Self-regulation of cognition and action can be measured in the laboratory by registering responses to tasks that involve conflict. Common conflict tasks such as the classic Stroop task require the participant to avoid paying attention to aspects of the stimulation (e.g., the word WHITE) that may be dominant (i.e., semantic information contained in the word) while responding to nondominant features (i.e., the color in which the word is written). From 2 years of age and older, children are able to perform simple conflict tasks in which their RT can be measured. The SCT (Gerardi-Caulton, 2000) induces conflict between the identity and the location of an object. In this task, pictures of the houses of two animals (e.g., a duck and a cat) are presented at the bottom left and bottom right sides of the screen; then one of the two animals appears either on the left or right side of the screen in each trial and the child is required to show the animal what its house is by touching it. Location is the dominant aspect of the stimulus, although instructions require responding according to its identity. Thus, conflict trials in which the animal appears on the side of the screen opposite to its house usually result in slower responses and larger error rates than nonconflict (when the animal appears on the same side as its house) trials. Between 2 and 4 years of age, children progressed from an almost complete inability to carry out the task to a relatively good performance. Although 2-year-old children tended to perseverate on a single response, 3-year-old children performed at high accuracy levels, although, like adults, they responded more slowly and with reduced accuracy to conflict trials (Gerardi-Caulton, 2000; Rothbart et al., 2003).

The detection and correction of errors is another form of action monitoring. While performing the SCT, 30- and 36-month-old children showed longer RTs following erroneous trials than those following correct ones, indicating that children were noticing their errors and using them to guide their performance on the next trial. However, no evidence of slowing following an error was found at 24 months of age (Rothbart et al., 2003). A similar result with a different time frame was found when using a version of the Simple Simon game. In this task, children are asked to execute a response when a

command is given by a stuffed animal, while inhibiting responses that are commanded by a second animal (Jones et al., 2003). Children of age 36–38 months were unable to inhibit their response and showed no slowing following an error, but at 39–41 months of age, children showed both an ability to inhibit action and a slowing of RT following an error. These results suggest that between 30 and 39 months, children greatly develop their ability to detect and correct erroneous responses and that this ability may be related to the development of inhibitory control.

The development of executive attention has also been traced into the primary school period (Rueda et al., 2004a) using the child version of the Attention Networks Test (ANT). Overall, children's RTs were much longer than those of adults, but considerable development in the speed of resolving conflict from age 4 to about 7 years was observed. However, the ability to resolve conflict on the flanker task, as measured by increases in RT and percentage of errors produced by the presence of incompatible compared to compatible flankers, remained about the same from age 7 years to adulthood. Nonetheless, studies in which the difficulty of the conflict task is increased by other demands, such as switching rules or holding more information in working memory, have shown further development of conflict resolution between late childhood and adulthood (Davidson et al., 2006).

To study the brain mechanisms that underlie the development of executive attention, some developmental studies have been carried out using event-related potentials (ERPs) and conflict tasks. In one of these studies, a flanker task was used to compare conflict resolution in three groups of children aged 5–6, 7–9, and 10–12 years, and a group of adults (Ridderinkhof and van der Molen, 1995). In this study, developmental differences were examined in two ERP components, one related to response preparation (lateralized readiness potential (LRP)) and the other related to stimulus evaluation (P3). The authors found differences between children and adults in the latency of the LRP peak, but not in that of the P3 peak, suggesting that developmental differences in the ability to resist interference are mainly related to response competition and inhibition, but not to stimulus evaluation.

Brain responses to errors are also informative of the function of the executive attention system. The error-related negativity (ERN) is a potential with a frontocentral scalp distribution that appears some time (usually between 60 and 120 ms) after an error response (Gehring et al., 1993) and is thought to be generated by the ACC (van Veen and Carter, 2002). The amplitude of the ERN seems to reflect detection of an error as well as salience of the error for a particular individual in the context of the task, and it is therefore subject to individual differences in affective style or motivation. Generally, larger ERN amplitudes are associated with

greater engagement in the task and/or greater efficiency of the error detection system (Santesso et al., 2005; Tucker et al., 1999). Developmentally, the amplitude of the ERN shows a progressive increase during childhood into late adolescence (Segalowitz and Davies, 2004), with younger children (aged 7–8 years) less likely to show the ERN to errors than older children and adults. This is likely to reflect the progressive maturation of the brain system for action monitoring and regulation.

Another evoked potential, the N2, has been related to situations that require executive control (Koop et al., 1996) and has been directly associated with activation coming from the ACC (van Veen and Carter, 2002). An ERP study was conducted in which the fish flanker task of the child ANT was used on 4-year-old children and on adults (Rueda et al., 2004b). Adults showed larger N2 for incongruent trials than for congruent trials over the midfrontal leads. Four-year-old children also showed a larger negative deflection for the incongruent condition at the midfrontal electrodes that, compared to adults, had greater amplitude and was extended over a longer period. While the frontal effect was evident in adults at around 300 ms post target, children did not show any effect until approximately 550 ms after the target. In addition, the effect was sustained over a period of 500 ms before the children's responses, in contrast with only 50 ms in the case of adults. Another important difference between 4-year-old children and adults was the distribution of effects over the scalp. In adults, the frontal effects appear to be focalized on the midline, whereas in children, the effects were observed mostly at prefrontal sites and in a broader number of channels, including the midline and lateral areas.

The focalization of signals in adults as compared to children is consistent with neuroimaging studies conducted with older children in which children appeared to activate the same network of areas as adults when performing similar tasks, but the average volume of activation appeared to be remarkably greater in children than in adults (Casey et al., 2002; Durston et al., 2002). Altogether, these data suggest that the brain circuitry underlying executive functions becomes more focal and refined as it gains in efficiency. This maturational process not only involves greater anatomical specialization but also reduces the time these systems need to resolve each of the processes implicated in the task. This is consistent with the recent findings that the network of brain areas involved in attentional control shows increased segregation of short-range connections but ncreased integration of long-range connections with maturation (Fair et al., 2007). Segregation of short-range connectivity may be responsible for greater local specialization, whereas integration of long-range connectivity likely increases efficiency by improving coordinated responses between different processing modules.

