al., 2004). But how are the neural mechanisms for action perception and theory of mind related?

The neuroimaging findings reviewed above indicate that action perception (including watching hand, body, and head movements) recruits a region near the right TPJ, in the right posterior STS (Allison et al., 2000; Pelphrey et al., 2003, 2005; Puce et al., 1998). Critically, the posterior STS response depends not only on the pattern of biological motion but on its relation to the environmental context, suggesting that these regions are involved in interpreting human behavior in terms of intentions and goals (Brass et al., 2007; Pelphrey et al., 2004b,c; Saxe et al., 2004b). Early reviews of the adult neuroimaging literature proposed the existence of a single neural substrate (sometimes called posterior STS/TPJ) 'for detection of the behavior of agents and analysis of the goals and outcomes of this behavior' (Frith and Frith, 1999). However, more recent research has revealed that, at least in adults, these two regions are functionally distinct (Gobbini et al., 2007). The posterior STS shows a high response during action observation, and the TPJ shows a high response during reasoning about beliefs, but not vice versa. The possibility remained that theory of mind and action perception initially depend on a single region in posterior STS and TPJ, which then differentiates into two separate regions with distinct functions, later in development. In order to test this hypothesis, Saxe et al. (2009) compared the patterns of brain activation associated with perceiving biological motion (see Figure 19.4) and thinking about thoughts, in the same children.

Children's brains differentiated, within ongoing stories, sections that described the characters' thoughts from sections describing the physical context. Regions in precuneus and bilateral TPJ showed significantly higher responses during the mental rather than physical sections, as did mPFC, but at a lower threshold. To investigate selectivity for thinking about thoughts, the responses to people versus physical and mental versus people subsections in each ROI were compared. All the regions showed a significantly higher response for people rather than physical sections as well as a higher response for mental rather than people sections, except the mPFC, in which this latter difference did not reach any significance. That is, we did not find evidence that the mPFC reliably differentiated information about characters' thoughts from any other facts about people, although the average response in the mPFC was also not significantly different from that observed in the other regions in a direct comparison. These results suggest that in children, unlike previous results in adults, the right TPJ is not significantly more selective for mental state facts, relative to other social facts, than the mPFC. In order to determine whether this difference reflected a developmental change, changes in response patterns with age were examined. A selectivity index was calculated for each brain region, used to measure the difference (in units of percent signal change from rest) between the mental and people sections, relative to the difference between the mental and physical sections, for each individual: $100 \times (\text{mental} - \text{people})/(\text{mental} - \text{physical})$.

Only one brain region showed a significant correlation between age and the selectivity index: the right TPJ. Critically, the brain regions implicated in theory of mind did not overlap with those recruited during perception of biological motion.

This finding of age-related change in brain activation raises as many questions as it answers. There is a broad consensus among developmental psychologists that theory of mind is largely mature well before age 6 years (Onishi and Baillargeon, 2005; Southgate et al., 2007; Wellman et al., 2001). The above neuroimaging results, in contrast, suggest that a key component of the neural organization underlying theory of mind is still changing 3 years later, around age 9 years. So what are the cognitive (and behavioral) correlates of the increased neural specialization? The observed changes are hypothesized to reflect changes in neural organization, specifically in the selectivity of the right TPJ neural response, and are consistent with the pattern of anatomical development of human cortex as revealed in longitudinal MRI studies (e.g., Gogtay et al., 2004). Additionally, a longitudinal study found that gray matter does not reach mature density in 'higher order association areas,' including regions near the TPJ, until early adolescence (Gogtay et al., 2004). The aforementioned findings suggest that the strong selectivity observed in adult brain regions for social perception is not innate but emerges gradually over many years in childhood. In particular, regions showing the most selective response profiles in adulthood show late developmental change (the right TPJ in this study), whereas regions with more general response profiles in adulthood show less developmental change (the mPFC in this study). For both perceiving and reasoning about other people, these results suggest that the basic cognitive signatures of domain specificity may be in place long before the brain systems underlying these processes have reached an adult-like state. The implications of this conclusion are as yet unclear. But one conclusion does seem clear: the finding of late-emerging cortical selectivity undermines the interpretation of category-selective brain regions in adults as evidence for innate and early-maturing domain-specific cognitive or perceptual modules. In particular, our results in the right TPJ are challenging for theories of cognitive development that emphasize an innate and early-maturing domain-specific module for theory of mind.

19.3　A DEVELOPMENTAL MODEL OF SOCIAL PERCEPTION

To date, the field of developmental social neuroscience has begun to dissect some of the neurobiological mechanisms underlying key aspects of social perception and social cognition in infants, children, and adolescents.

This initial work and associated methodological developments have provided the exciting opportunity to address a number of fascinating theoretical questions including: (1) Do later-developing social cognition abilities colonize the systems engaged by earlier-developing abilities? Or, as development proceeds, are new regions recruited into a more basic underlying network? (2) How do the components of the social brain come to interact with each other and with other brain circuits involved in such activities as executive function and language? (3) What are the constraints for specific regions to take on aspects of social perception and social cognition (e.g., proximity and connectivity to motion and speech decoding)?

As our review has illustrated, there is a diverse set of brain regions that contribute to the complex set of social information processing tasks that we call 'social perception.' Given principles of division of labor in the brain, we would expect that each of these regions would show functional specialization. However, social perception emerges from the joint activity and connectivity of each brain region as it contributes to information processing. Early in development, the main source of social input comes from looking at faces and actions of others. Panel (a) of Figure 19.6 depicts this early social network. External input is processed for its basic social components – emotionality in the limbic areas, static faces and body information in the VOTC, and dynamic biological motion in the STS. This information can be used to anticipate other actions and guide social exploration, but only if it is integrated across these individual domains and sensory modalities. We know that in school-age children and adults, the integration of information for the understanding of action takes place in the STS, but we do not know when this begins to happen (Mosconi et al., 2005).

This early circuit relies on sensory input available to even young infants and probably does not require sophistication on the part of the child in terms of their ability to represent complex environmental knowledge or knowledge about others' mental states (Senju et al., 2006). However, it is the very simplicity that provides the child with their first abilities to perceive and anticipate the actions of others and to reap the positive rewards of being able to do so. With this early success, the child (and their social perception system) would be motivated to dedicate more resources to the problem of predicting and understanding others.

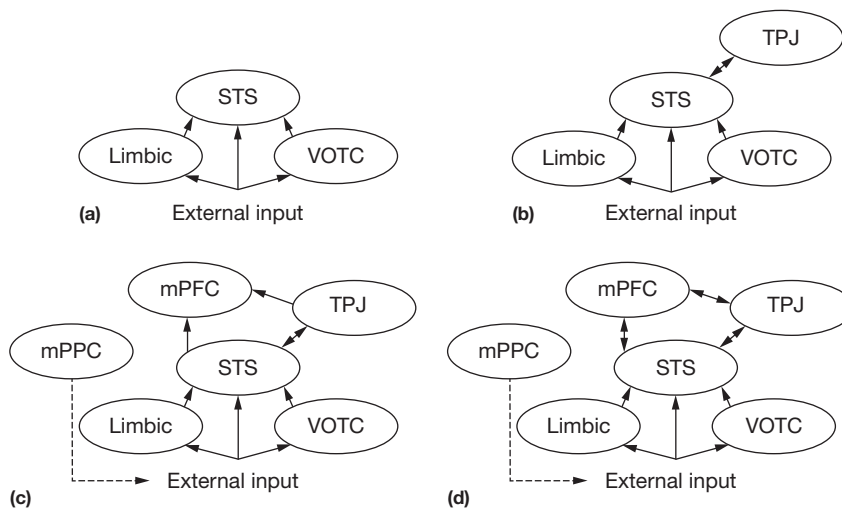
Indeed, this simple circuit, while probably remaining critically important throughout life, can only make very temporally limited predictions. For example, while smiling and reaching may provide information enough to anticipate actions over the next few seconds, it probably cannot be used to predict what a person will be doing an hour from now. To predict this longer scale of actions,


FIGURE 19.6 A developmental model of social perception development.

more sophisticated and enduring constructs about others need to be built. At this point, the TPJ is recruited (panel (b)) to allow the attribution of more abstract mental states, most likely by communicating with other areas representing language and semantic knowledge (not shown). It also must communicate with the STS, with initial projections from the STS to the TPJ needed to keep the latter informed about the current state of action, as it is perceived. Reciprocal connections from the TPJ back to the STS would allow the system to take advantage of the knowledge about how intentions (and more sophisticated representations) can unfold into action.

Further development of the system (panel (c)) would bring online prefrontal areas. It is well known that prefrontal regions and connections to the prefrontal regions from the posterior portion of the brain continue to develop well into adulthood. Thus, in early stages, the prefrontal contribution to social perception is probably limited and impoverished. However, as these regions develop, children gain the ability to reason and simulate social interactions, albeit with limited capacity. Additionally, mPPC regions such as the precuneus may begin to allow the child to switch between internal and external foci, instead of being driven completely by external stimuli. Behaviorally, this likely manifests in and is strengthened by pretense (the capability to make believe or to act 'as if'), which could be thought of as a precursor to adult-like abilities to deliberately ruminate and ponder. Indeed, pretense may be critical for adult-level performance for two reasons. First, pretense allows the child to generate scenarios, including social situations, which can be reprocessed for additional learning. Second, by reducing the dominance of external factors, the frontal-executive control of posterior areas, which may be relatively weak, can be developed.

In the final stage (panel (d)), the child develops adult-like control over posterior areas representing social information. These regions can still provide bottom-up processing of social information but can now also be activated by top-down mechanisms. One consequence of this is that social events that are separate in time can be brought together for the purposes of deliberate social reasoning. For example, we might be able to recollect an expression we perceived our friend make earlier in the day (via top-down reactivation of limbic and FFA regions) and couple that with body language we are perceiving now (via the STS) and reach a conclusion about her mental state.

19.4 FUTURE DIRECTIONS

The work reviewed in this chapter has set the stage for critical research to inform our neural systems level understanding of autism spectrum disorder (ASD). ASD is a common, early-onset neurodevelopmental disorder characterized by difficulties in social interaction and communication and repetitive or restricted interests and behaviors. ASD displays great phenotypic heterogeneity and etiological diversity, but social dysfunction is its hallmark and unifying feature. This social dysfunction is revealed by abnormalities in both simple behaviors, such as sharing gaze, and more complex social behaviors, such as triadic attention sharing. Anomalies of social perception, unlike communication problems or repetitive behaviors that are present in numerous disorders (such as anxiety or expressive language impairment), are unique to ASD and are documented across sensory modalities. Autism is a developmental disorder; early deficits derail subsequent experiences, thereby canalizing development toward more severe dysfunction and creating sequelae in additional domains of function. Consequently, the lack of reliable predictors of the condition during the first year of life has been a major

impediment to the effective treatment of ASD. Without early predictors and in the absence of a firm diagnosis until behavioral symptoms emerge, treatment is often delayed for 2 or more years.

A significant body of research has already informed our understanding of the brain basis of ASD via research on the development of systems for social perception in children and adults with and without autism (for a recent review of this research, please see McPartland et al., 2011). There is, however, a noticeable lack of information about the very early development (e.g., the first 2–3 years) of brain systems for social perception in infants and toddlers with or without ASD. This is because of the enormous challenge involved in successfully conducting this research. However, a recent study by Elsabbagh et al. (2012) illustrates the great potential for neuroimaging to contribute to our understanding and early diagnosis of ASD. They tested the hypothesis that neural sensitivity to eye gaze in early infancy would predict development of ASD in toddlerhood. The study involved a prospective longitudinal sample of infants at high familial risk for ASD and a comparison group of infants at low risk. The researchers recorded electrophysiological brain responses (event-related potentials; ERPs) while 6–10-month-old infants viewed faces with dynamic eye gaze directed either toward them or away from them. Approximately 18–30 months later, these children were clinically evaluated for the presence of an ASD. Strikingly, neural responses to dynamic eye gaze shifts during the first year predicted clinical outcomes at 36 months, despite similar patterns of gaze as measured by eye tracking. The authors conclude that ERP responses to eye gaze in the first year of life reflect developmental processes leading to the later emergence of ASD.

As the field strives for earlier methods of detecting autistic development, these remarkable findings offer hope for future clinical practice, suggesting the possibility of noninvasive, brain-based screening methods that could detect differences prior to behavioral emergence. Of course, prior to realization of such clinical benefits, it will be critical to investigate the specificity of this biomarker to autism, its presence in an unselected, population-based sample, and, most importantly, its viability in individual patient data. Given historical difficulty parsing heterogeneity in ASD, these findings suggest the potential power of systems neuroscience approaches to identify meaningful subtypes of ASD to inform treatment and predicting outcome. For the future, a strategy of deep behavior and brain phenotyping over longitudinal development is envisioned to offer a detailed profile of brain–behavior performance for a given individual for the purpose of detection of atypical development, subcategorization (e.g., for genetic analysis), treatment selection, and prediction of treatment response (see Rubenstein and Rakic, 2013).

> *It's the best possible time to be alive, when almost everything you thought you knew is wrong.*
>
> **Arcadia, by Tom Stoppard**

Imagine you arrive back at the laundromat and see a stranger take your clothes out of the dryer and start to fold them. What is going on? With only seconds of perceptual data about this stranger, you can immediately conjure up multiple plausible explanations: maybe he intends to steal your clothes, maybe he is feeling amazingly generous and wants to help someone out, or maybe he just falsely believes that those are his own clothes. In this example and in countless other brief and extended social interactions every day, we do not just describe people's actions as movements through space and time. Instead we seek to explain and judge and predict their actions, and we do so by appealing to a rich but invisible causal structure of thoughts, beliefs, desires, emotions, and intentions inside their heads. This capacity to reason about people's actions in terms of their mental states is called a 'theory of mind' (ToM).

This chapter is about what we know, and what we do not know, about how the human brain acquires its amazing capacity for ToM. In the past few decades, ToM has been studied intensively in childhood development (using behavioral measures) and in the adult human brain (using functional neuroimaging). Converging evidence from these two approaches provides insight into the cognitive and neural basis of this key human cognitive capacity. However, as we highlight later, we are especially excited about the future of ToM in developmental cognitive neuroscience: studies that combine both methods, using neuroimaging methods to directly study cognitive and neural development in childhood.

We start by describing an account of ToM, in development and in neuroscience, that we shall call the 'Standard' view. Next, we describe some recent challenges that shake the foundations of the Standard view. Finally, we point to the open questions, and especially the key contributions that developmental cognitive neuroscience can make in the next generation of studies of ToM.

20.1 WHAT WE THOUGHT WE KNEW: THE STANDARD VIEW

20.1.1 Development

The laundromat example makes clear a central feature of ToM: it is especially useful when other people have false beliefs. When strangers fold their own laundry,

no special explanation seems warranted. We can describe their actions in behavioral terms: folding laundry is a thing people frequently do in laundromats. However, when a stranger starts to fold your laundry, then it becomes important to figure out: what are they thinking? The understanding that they may have a false belief makes an otherwise highly unlikely action suddenly predictable. If they believe it is their own laundry, then of course they will start folding it.

Because false belief scenarios are so diagnostic of ToM inferences, understanding of false beliefs has been considered a key milestone in ToM development. Children's ability to predict and explain actions based on a false belief is typically assessed in a 'false belief task' (see Figure 20.1). In a typical example, children hear a story like this one: Sally sees her dog run to hide behind the sofa; then, while Sally is out of the room, the dog moves to behind the TV. Children are then asked to predict where Sally will look first for her dog when she returns to the room (Baron-Cohen et al., 1985; Wimmer and Perner, 1983).

Adults immediately recognize that Sally will look for her dog behind the sofa, where she thinks it is. Surprisingly, 3-year-olds systematically make the opposite prediction; they confidently insist that Sally will look behind the TV, where the dog really is (Wellman et al., 2001). Moreover, if 3-year-olds actually see Sally looking behind the sofa, they still do not appeal to Sally's false belief to explain her action, but instead appeal to changed desires (e.g., 'she must not want the dog,' Goodman et al., 2006; Moses and Flavell, 1990). In contrast, typical 5-year-old children correctly predict and explain Sally's action, by appealing to her false belief.

This pattern of children's judgments, over development, is incredibly robust; it has been replicated in hundreds of studies conducted over four decades. The same shift in understanding false beliefs and the ability to use beliefs to explain actions occurs between 3 and 5 years in children from rural and urban societies, in Peru, India, Samoa, Thailand, and Canada (Callaghan et al., 2005) and even in children of a group of hunter-gatherers in Cameroon (Avis and Harris, 1991).