22.5.4 Summary

The attention network shows substantial development during childhood. Rates of development appear to differ among the three networks, with alerting showing a very slow developmental time course. While the ANT shows most of the development in the executive network to occur before the age of 7 years, the connectivity data (Figure 22.2) indicate increased segregation between orienting and executive networks beyond the age of 9 years.

22.6 GENES AND EXPERIENCE BUILD NETWORKS

The finding that common brain networks are involved in self-regulation provides an important approach to evolution by looking at commonalities and differences in nonhuman organisms. Another approach of equal importance involves an examination of individual differences in the efficiency of this network. Such differences could rest in part on the genetic variation known to exist among individuals and in part on differences in cultural or individual experiences. The study of temperament examines individual differences in reactivity and self-regulation that are biologically based (Rothbart and Bates, 2006). One of the most important individual differences has been called 'effortful control.' It is a higher order factor consisting of a number of subscales measuring attentional and behavioral control.

22.6.1 Effortful Control

EC is derived from parents and self-reports of behavior in dimensions such as inhibitory control, attentional control, and low-intensity pleasure.

22.6.2 Attention Network Test

The ANT was used in a sample of 40 normal adults (Fan et al., 2002) where each of these measures was found to be reliable over repeated presentations. In addition, no correlation was found among the measures. An analysis of RTs in this task showed large main effects for cue type and target type. There were only two small interactions indicating some lack of independence among the cue conditions. One of these interactions was found when a cue directed orienting to the correct target location and the influence of the surrounding flankers was reduced. In addition, omitting a cue, which produces relatively long RTs, also reduced the size of the flanker interference. Presumably, this is because some of conflict is resolved in parallel with alerting.

Subsequent work has confirmed the relative independence among networks, while showing that they can interact when conditions are made more difficult or otherwise changed (Fan et al., 2009). A study using fMRI showed that the anatomy of these three networks was for the most part independent (Fan et al., 2005). In addition, each of the networks has a dominant neuromodulator arising from the subcortical brain areas. The alerting network is modulated by norepinephrine produced in the lc; the orienting network, by acetylcholine from the basal forebrain; and the executive network, by dopamine from the ventral tegmental area (Posner and Fan, 2008).

Scores on the conflict network of the ANT have been shown to correlate with the temperament factor of EC at several ages during childhood. Gerardi-Caulton (2000) carried out some of the first research linking EC to underlying brain networks of executive attention using spatial conflict as a laboratory marker task. Similar findings linking parent-reported EC to performance on laboratory attention tasks have been shown for 24-, 30-, and 36-month-old children (Rothbart et al., 2003); 3- and 5-year-old children (Chang and Burns, 2005); and 7-year-old children (Gonzalez et al., 2001). Some adult studies have also found a correlation between conflict resolution ability and EC (Kanske, 2008), and some disorders involve both executive attention (Fernandez-Duque and Black, 2006) and EC.

22.6.3 Daily Life

The correlation between conflict scores in this simple and easily administered cognitive task and parental reports of EC forms the basis for the association between self-regulation and executive attention.

As discussed, ANT executive attention scores and EC have been related to many aspects of child development. EC is related to the empathy that children show toward others, their ability to delay an action, and their ability to avoid behaviors such as lying or cheating when given the opportunity (Posner and Rothbart, 2007b; Rothbart and Rueda, 2005). High levels of EC and the ability to resolve conflict are related to fewer antisocial behaviors such as truancy in adolescents (Ellis et al., 2004). These findings have convinced the authors that self-regulation, a psychological function crucial for child socialization, can also be studied in terms of specific anatomical areas and their connections.

The common nature of brain networks such as those in Figure 22.1 argues strongly for the role of genes in their construction. This has led cognitive neuroscience to incorporate data into the growing field of human genetics (Green et al., 2008; Posner et al., 2007). One method for doing this relates individual variations in genes (genetic alleles) to aspects of human behavior. Brain activity

can serve as an intermediate level for relating genes to behavior. As one example, the ANT has been used to examine individual differences in the efficiency of executive attention. Strong heritability of the executive network (Fan et al., 2002) supported the search for genes related to individual differences in network efficiency.

22.6.4 Neuromodulators

The association of the executive network with the neuromodulator dopamine provides a way of searching for candidate genes that might relate to the efficiency of the network (Fossella et al., 2002; Posner and Fan, 2008). For example, several studies using conflict-related tasks have found that alleles of the *catechol-O-methyl transferase* (COMT) gene were related to the ability to resolve conflict (Blasi et al., 2005; Diamond et al., 2004). A number of other dopamine genes have also been found to be related to this form of attention, and research has suggested that genes related to serotonin transmission also influence executive attention (see Posner et al., 2007, for a summary). It has also been possible to show in brain imaging studies that some of these genetic differences are related to the degree to which the anterior cingulate is activated during task performance (Fan et al., 2003). In the future, it may be possible to relate genes to specific nodes within neural networks, allowing a much more detailed understanding of the origins of brain networks underlying attention.

22.6.5 Longitudinal Study

One goal of our longitudinal study was to see if the genes that were shown to influence attention in adults (Posner et al., 2007) would have specific roles in the development of self-regulation during infancy and childhood. The study began when the infants were 7 months old. The children were retested and genotyped at age 2 years and were tested a final time at age 4 years when they are able perform the ANT as a measure of executive attention.

Rothbart and Derryberry (1981) proposed a distinction between reactive and self-regulatory aspects of child temperament. They argued that early in life, negative affect, particularly fear and orienting of attention, served as regulatory mechanisms that were supplemented by parental regulation. Rothbart and Bates (2006) argued for developmental changes in which EC arose at about 3–4 years when parents could first report on their children's self-regulatory ability.

The longitudinal study has not only confirmed but also revised and extended this analysis. A negative correlation was found at 7 months between parental reports of infant orienting of attention and negative affect.

Orienting also correlates positively with reports of positive affect. By 2 years, orienting is no longer related to affect, but EC shows modest nonsignificant negative correlations with both positive and negative affect. There is substantial evidence that for children, adolescents, and adults, EC shows a negative correlation with negative affect in Western countries, although Ahadi et al. (1993) found that in China, EC was negatively correlated with positive affect in children. They argued that culture shaped the direction of the interaction between EC and emotion.

As discussed previously, the results of the longitudinal study suggest that early in life, orienting serves as a regulatory system, and it both reduces negative affect (Harman et al., 1997) and increases positive affect. In this view, both orienting and executive networks serve parallel regulatory functions during infancy. Later on, executive attention appears to dominate in regulating emotions and thoughts, but orienting still serves as a control system. This parallel use of the two networks fits with the findings of Dosenbach et al. (2007) showing that in adults their frontoparietal network controls behavior at short time intervals while their cinguloopercular network exercises strategic control over long intervals. These changes in regulation during early childhood served as a framework to examine continuities and discontinuities in the influence of genetic variations.

22.6.5.1 CHRNA4

The nicotinic cholinergic receptor modulates the release of dopamine in the mesolimbic system. Polymorphisms in the CHRNA4 gene have been associated with nicotine dependence in humans and with cognitive performance (Rigbi et al., 2008). The CHRNA4 C1545T polymorphism (rs1044396) has been associated with variation in performance of shifts of attention during visual search (Parasuraman et al., 2005) and in brain activity when performing visual attention tasks (Winterer et al., 2007).

During infancy, the T/T allele of CHRNA4 is related to a better performance in anticipatory looking, but at 18 months, the C/C homozygotes have the higher scores on EC (Voelker et al., 2009). The finding that alleles associated with higher attention during infancy (as measured by anticipation) have lower parent-reported EC at age 2 years may indicate that infants who exercise control through orienting are slower to transition to control via the executive network. As the measurement at 18–20 months occurs well before regulation by executive attention is complete, infants with strong orienting may not yet have made the transition.

As visuospatial attention requires orienting, the CHRNA4 polymorphism was expected to influence orienting in the subjects, and it was thought that it might also influence higher-order attention. The authors'

genetic findings provided support for the parallel model of regulation discussed earlier. At 7 months, CHRNA4 is related to aspects of anticipatory looking (Sheese et al., 2008). At about 2 years, the main influence of this gene appears to be on EC, which depends on executive attention. In adults, CHRNA4 seems to be related to tasks that clearly involve the orienting network (Parasuraman et al., 2005), but these tasks may involve executive attention as well. These findings support the idea that gene expression during development may vary as different brain networks change in importance.

22.6.5.2 Catechol-O-methyl Transferase

COMT plays an important role in dopamine metabolism by modulating extracellular levels of dopamine. The functional Val/Met polymorphism of COMT has a measurable effect on COMT enzyme activity, with the Val allele degrading extracellular dopamine more quickly than the less enzymatically active Met allele. The Met allele has been associated with anxiety and negative mood states (Drabant et al., 2006), affective disorders (Karayiorgou et al., 1997), and decreased novelty seeking (Reuter and Hennig, 2005).

A finding from the authors' current longitudinal study is that the COMT gene, which has consistently been shown to be related to executive attention in adults and older children (Blasi et al., 2005; Diamond et al., 2004), is also related to aspects of attention in toddlers (Voelker et al., 2009). It was found that haplotypes of the COMT gene (Diatchenko et al., 2005) influenced both anticipatory looking and nesting cup activity at 18–20 months, both tasks thought to be at least partly related to executive attention. At 7 months, COMT was also related to positive affect as reported by parents. The finding of a relation of COMT to positive affect together with the influence of this gene on executive attention at 18–20 months could provide a genetic link between reactive emotion and emotional regulation during early development. However, it is also possible that COMT's relation to positive affect in infancy is mediated by regulatory aspects of executive attention. Evidence for this is mixed in the authors' current study in that positive affect in infancy was unrelated to later EC, but other studies have shown such a connection (Rothbart and Rueda, 2005).

22.6.5.3 DRD4

The 7-repeat allele of the DRD4 gene has been linked to attention deficit hyperactivity disorder (ADHD) and to the temperamental dimension of risk taking. Adults and children with the 7-repeat allele have been shown to be higher in the temperamental quality of risk-taking and at greater risk for attention deficit disorder than those with fewer repeats (Auerbach et al., 1999). In one series of studies (Auerbach et al., 1999), it was found that the orienting of 2-month-old infants as rated by parents and as observed during inspection of toys was related to the presence of the 7-repeat allele of the dopamine 4 receptor gene. This allele appears to interact with a gene related to serotonin transmission (5-HTT) to influence orienting.

Evidence that the environment can have a strong influence in the presence of the 7-repeat alleles has been reported by other investigators (Bakermans-Kranenburg and van Ijzendoorn, 2006; van Ijzendoorn and Bakermans-Kranenburg, 2006). The same group (Bakersmans-Kranenburg et al., 2008) carried out a parenting training intervention and found that the training decreased externalizing behavior, but only for those children with the DRD4 7-repeat allele. This finding is important because assignment to the training group was random, ensuring that the result was not due to something about the parents other than the training.