Developmental psychologists do not disagree about these data; they disagree about the interpretation. To start with, we will articulate two claims we call the 'Standard' interpretation of these results. This is the view that most informed, and converged with, the first neuroimaging studies of ToM in the adult brain. It was never, however, a consensus opinion; in whole and in part, every aspect of the Standard view has been hotly debated all along.

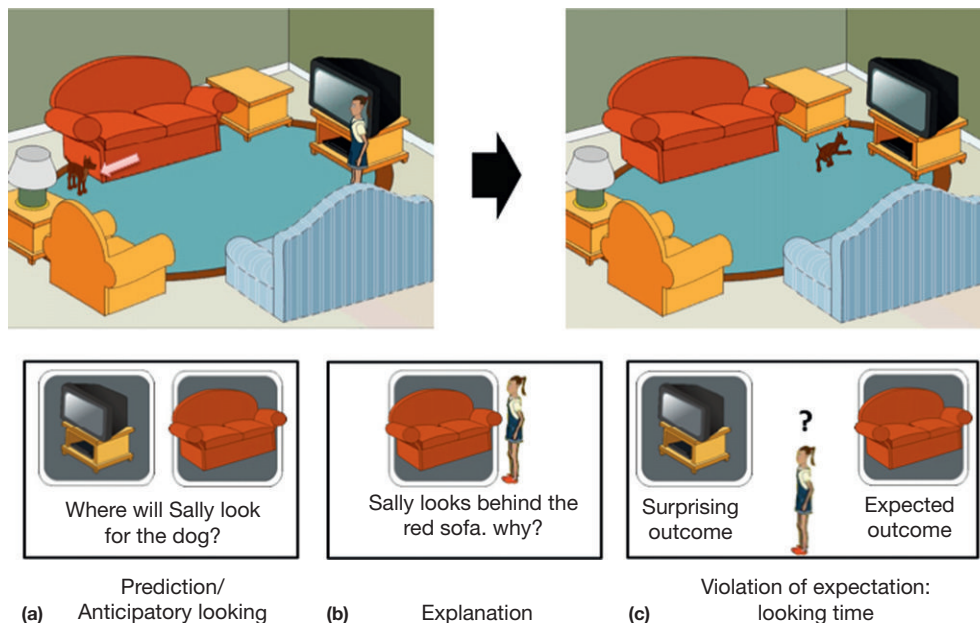
First, the Standard view of development on the false belief task proposes that children undergo a key conceptual change in their ToM between ages 3 and 5 years. They


FIGURE 20.1 An example of a standard false belief scenario. Sally sees her dog hide behind the red sofa, but the dog moves to behind the TV while she is out of the room. Children's understanding of false beliefs at different developmental stages can be assessed using various methods: (a) by asking children to predict where Sally will look, or measuring their anticipatory look when Sally comes back to find her dog; (b) by asking children to explain Sally's action; or (c) by comparing infants' looking times to observing Sally go toward the sofa (the 'expected' outcome, if they understand false beliefs) or the TV ('unexpected' outcome). In spite of the logical similarity between these tasks, children make the correct prediction/explanation (Sally will look behind the sofa) around age 4 years, but make correct anticipatory looks/longer looking to the unexpected outcome around age 15–24 months. Art thanks to Steven Green.

are slowly acquiring a fully 'metarepresentational' ToM (Perner, 1991), which lets them understand people's beliefs and thoughts as representations of the world. Representations are designed to accurately reflect the real world, but sometimes fail to do so. So a representational ToM allows children to understand when and how the content of a person's belief can be false (Gopnik and Astington, 1988; Wellman et al., 2001), and that in these cases, people's actions will depend on what they believe, not on what's really true.

Note that learning to understand false beliefs involves change within a child's ToM, not the acquisition of a ToM. Even very young infants understand that people's actions depend on what they want (e.g., Phillips and Wellman, 2005; Woodward, 1998; see Gergely and Csibra, 2003 for a review), and what they can see (Meltzoff and Broks, 2008). That is already a sophisticated ToM, and it makes the right predictions for people's actions in many, if not most, circumstances. Specifically, when someone has a false belief, though, a ToM based mainly on understanding intentions makes the wrong prediction: if Sally wants her dog, she will go get her dog, so she will go where it is, behind the TV. Thus, on the Standard view, young children do have a ToM founded upon very early developing concepts of intention and perception. Nevertheless, their ToM changes substantially between ages 3 and 5 years by the addition of a full concept of 'belief.'

Second, the Standard view proposes that changes in false belief understanding reflect maturation of a 'domain-specific' mechanism for ToM. Between the ages of 3 and 5 years, children change and mature in many ways: they come to have a richer vocabulary and a better memory and a larger shoe size. However, on the Standard view, ToM develops separately: ToM task performance is not just a matter of getting smarter or faster in general, but specifically of conceptual change within ToM.

One way to assess domain specificity is to compare children's development of reasoning about false beliefs with their ability to solve very similar puzzles about other false representations: outdated photographs. For example, children might see Sally take a photograph of the dog behind the sofa; after the dog moves to the TV, the children are asked where the dog is in the photograph. The false photograph task is logically very similar to the false belief task, requiring very similar capacities for language, memory, and inhibitory control (e.g., the ability to choose between two competing response alternatives). Nevertheless, young children are significantly better at the false belief task (Zaitchik, 1990), possibly because they have a 'special mechanism' for ToM which gives their performance a boost.

Stronger evidence that ToM is separate from other parts of cognition comes from studies of children with neurodevelopmental disorders. Children diagnosed with autism spectrum disorders (ASDs) are significantly delayed in passing false belief tasks, compared with typically developing children or children with other developmental disorders like Down syndrome (Baron-Cohen, 1997; Baron-Cohen et al., 1985). On a larger set of tasks, tapping multiple different aspects of ToM (e.g., understanding desires, beliefs, knowledge, and emotions), children with ASD show both delayed development and also disorganized development. That is, typically developing children pass these tasks in a stable order (e.g., understanding false beliefs is easier than understanding false emotions), but children with autism pass the tasks in a scrambled order, as if they were passing for different reasons (Peterson et al., 2005). Furthermore, the difficulty seems to be specific to ToM: compared with typically developing children matched for IQ and verbal abilities, children with autism show comparable (or even better) performance on nonsocial tasks that require similar logical and executive capacities, like the false photograph task (Charman and Baron-Cohen, 1992; Leekam and Perner, 1991; Leslie and Thaiss, 1992).

The observation that a neurobiological developmental disorder, ASD, could disproportionately affect development of ToM supports the Standard view that ToM development depends on a distinct neural mechanism. That is, some brain region, chemical, or pattern of connectivity might be specifically necessary for ToM, and disproportionately targeted by the mechanism of ASD. This hypothesis was difficult to test, though, until the advent of neuroimaging allowed researchers to investigate the brain regions underlying high-level cognitive functions like ToM.

20.1.2 Neuroimaging

The Standard view proposes that children undergo a conceptual change in their ToM between the ages of 3–5 years, from a conception involving actions and goals to one involving beliefs, and that this development of ToM is supported by a domain-specific mechanism. Early neuroimaging studies of ToM in adults appeared to converge nicely with both of these predictions.

Following the tradition in developmental psychology, the early neuroimaging studies of ToM required participants to attribute false beliefs to characters in stories or cartoons. Meanwhile, the scientists measured the oxygen in the blood of the participant's brain, either using radioactive labels (positron emission tomography, PET; Happe et al., 1996) or by measuring intrinsic differences in the magnetic response of oxygenated blood (functional magnetic resonance imaging, fMRI; Brunet et al., 2000; Fletcher et al., 1995; Gallagher et al., 2000; Goel et al., 1995; Saxe and Kanwisher, 2003; Vogeley et al., 2001). At that point, something remarkable happened.
FIGURE 20.2 ToM brain regions in adults (top) and children aged 5–12 years (bottom): the right temporoparietal junction (RTPJ), left temporoparietal junction (LTPJ), precuneus, and dorsal medial prefrontal cortex (yellow circle, from left to right). The bilateral TPJ and precuneus are shown on the coronal section, and all four regions (except for the precuneus in adults) are shown on the horizontal section. *Data shown are from Gweon et al. (2012).*

Across different labs, countries, tasks, stimuli, and scanners, every lab that asked 'which brain regions are involved in ToM?' got basically the same answer: a group of brain regions in the right and left temporoparietal junction (TPJ), right anterior superior temporal sulcus (STS) and temporal pole, the medial precuneus and posterior cingulate (PC), and the medial prefrontal cortex (MPFC; Castelli et al., 2000; Fletcher et al., 1995; Gallagher et al., 2000; German et al., 2004; Goel et al., 1995; Saxe and Kanwisher, 2003; Vogeley et al., 2001; see Figure 20.2). These studies provided initial evidence for a distinct mechanism for ToM, which converged with the predictions of the Standard view.

First, these regions did not respond to other tasks that require similar logical and executive capacities as the false belief task. As described earlier, the 'false photograph' task requires participants to answer questions based on a physical, tangible representation of the past (i.e., a photograph) that used to be true but is currently false. Similar to the false belief task is the false sign task (Parkin, 1994). Understanding a false directional sign involves the use of a symbolic representation that misrepresents the current reality: for example, a signpost indicates that an object is in location A, but the object is then moved to location B. The false photograph and false sign task provide a good test of 'domain specificity' for brain regions; these tasks are very similar to the false belief task in most cognitive demands, and differ mainly in whether they require reasoning about a belief. Using that logic, we can claim that at least some brain regions in human adults are specific for ToM. The bilateral TPJ, MPFC, and PC all respond much more during false belief compared with false photograph stories (Saxe and Kanwisher, 2003). Of these regions, the right TPJ (RTPJ) in particular responds more during stories about false beliefs compared with very closely matched stories about false signs (Perner et al., 2006). Also, identical nonverbal cartoon stimuli elicit RTPJ activity when participants construe the cartoons in terms of a character's false beliefs, but not when participants produce the exact same responses using a nonsocial 'algorithm' (Saxe et al., 2006). So at least the RTPJ, and possibly the other regions in this group, are plausible candidates for the domain-specific mechanism predicted by the Standard view.

Second, brain regions for thinking about beliefs and desires are near, but distinct from, brain regions involved in understanding actions and goals. In the right temporal lobe are brain regions involved in perceiving human bodies and body postures (extrastriate body area, EBA; Downing et al., 2001), movements (MT/V5; Grossman et al., 2000; Tootell et al., 1995), and in particular, people's facial expressions and bodily movements (right posterior STS, pSTS; Howard et al., 1996; see Chapter 19). Interestingly, the activity in the right pSTS depends not just on the action itself; it responds more to actions that are unexpected or incongruent in context (Brass et al., 2007; Pelphrey et al., 2003, 2004). For example, Brass et al. (2007) showed that the pSTS response is enhanced when participants look at a man using his knee to push an elevator button with nothing in his hands, compared with a man performing the same action but with his arms full of books (i.e., when using his knee is rational, in context).

The right pSTS response to intentional actions is impressive, but it would not support your inference about the stranger folding your clothes in the laundromat: in addition to detecting his action as intentional, you specifically need to infer his beliefs and desires (does he know those are your clothes? does he want to help or harm you?) in order to explain why he is doing so. These inferences appear to depend especially on the RTPJ.

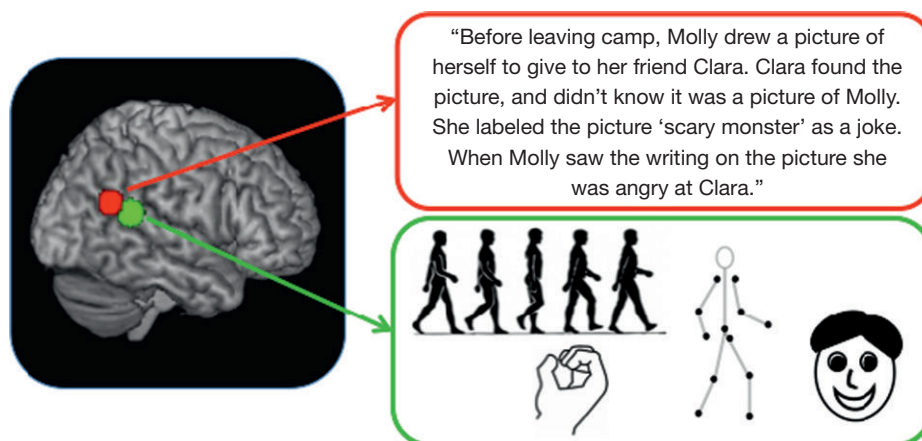
The RTPJ is adjacent to the right pSTS (Gobbini et al., 2007), but has a different response profile (see


FIGURE 20.3 The RTPJ (red) and the right posterior superior temporal sulcus (pSTS) (green). The RTPJ responds to stimuli that invoke reasoning about thoughts and beliefs, whereas the right pSTS responds to human actions such as walking, grasping, eye gazes, and mouth movements.

Figure 20.3). The RTPJ is recruited during stories or cartoons that depict a person's thoughts, but not in general for depictions of human actions, whereas the right pSTS is recruited when watching movies of simple actions, like reaching for a cup, but not for verbal descriptions of actions. The RTPJ also does not respond to photographs of people (Saxe and Kanwisher, 2003) or to descriptions of people's physical appearance (Saxe and Kanwisher, 2003; Saxe and Powell, 2006). Activity in the RTPJ is low during descriptions of people's physical sensations like hunger, thirst, or tiredness (Bedny et al., 2009; Saxe and Powell, 2006). Even within a single story about a person, the timing of the response in the RTPJ is predicted by the timing of sentences describing the character's thoughts. The response in the RTPJ shows a peak just at the time someone's thoughts are described (Saxe & Wexler, 2005; Saxe et al., 2009).

In sum, neuroimaging studies on ToM with adults provide compelling evidence for a domain-specific mechanism for reasoning about thoughts. Moreover, these studies show that the brain regions involved in ToM are distinct from regions that respond to the perception of goal-directed motion. These results converge nicely with the Standard view, which proposes that children gradually shift from an earlier understanding of goals and intentions (perhaps relying on the pSTS) to the concept of 'beliefs' as reasons for people's actions (relying on the RTPJ).

20.1.3 Developmental Cognitive Neuroscience

The Standard view thus makes a set of testable predictions for the future of ToM studies in developmental cognitive neuroscience (Saxe et al., 2004a).

First, there should be qualitative changes in the anatomy of ToM brain regions, especially including the TPJ and dorsal medial prefrontal cortex (DMPFC), around age 4 years, correlated with children's acquisition of the concept of false belief.

Second, prior to age 4 years, children should rely on early-maturing neural mechanisms for social cognition, especially including the pSTS representation of action, that support recognition of goal-directed actions, but not a theory of mental states like beliefs.

Third, after age 4 years, continued development is more likely to occur outside of the ToM regions, in brain systems that support difficult task performance more generally. That is, children might get generally faster or better at resolving conflicting representations, or more sophisticated in their use of language to describe mental states. But the most momentous shift in the neural mechanisms for ToM would already be complete.

The first prediction of the Standard view is that around age 4, the emergence of children's concept of 'false belief' would be supported by qualitative maturational changes in the ToM brain regions. And, in an initial test, this prediction received impressive support. Sabbagh et al. (2009) first tested a large group of 4-year-old children on standard false belief tasks. As predicted, false belief task performance in this group of children was liminal: some reliably passed the false belief tasks, some reliably failed, and some were intermediate. Next, Sabbagh and colleagues used electroencephalograms (EEG) to measure the amplitude and coherence of alpha waves in the same children's brains, while they were just sitting quietly at rest. These measures are thought to reflect anatomical maturation in a cortical region (Thatcher, 1992). Through an analysis technique called standardized low-resolution brain electromagnetic tomography (sLORETA; Pascual-Marqui et al.,

2002), researchers can use these measures to estimate the current density of alpha waves independently in every region. So Sabbagh and colleagues could then ask: where in the child's brain is maturational change specifically predictive of performance on false belief tasks (controlling for both age, and performance on other demanding tasks)? That is, in which brain regions is the density of the alpha signal best correlated with children's ToM development? The answer was: in the RTPJ and DMPFC – the same two regions most commonly associated with ToM in functional neuroimaging studies of adults!

Sabbagh et al.'s (2009) results are exciting because (1) they offer converging evidence implicating the RTPJ and DMPFC in ToM development, using a completely different method and experimental design, and (2) they support the a priori prediction of an association between anatomical maturation in these brain regions, and performance on standard false belief tasks, when children are around 4 years old.