In the longitudinal study, the authors added an observation of caregiver–child interaction in which the children played with toys in the presence of one of their parents. Raters observed the caregiver–child interaction and rated the parents on five dimensions of parental quality according to a schedule developed by NICHD (1993): the ratings included support, autonomy, stimulation, lack of hostility, and confidence in the child. Although all the parents were likely concerned and caring, they did differ in their scores, and the combined scores were divided at the median into two groups. One of the groups was considered to show a higher quality of parenting and the other a lower quality.

A strong interaction was found between genes and parenting. For children without the 7-repeat polymorphism, variations in parenting within the range examined were unrelated to the children's scores on impulsivity and risk taking. For children carrying the 7-repeat gene variant, however, variations in parenting quality mattered. Children with this allele and high-quality parenting showed normal levels of risk taking, but those with lower-quality parenting showed very high values for risk taking. It seems paradoxical that the 7-repeat allele associated with developmental psychopathology (ADHD) is also under positive selective pressure in recent human evolution (Ding et al., 2002). Why should an allele related to ADHD be positively selected? It is the authors' view that positive selection of the 7-repeat allele could well arise from its sensitivity to environmental influences.

Parenting provides training for children in the values favored by the culture in which they live. For example, Rothbart and colleagues (Ahadi et al., 1993) found that in Western culture, EC appears to regulate negative affect (sadness and anger), while in China (at least in the 1980s), it was found to regulate positive affect (outgoingness and enthusiasm). In recent years, the genetic part of the nature by nurture interaction has been given a lot of emphasis, but if genetic variations are selected according

to the sensitivity they give children to cultural influences, this could support a greater balance between genes and environment. Theories of positive selection in the DRD4 gene have stressed the role of sensation seeking in human evolution (Wang et al., 2006). The authors' findings do not contradict this emphasis but suggest an interpretation that could have even wider significance. It remains to be seen whether the other 300 genes estimated to show positive selection would also increase an individual's sensitivity to variations in rearing environments.

How could variation in genetic alleles lead to enhanced influence of cultural factors such as parenting? The anterior cingulate receives input on both reward value and pain or punishment, and this information is clearly important in regulating thoughts and feelings. Dopamine is the most important neuromodulator in these 'reward' and 'punishment' pathways. Thus, changes in the availability of dopamine could enhance the influence of signals from parents related to reward and punishment. Another interaction has been reported between the serotonin transporter gene and parental social support on the temperamental dimension of behavioral inhibition or social fear (Fox et al., 2005). To explain this interaction, Fox et al. (2007) argue that children with a short form of the serotonin transporter gene who also have lower social support from parents show enhanced attention to threat and greater social fear. In the authors' study of the DRD4, however, attention did not appear to be the mechanism by which the genetic variation influenced the child's behavior. In the authors' study, there was no influence of the 7-repeat allele on executive attention; instead, gene and environment interacted to influence the child's behavior as observed by the caregiver. However, an interaction between the DRD4 7-repeat allele and EC as rated by parents did appear at age 4 years and older (Sheese et al., 2012). This finding lends support to the idea that control shifts to the executive network during childhood. The authors also found that the COMT genotype showed an interaction between attention and parenting quality, and unlike the DRD4, it did operate through attention even at age 2 years. However, in the case of COMT, attention involved anticipatory looking, which is at least partly influenced by orienting at this age.

Overall, the authors found both continuity and discontinuity in the influence of genetic variation in early childhood. The DRD4 influence on executive attention emerged only at age 4 years and continued into adulthood, while the COMT influence on tasks involving attention shifting was exhibited as early as 2 years. The CHRNA4 genetic variation was most variable for attention changes between infancy and adulthood. These variations appear related to the changes in dominant control networks described in this chapter.

22.6.6 Summary

While a few candidate genes have been related to individual differences between infants and young children, these account for only a small portion of the differences in temperament and behavior. One reason for these small effects is that parenting and other forms of cultural variation interact with genes in determining behavior. However, it is likely that the genes whose variation is related to individual differences in attention are also those important in building the common attentional networks. Combined human and animal studies may be helpful in further explicating connections between genes and control networks. See also Chapter 38 and Rubenstein and Rakic, 2013.

22.7 FUTURE RESEARCH

In this chapter, the authors have examined some of the tools used in studies of the human brain and mind during development. These tools may allow for a deeper understanding of how the developing brain makes possible the changes in attention and self-regulation that occur in behavior early in life. Future research should enable the use of these tools to understand how developmental changes in functional activation and connectivity relate to the specific behavioral markers at the same age. Research can help one understand how changes in activation relate to differences found in functional connectivity and in white and gray matter. Is there a fixed order of these changes, or does their rate and order of occurrence depend on whether they take place as the result of development or from practice on a task? Better coordination of human and nonhuman animal work may allow one to determine the relationship of changes found with noninvasive imaging to those seen in studies of the microanatomy and circuitry of brain areas in animal research.

It is also difficult to know how brain changes relate to behavioral changes found at the same time. Longitudinal studies will allow one to better define this relationship. Doing so may require the use of tasks and methods that remain relatively stable across ages. The use of resting fMRI may be the most important of these since it allows testing of different ages without the need to develop comparable tasks (Fair et al., 2007). The discovery that the electroencephalogram signal for error detection involves similar brain areas at 7 months as it does for adults provides another means of examining an event that may be comparable across wide differences in age. The use of more analytic behavioral observations (e.g., anticipatory eye movement, the ANT, and parent reports of temperament) may allow for the mapping of changes in mental operations to brain changes in development.

The growing knowledge of genetic and epigenetic methods has only just begun to influence research in human development. Mainly genetic variation has been related to individual differences in behavior (Posner et al., 2007). However, it seems likely that the same genes related to individual differences are involved in building the common networks underlying attention. Thus, studies designed to relate the expression of genes at particular nodes in neural networks to key aspects of behavior will be of great importance in realizing the goal of understanding how neural networks become organized in development.

Although it is known that some genetic variants interact with environmental experience, the actual mechanisms involved are not yet known, as genetic variations are expressed at numerous places in the brain and the rest of the body. As the mechanisms by which genes can be altered by the environment are enlarged in the field of epigenetics, it is possible to learn more about how training influences development.

The Neural Correlates of Cognitive Control and the Development of Social Behavior

A. Lahat[1], N.A. Fox[2]

[1]McMaster University, Hamilton, ON, Canada; [2]University of Maryland, College Park, MD, USA

23.1 THE DEVELOPMENT OF COGNITIVE CONTROL AND ITS NEURAL BASIS

With development, children and adolescents improve in their ability to control their thoughts, behavior, and impulses and create long-term goals while ignoring distracting information (Casey et al., 2005; Diamond, 2002; Zelazo, 2004). This ability has been termed *cognitive control* or *executive function* (EF) (Bunge and Crone, 2009). According to Bunge and Crone (2009), cognitive control is not a single mechanism, but rather includes several specific functions. This chapter focuses on two of these specific functions. The first function is inhibitory control, or the ability to inhibit dominant responses in favor of more appropriate responses (Rothbart et al., 2003). The second function includes two processes thought to reflect self-monitoring: conflict monitoring, which is indicative of interference and interactions between different information processing pathways (Braver et al., 2001), and error/feedback monitoring, or updating a response based on feedback and error detection (Bunge and Crone, 2009).

The chapter examines these cognitive control functions and their relation to the development of social behavior. First, the development of cognitive control and its neural correlates is reviewed, focusing on the specific functions of inhibitory control and self-monitoring (including conflict and error monitoring). Then, individual differences associated with the development of these functions and their neural correlates are reviewed. Specifically, the relationship between temperament and inhibitory control/self-monitoring is examined. Temperament refers to stable behavioral and psychological profiles in infancy that shape patterns of behavior across contexts early in development (Kagan, 2001). It is important to examine how intrinsic factors, such as cognitive control processes, are related to temperament because they may influence developmental outcomes. Data suggesting cross-cultural variations in these abilities also are presented. Finally, the role of these functions in the

neurodevelopment of decision making and motivation, including moral and social decisions, as well as moral behavior, is reviewed. This chapter focuses mostly on childhood and adolescence because the neural correlates of cognitive control develop markedly during this period.

23.1.1 Inhibitory Control

Inhibitory control, as defined earlier, is the ability to inhibit a dominant response in favor of a more appropriate response (Rothbart et al., 2003). This function includes the ability to restrain a prepotent response or choosing an alternative response pattern. It has a well-characterized developmental course, with improvements in children's ability to inhibit prepotent responses detected during toddlerhood (Gerardi-Caulton, 2000) and improvements in inhibitory control occurring during the preschool years (e.g., Gerstadt et al., 1994; Rueda et al., 2004; Zelazo, 2006), with marked improvements in inhibitory control continuing during middle childhood (e.g., Simonds et al., 2007) and adolescence (e.g., Anderson, 2002; Huizinga et al., 2006).

Research has pointed to several changes that occur with development in neural activation during inhibitory control tasks. For example, several studies have indicated that activation in the prefrontal cortex (PFC) becomes more focal with age (e.g., Bunge et al., 2002; Durston et al., 2006; Luna et al., 2001). These studies show that activation in certain brain regions increases with age while, at the same time, activation in other brain regions decreases. For example, in a study examining inhibitory control (Durston et al., 2006), decreased activation with development was found in prefrontal regions that were not relevant for task performance. However, an increase in activation, which was associated with improved task performance, was found in the ventrolateral PFC (VLPFC).

In a study examining developmental changes in inhibitory control, Bunge et al. (2002) administered to children between the ages of 8 and 12, as well as adults, a task that combined elements of the go/no-go (response inhibition) and the flanker (interference suppression) paradigms. In a typical go/no-go paradigm, participants are asked to respond to the majority of trials (go trials) and to withhold their response on a minority of the trials (no-go trials). In a typical flanker paradigm, participants are asked to respond on the basis of a central stimulus while ignoring flanking stimuli (flankers). In the task administered by Bunge et al. (2002), participants were asked to press a left button when a central arrow pointed to the left and press a right button when it pointed to the right. The flanker stimuli were congruent with the central target (go trials), incongruent with the target

(go trials), or Xs, in which case participants were asked to refrain from responding (no-go trials).

The findings indicated that for both interference suppression (flanker) and response inhibition (go/no-go), children failed to engage a region in the right VLPFC that young adults recruited (Bunge et al., 2002). The findings also revealed decreased activation with age in the left VLPFC for interference suppression (flanker) and in the parietal and temporal cortices for response inhibition (go/no-go). According to Bunge et al. (2002), these data show that for different types of inhibitory control, children recruit different brain regions to adults. Specifically, children in this study failed to recruit a region in the right VLPFC, which was most robustly activated by both tasks in adults. This can be a result of immature brain structures in children or due to a shift in cognitive strategy between childhood and adulthood (Bunge et al., 2002).

Patterns of increasing and decreasing activation with development have been observed in other studies using the go/no-go paradigm. For example, Tamm et al. (2002) found age-related decreases in activation in the superior and middle frontal gyri as well as increased activation in the left inferior frontal gyrus between ages 8 and 20. In a study by Rubia et al. (2006), functional brain activation was compared between adolescents and adults during three different executive tasks measuring inhibitory control (go/no-go), cognitive interference inhibition (Simon task, also called the directional or motor Stroop task, in which participants are presented with congruent and incongruent stimuli on either side of a computer screen indicating a left or right button press), and attentional set shifting (switch task, during which interference from a previous stimulus–response association has to be inhibited). In all three tasks, adults recruited portions of the PFC, the anterior cingulate cortex (ACC), and the striatum more strongly than adolescents. Additionally, adults engaged the inferior parietal cortex more strongly than adolescents on the Simon and switch tasks, a finding similar to that reported for the go/no-go task by Bunge et al. (2002).