While source localization methods such as LORETA are shown to render reliable results in estimating the sources of EEG signals (Pascual-Marqui et al., 2002; Wagner et al., 2004), EEG methods still offer much lower spatial resolution compared with other neuroimaging techniques such as functional magnetic resonance imaging (fMRI). So the three basic predictions of the Standard view remain to be thoroughly tested.

But what's most exciting is that the most recent research suggests that each of these predictions is at least partly wrong.

20.2 EVERYTHING WE THOUGHT WE KNEW WAS WRONG

20.2.1 Infants

The biggest challenge for the Standard view comes from a rapidly growing body of research showing that even 15–18-month-old infants understand that people can have, and act on, false beliefs. If so, there is a big lacuna in the foundation of the Standard view. Four-year-old children cannot be acquiring a concept of 'false belief' if that concept is already available to one-and-a-half year olds!

The first report that infants understand false beliefs was a looking-time study by Onishi and Baillargeon (2005). The basic logic of a looking-time study with infants is that first one shows the infants a partial event, setting up an expectation of what will happen next. Then, one shows the infants two possible 'completions' for that event. One of the completions is designed to fit the infants' expectations, and the other completion is designed to violate those expectations. Even preverbal infants can then show which completion they 'expected,'

by looking longer at the unexpected completion. Onishi and Baillargeon (2005) made very elegant use of this logic to test what infants expect a person to do when she is acting based on a false belief (see Figure 20.1).

In the original study, 15-month-olds watched an experimenter repeatedly hide, and then retrieve, a toy in one of two boxes (a yellow box and a green box). Then, on the critical trial, the experimenter hid the toy in the yellow box. After a short pause, the toy then moved by itself to the green box. The key manipulation was that either the experimenter watched the toy move ('true belief') or the experimenter turned away, and did not see the toy move ('false belief'). Finally, the experimenter reached either into the green box (where the toy really was) or into the yellow box (where she last put the toy). Which reaching action did the infants expect? Consistent with previous evidence that infants understand goal-directed actions, when the experimenter had a true belief, infants looked longer when she reached into the yellow box, than when she reached into the green box, where the toy was. Amazingly, though, when the experimenter had not seen the toy move, infants looked longer when she reached into the green box than into the yellow box – as if these 15-month-old infants expected her to reach for the toy where she falsely believed it to be.

Initially, these results were met with some skepticism, as they seem to contradict so much evidence that children do not understand false beliefs until many years later. However, in the intervening years, more and more studies of false belief understanding in infants and toddlers have accumulated. Baillargeon and colleagues have conducted a whole series of elegant studies, expanding on their original results. In these experiments, 1-year-olds (12–24 months) have demonstrated systematic expectations about actions based on false beliefs about contents as well as locations, based on indirect inferences as well as direct perception, and based on beliefs updated from other people's verbal reports as well as from observation (Onishi and Baillargeon, 2005; Scott and Baillargeon, 2009; Song et al., 2008; Surian et al., 2007).

Evidence that toddlers understand false beliefs is not restricted to studies using violation of expectation looking-time measures. Using anticipatory looking, Southgate et al. (2007) measured infants' predictions about where the experimenter would reach for her toy. If the experimenter had a false belief about her toy, 24-month-olds (but not 18-month-olds) anticipated that she would reach for her toy in the location where she saw it last, on the very first trial of the experiment.

Apparently, by their second year of life, children are already able to use inferred false beliefs to correctly predict others' actions. Why, then, is there a dramatic change in false belief task performance, when children are 4 years old? Baillargeon and colleagues suggest that 2- and 3-year-old children have a fully mature

understanding of representational mental states, but the demanding format of standard false belief tasks masks their abilities, rendering them incapable of expressing their knowledge (Baillargeon et al., 2010).

If so, the predictions for developmental cognitive neuroscience studies of ToM should be very different (Scott and Baillargeon, 2009). Brain regions specifically involved in ToM, like the TPJ and DMPFC, should not show any distinct qualitative developmental change around age 4 years, when children pass standard explicit false belief tasks. Instead, passing explicit false belief tasks should be associated with development in brain regions for executive function and language (see Botvinick et al., 2004; Caplan, 2007, for reviews). The developmental changes in ToM regions, by contrast, should occur much earlier, perhaps just after a child's first birthday.

Another interpretation of the infants' performance might be that while infants make systematic action predictions based on false beliefs, they do not actually have the same 'concept' of false beliefs that adults do. For example, infants may have a restricted, implicit understanding of beliefs, while 3–5-year-old children struggle to acquire a richer, more flexible, explicit concept of beliefs (Apperly and Butterfill, 2009). This view is plausible in part because a similar process occurs in other domains of cognition. The best-studied example is children's numerical concepts. Preverbal infants have representations with numerical content that allow them, for example, to track, differentiate, and even add and subtract small numbers (e.g., $1+1=2$; Feigenson et al., 2002; Wynn, 1992). Preverbal infants can also distinguish large numbers, when they differ by a large enough ratio (e.g., $8 > 4$, $16 > 8$; Xu and Spelke, 2000). However, these infants cannot form exact representations of large numbers that would let them, for example, distinguish between seven and eight objects (Carey, 2009; Xu and Spelke, 2000). Between the ages of 2 and 4 years, children then slowly and effortfully construct the concepts of the natural numbers, using as a necessary scaffold a culturally constructed list of names for numbers (Le Corre and Carey, 2007; Sarnecka and Gelman, 2004). The new concepts thus constructed are vastly more powerful than the infant's initial numerical conceptions.

It is thus tempting to believe that a similar process differentiates the infant's implicit conception of beliefs from the 4-year-old's explicit concept. Perhaps infants have an efficient, but limited, system for representing a person's belief about simple perceptual experiences (e.g., where she thinks the watermelon is). As they grow older, children gradually acquire an independent system that supports much richer representations that can be integrated with other processes to allow sophisticated explanations for others' behaviors, flexible revisions of the beliefs, and even moral judgments about others based on their beliefs. However, adherents of this view need

to provide a characterization of the implicit versus explicit systems of ToM. What kind of competence does the implicit system support, and what are the key restrictions or limitations on the implicit conception? How does the explicit system overcome the limitations of the implicit one? In order to address this question, we need to go beyond the format of the tasks (i.e., looking-time or anticipatory looking versus explicit pointing or verbal responses) and focus on the nature of beliefs entertained by the two systems. Apperly and Butterfill (2009), for example, proposed that an implicit ToM might be limited to 'tracking attitudes to object's locations,' so infants might not be able to 'track beliefs involving both the features and the location of an object (e.g., 'the red ball is in the cupboard').' Since then, Baillargeon and colleagues have shown that infants can track this kind of belief too (e.g., the belief that 'the disassembled toy penguin is in the opaque box'; Scott and Baillargeon, 2009). However, this kind of proposal is precisely what is needed to give substance to the idea of two independent 'systems' for ToM.

Developmental cognitive neuroscience could make a key impact here. If implicit ToM and explicit ToM are truly distinct systems, they might have distinct neural mechanisms. The distinction might appear in the recruitment of different brain regions for implicit versus explicit ToM tasks. Alternatively, there might be two distinct temporal phases in the development of a single brain region (or group of regions): an early change corresponding to the initial development of an implicit ToM, and a later change when the same region is coopted for a qualitatively different explicit ToM. All of these possibilities remain to be tested.

20.2.2 Neuroimaging

Functional neuroimaging of children is a new research program, so very few fMRI studies have looked at the development of ToM brain regions. However, these few studies also pose challenges to the predictions of the Standard view. Specifically, the Standard view predicted that very young children rely on the pSTS representation of intentional actions, and that sometime around age 4 there is qualitative change in the neural representations of beliefs and desires. What the Standard model certainly did not predict was that the neural representations of both intentional action and ToM would show qualitative functional change in 5–10-year-old children. But that is exactly what the recent fMRI studies are finding.

The first demonstration of a neural response to intentional action in children was provided by Mosconi et al. (2005), who showed that the right pSTS in 7–10-year-old children is sensitive to the intentionality of action as in adults: while any gaze shift evokes activity in the right

pSTS, the activity is higher when the gaze shift is directed to unexpected locations than when the shift predictively follows a moving target. Interestingly, Carter and Pelphrey (2006) found a developmental change in the functional profile of this region much later than what the Standard view would predict. They measured brain activity in 7–10-year-old children while they viewed animated clips of biological (e.g., a person walking) and nonbiological motion (e.g., a grandfather clock moving). While biological motion induced higher activity than nonbiological motion in general, they found that this difference grows larger with age. These results suggest that although the right pSTS is already sensitive to intentional action before age 7, there are still ongoing changes in the specificity of response in this region well beyond this age (see Chapter 19). Therefore, the prediction of the Standard view that the right pSTS develops early in childhood before age 4 seems at least partly wrong.

Similarly, the few existing developmental fMRI studies on ToM (Kobayashi et al., 2007a, 2007b; Saxe et al., 2009) have all reported activations in similar brain regions in children that are shown to be recruited for ToM in adults: these areas include the bilateral TPJ, PC, and the MPFC. However, these studies also found developmental changes in the neural basis of ToM between school-age children and adults (Kobayashi et al., 2007a), or among school-age children (Saxe et al., 2009) in some of these regions.

In a recent study, Gweon et al. (2012) asked children between 5 and 12 years of age and adults to listen to stories inside the scanner and measured their brain responses to these stories. The stories described people's thoughts, beliefs, and feelings (mental condition), people's appearance and their social relationships (social condition), or purely physical events involving objects that do not involve people or their mental states (physical condition). The first question was whether children, just like adults, show higher responses to mental stories compared with physical stories. The answer was yes: the regions that were significantly more active to mental versus physical condition in children were strikingly similar to those found in adults (see Figure 20.1). However, there was an age-related change in how some these regions respond to the social stories. In the older half of the participants (8.5–12 years), the bilateral TPJ and PC did not respond to the social stories but only showed heightened activity to mental stories just like in adults. In contrast, the same brain regions in the younger half of the participants (5–8.5 years) responded to both mental and social stories, and did not discriminate stories with and without mental state content. That is, the selectivity of these regions to mental states increased with age. Saxe et al. (2009) found the same pattern (see Figure 20.4). In line with the studies on developmental change in the right pSTS, these results suggest that although the neural basis for ToM seems to be already in place before age 5, there are qualitative changes in the response selectivity of these brain areas that occur well past age 5. Furthermore, the selectivity in the RTPJ was correlated with children's performance outside the scanner on tasks designed to tap into later-developing aspects of ToM, such as making moral decisions based on mental states or understanding nonliteral utterances in context. The role of maturational factors and experience in the neural and behavioral development remains to be tested. However, these results provide initial evidence for a link between neural and cognitive development in ToM.

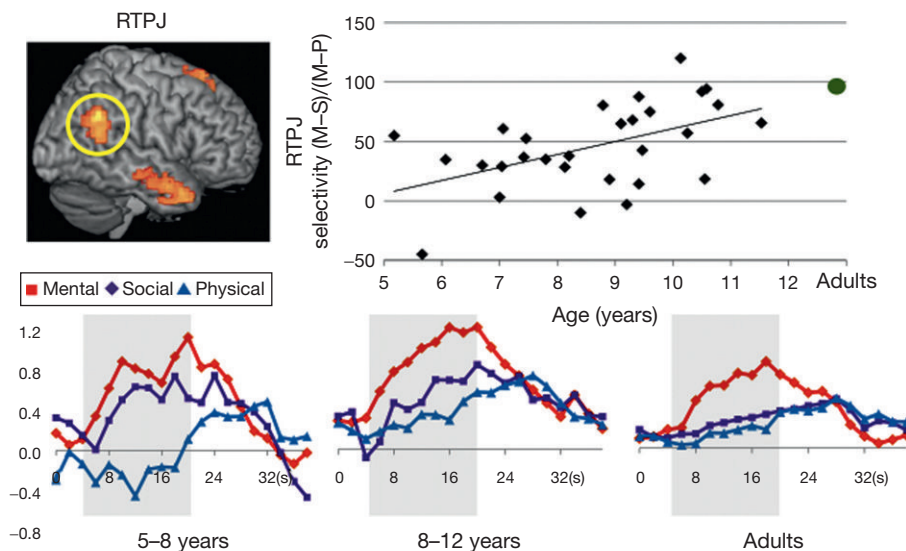
Rather than resolving the controversy between the Standard view and its more recent opponent, these results challenge both views and add another puzzle. The Standard view predicts that ToM brain regions


FIGURE 20.4 Developmental change in the RTPJ. The three graphs (bottom) show the time course of activation in the RTPJ in mental, social, and physical conditions in three different age groups (Gweon et al., 2012). The X-axis shows the time (seconds), and the Y-axis is the percent signal change in the activation relative to baseline. The stories were presented from 4 to 24 s, indicated by the shaded box. While the RTPJ in younger children responds to both mental and social conditions, the response to social conditions gets gradually lower as children grow older. That is, the RTPJ response becomes more 'selective' for mental stories. The scatterplot (upper right) shows that the selectivity of the RTPJ for mental, versus social, information becomes higher with age, in a cross-sectional sample of 32 children (combined data from Saxe et al., 2009; Gweon et al., 2012).

should show functional changes between the ages of 3 and 5 years. More recent data predict that significant changes in ToM brain regions should occur around the child's first birthday, when infants start to show signs of false belief understanding, with changes around age 4 years in regions supporting executive function. Therefore, the recent heated debates concerning the time course of development in the ToM mechanism have focused on these two age ranges (see Leslie, 2005; Perner and Ruffman, 2005; Scott and Baillargeon, 2009); neither predicted functional change in the neural basis of ToM well past 5 years of age.

Of course, these results do not provide direct evidence against either view, and these possibilities are not mutually exclusive. It remains possible that major changes occur in the ToM brain regions either around 12–15 months, or age 4 years, or both, supporting the acquisition of a concept of implicit and explicit false belief. However, if so, those hypothesized changes do not produce a brain region with a highly selective role in attributing mental states before 5 years of age: before age 8 years, children show normal brain regions involved in ToM (bilateral TPJ, PC, and regions in MPFC), but none of them are selectively recruited just for thinking about thoughts.

20.3 CONCLUSIONS

In sum, cognitive scientists have made foundational discoveries about the development of ToM in childhood, and about the neural basis of ToM in adulthood. Initially, these two independent methods of inquiry seemed to provide converging evidence of the structure of ToM: a domain-specific, human-unique mechanism that undergoes qualitative change in early childhood. Just recently, however, this unified view has begun to fracture, and much of what we thought we knew seems to be wrong.

The current evidence from behavioral studies of ToM suggests that infants have some understanding of false beliefs and how they affect actions, while 3-year-olds struggle to apply the same knowledge in similar tasks. Furthermore, while behavioral studies push the critical age for ToM development younger, neuroimaging studies suggest that the whole ToM system in the brain undergoes significant functional change much later, around age 8 years.

Of course, these puzzles may be partially due to the limitations in methods and the difficulty in using the same paradigm across different age groups. For example, standard false belief tasks have been mostly used for children past 3 years of age, whereas nonverbal false belief tasks using looking-time methods have been mostly used with infants and toddlers (but see Scott et al., 2012; Senju et al, 2009). This makes it difficult to directly test the differences in the nature of belief representations in infants and older children. Similarly, the available methods for measuring neural responses to these tasks vary by age. fMRI, which has been most extensively used for studies of ToM in adults and older children, is currently not useful for children younger than 4–5 years of age. In the future, it will be necessary to establish a clear relationship between fMRI results and those from other neuroimaging methods such as near infrared spectroscopy (NIRS), EEG, or magnetoencephalography (MEG), available for younger children.

The impact of a new understanding of the neural development of ToM could be tremendous. ToM deficit is a central issue in ASD. Knowing how brain regions for ToM emerge during typical development will provide the foundation for understanding how this development can go awry.

We are confident that the current uncertainty provides an important window of opportunity for new methods to make key theoretical contributions. We look forward to the emerging developmental cognitive neuroscience of ToM.

21.1 INTRODUCTION

Developmental affective neuroscience is an emerging area of research that has the potential to improve one's understanding of human social behavior by integrating theory and research into psychology, neuroscience, clinical psychology, and neuropsychiatry. Among the psychological processes that are the basis for much of social perception and smooth social interaction, empathy and sympathy play key roles. Empathy-related responding, including caring and sympathetic concern, motivates prosocial behavior, inhibits aggression, and paves the way to moral conduct. On the other hand, certain developmental disorders, such as conduct disorder (CD), are marked by psychopathic tendencies and empathy deficits, which likely influence antisocial responses to others' distress, for example, active aggression. Understanding how these behaviors are implemented in the brain, in both typically developing children and children with aggressive tendencies can help elucidate why empathy does or does not automatically lead to prosocial behavior.

This chapter critically examines one's current knowledge about the development of the mechanisms that support the experience of empathy and associated behavioral responses such as prosocial behavior. The affective and cognitive components that give way to empathy are reviewed, starting first with the automatic proclivity to share emotions with others, and then the cognitive processes of perspective taking and executive control, which allow individuals to be aware of the intentions

and feelings of others and keep separate self and other perspectives. The goal is to address the underlying cognitive and affective neural architecture that instantiates empathy and to examine the dysfunction of these processes in developmental disorders marked by social-cognitive impairments.

Based on the theoretical and empirical evidences from developmental psychology, cognitive neuroscience, and lesion studies, it can be argued that a number of distinct and interacting components contribute to the experience of empathy: (1) affective sharing, a bottom-up process grounded in affective arousal; (2) understanding emotion that relies on a sense of agency, self-awareness, and other awareness and critically involves the medial and ventromedial prefrontal cortex (vmPFC) and temporoparietal junction; and (3) executive functions instantiated in the prefrontal cortex, which operate as a top-down mediator, helping to regulate emotions, appraise social context, and yield mental flexibility (Decety, 2011; Decety and Jackson, 2004; Decety and Meyer, 2008).

Drawing from multiple sources of data can help paint a more complete picture of the phenomenological experience of empathy, as well as an understanding of the development and interaction between the respective mechanisms that drive the phenomenon. Furthermore, studying subcomponents of more complex psychological constructs such as empathy can be particularly useful from a developmental perspective because only some of its components or precursors may be observable. Developmental studies can provide unique opportunities to see how the components of the system interact in ways that are not possible in adults – where all the components are fully mature and operational (De Haan and Gunnar, 2009). Until quite recently, research on the development of empathy-related responding from a neurobiological level of analysis has been relatively sparse. It is believed that integrating this perspective with behavioral work can shed light into the neurobiological mechanisms underpinning the basic building blocks of empathy and sympathy and their age-related functional changes. Such integration can help to understand the neural processes that underpin prosocial behavior including pathological altruism while also benefiting interventions for individuals with atypical development, such as antisocial behavior problems.

21.2 CLEARING UP DEFINITIONAL ISSUES

The construct of empathy is applied to various phenomena that cover a broad spectrum. This spectrum ranges from feeling concern for others (creating a motivation to help them), experiencing emotions that match another individual's emotions, knowing what another is thinking or feeling, to blurring the line between self and other (Hodges and Klein, 2001).

Key concepts
- Empathy is a construct that can be decomposed into a model that includes bottom-up processing of affective sharing and emotion awareness and top-down processing in which the perceiver's motivation, memories, intentions, and self-regulation influence the extent of an empathic experience
- The experience of empathy can lead to sympathy, which refers to feelings of concern for the wellbeing of another. It includes another-oriented motivation or an egoistic motivation to reduce stress by withdrawing from the stressor in the case of personal distress
- Empathy and sympathy play key roles in motivating prosocial behavior and provide the affective and motivational foundation for moral development
- Empathy is implemented by a network of distributed, often recursively connected, interacting neural regions, including the brainstem, hypothalamus, superior temporal sulcus, insula, medial and orbitofrontal cortices, amygdala, and anterior cingulate cortex (ACC), as well as autonomic and neuroendocrine processes implicated in social behaviors and emotional states
- Neurodevelopmental studies provide unique opportunities to explore how the components of empathic responding interact in ways that are not possible in adults
- Investigating dysfunction of the components of empathy provides important clues for understanding deviations that can lead to the lack of empathy and concern for others

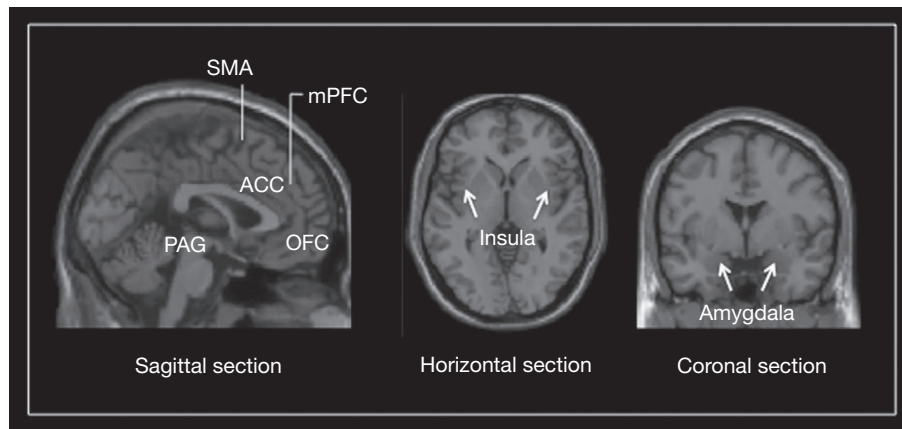
In developmental psychology and social psychology (the two academic disciplines that have produced most of the research on this subject), empathy is generally defined as an affective response stemming from the understanding of another's emotional state or a condition similar to what the other person is feeling or would be expected to feel in the given situation (Eisenberg et al., 1991). Other theorists more narrowly characterize empathy as one specific set of congruent emotions – those feelings that are more other-focused than self-focused (Batson, 2009; Batson et al., 1987). Very often, empathy and sympathy are conflated. Here, the authors distinguish between empathy (the ability to appreciate the emotions and feelings of others with a minimal distinction between self and other) and sympathy (feelings of concern about the welfare of others). While empathy and sympathy are often confused, the two can be dissociated. Although sympathy may stem from the apprehension of another's emotional state, it does not have to be congruent with the affective state of the other. The experience of empathy can lead to sympathy (which includes another-oriented motivation) or personal distress (an egoistic motivation to reduce stress by withdrawing from the stressor, thereby decreasing the likelihood of prosocial behavior). Emotion regulation is a critical component of empathy because the modulation of emotional experience allows the person to remain aware of a situation without being overwhelmed or


FIGURE 21.1   Brain regions that play crucial roles in the experience of empathy and associated phenomena such as sympathy labeled on sagittal, horizontal, and coronal sections of a structural MRI scan. Functional imaging studies reveal that the anterior insula and the anterior cingulate cortices are conjointly activated during the experience of emotion and during the perception of emotion in others. The insula provides a foundation for the representation of subjective bodily feelings, which substantiates emotional awareness. The ACC can be divided anatomically based on cognitive (dorsal) and emotional (ventral) components: the dorsal part is connected with the prefrontal cortex and parietal cortex as well as the motor system, making it a central station for processing top-down and bottom-up stimuli and assigning appropriate control to other areas in the brain; by contrast, the ventral part of the ACC is connected with amygdala (a structure involved in assigning affective significance to stimuli), ventral striatum, hypothalamus, and anterior insula and is involved in assessing the salience of emotion and motivational information. Many functions are attributed to ACC, such as error detection, anticipation of tasks, motivation, and modulation of emotional responses. The medial prefrontal cortex (mPFC) is critically associated with theory of mind processes and emotion understanding. The orbitofrontal cortex (OFC) is involved in sensory integration, in representing the affective value of reinforcers, and in decision making and expectation. In particular, the OFC is thought to regulate planning behavior associated with sensitivity to reward and punishment and is closely connected to the anterior insula and amygdala.

numbed by it. This is especially important in the case of negative arousal (Decety and Lamm, 2009). Developmental research also indicates that children who can regulate their emotions and emotion-related behavior should be relatively likely to experience sympathy rather than personal distress (Eisenberg and Eggum, 2009).

The complex construct of empathy can be decomposed into a model that includes bottom-up processing of affective sharing and top-down processing in which the perceiver's motivation, intentions, and self-regulation influence the extent of an empathic experience. Shared neural circuits, self-awareness, emotion understanding, and self-regulation constitute the basic macrocomponents of empathy, which are mediated by specific and interacting neural circuits, including aspects of the prefrontal cortex, ACC, medial prefrontal cortex (mPFC), orbitofrontal cortex (OFC), insula, limbic system, and frontoparietal attention networks (Decety, 2011). Consequently, this model assumes and predicts that dysfunction in either of these macrocomponents may lead to an alteration of the experience of empathy and corresponds with selective social cognitive disorders depending on which aspect is disrupted (Blair, 2005; Decety and Moriguchi, 2007; Figure 21.1).

It is also important to keep in mind that both interpersonal as well as contextual factors impact a person's subjective experience of empathy. For instance, mood states, relationship to the person, and the social context in which the interaction occurs influence the way and the extent to which the observer will react.

Recent affective neuroscience research with children and adult participants indicates that the affective, cognitive, and regulatory aspects of empathy involve interacting yet partially nonoverlapping neural circuits. Furthermore, there is now evidence for age-related changes in these neural circuits, which together with behavioral measures reflects how brain maturation influences the reaction to the distress of others (Decety and Michalska, 2010).

21.3 THE DEVELOPMENT OF EMPATHY

Empathy is one of the higher-order emotions that typically emerges as a child comes to a greater awareness of the experience of others, during the second and third years of life, and that arises in the context of someone else's emotional experience (Robinson, 2008). Each of the components of empathy (affective sharing, cognitive understanding, and emotion regulation) will be considered separately from both a developmental and neuroscience perspective. These components are indeed dissociable as documented in neurological patients (Strum et al., 2006), yet mature empathic sensitivity and concern depend on their functional integration in the service of goal-directed social behavior. In addition,

both genetic and environmental factors contribute to the development of empathy and prosociality (Knafo et al., 2008).

21.3.1 Affective Sharing

While there is some controversy concerning the nature of empathic responding in very young children, there is ample behavioral evidence demonstrating that the affective component of empathy develops earlier than the cognitive component. Affective responsiveness is known to be present at an early age, is involuntary, and relies on somato-sensorimotor resonance between other and self (Decety and Meyer, 2008). The general consensus of work in this area is that infants and toddlers are sensitive and responsive to others' emotional cues and that some of the basic building blocks of empathy, such as emotion sharing, are present in the first days of life.

Discrete facial expressions of emotion have been identified in newborns, including joy, interest, disgust, and distress (Izard, 1982), suggesting that subcomponents of full emotional experience and expression are present at birth and supporting the possibility that these processes are hardwired in the brain. Very young infants are able to send emotional signals and to receive and detect the emotional signals sent by others. Human newborns are capable of imitating expressions of fear, sadness, and surprise (Field et al., 1982; Haviland and Lewica, 1987), preparing individuals for later empathic connections through affective interactions with others. Moreover, both infant humans and nonhuman primates are known to respond to others' distress with distress. Infants exposed to newborn cries cry significantly more often than those exposed to silence and those exposed to a synthetic newborn cry of the same intensity (Dondi et al., 1999; Sagi and Hoffman, 1976). A study by Martin and Clark (1987), which examined infants' reactions to audiotapes of neonatal crying, showed not only that 1-day-old babies cry in response to other infant cries but also that newborns do not respond to the sound of their own cries. Together, these findings demonstrate that infants' auditory perception of another's aversive affective state elicits the same distressful emotional state in the self and suggests a neurobiologically based predisposition for humans to be connected to others. The latter results also indicate that there is some self–other distinction already functioning at birth.

Research using measures of facial electromyography (EMG) in adult participants demonstrates that viewing facial expressions triggers distinctive patterns of facial muscle activity similar to that of the observed expression, even in the absence of conscious recognition of the stimulus (Dimberg et al., 2000). In one such study, participants were exposed very briefly (56 ms) to pictures of happy or angry facial expressions and EMG was recorded from their faces (Sonnby-Borgstrom et al., 2003). Results demonstrated facial mimicry despite the fact that the participants were unaware of the stimuli. A study conducted with school-age boys demonstrated that angry and happy facial stimuli spontaneously elicit different EMG response patterns (de Wied et al., 2006). Angry faces evoked a stronger increase in corrugator activity than happy faces, while happy faces evoked a stronger increase in zygomaticus activity than angry faces. Such a mimicry mechanism may be driven by the so-called mirror neuron system (somatosensory motor neurons localized in the premotor, motor, and posterior parietal cortices) that directly links perception and action.

This automatic emotional resonance between other and self provides the basic mechanism on which intersubjective feelings develop. Infant arousal in response to the affects and emotions signaled by others can serve as an instrument for social learning, reinforcing the significance of the social exchange, which then becomes associated with the infant's own emotional experience. As a consequence, infants come to experience emotions as shared states and learn to differentiate their own states partly by witnessing the resonant responses that they elicit in others.

21.3.2 Emotion Understanding

Thus, it is clear that from very early on in development, infants are capable of emotional resonance, which is one important precursor of empathy (Hoffman, 2000). Although the capacity for two people to resonate with each other emotionally before any cognitive understanding is the basis for developing shared emotional meanings, it is not enough for mature empathic understanding. Such an understanding requires forming an explicit representation of the feelings of another person, an intentional agent, which necessitates additional computational mechanisms beyond the emotion-sharing level, as well as self-regulation to modulate negative arousal in the observer (Decety and Moriguchi, 2007; Decety et al., 2008). The cognitive components that give way to empathic understanding have a more protracted course of development than the affective components, even though many precursors are already in place very early in life.

Emotion understanding refers to conscious knowledge about emotion processes or beliefs about how emotions work. Such understanding includes the recognition of emotion expression and knowledge about one's own and others' emotions, the detection of cues for others' feelings, as well as ways of intentionally using emotion

expression to communicate to others (or vice versa; e.g., hiding emotions). Children's development of gradually more sophisticated understanding of emotion fosters many adaptive processes, such as social functioning and coping. Consequently, delayed or limited emotion understanding may place youth at risk for disorders.

As discussed in the previous section, children recognize facial expressions associated with emotions at an early age (Haviland and Lewica, 1987). Some questions remain as to whether these early reactions represent recognition of emotion in another or simple mimicry. Either way, most children are using emotion labels for facial expressions and are talking about emotion topics by the age of 2 years (Gross and Ballif, 1991). Recent work has also documented that even very young children (18–25 months old) can sympathize with a victim even in the absence of overt emotional cues (Vaish et al., 2009), which suggests some early form of affective perspective taking that does not rely on emotion contagion or mimicry. Prior work by Zahn-Waxler et al. (1992) demonstrated that prosocial behaviors (help, sharing, and provision of comfort) emerge between the ages of 1 and 2 and that these behaviors are linked to expressions of concern as well as efforts to understand the other's plight. Regarding the causes and effects of emotion and the cues used in inferring emotion, developmental research has detailed a progression from situation-bound, behavioral explanations of emotion to broader, more mentalistic understandings (Harris et al., 1981). For example, children's early explanations of emotion are largely based on the external world (e.g., 'I am sad because someone took my toy.'), whereas as children develop, their explanations of emotions focus more on internal causes (e.g., 'I am sad because that toy was important to me.'). As children develop, their emotional inferences contain a more complex and differentiated use of several types of information, such as moral variables (Nunner-Winkler and Sodian, 1988), relational and contextual factors, and the target child's goals or beliefs (Harris, 1994). This development appears to be somewhat slower for complex emotions such as pride, shame, or embarrassment (Lewis, 2000). Children also develop an understanding of multiple emotions, comprehending that a person can feel more than one emotion at a time. Development of this understanding proceeds from lack of acknowledgment of multiple emotions in younger children, to acknowledgment, and to an appreciation of different variables, such as emotion valence and emotion intensity (e.g., one very strong and one very weak emotion are easier to understand than two strong ones; Carroll and Steward, 1984).

Understanding that appraisal can modulate a person's emotional experience to a given situation develops from being desire-based to being belief-based. At first, 2- and 3-year-old children understand the role that desires or goals play in determining a person's appraisal and ensuing emotion (Repacholi and Gopnik, 1997). By 18 months, infants can not only infer that another person can hold a desire that may be different from their own but also recognize how desires are related to emotions and understand something about the subjectivity of these desires. By 4 and 5 years of age, this desire-based concept of emotion develops to include beliefs and expectations. Children at this age begin to understand that an emotion is not necessarily triggered by whether or not a desire and an outcome match but rather whether a desire and an expected outcome match. The shift from a desire to a belief–desire conception of mind and emotion is well established. For example, Bartsch and Wellman (1995) have examined children's references to other people's mental states and demonstrated that children talk systematically about desires and goals throughout their third year, but that beginning at about their third birthday, children also begin to make reference to beliefs. At about 5 years of age, talk about beliefs becomes as frequent as talk about desires.