Additional evidence for focalization comes from a study by Luna et al. (2001), who administered an anti-saccade task to children (7–12 years), adolescents (13–17 years), and young adults (18–22 years). This task requires participants to suppress looking at a visual target that appears suddenly in the peripheral visual field and instead look away from the target in the opposite direction. The findings indicate that, with age, activation decreased in the superior middle gyrus but increased in the striatum, intraparietal sulcus, frontal eye field, and lateral cerebellum. Additionally, activation in the dorsolateral PFC (DLPFC) was greatest for adolescents as compared with children and young adults.

In a functional magnetic resonance imaging (fMRI) study using the Stroop task (a classic task tapping inhibitory control), Adleman et al. (2002) studied children (ages 7–11 years), adolescents (ages 12–16 years), and young adults (ages 18–22 years). In this task, participants are asked to name the color of ink in which a color word is displayed. Adleman et al. (2002) found that young adults showed increased activation compared to adolescents in the left frontal gyrus. Additionally, young adults showed greater activation than children in the ACC and left parietal and parietooccipital regions as well as in the left frontal gyrus. Compared to children, adolescents showed greater activation in the parietal cortex. Adult and adolescent groups, however, did not differ in activation for this region. These findings suggest that when performing the Stroop task, young subjects are able to recruit parietal structures while PFC function contributing to performance on this task continues to develop into young adulthood. These age-related increases in activation occurred in conjunction with improvements in behavioral performance. These findings suggest that with development, resource recruitment becomes more focal.

Electrophysiological studies have pointed to increased cortical efficiency with age during tasks that require inhibitory control (Lewis et al., 2006). For example, Lewis et al. (2006) used dense-array electroencephalography (EEG) to measure event-related potentials (ERPs) as children and adolescents performed a go/no-go task. The N2 component of the ERP, an index of inhibitory control, was found to decrease in amplitude and latency with age. Additionally, source modeling of the N2 indicated a developmental decline in posterior midline activity, which was paralleled by increasing activity in frontal midline regions suggestive of the ACC. This pattern of frontalization is in line with other studies that observed reliance on more anterior regions of PFC with improvement of cognitive control (e.g., Lamm et al., 2006; Rubia et al., 2000). For example, Lamm et al. (2006) found that the N2 in a go/no-go task was source-localized to the cingulate cortex and orbitofrontal cortex (OFC). However, the source of the N2 in older children and in children who showed improved inhibitory control (regardless of age) was estimated to be in the ACC compared to younger children and children who performed poorly, whose N2 source was estimated in the posterior cingulate cortex.

In sum, research examining the neural correlates of the development of inhibitory control suggests that, with age, improvements in this ability are associated with increased focalization and efficiency in recruitment of the PFC. Thus, with development, brain regions that are not relevant for task performance decrease in their activation, while regions relevant for the task increase in their activation. This focalization of the PFC has been consistently found with various tasks that tap inhibitory control, including flanker, go/no-go, and Stroop tasks.

These changes in functional activation of inhibitory control that occur with development may reflect disengagement from immature neural circuits used by children and adolescents and recruitment of more mature alternative neural networks. However, the differences in activation patterns between children and adults may also reflect children's reliance on different cognitive strategies compared with adults. It is also possible that children engage in ongoing strategy-learning processes or differ from adults in their efforts to complete the task (Ernst and Mueller, 2008).

23.1.2 Self-Monitoring: Conflict and Error Monitoring

Self-monitoring is often measured through cognitive tasks (e.g., Stoop, flanker, and go/no-go paradigms) by examining response times on trials following an error as compared to response times following correct trials. If inaccurate performance is particularly salient to an individual, more controlled and slower responding in the trial following an error is typically exhibited (Davies et al., 2004; Luu et al., 2000). This form of self-monitoring can be viewed as a compensatory strategy where subjects slow their reaction time (RT) after an error in order to maximize accurate performance on the upcoming trial.

Studies have examined whether children, after making an error, respond more slowly on subsequent trials. Backen Jones et al. (2003) found that as 3- to 4-year-old children's performance on a Simon Says-type task improved, they tended to show posterror slowing. Using a more fast-paced task-switching paradigm, however, Davidson et al. (2006) failed to find evidence of posterror slowing in 4- to 5-year-old children. Typically, younger children make more errors than adults and may be less aware of them. Some studies have shown that children are able to detect errors, but are unable to correct them. For example, Bullock and Lutkenhaus (1984) found that 18- and 24-month-old children could distinguish between correctly and incorrectly built towers, even when they themselves failed to build the towers correctly. In a study designed to examine this question with preschool children, Jacques et al. (1999) presented 3-year-old children with the dimensional change card sort, in which children are shown two target cards (e.g., a blue rabbit and a red boat) and are asked to sort a series of test cards (e.g., red rabbits and blue boats) first according to one dimension (e.g., color) and then according to the other (e.g., shape). Most 3-year-olds perseverate during the postswitch phase, continuing to sort test cards by the first dimension (e.g., Zelazo et al., 2003). In order to

assess error detection, Jacques et al. (1999) asked children to evaluate the sorting of a puppet. When 3-year-olds watched the puppet perseverate, they judged the puppet to be correct. When they saw the puppet sort correctly, they judged the puppet to be wrong, which suggests that 3-year-olds' perseverating performance and error detection are closely linked in this task.