Young children's understanding of emotions has been shown to be related to a number of factors, including children's language ability, family discourse about feelings, and the quality of family relationships. Families vary in the linguistic environment that they offer to children for the interpretation and regulation of emotion. A child with a parent who frequently discusses emotions will have a different kind of conversation partner than a child with a parent who is much more controlled in talking about emotions. Research has established that there is indeed substantial variation among the extent to which emotions are discussed in the home. The frequency with which children engage in discussion about emotions and their causes is correlated with their later ability to identify how someone feels (Brown and Dunn, 1996). While it is possible that such a correlation reflects some disposition of the child that manifests itself in both talking about emotions and sensitivity to emotions, it is more likely that frequent family discussion may prompt children to talk about emotion and increase their understanding and perspective-taking abilities (Harris, 2000). Consistent with this idea, Lewis (2000) demonstrated that 3-year-olds who normally do poorly on a standard test of psychological understanding (the false belief task) perform better if they are prompted to structure the events leading to the false belief into a coherent narrative. Allowing children to express emotion and report on current and past emotions also provides them with an opportunity to share, explain, and regulate emotional experience. Conversation helps to develop empathy, for it is often here that people learn of shared experiences and feelings.

With cognitive empathy, an individual is thought to use perspective-taking processes to imagine or project

into the place of the other in order to understand what she/he is feeling. This aspect of empathy is closely related to processes involved in mental state attribution (also known as theory of mind), which requires executive functions such as cognitive flexibility, inhibitory control, and working memory (Decety and Jackson, 2004; Stone and Gerrans, 2006). While relatively little is known about whether children who have a strong grasp of mental states also are advanced in their understanding of emotions, emotion understanding and mental state understanding seem to engage common, as well as distinct, computational processes. When seeing another child who is upset, a child has to hold two different perspectives in mind in order to correctly identify what that child is feeling and comfort them and their own perspective (and emotions), which may not be congruent with that of the other child, and the point of view of the other child. There is indeed some evidence for a link between understanding of mental state reasoning and emotion. Several studies have shown that by around 4 years of age, children can appreciate that the emotion a person feels about a given event depends on that person's perception of the event and their beliefs and desires about it. Hughes and Dunn (1998) conducted a longitudinal study of 50 children aged 47–60 months, examining developmental changes in understanding of false belief and emotion and mental state in their conversation with friends. They found that individual differences in understanding of both false belief and emotion were stable over this time period and were significantly related to each other.

Emotion recognition continues to develop into later adolescence (Tonks et al., 2007), which might improve social cognition performance. Social performance as a whole continues to improve into adulthood, but it is unclear if this reflects changes in social cognition *per se* or the continued development of cognitive functions that are not specific to social behavior, such as declarative knowledge, metacognition, speed of processing, and working memory.

Neuroimaging studies that have examined the neural systems engaged during mental state understanding in adults consistently identify a neural network involving the mPFC, the posterior temporal cortex at the junction of the parietal cortex (TPJ), and the temporal poles (e.g., Brunet et al., 2000; Frith and Frith, 2003). These regions were activated in children aged 6–11 years, while they listened to sections of a story describing a character's thoughts compared to sections of the same story that described a physical context (Saxe et al., 2009). Furthermore, change in response selectivity with age was observed in the right TPJ, which was recruited equally for mental and physical facts about people in younger children, but only for mental facts in older children. Further support for age-related changes in brain activity

associated with metacognition is provided by a neuroimaging investigation of theory of mind in participants whose age ranged between 9 and 16 years (Moriguchi et al., 2007). Both children and adolescents demonstrated significant activation in the neural circuits associated with mentalizing tasks, including the TPJ, the temporal poles, and the mPFC. Furthermore, the authors found a positive correlation between age and the degree of activation in the dorsal part of the mPFC. Direct evidence for the implication of these regions during accurate identification of interpersonal emotional states was documented in a recent functional magnetic resonance imaging (fMRI) study in which participants were requested to rate how they believe target persons felt while talking about autobiographical emotional events (Zaki et al., 2009).

In sum, the neural circuits implicated in emotion understanding largely overlaps with those involved in ToM processing, especially the mPFC and right TPJ. They continue to undergo maturation until late adolescence.

21.4 EMOTION REGULATION

The regulation of internal emotional states and processes is particularly relevant to the modulation of vicarious emotions and the experience of empathy. Given the shared nature of the representations of one's own emotional states and others' emotional states, it would seem difficult not to experience emotional distress while viewing another's distressed state (while personal distress does not contribute to the empathic concern and prosocial behavior). Personal distress can actually deter one's inclination to soothe another person's distress. It is, therefore, adaptive for this automatic sharing mechanism between self and other to be modulated by cognitive control. To this end, executive functions (i.e., the processes that serve to monitor and control thoughts and actions, including effortful control, planning, cognitive flexibility, and response inhibition; Russell, 1996), work in a top-down fashion to regulate one's inclinations to be biased in one's self-perspective while judging another person's emotional state and promoting a sympathetic regard for the other, rather than a desire to escape aversive arousal (Decety, 2005). Difficulty in the ability to regulate emotions can result in deleterious emotional arousal, thereby hindering the ability to socially function adaptively and appropriately.

Although research on emotion regulation has increased rapidly in the past decade, definitions of emotion regulation have typically been implied and not stated. While researchers agree that the construct of emotion regulation involves both emotion as a *behavior regulator* and emotion as a *regulated phenomenon*, the authors

emphasize the latter – that is, how one attempts to regulate emotion – and examine various regulatory processes. As an example, Thomson (1994) defined emotion regulation as the extrinsic and intrinsic processes responsible for monitoring, evaluating, and modifying emotional reactions especially their intensive and temporal features, to accomplish one's goals.

Sympathy is strongly related to effortful control, with children high in effortful control showing greater empathic concern (Rothbart et al., 1994). A number of developmental studies conducted by Eisenberg and her colleagues (1994) found that individual differences in the tendency to experience sympathy versus personal distress vary as a function of dispositional differences in individuals' abilities to regulate their emotions. Well-regulated children who have control over their ability to focus and shift attention have been found to be relatively prone to sympathy regardless of their emotional reactivity. This is because they can modulate their negative vicarious emotions to maintain an optimal level of emotional arousal. In contrast, children who are unable to regulate their emotions, especially if they are dispositionally prone to intense negative emotions, are found to be low in dispositional sympathy and prone to personal distress (Eisenberg et al., 1994).

Interestingly, the development of executive functions is functionally linked to the development of mental state understanding. There is now increasing evidence of a specific link between the development of mentalizing and improved self-control at around the age of 4 years (Carlson and Moses, 2001). Improvement in inhibitory control corresponds with increasing metacognitive abilities (Zelazo et al., 2004), as well as with maturation of brain regions that underlie working memory and inhibitory control (Tamm et al., 2002). A series of studies by Posner and Rothbart (2000) strongly suggest that executive regulation undergoes dramatic change during the third year of life.

Emotion regulation taps into executive function resources implemented in the prefrontal cortex (Zelazo et al., 2008), with different regions subserving distinct functions. Ventral and dorsal regions of the prefrontal cortex have been associated with response inhibition and self-control, which are both key components of emotion regulation (Ochsner et al., 2002). Support for this hypothesis in the domain of empathy comes from a study that compared the neurohemodynamic response in a group of physicians and a group of matched control participants when they were exposed to short video clips depicting hands and feet being pricked by a needle (painful situations) or being touched by a Q-tip (non-painful situations; Cheng et al., 2007). Unlike control participants, physicians showed a significantly reduced neurohemodynamic empathic response in the anterior insula, anterior medial cingulate cortex (aMCC), and

dorsal anterior cingulate cortex (dACC) and no activation of the periaqueductal gray (PAG; a mediator of the flight-or-fight response) when shown video clips of body parts being pricked by a needle. Instead, cortical regions underpinning executive functions and self-regulation (dorsolateral and mPFC) and executive attention (precentral, superior parietal, and temporoparietal junction) were found to be activated. Connectivity analysis further demonstrated that activation in the medial and dorsolateral prefrontal cortices subserving executive control and self-regulation (Ochsner and Gross, 2005) was inversely correlated with activity in the insular cortex in the physicians, indicating executive suppression of the emotional response to the others' pain.

It is well documented that the prefrontal cortex and its functions follow an extremely protracted developmental course and age-related changes continue well into adolescence (Bunge et al., 2002; Casey et al., 2005; Sowell et al., 1999). Frontal lobe maturation is associated with an increase in a child's ability to activate areas involved in emotional control and exercise inhibitory control over their thoughts, attention, and action. The maturation of the prefrontal cortex also allows children to use verbalizations to achieve self-regulation of their feelings (Diamond, 2002). It is, therefore, likely that different parts of the brain may be differentially involved in empathy at different ages. For example, Killgore et al. (2001) and Killgore and Yurgelun-Todd (2007) provided evidence that as a child matures into adolescence there is a shift in response to emotional events from using more limbic-related anatomic structures, such as the amygdala, to using more frontal lobe regions to control emotional responses. Thus, not only may there be less neural activity related to the regulation of cognition and emotion in younger individuals but the neural pattern itself is likely to differ.

21.5 PERCEIVING OTHER PEOPLE IN DISTRESS

Pain evolved as a protective function by not only warning a person suffering that something is awry but also impelling expressive behaviors that attract the attention of others. It has been argued that the long history of mammalian evolution has shaped maternal brains to be sensitive to signs of suffering in one's own offspring (Haidt and Graham, 2007). In many primates and other social animals, this sensitivity extends beyond the mother–child relationship, so that all typically developed individuals dislike seeing others suffering.

A growing number of functional MRI studies have demonstrated that the same neural circuits involved in the experience of physical pain are also involved in the perception or the imagination of another individual in

pain (Jackson et al., 2006). This neural network includes the supplementary motor area (SMA), cerebellum, dACC, aMCC, and anterior insular cortex. In addition, studies using different modalities of neuroimaging including transcranial magnetic stimulation (Avenanti et al., 2005), somatosensory-evoked potentials (Bufalari et al., 2007), functional MRI (Lamm et al., 2007), and magnetoencephalography (Cheng et al., 2008) indicate that areas processing the sensory dimension of pain (the somatosensory cortex and posterior insula) are also activated by the mere visual perception of others' pain. It is worth mentioning, however, that activation of these regions reflects a general aversive response not specific to nociception (i.e., the neural processing of noxious stimuli). This network of regions underpins a physiological mechanism that mobilizes the organism to react – with heightened arousal and attention – to threatening situations. The dACC plays a key role in conflict monitoring; the aMCC is involved in autonomic regulation associated with processing of fear and anxiety; the anterior insula processes visceral bodily sensations; the PAG integrates physiological changes in response to stress, and in the context of danger, the SMA as a result of feedback from the limbic system represents one anatomical substrate for activating motor responses associated with danger and threats (Decety, 2011; Yamada and Decety, 2009).

Distress, of course, often does not occur in a social vacuum. The social context in which pain occurs influences cognitive appraisal and the neural mechanisms underpinning its perception in the observer. To evaluate whether the neural processing in the pain matrix is modulated by social context, a study that compared patterns of brain activation while adult participants observed painful situations occurring by accident and painful situations intentionally caused by another individual (Akitsuki and Decety, 2009). Since pain is the result of a type of social interaction in the latter situation, its recognition is likely to involve not only the perception of pain but also the cognitive evaluation of the social interaction.

Results show that attending to painful situations caused by accident is associated with activation of the pain matrix, including the aMCC, insula, PAG, and somatosensory cortex. Interestingly, when watching another person intentionally inflicting pain onto another, regions that are consistently engaged in mental state understanding and affective evaluation (mPFC, TPJ, OFC, and amygdala) were additionally recruited. Furthermore, stronger connectivity between the left amygdala and the vmPFC was found when participants perceived painful situations caused by another individual relative to situations where pain occurred accidentally. These data demonstrate the impact of social context on the neural response to the perception of others' pain. Similar data were obtained with a group of young children (Decety et al., 2008) and adolescents (Decety et al., 2009). When watching sympathy-eliciting stimuli, increased effective connectivity was found between regions of the mPFC and the frontoparietal supramodal attention network, as well as between the right TPJ and the mPFC.

21.6 NEURODEVELOPMENTAL CHANGES IN EMPATHIC RESPONDING

One limitation of these above-mentioned studies is that they cannot capture any continuous functional changes across age. This is unfortunate because among areas of the brain undergoing considerable remodeling from childhood to adolescence is the prefrontal cortex, both dorsal and ventromedial, which plays a key role in understanding and experiencing social emotions (Kringelbach and Rolls, 2004; Shamay-Tsoory et al., 2006). Furthermore, both the insula and the amygdala may differentially contribute to the experience of interpersonal sensitivity during development. While human neuroimaging studies using pain empathy paradigms all report activations in the insula, no systematic attention has been paid to the anatomical subdivisions of the insula, particularly regarding their respective functional contribution across age.

To examine age-related changes associated with empathy and sympathy, functional MRI and behavioral data were collected from a group of 57 participants ranging from 7 to 40 years of age (Decety and Michalska, 2010). Results at the whole group level showed that attending to accidentally caused painful situations was associated with activation of the pain matrix, including the aMCC, insula, PAG, and somatosensory cortex. Interestingly, when watching one person intentionally inflicting pain onto another, regions that are consistently engaged in mental state understanding and affective evaluation (mPFC, TPJ, and OFC) were also recruited. The younger the participants, the more strongly the amygdala, posterior insula, and SMA were recruited when they watched painful situations that were accidentally caused. While participants' subjective ratings of the painful situations decreased with age and were significantly correlated with hemodynamic response in the mPFC, increases in pain ratings were correlated with bilateral amygdala activation (Figure 21.2).

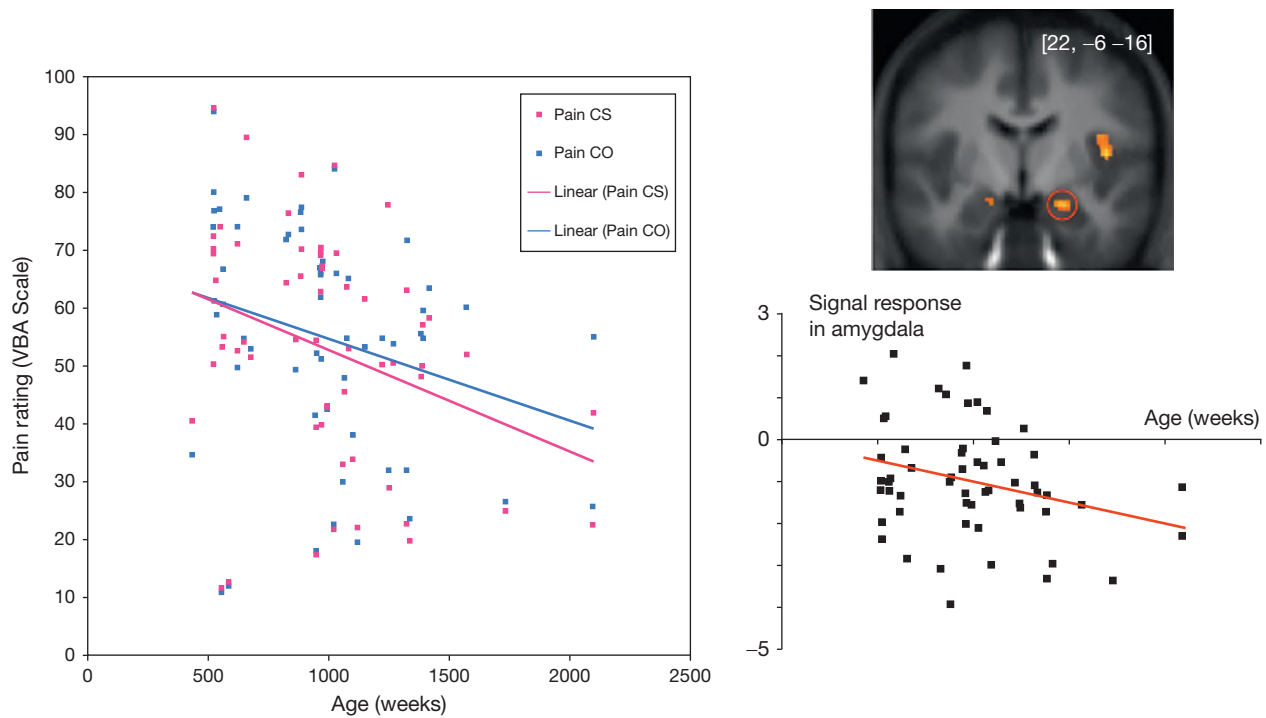
A significant negative correlation between age and degree of activation was found in the posterior insula. In contrast, a positive correlation was found in the anterior portion of the insula. A posterior-to-anterior progression of increasingly complex rerepresentations in the human insula is thought to provide a foundation for the sequential integration of the individual homeostatic


FIGURE 21.2 Left: Subjective ratings to dynamic visual stimuli depicting painful situations accidentally caused by self (Pain CS) and painful situations intentionally caused by another individual (Pain CO) across age (in weeks) in 57 participants (from 7 to 40 years old). A gradual decrease in the subjective evaluation of pain intensity for both painful conditions was found across age, with younger participants rating them significantly more painful than older participants (for Pain CS $r = -0.327$, $p < 0.01$; for Pain CO $r = -0.267$, $p < 0.05$). Further, while on an average participants rated the pain caused intentionally (Pain CO) conditions as significantly more painful than when pain was accidentally caused by self (Pain CS; $t(56) = 2.581$, $p < 0.01$), this effect was not driven by age. Right: Significant negative correlation between age and degree of activation in the amygdala when the participants are exposed to painful situations accidentally caused. *Adapted from Decety J and Michalska KJ (2010) Neurodevelopmental changes in the circuits underlying empathy and sympathy from childhood to adulthood.* Developmental Science *13: 886–899.*

condition with one's sensory environment and motivational condition (Craig, 2004). The posterior insula receives inputs from the ventromedial nucleus of the thalamus that is highly specialized to convey emotional and homeostatic information such as pain, temperature, hunger, thirst, itch, and cardiorespiratory activity. It serves as a primary sensory cortex for each of these distinct interoceptive feelings from the body. The posterior part has been shown to be associated with interoception, due to its intimate connections with amygdala, hypothalamus, and cingulate and orbitofrontal cortices (Jackson et al., 2006). It has been proposed that the right anterior insula serves to compute a higher-order metarepresentation of the primary interoceptive activity, which is related to the feeling of pain and its emotional awareness (Craig, 2003).

Results from this study also showed that activation in the OFC in response to sympathy-eliciting stimuli shifts from the engagement of the medial portion in young participants to the lateral portion in older participants. The medial OFC appears integral in guiding visceral and motor responses, whereas lateral OFC integrates the external sensory features of a stimulus with its impact on the

homeostatic state of the body (Hurliman et al., 2005). Greater signal change with increasing age was associated with prefrontal regions that are responsible for cognitive control and response inhibition, such as the dorsolateral prefrontal cortex (dlPFC) and the inferior frontal gyrus (IFG). Indeed, the older the participants the greater the activity in the dlPFC and IFG, which are involved in cognitive control and response inhibition (Kawashima et al., 1996; Swick et al., 2008). This is in line with evidence that regulatory mechanisms continue into late adolescence and early adulthood.

Overall, this pattern in the amygdala and insula can be interpreted in terms of the frontalization of inhibitory capacity, hypothesized to provide a greater top-down modulation of activity within more primitive emotion-processing regions (Yurgelun-Todd, 2007). This finding provides neurophysiological support for developmental studies showing that emotion regulation is an important aspect of empathy and sympathy, especially in relation with prosocial behavior. Indeed, this pattern of developmental change in the OFC appears to reflect a gradual shift between the monitoring of somatovisceral responses in young children, mediated by the medial aspect of the

OFC, and the executive control of emotion processing implemented by its lateral portion in older participants.

In light of these neurophysiological considerations, the authors posited that the anatomical progression (from sensory to emotional awareness) parallels the neurodevelopmental response to seeing people in pain or distress. In other words, a visceral response to painful stimuli associated with danger and negative affect is less likely to occur with increasing age and such a response may be replaced by a more detached appraisal of the stimulus. This was indeed confirmed by having participants rate the pain of the people in the clips outside of the scanner. It was found that on an average, all participants rated the pain caused intentionally conditions as significantly more painful than when pain was caused accidentally by the self. Interestingly, the results also indicated a gradual decrease in the subjective evaluation of pain intensity for both these conditions across age, with younger participants rating them as significantly more painful than older participants. Moreover, while decreases in pain evaluation were significantly correlated with hemodynamic response in the mPFC, increases in pain ratings were correlated with bilateral amygdala and somatosensory cortex activation. These behavioral results are important for interpreting region-specific differences in activation with age as reflecting functional maturation and not simply differences in performance.

In sum, the behavioral evaluations of pain intensity and the pattern of brain activation from childhood to adulthood reflect a gradual change from a visceral emotional response critical for the analysis of the affective significance of stimuli to a more evaluative function.

21.7 ATYPICAL EMPATHIC PROCESSING IN CHILDREN WITH ANTISOCIAL BEHAVIORAL DISORDERS

Children and adolescents diagnosed with antisocial behavioral disorders are marked by lack of regard for others, inability to feel remorse, and even a derivation of pleasure from the distress of others. It has been hypothesized that empathy and sympathetic concern for others are essential factors inhibiting aggression toward others (Eisenberg, 2005; Zahn-Waxler et al., 1995). That is, if a person vicariously experiences the distress that they have caused to others because of their aggression, they will be less likely to continue to hurt others and more likely to help them. Conversely, lack of sympathy is an important risk factor for antisocial behavior problems such as CD (Lahey and Waldman, 2003). The propensity for aggressive behavior has been thought to reflect a blunted empathic response to the suffering of others (Blair and Blair, 2009) and may be a consequence of a failure to be aroused by others' distress (Raine, 1997).

It has also been suggested that aggressive behavior can arise from abnormal processing of affective information, resulting in a deficiency in experiencing fear, empathy, and guilt, which in normally developing individuals, inhibits acting out violent impulses (Davidson et al., 2000).

Another hypothesis regarding the relation between affect and aggression can be drawn from the research with animal models and psychiatric populations, which indicates that there may in fact be no blunting of the emotional response toward the other. Rather, heightened emotional reactivity, potentially coupled with diminished regulatory processes may trigger aggressive impulses (Coccaro et al., 2007). This emotional reaction can have either a negative or a positive valence. Previous work has shown that negative affect is generally positively associated with aggression, suggesting that empathic mimicry in conjunction with poor emotion regulation might produce negative affect that increases aggression. For instance, there are numerous empirical studies that document that physical pain often instigates aggressive inclinations (Berkowitz, 1993). The role of heightened negative emotional arousal in antisocial boys, including callous disregard for victims in distress (either caused or observed by aggressive youth) has been examined in young children with normative, subclinical, or clinical levels of behavior problems (Hastings et al., 2000). Results showed that this process can develop early. Boys (but not girls) with clinical levels of aggressive/disruptive problems showed more callous disregard toward victims during simulated distresses than typically developing children (at 4–5 years and again at 7 years). Despite this, 4- to 5-year-old children with clinical problems also showed as much empathic concern as controls at ages of 4–5 years. But by 7 years of age, the clinical group was less empathic than controls according to parent, teacher, and child reports, as well as when observed in the laboratory. Thus, early emotional negativity/callous disregard may have long-term adverse effects.

A recent study by Cheng et al. (2012) found that incarcerated juvenile psychopaths who scored high callous–unemotional traits, compared to participants with low callous–unemotional traits exhibited a reduced frontal N120 (measured with ERPs) in response to visual stimuli depicting people in pain, indicating an absence of early affective arousal. However, there was no deficit in sensorimotor resonance in both groups, as assessed by measures of the *mu* suppression over the sensorimotor cortex, which is considered as a reliable index of the mirror neuron system. This finding indicates that affective arousal is not mediated by the mirror neuron system.

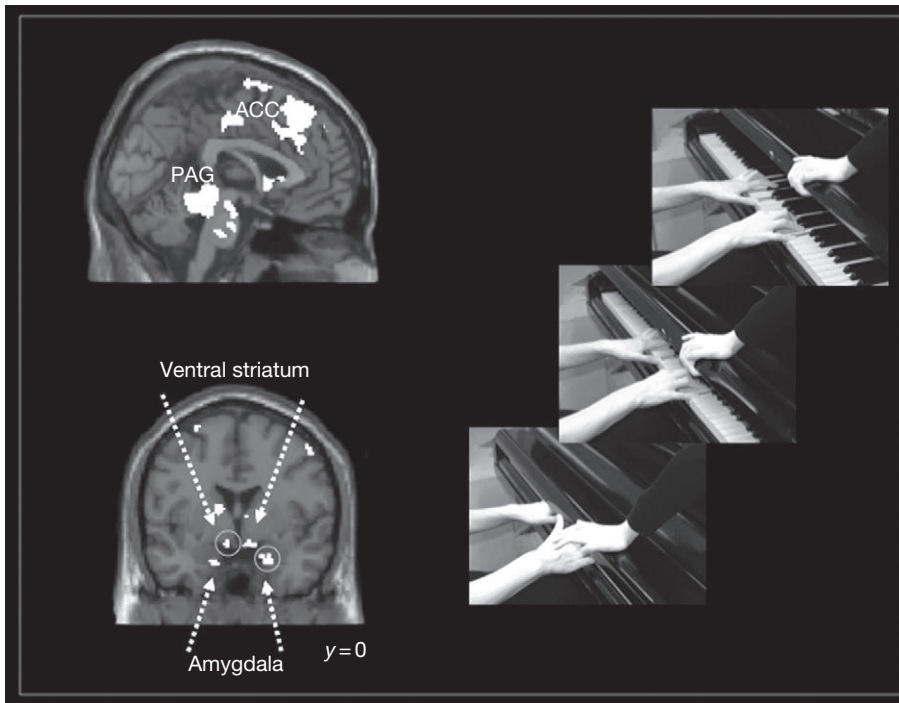
In an fMRI study by Decety et al. (2009), two groups of 16–18-year-olds (matched on age, sex, and race–ethnicity) were scanned using the same animated stimuli and procedures as used with normally developing


FIGURE 21.3 When youth with aggressive conduct disorder (CD) watch an individual intentionally hurting another (such as closing a piano lid), regions of the brain that process nociceptive information were activated (anterior insula, dorsal and ventral ACC, somatosensory cortex, and PAG), as well as the amygdala and ventral striatum which are part of the neural circuit involved in reward processing. These latter regions were not engaged in healthy control adolescents. Dispositional ratings of daring and sadism in youth with CD correlated with amygdala and striatal response ($p < 0.005$). These adolescents seem to enjoy seeing people in pain, and this may be rewarding and lead to repeated aggression. *Adapted from Decety J, Michalska KJ, Akitsuki Y, and Lahey B (2009) Atypical empathic responses in adolescents with aggressive conduct disorder: A functional MRI investigation.* Biological Psychology *80: 203–211.*

children (Decety et al., 2008, 2010). Results showed that the pain matrix (anterior insula, aMCC, and PAG) was significantly activated in both groups when viewing others in pain, but there was significantly greater activation of the pain matrix and somatosensory cortex in adolescents with CD than in non-CD controls (Figure 21.3).

This suggests that youth with CD do not fail to respond to viewing pain in others. Indeed, this somatic sensorimotor resonance was significantly greater in participants with CD than those without CD. In addition, there was significantly greater activation of the temporal pole in youth with CD than in controls. The temporal pole is part of a system that modulates visceral responses to emotionally evocative stimuli, and electrical stimulation of the TP produces increases in heart rate, respiration, and blood pressure (Gloor et al., 1982). In addition, the temporal poles are tightly connected with the limbic system and project to the hypothalamus, a neuromodulatory region important for autonomic regulation. There is evidence that the temporal pole is involved in the processing of both positive and negative affects (Olson et al., 2007).

Furthermore, adolescents with CD exhibited significantly greater activation of both the amygdala and the ventral striatum when viewing others in pain versus others not in pain. It was also observed that in participants with CD, the extent of amygdala activation to viewing pain in others was positively correlated with their number of aggressive acts and their ratings of daring and sadism scores on the child and adolescent

dispositions scale (CADS). This is consistent with greater affective response in youth with CD to viewing others in pain.

What these findings suggest is that individuals with CD actually react to viewing pain in others at least similarly or possibly to a greater extent in some important brain regions than youth without CD, especially in the insula, amygdala, and aMCC. This stands in contrast with one previous fMRI study that reported reduced amygdala response in youth with CD during the viewing of pictures with negative emotional valence (Marsh et al., 2008). The study by Decety and colleagues suggests that youth with CD do not exhibit reduced amygdala response to all negatively valenced stimuli; indeed, they appear to exhibit enhanced response to images of people in pain, including a specific activation of the ventral striatum.

Different patterns of response were detected in the OFC across the two groups. While the lateral OFC was selectively activated in control participants when observing pain inflicted by another, activation of the medial OFC was found in the participants with CD. A direct comparison between the groups confirmed this finding. The OFC/mPFC has been specifically implicated in a variety of areas relevant to CD and aggression, including the regulation of negative affect (Phan et al., 2005). Importantly, functional connectivity analyses demonstrated significantly greater amygdala/PFC coupling when watching pain being intentionally caused by another individual in the control group than those

in the CD group. In particular, in healthy adolescents, left amygdala activity covaried with activity in the prefrontal cortex to a greater extent while watching situations of pain being intentionally caused compared to viewing accidentally caused pain. Adolescents with CD showed no significant functional connectivity between frontal regions and the amygdala.

These findings are consistent with at least two hypotheses that are currently being investigated with younger children who meet diagnosis for CD:

– The first hypothesis is that highly aggressive antisocial youth enjoy seeing their victims in pain and, because of their diminished PFC/amygdala connectivity, may not effectively regulate positively reinforced aggressive behavior. The amygdala is involved in the processing of more than just negative affect. Several studies point to a role for the amygdala in positive affect, and its coupling with the striatum enables a general arousing effect of reward (Murray, 2007). It is possible, therefore, that the robust hemodynamic response in the amygdala to viewing others in pain in youth with aggressive CD reflects a positive affective response (e.g., 'enjoyment' or 'excitement'). The finding that CADS ratings of daring items (which reflect enjoyment of novel and risky situations) and sadism items (which reflect enjoyment of hurting others or viewing people or animals being hurt) correlated positively with amygdala response in youth with CD is in line with this hypothesis. In addition, this interpretation is consistent with the significant activation among youth with aggressive CD of the ventral striatum, which is part of the system implicated in reward and pleasure, among other things.

– The second hypothesis is that youth with CD have a lower threshold for responding to many situations with negative affect, including viewing pain in others, and are less able to regulate these negative emotions through cortical processes. Many studies indicate that individuals with CD tend to respond to aversive stimuli with greater negative affect than most other youth (Lahey and Waldman, 2003). This is potentially important as their negative affect may increase the likelihood of aggression, especially in the absence of effective emotion regulation (Berkowitz, 2003). This interpretation fits well with the hypothesis of a dysfunction in the neural circuitry of emotion regulation (Davidson et al., 2000) and is consistent with the analyses of effective PFC/amygdala connectivity. Aggression may be related to instability of negative affect and poor impulse control (Raine, 2002). Children with aggressive behavior problems have difficulties regulating negative emotions, which may result in harmful patterns of interpersonal behavior. Often triggered by hypersensitivity to specific stimuli, aggressive adults experience escalating agitation followed by an abrupt outburst of aggressive and threatening behavior (Gollan et al., 2005). Failure to discriminate between pain to others and to oneself may further lead to negative emotion when viewing others in pain. Research with nonhumans demonstrates that physical pain often elicits aggression (Berkowitz, 2003). It has been hypothesized that aggressive persons are disposed to experience negative affect (Lahey and Waldman, 2003). This suggests that in certain situations, empathic mimicry might produce high levels of distress in youth predisposed to be aggressive that, ironically, increases their aggression. It is possible that strong activation of neural circuits that underpin actual pain processing is associated with negative affect in youth with CD. This, in conjunction with reduced activation in areas associated with emotion regulation, could result in a dysregulated negative affective state, which may instigate aggression under some circumstances. For example, youth with CD who see an injured friend (or fellow member of a gang) may be more likely to respond aggressively than other youth for this reason. Finally, the strong and specific activation of the amygdala and ventral striatum in the aggressive adolescents with CD during the perception of pain in others is an important and intriguing finding, which necessitates additional research in order to understand the relative roles of negative and positive affect when viewing others in pain in aggression and empathic dysfunction.