Behavioral measures used to study self-monitoring can also be supplemented with psychophysiological methods to obtain a more comprehensive picture of ACC and PFC involvement in monitoring processes. A good deal of work studying these functions has focused on an error-related potential known as the error-related negativity (ERN). The ERN is a specific neural activity pattern associated with cognitive monitoring that is produced after the commission of an error and has a centromedial scalp distribution (Falkenstein et al., 1991; Gehring et al., 1993; van Veen and Carter, 2002). It is usually observed between 50 and 150 ms postresponse when participants make errors (Falkenstein et al., 1991; Scheffers et al., 1996). Due to its localization and involvement with monitoring, the ERN is seen as part of a neural system that interacts with the PFC to contribute to more efficient cognitive processing (Luu and Tucker, 2001; van Veen and Carter, 2002). The ERN is followed by a positive deflection (Pe) peaking between 200 and 500 ms after the ERN (Davies et al., 2004) and has been associated with awareness of an error (Nieuwenhuis et al., 2001). Source localization models have indicated a generator for the ERN in ACC (e.g., van Veen and Carter, 2002).

Although debate remains as to whether the ERN is a result of error detection (Falkenstein et al., 1991; Gehring et al., 1993) or response conflict processes (Carter et al., 1998; Gehring and Fencsik, 2001), it is generally hypothesized that the ERN is part of a larger performance monitoring system that is influential in the development of self-regulatory skills. As such, the ERN is suggested to serve as a feedforward control mechanism by which self-monitoring can influence future cognitive strategies and overall behavioral performance (Rodriguez-Fornells et al., 2002).

Davies et al. (2004) examined error detection in children using a flanker task and found smaller (i.e., more positive) ERN amplitudes for 7- to 8-year-old children as compared to adolescents. Although ERN amplitudes increase slowly with age, these young children showed behavioral evidence of error detection because, as found in adults, their responses slowed down following an erroneous response. Furthermore, even the youngest children in the study showed evidence of the Pe component, further demonstrating error detection (Davies et al., 2004).

Another type of self-monitoring is known as *conflict monitoring*. As mentioned above, conflict monitoring can be defined as interference and interactions between different information processing pathways (Braver et al.,

2001). Conflict monitoring includes the ability to identify discrepancies in self-performance, and some consider error monitoring as detection of postresponse conflict as opposed to preresponse conflict. Indeed, research has shown an overlap in brain regions associated with both conflict and error monitoring (Ridderinkhof et al., 2004). Conflict monitoring has been found to have a neural basis in ACC. Studies have shown activation in this region for both the conflict elicited by the external environment and that elicited by the individual's own behavior or thoughts (e.g., Carter and van Veen, 2007; Casey et al., 1997a; Posner and Fan, 2004). Once conflict has been detected, the ACC signals for the recruitment of higher-order cognitive processes associated with PFC activation in order to alleviate this conflict (Kerns et al., 2004).

While the majority of neuroimaging work demonstrating ACC activation during conflict monitoring has been found with adults, research shows that this structure also underlies conflict monitoring in children and adolescents (Rubia et al., 2007). For example, in a neuroimaging study with 5- to 16-year-old children, performance on a visual discrimination task that required attention to conflict was positively correlated with the size of a child's right ACC (Casey et al., 1997a). Additionally, in a study with 7- to 12-year-old children, behavioral performance on a go/no-go task was correlated with the degree of ACC activation (Casey et al., 1997b).

In sum, review of studies examining self-monitoring and its neural correlates in children suggests that even young children are capable of self-monitoring, as reflected in error and conflict monitoring. Behaviorally, children have been found to be capable of detecting errors in simple tasks, but incapable of correcting them or identifying them in more complex situations. In addition, for certain tasks, children slow down their responses following an error. Although evidence has been found for self-monitoring in children, this function continues to develop with age as evidenced by increasing ERN amplitude. Thus, the research reviewed suggests that, to a certain degree, children recruit similar neural functions associated with self-monitoring as adults. Specifically, children have been found to recruit the ACC, which has been associated with both error and conflict monitoring.

23.2 INDIVIDUAL DIFFERENCES IN COGNITIVE CONTROL

23.2.1 The Role of Temperament in Cognitive Control

Individual differences in the development of cognitive control have been reported (e.g., Gehring et al., 2000; Henderson, 2010; Lewis et al., 2006; McDermott

et al., 2009; Stieben et al., 2007; White et al., 2011) and have been linked to social outcomes in children. For example, behavioral and physiological measures of cognitive control have been linked to negative mood induction conditions (Lewis et al., 2006, 2007) and to heightened levels of trait anxiety and internalizing symptoms (e.g., Gehring et al., 2000; Stieben et al., 2007). Differences among individuals in cognitive control have also been associated with different types of temperament. For example, a number of studies from different laboratories have found that specific cognitive control functions moderate the developmental trajectory of behavioral inhibition (BI) in children (Henderson, 2010; Thorell et al., 2004; White et al., 2011). BI is a temperament identified early in childhood that predicts heightened emotional reactivity throughout childhood (Fox et al., 2005) and increased risk for anxiety in adolescence (Chronis-Tuscano et al., 2009).

For example, Thorell et al. (2004) examined how BI and inhibitory control assessed at 5 years of age were associated with socioemotional functioning at 9 years of age. The results indicated that behaviorally inhibited children with high levels of inhibitory control were reported as being more socially anxious than behaviorally inhibited children with low levels of inhibitory control. Similarly, Fox and Henderson (2000) found that behaviorally inhibited 4-year-olds with high inhibitory control were less socially competent and more socially withdrawn than behaviorally inhibited children with low inhibitory control.

These findings about the role of inhibitory control for temperamental BI are the opposite of results regarding another EF, attention shifting (Eisenberg et al., 1998). For example, Eisenberg et al. (1998) found that children low on attention shifting and high on parental reports of negative emotions, such as fear, sadness, and anxiety, were rated by their parents and teachers as more shy 2 years later.