Overall, youth with aggressive CD show atypical patterns of hemodynamic response and effective connectivity in regions that regulate emotion when exposed to the distress of others, as well as reward-related activation. More work is needed to disambiguate how such abnormal emotional processing is associated with callous disregard for others, insensitivity to their distress, or even enjoyment that may lead to rewarding offending behavior.

21.8 CONCLUSION

Empathy and sympathy develop as a result of complex biological and psychological processes involving emotion sharing, emotional regulation, mental state understanding, and cognitive abilities that are continuously interactive between the individual and the social environment. Empathy can be viewed as both intrapersonal and interpersonal processes. Breaking down empathy and related phenomena into components and

examining their neurodevelopment can contribute to a more complete model of interpersonal sensitivity. Likewise, drawing from multiple sources of data can improve one's understanding of the nature and causes of empathy deficits in individuals with antisocial behavior disorders. Recent advances in cognitive neuroscience indicate that distinct but interacting brain circuits underpin the different components of empathy, each having their own developmental trajectory.

One important direction for future research is investigating the functional link between empathy, prosocial behavior, and reward. Several studies have documented that the frontomesolimbic reward network is engaged to the same extent when individuals receive monetary rewards and when they freely choose to donate money to charity, and even more so when they are observed by others, suggesting that altruism draws on general mammalian neural systems of reward and social attachment (e.g., Izuma et al., 2010; Moll et al., 2006). Thus, prosocial behaviors may stem from a plurality of motives and intertwined social and motivational contingencies. For instance, witnessing people in pain or distress triggers a neural response associated with aversion. This response, in turn, may initiate helping or soothing behaviors motivated to both reduce one's own discomfort and to feel good about oneself, as well as to lessen another's distress. These behaviors may be reinforced by both endogenous reward (dopamine system) and positive social feedback from others.

Given the importance of empathy for healthy social interaction, it is clear that a developmental approach using functional neuroimaging to elucidate the computational mechanisms underlying affective reactivity, regulation and behavioral outcomes is essential to complement traditional behavioral methods and gain a better understanding of how deficits may arise in the context of development.

22.1 INTRODUCTION

William James (1890) defined attention as follows:

> Attention is the taking possession of the mind in clear and vivid form of one out of what seem several simultaneous objects or trains of thought.

James' definition, however, provides little perspective toward an understanding of the normal development of attention or its pathologies. The theme of this chapter is that it is now possible to view attention much more concretely as an organ system. The authors follow the Webster's Dictionary definition of an organ system:

> An organ system may be defined as differentiated structures in animals and plants made up of various cells and tissues and adapted for the performance of some specific function and grouped with other structures into a system.

The authors believe that viewing attention as an organ system aids in answering many perplexing issues raised in developmental psychology, psychiatry, and neurology. Neuroimaging studies have systemically shown that a wide variety of cognitive tasks activate a distributed set of neural areas, each of which can be identified with specific mental operations (Posner and Raichle, 1994, 1998). These areas of activation may be more consistent for the study of attention than for any other cognitive system. Attention can be viewed as involving

specialized networks to carry out functions such as achieving and maintaining the alert state, orienting to sensory events, and controlling thoughts and feelings.

The goals of this chapter are first to delineate the attentional networks of the human brain (Section 22.2), mostly from adult studies. There are obvious changes in behavior between infancy and adulthood, and in the next two sections (Sections 22.3 and 22.4), the authors describe brain changes at these ages and seek to link them to developmental differences in behavior. Section 22.5 examines changes in the attention networks themselves during child development and discusses how adult control relates to these changes. The authors use the connection between attention networks and neuromodulators to discuss some of the genes that influence individual differences and network development (Section 22.6). Finally, some likely new areas for research are outlined (Section 22.7).

22.2 BRAIN NETWORKS

22.2.1 Taxonomies of Attention

Although many efforts have been made to develop taxonomies of attention, imaging studies have suggested that at least three somewhat independent networks are involved in different aspects of attention, carrying out the functions of alerting, orienting, and executive attention (Posner and Fan, 2008) (Figure 22.1). Alerting refers to achieving and maintaining a state of high sensitivity to incoming stimuli, orienting refers to the selection of information from sensory input, and executive attention

includes mechanisms for monitoring and resolving conflict between thoughts, feelings, and responses.

The brain network involved in achieving and maintaining the alert state is represented by squares in Figure 22.1. Alertness is an important prerequisite for other attentional operations. Although the alert state is often contrasted with sleep, it is probably better to consider it in relation to the default state. The default state is defined in studies using functional magnetic resonance imaging (fMRI) with an instruction not to actively process anything (Raichle, 2009). The default state is characterized by a slow oscillation between two large-scale networks. A warning signal moves the brain away from the default state toward a high level of alertness. This change involves widespread variation in autonomic signals such as heart rate (Kahneman, 1973) and cortical changes, for example, a negative shift in the scalp recorded an electroencephalogram called the contingent negative variation (CNV) (Walter, 1964).

Much of attention research involves orienting to sensory events. The ease with which the experimenter can control the presentation of visual and auditory stimuli probably accounts for the popularity of studying orienting in different organisms and ages. Precisely controlling the presentation of stimulation also allows the study of overt and covert forms of orientation. Overt orienting involves eye movements, head movements, or both toward the source of stimulation and usually occurs when sufficient time is allowed between the presentation of an orienting cue and the target. Covert orienting involves only orientation of attention and can be studied when not enough time is allowed to move the eyes, head, or both or by instructing individuals to attend to the cue
FIGURE 22.1 The alerting, orienting, and executive attention networks. The triangles, circles, and squares indicate nodes of activation of each network.

without looking at it. The close relation of eye movements and covert shifts of attention has led to studies examining their relationship. In general, the same brain areas active before saccades also are active before covert shifts of attention (Corbetta and Shulman, 2002). However, cellular studies of alert monkeys have found that within the frontal eye fields there exist two different but overlapping populations of cells. One is active before saccades and the other before attention shifts not leading to saccades (Thompson et al., 2005). These findings suggest that eye, head, and covert attention movements become coordinated during early development so that in adults it becomes difficult, but still possible, to separate them.

Every sensory signal provides input to both sensory-specific cortical pathways and brain stem arousal systems related to alerting. Together, these signals may yield changes in a brain network of parietal and frontal areas (see circles in Figure 22.1) that orchestrate covert shifts of attention. The orienting network acts to boost the strength of input signals in sensory-specific pathways in comparison with nonattended signals.

The executive attention network is involved in the regulation of feelings (emotions), thoughts (cognitions), and actions (Posner and Rothbart, 2007a,b). The anterior cingulate gyrus, one of the main nodes of the executive attention network, has been linked to a variety of specific self-regulating functions. These include the monitoring of conflict (Botvinick et al., 2001), control of working memory (Duncan et al., 2000), regulation of emotion (Bush et al., 2000), and response to error (Holroyd and Coles, 2002). In emotional studies, the cingulate often is seen as part of a network involving the orbital frontal cortex and the amygdala that regulates our emotional response to input. Activation of the anterior cingulate is observed when people are asked to control their natural reactions to strong positive (Beauregard et al., 2001) or negative emotions (Ochsner et al., 2002). Analysis of the functional connectivity between brain areas has shown that when emotionally neutral sensory information is involved, there is strong connectivity between the dorsal anterior cingulate cortex (ACC) and the relevant sensory area (Crottaz-Herbette and Mennon, 2006); when emotional control is involved, there is functional connectivity between the ventral ACC and the amygdala (Etkin et al., 2006).

22.2.2 Sites and Sources of Attention

Normally, all sensory events contribute to both a state of alertness and an orienting of attention. In order to distinguish the brain areas involved in alerting and orienting (sources) from the sites at which they operate, it is useful to separate the presentation of a cue indicating where a target will occur from the presentation of the target requiring a response (Corbetta and Shulman, 2002; Posner, 1978). This methodology has been used in behavioral studies with normal individuals (Posner, 1978), patients (Posner and Fan, 2008), and monkeys (Marrocco and Davidson, 1998), and in studies using scalp electrical recording and event-related neuroimaging (Corbetta and Shulman, 2002). Two types of cue are of interest. Some cues provide information only on when the target will occur. These warning signals lead to changes in a network of brain areas related to alerting. Other cues provide information on aspects of the target, such as where it will occur, and lead to changes in the orienting network.

Studies using event-related fMRI have shown that following the presentation of the cue and before the target is presented, a network of brain areas becomes active (Corbetta and Shulman, 2002). There is widespread agreement on the identity of these areas, but a considerable amount of work remains to be done to understand the function of each area.

When a target is presented in isolation at the cued location, the subsequent target is processed more efficiently than when no cue to its location has been presented (see Posner and Fan, 2008, for a review). The brain areas influenced by orienting will be those that would normally be used to process the target. For example, in the visual system, orienting can influence sites of processing in the primary visual cortex or in a variety of extrastriate visual areas where the computations related to the target are performed. Orienting to target motion influences area MT (V5) while orienting to target color influences area V4. This principle of activation of brain areas also extends to higher-level visual input. For example, attention to faces modifies activity in the face-sensitive area of the fusiform gyrus. The finding that attention can modify activity in primary visual areas has been of particular importance because this brain area has been more extensively studied than any other. When multiple targets are presented, they tend to suppress the normal level of activity that they would have produced if presented in isolation. One important role of orienting to a particular location is to provide a relative enhancement of the target at that location in comparison with other items presented in the visual field.

22.3 BRAIN CHANGES IN HUMAN DEVELOPMENT

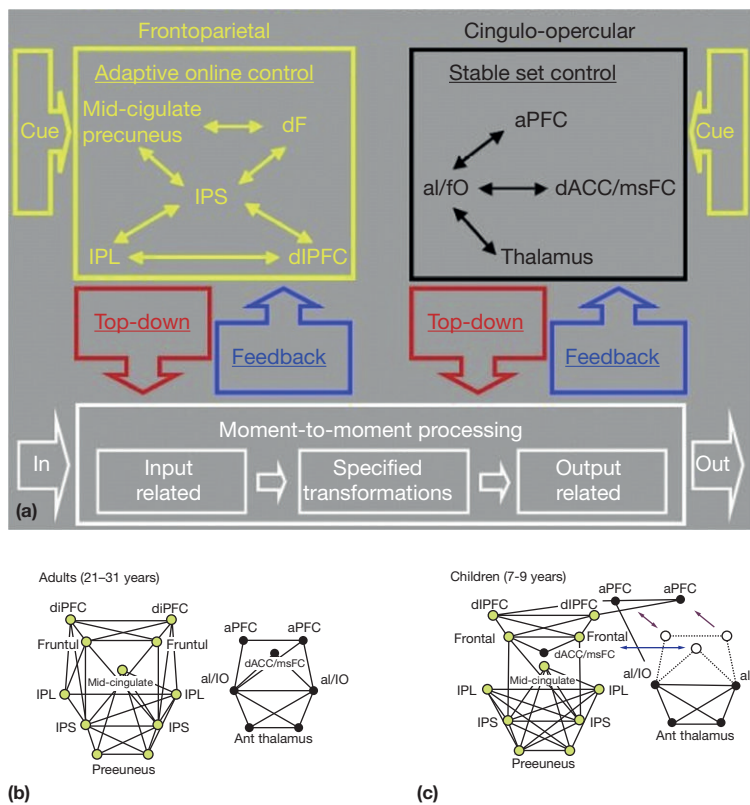
Much of this handbook reviews the developmental brain changes that have been traced in nonhuman animals. They include material on migration of cells into cortical areas and the changes that take place in synaptic density and myelination with age. Also well


FIGURE 22.2 The frontoparietal (orienting) and cingulo-opercular (executive) networks following the work of Dosenbach et al. (2007) (a) Greater long connections and more separation of networks in adults (b) than children (c).

documented in this volume is the role of experience in helping to sculpt gray and white matter development. This chapter deals with efforts to trace changes in development in resting connectivity and in brain activation during cognitive tasks in humans using fMRI.

An important finding was that even at rest, there is a common set of brain areas that appear to be active together (default state). While evidence for connection between brain areas related to attention is found even in infancy (Gao et al., 2009), studies suggest that the connectivity between these areas changes over the course of development. Figure 22.2 illustrates two sets of attention-related brain networks that are active at rest: they are a network of frontoparietal brain areas (related to orienting) and a cingulo-opercular (related to executive attention) network. The frontoparietal network (see top left panel of Figure 22.2) in adults is involved in short-term control operations common when orienting to sensory signals. The cinguloparietal network (see top right panel of Figure 22.2) is involved in longer, more strategic control that fits well with an executive system (Dosenbach et al., 2007).

Connections change over the life span. The bottom panels of Figure 22.2 show that adults (left panel) have separate networks related to orienting and executive attention, while these are more integrated in children. Children at age 9 years show many shorter connections.

Adults show more segregation of the two networks and longer connections (Dosenbach et al., 2007; Fair et al., 2007, 2008). Because resting connectivity analysis requires no task, it has been studied during infancy (Gao et al., 2009). During the first year of life, the anterior cingulate shows little or no connectivity to other areas. After the first year, infants begin the slow process of developing the long-range connectivity that is typical of adults.

Some of the same brain areas found active during rest change when the person is given a task. For example, while the organization of anatomical areas in alerting and orienting is not fully known, some promising beginnings have taken place (see Posner, 2008, for a review). In alerting, the source of attention appears to be the locus coeruleus (lc). Cells in the lc have two modes of processing. One mode is sustained and is perhaps related to the tonic level of alertness over long time intervals. This function is known to involve the right cerebral hemisphere more strongly than the left. Alertness is influenced by sensory events and by the diurnal rhythm. However, its voluntary maintenance during task performance may be orchestrated from the anterior cingulate. More phasic shifts of alerting can result from presenting any environmental signal. However, if the signal is likely to warn of an impending target, this shift results in a characteristic suppression of the intrinsic brain rhythms (e.g., alpha) within a few tens of milliseconds and a

strong negative wave (CNV) recorded from surface electrodes that moves from a frontal generator toward the sensory areas of the hemisphere opposite the expected target.

Another aspect of attention, especially prominent in the transition between infancy and early childhood, is self-regulation. Effortful and voluntary control is central to a broad range of abilities in executive functioning, such as error detection, planning, memory, and problem solving. There is evidence that effortful control (EC) is linked to the executive attention network (see triangles in Figure 22.1).

It has been possible to show that infants carry out at least one of the important functions related to the anterior cingulate, the recognition of error. In one study, 7-month-old infants were found to look longer at erroneous rather than correct events (Wynn, 1992). Error events appear to cause a scalp negative electrical potential over a set of electrodes that have been localized in the anterior cingulate (Berger et al., 2006; Dehaene et al., 1994). However, the typical regulation of behavior found in adults, that is, to slow down following an error, does not seem to emerge until about the age of 3 years (Jones et al., 2003). Together, the connectivity and task data fit well with the idea that infants can process information and use executive attention to a limited degree, but they are unable to show regulation of their behavior by this network.

22.4 BEHAVIORAL DEVELOPMENT IN INFANCY

Attention in infancy is less developed than it is later in life, and the functions of alerting, orienting, and, particularly, executive control are less independent during infancy. Alerting and orienting are examined first, and then, executive attention in relation to self-regulation is considered. The measurement of these variables must be different in infancy than later when voluntary responses can be directed by the experimenter. Efforts have been made to design tasks that can be performed by infants that tap the same networks of brain areas shown in Figure 22.1.

22.4.1 Alerting and Orienting

The early life of the infant is concerned with changes in state. Sleep dominates at birth, and the waking state is relatively rare at first. The newborn infant spends nearly three-quarters of the time sleeping at birth (Colombo and Horowitz, 1987). Many of the changes in the alert state depend on external input. Arousal of the central nervous system involves input from brain stem systems that modulate activation of the cortex. As in adults, primary

among these is the lc, which is the source of the brain's norepinephrine. It has been demonstrated that the influence of warning signals operates via this brain system, since drugs that block it also prevent the changes in the alert state that lead to improved performance after a warning signal has been provided (Marrocco and Davidson, 1998). It is likely that the endogenous changes during waking that take place without external input also involve this system.

There is a dramatic change in the percentage of time in the waking state over the first 3 months of life. By the 12th postnatal week, the infant has become capable of maintaining the alert state during much of the daytime. This ability still depends heavily on external stimulation, much of it provided by the caregiver.

Much of the response to external stimuli involves orienting toward a stimulus. Newborns show head and eye movements toward novel stimuli. Eye movements are preferentially directed toward moving stimuli and have been shown to involve properties of the stimulus, for example, how much they resemble human faces (Johnson and Morton, 1991). It has also been demonstrated that newborns can make imitative responses. When shown, for example, a face with a protruding tongue, they respond with a similar movement (Meltzoff and Moore, 1977). However, the reliability and complexity of these responses to sensory input change dramatically over the first months of life.

The most frequent method of studying orienting in infancy involves tracking of saccadic eye movements. As in adults, there is a close relation, but not identity, between the direction of gaze and the infants' attention. The attention system can be driven by external input from birth (Richards and Hunter, 1998); however, the system continues to improve in precision over many years. Infant eye movements often fall short of the target, and peripheral targets are often foveated by a series of head and eye movements. Although not as easy to track, the covert system likely follows a similar trajectory. Studies that have attempted to examine the covert system by the use of brief cues that do not produce an eye movement, followed by targets that do, show that the speed of the eye movement to the target is enhanced by the cue and this enhancement improves over the first year of life (Butcher, 2000). In more complex situations, for example, when there are competing targets, the improvement may continue for longer periods.

Orienting to sensory input is a major mechanism for regulating distress. Infants often have a hard time disengaging from high spatial frequency targets and may become distressed before they are able to move away from the target. Caregivers provide a hint of how attention is used to regulate the state of the infant when they attempt to distract the infants by bringing their attention to other stimuli. As infants orient, they are often quieted, and

their distress appears to diminish. In one study, 3- to 6-month-old infants were first shown a sound and light display; about 50% of the infants became distressed by the stimulation, but then they strongly oriented to interesting visual and auditory soothing events when these were presented (Harman et al., 1997). While the children oriented, facial and vocal signs of distress disappeared. However, as soon as the orienting stopped, for example, when the object was removed, the infants' distress returned to almost the same levels as before the presentation of the soothing object. An internal system, which was termed the *distress keeper*, and which the authors believe involves the amygdala, appears to hold a computation of the initial level of distress so that it returns if the infant's orientation to the novel event is lost. Interestingly, infants were quieted by distraction for as long as 1 min, without changing the eventual level of distress reached once the orienting ended (Harman et al., 1997).

For newborn infants, the control of orienting is initially largely in the hands of caregiver presentations. By 4 months, however, infants have gained considerable control over disengaging their gaze from one visual location and moving it to another, and greater orienting skill in the laboratory is associated with lower temperamental negative emotion and greater soothability as reported by parents (Johnson et al., 1991). Late infancy is the time when self-regulation develops. Increasingly, infants are able to gain control of their emotions and other behaviors. This transition marks the development of the executive attention system.

22.4.2 Executive Attention in Infancy

It is difficult to assess executive attention in infants because, as outlined earlier, caregivers provide most of the regulation of infant behavior. Effortful control (EC) is a high-level factor from parental reports on children's temperament (Rothbart and Rueda, 2005). This factor is defined as the ability to withhold a dominant response to carry out a nondominant one. Parents observing their children's behavior in particular daily-life situations (e.g., putting away toys on command) can readily respond to questions that relate to this factor. This can be done for children about 2 years of age and older. Below this age, temperament questionnaires (Rothbart et al., 1994) are confined to factors such as orienting and positive and negative affect. Older children receive scores on EC. Moreover, children older than 2 years can be scored on tasks that involve voluntary responding, such as pressing keys to visual input.

As mentioned earlier, there is evidence of the presence of the executive attention network at about 7 months for the detection of error. Later in the first year of life, there is evidence of further development of executive attention. One example is Diamond's work using the 'A not B' task and the reaching task. These two marker tasks involve inhibition of an action that is strongly elicited by the situation. In the 'A not B' task, the experimenter shifts the location of a hidden object from location A to location B after the infant's retrieving from location A had been reinforced as correct in the previous trials (Diamond, 1991). In the reaching task, visual information about the correct route to a toy is put in conflict with the cues that normally guide reaching. A toy is placed under a transparent box. The opening of the box is on the side (it can be the front side, the back side, etc.), and the infant can reach it only if the tendency to reach directly along the line of sight through the transparent top of the box is inhibited. Important changes in performance on these tasks are observed from 6 to 12 months. Comparison of performance between monkeys with brain lesions and human infants on the same marker tasks suggests that the tasks are sensitive to the development of the prefrontal cortex, and maturation of this brain area seems to be critical for the development of this form of inhibition.

Another task that reflects the executive system involves anticipatory looking in a visual sequence task (Clohessy et al., 2001; Haith et al., 1988). In the visual sequence task, stimuli are presented to the infant in a fixed and predictable sequence of locations. The infant's eyes are drawn reflexively to the stimuli because they are designed to be attractive and interesting. After a few trials, some infants will begin to anticipate the location of the next target by correctly moving their eyes in anticipation of the target. It has been shown that anticipatory looking occurs with infants as young as 3.5–4 months (Clohessy et al., 2001; Haith et al., 1988). Learning more complex sequences of stimuli, such as sequences in which a location is followed by one or two or more different locations, the particular location depending on the location of the previous stimulus within the sequence (e.g., 121312...), requires the monitoring of context and, in adult studies, has been shown to depend on the lateral prefrontal cortex (Keele et al., 2003). It was found that infants of 4 months do not learn to go to locations where there is conflict as to which location is the correct one. The ability to respond when such conflict occurs is not present until about 18–24 months of age (Clohessy et al., 2001). At 3 years, the ability to respond correctly when there is conflict in the sequential looking task correlates with the ability to resolve conflict in a spatial conflict task (SCT) (Rothbart et al., 2003). These findings support the slow development of the executive attention network during the first and second years of life.

The visual sequence task is related to other features that reflect control. One of these is the cautious reach toward novel toys. Rothbart and colleagues found that

the slow cautious reach of infants at 10 months predicted higher levels of EC as measured by parent report at 7 years of age (Rothbart et al., 2001). Infants of 7 months who show higher levels of correct anticipatory looking in the visual sequence task also show longer inspection times before reaching toward novel objects and slower reaching toward the objects (Sheese et al., 2008). This suggests that successful anticipatory looking at 7 months is one feature of self-regulation. In addition, infants with higher levels of correct anticipatory looking also showed evidence of higher levels of emotionality in a distressing task and more evidence of efforts to self-regulate their emotional reactions. Even at 7 months, the executive attention system is showing some properties of self-regulation, even though it is not yet sufficiently developed to resolve conflict in the visual sequence task (Clohessy et al., 2001) or the task of reaching away from the line of sight in the transparent box task (Diamond, 1991).

An important question about early development of executive attention is its relationship to the orienting network (Figure 22.1). Recall that the orienting network develops very early and has a critical role in regulation of emotion by the caregiver as early as 4 months. It was also found that orienting as measured from the Infant Behavior Questionnaire at 7 months was not correlated with EC as measured in the same infants aged 2 years (Sheese et al., 2009). However, orienting did show some early regulation of emotional responding in the infants. Orienting was positively related to positive affect and negatively related to negative affect. It was expected that orienting would be positively related to positive affect because previous work had shown that the duration of orienting as reported by caregivers was longer for children who smiled and laughed more. It was also expected that orienting would be negatively related to negative affect during infancy, given its use as a tool for soothing infants (Harman et al., 1997). It was also found that when the same infants were run in a conflict task (child Attention Network Test (ANT), see Section 22.5.1) at age 4 years, the regulatory functions found at 7 months were correlated more with the orienting network than with the executive network (Posner et al., 2012). As it was also found in parent reports that at the age of 2 years, the orienting network was related to control of emotion as mentioned earlier, it was concluded that in infancy and very early childhood, control is exercised by the orienting network, and only later as it becomes more connected does the executive network exert the major control.

By 2 years of age, parents can give reports that lead to a measure of EC. Two-year-old children, however, did not show the usual pattern of negative relationships between EC and negative affect that has been repeatedly found at other ages (Rothbart and Rueda, 2005). This

was unexpected, and it is possible that toddlers may be at a transition stage between emotional control by orienting and control by executive attention.

Colombo (2001) presented a summary of attentional functions in infancy, which included alertness, spatial orienting, object-oriented attention, and endogenous attention. This division is similar to the network approach but divides orienting into space and features and includes the functions of interstimulus shifts and sustained attention as part of endogenous attention. The researcher argues that alerting reaches the mature state at about 4 months, orienting by 6–7 months, and endogenous attention by 4–5 years. This schedule is similar to the order of development described earlier, but as discussed in the next major section, all these functions continue to develop during childhood. The genetic findings discussed below are new since the Colombo summary and add additional substance to the distinctions between functions and their integration in the achievement of self-regulation.

22.4.3 Summary

The findings to date suggest that orienting plays some of the regulatory roles in early infancy that are later exercised by the executive network. This fits with the more integrated networks shown in childhood at the bottom of Figure 22.2. Parenting may play an important role in the development of the executive attention network, perhaps partly through the presentation of novel objects that have been shown to activate the executive network in adults (Shulman et al., 2009). Further evidence for the role of parenting is presented in Section 22.6.

22.5 ATTENTIONAL NETWORKS AND CHILD DEVELOPMENT

22.5.1 Alerting Network

As discussed earlier, the state of alertness can be elicited by external stimulation, but it also varies in a regular rhythm over the course of the day and can be attained in a voluntary endogenously generated way. Young infants are able to attain the alert state when elicited by external stimulation, and they show a progressive increase in the frequency and duration of alert periods during the first year of life, whereas the ability to voluntarily deploy attention seems to emerge later and shows a steadier developmental course during childhood (Colombo, 2001).

Preparation from warning cues (phasic alertness) can be measured by comparing the speed and accuracy of response to stimulation with and without warning signals (Posner, 2008). Presentation of warning cues prior to

targets allows the individual to get ready to respond by increasing the state of alertness. This commonly results in increased response speed, although it may also cause declines in the accuracy of the response, particularly at short intervals between the warning cue and target (Posner, 1978).

The difficulty of using reaction time (RT) tasks with very young children makes studying developmental differences in preparation from alerting cues more challenging; yet several studies have examined developmental changes in phasic alertness between preschoolers, older children, and adults. In the authors' work, the ANT has been used to examine the efficiency of the three brain networks underlying attention: alerting, orienting, and executive attention (Fan et al., 2002). The task requires the person to press one key if the central arrow points to the left and another if it points to the right. Conflict is introduced by having flankers surrounding the target point in either the same (congruent) or the opposite (incongruent) direction as the target. Cues presented prior to the target provide information on where or when the target will occur. RTs for the separate conditions are subtracted, providing three measures that represent the efficiency of the individual in alerting, orienting, and executive networks. The child ANT is the same as described previously, but instead of arrows, fish are used and the child presses the key to feed or catch the central fish. Using the child ANT, Mezzacappa (2004) observed a trend to larger alerting scores (difference between RT in trials with and without warning cues) with age in a sample of 5- to 7-year-old children. Increasing age was associated with larger reductions in RT in response to warning cues. Older children also showed lower rates of omissions overall, indicating greater ability to remain vigilant during the task period. Young children (aged 5 years) also appear to need more time than older children (aged 8 years) and adults to get full benefit from a warning cue, and they also seem to be less able to sustain the optimal level of alertness over time (Morrison, 1982). The difficulty of maintaining the alert state without a cue is also observed in older children (aged 10 years) when compared to adults (Rueda et al., 2004a), suggesting that tonic or sustained attention continues to develop through late childhood.

Sustained attention is frequently measured by examining variations in performance on a task over a relatively extended period, as in the so-called Continuous Performance Tasks (CPT). Variations in the level of alertness can be observed by examining the percentage of correct and/or omitted responses to targets or through indexes of perceptual sensitivity (d') over time. With young children, the percentage of individuals able to complete the task can also indicate maturational differences in the ability to sustain attention. In a study conducted with preschoolers, only 30–50% of those aged 3–4 years were able to complete the task, whereas the percentages rose to 70% for those aged 4–4½ years and close to 100% for those older than 4½ years (Levy, 1980). Even though the largest development of vigilance seems to occur during the preschool period, children continue to show larger declines in performance in CPT over time than adults through middle and late childhood, especially under more difficult task conditions, reaching the adult level by approximately 13 years of age (Curtindale et al., 2007; Lin et al., 1999).

Developmental changes in alertness during childhood and early adolescence appear to relate to continuous maturation of frontal systems during this period. One way to examine brain mechanisms underlying changes in alertness is by registering patterns of brain-generated electrical activation through electrodes placed on the scalp while warning cues are processed. Typically, several hundred milliseconds after a cue predicting the upcoming occurrence of a target stimulus is presented, a negative variation of brain activity is generated up until the target appears (Walter, 1964). This electrophysiological index is called the CNV, and it appears to be related to a source of activation in the right ventral and medial frontal (ACC) brain areas (Segalowitz and Davies, 2004). The CNV is related to performance on various measures of intelligence and executive functions as well as to the functional capacity of the frontal cortex (Segalowitz et al., 1992). The CNV and other slow waves have been related to changes in activation as studied by fMRI (Raichle, 2009). Various studies have shown that the amplitude of the CNV increases with age, especially during middle childhood. For instance, Jonkman found that the CNV amplitude is significantly smaller in 6- to 7-year-old children than in adults, but no differences were observed between 9- and 10-year-old children and adults (Jonkman, 2006). The difference in CNV amplitude between children and adults seems to also be restricted to early components of the CNV observed over the right frontocentral channels (Jonkman et al., 2003), suggesting a role of maturation of the frontal alerting network.

22.5.2 Orienting Network

Infants are able to orient attention to external stimulation from early in their life. Nonetheless, aspects of the attention system that increase precision and voluntary control of orienting continue developing throughout childhood and adolescence. Most infant studies examine overt forms of orienting. By the time children are able to follow instructions and respond to stimulation by pressing keys, both overt and covert orienting can be measured with this method. The cuing task has been

widely used to study the development of visual orienting over the life span. In this task, a cue is displayed prior to the presentation of a target to which a response, usually a key press, is required. The cue is aimed to induce orientation of attention to a particular location. Then, the target may appear at the cued location or at an uncued one. When the target appears at the cued location, benefits of orienting attention to that location in the RT and the accuracy of response to the target can be measured. When the cue is presented at a location different from that of the target, a decrease in RT is observed that is thought to be due to operations of disengagement of attention from the cued location and reorientation to the location occupied by the target. Imaging research and studies on patients have provided information on the brain anatomy related to each of these orienting operations (Posner and Fan, 2008). For example, endogenous (voluntary) orientation of attention is associated with structures of the superior parietal lobe and the frontal eye fields, whereas exogenous (automatic) orienting seems to be the function of a network comprised by the temporoparietal junction and ventral frontal cortex, largely lateralized to the right hemisphere (Corbetta and Shulman, 2002). Activation of these cortical areas is required for disengaging from the current focus of attention. Moving attention from one location to another involves the superior colliculus, whereas engaging attention requires thalamic areas such as the pulvinar nucleus.

Mostly using a cuing paradigm, several studies have examined the development of orienting during childhood. Despite a progressive increase in orienting speed to valid cues during childhood (Schul et al., 2003), data generally show no age differences in the orienting benefit effect among young children (5–6 years of age), older children (aged 8–10 years), and adults (Enns and Brodeur, 1989), regardless of whether the effect is measured in covert or overt orienting conditions (Wainwright and Bryson, 2002). However, there seems to be an age-related decrease in the orienting cost (Enns and Brodeur, 1989; Schul et al., 2003; Wainwright and Bryson, 2002). In addition, the effect of age when disengaging and reorienting to an uncued location appears to be larger under endogenous orienting conditions (e.g., longer intervals between cue and target) (Schul et al., 2003; Wainwright and Bryson, 2005). This suggests that mostly aspects of orienting related to the control of disengagement and voluntary orientation, which depend on cortical regions of the parietal and temporal lobes, improve with age during childhood. In a study in which endogenous orienting was examined in children aged 6–14 years and in adults, all groups but the youngest children showed larger orienting effects, calculated as the difference in RT to targets appearing at cued and uncued locations, with longer cue–target

intervals (Wainwright and Bryson, 2005). This indicates that young children seem to have problems endogenously adjusting the scope of their attentional focus. This idea was also suggested by Enns and Girgus (1985), who found that attentional focusing as well as the ability to effectively divide or switch attention between stimuli improves with age, between ages 5, 8, and 10 years and adulthood.

22.5.3 Executive Attention Network