White et al. (2011) examined how attention shifting and inhibitory control, which were tested at 48 months of age, moderated the association between BI assessed at 24 months of age and anxiety problems in the preschool years. The results indicated that high levels of inhibitory control increased the risk for anxiety disorders among behaviorally inhibited children whereas high levels of attention shifting decreased the risk for anxiety problems in these children.

In a different study, Lahat et al. (2012a) examined how these two EFs – attention shifting and inhibitory control – moderated the relation between exuberant temperament in infancy and propensity for risk taking in childhood. Temperamental exuberance has been defined by positive reactivity to novelty, approach behavior, and sociability (Putnam and Stifter, 2005). Children with an exuberant temperament are also characterized by impulsivity, sensitivity to reward, fearlessness, and risk

taking (Fox et al., 2001; Polak-Toste and Gunnar, 2006; Rothbart and Bates, 2006). EF was assessed at 48 months of age. Risk-taking propensity was measured when children were 60 months of age. The results indicated that exuberance was positively associated with risk-taking propensity among children relatively low in attention shifting but unrelated for children high in attention shifting. Inhibitory control did not significantly moderate the link between exuberance and risk-taking. Taken together, the findings from these sets of studies on temperament and different types of EF demonstrate that attention shifting and inhibitory control have differential influences on levels of risk or adaptation. Furthermore, these two studies (Lahat et al., 2012a; White et al., 2011) suggest that high levels of attention shifting may serve as a protective factor in the link between temperament and negative outcomes. This conclusion may have important implications for prevention and intervention efforts in the form of training in order to improve attention-shifting skills.

McDermott et al. (2009) provided neurophysiological evidence for the role of cognitive control among individuals with different temperaments. These authors studied adolescents who were part of a larger longitudinal study and were assessed during infancy and early childhood for BI. These adolescents were administered a flanker task, during which ERPs were recorded. The study focused on the ERN component, which is a negative deflection in the ERP waveform produced after the commission of an error. The ERN was found to be larger for adolescents with high childhood BI than for adolescents low on childhood BI. This finding suggests increased error monitoring among highly behaviorally inhibited individuals. In addition, adolescents and their parents completed semistructured diagnostic interviews to assess lifetime presence or absence of anxiety disorders. The results indicated that the ERN moderated the relation between early BI and later anxiety disorders such that, for the participants high on BI, larger ERNs were related to a higher risk of anxiety disorders (McDermott et al., 2009).

In a recent study using dense-array ERPs and source analyses, Lamm et al. (2012) showed that, during an inhibitory control task, children high in temperamental fearfulness showed modeled source activation in areas suggestive of VLPFC across both emotional and nonemotional conditions of the task. However, children low in temperamental fearfulness only showed this pattern of activation during the emotional condition. Results from this study suggest that while children low in temperamental fearfulness recruited increased inhibitory control only during the emotional conditions, or those conditions in which more cognitive control recourses were likely needed, children with high fearful temperaments sustain this increased level of inhibitory control across both neutral and emotional contexts (Lamm et al., 2012). These

findings suggest that temperamentally fearful individuals show increased vigilance not only in emotional situations but also in nonemotional ones. Thus, these fearful individuals may refrain even from social situations that do not induce negative emotions.

Other neurophysiological evidence for the moderating role of inhibitory control has been found for the association between shyness and social–emotional maladjustment (Henderson, 2010). Henderson (2010) examined the associations between shyness, N2 component of ERP, and social adjustment in 9- to 13-year-old children. Participants were administered a flanker task while ERPs were being recorded. In addition, they completed questionnaires assessing temperament, social anxiety, attribution style, and self-perceptions. The results indicated that shyness was associated with poor social outcomes primarily among children with relatively large N2 amplitudes. The results point to the role of conflict in shy children's social adjustment (Henderson, 2010).

Individual differences in cognitive control and their association with social and cognitive adjustment have also been studied using the Stroop task. Perez-Edgar and Fox (2003) examined 11-year-old children who were administered an emotional Stroop task in which emotionally charged words substitute the traditional color words. Based on their RT performance on this task, participants were divided into either an interference or a facilitation group. Children in the interference group were slower to respond to either negative or positive words, whereas children in the facilitation group were faster to respond to these words. The two groups were assessed on cognitive, emotional, and social measures collected at ages 4, 7, and 11. The interference group showed greater socioemotional (but not cognitive) maladjustment over time. In a second study, ERPs were collected during this task. The findings reveal that negative words, as compared with positive words, involve ERP components that are considered to tap attentional processes. Additionally, larger positive slow-wave amplitudes were observed for the facilitation group.

In a different study (Warren et al., 2010), using the emotional Stroop during fMRI, participants were also administered the Attachment Script Assessment in which they were asked to generate stories in response to attachment-related word prompts. This measure assesses secure-base-script knowledge or the degree to which an individual is able to generate narratives in a hypothetical situation in which attachment-related threats are recognized and resolved. The findings indicated that individuals with lower levels of secure-base-script knowledge showed increased activity in brain regions associated with emotion regulation, such as the right OFC, as well as activity in regions associated with inhibitory control, such as the left DLPFC, ACC,

and superior frontal gyrus. These findings suggest that insecure attachment is associated with a greater need in inhibitory control in order to attend to task-relevant nonemotional information (Warren et al., 2010).

In sum, studies examining individual differences in cognitive control and their social–emotional outcomes have shown links with negative mood inductions (Lewis et al, 2006) as well as anxiety disorders and other social problems (e.g., Fox and Henderson, 2000; McDermott et al., 2009; White et al., 2011). For example, highly behaviorally inhibited children, who are also high in inhibitory control, have been found to show negative social outcomes as well as increased anxiety disorders. Children with this temperament have also been found to show increased self-monitoring, as reflected by larger ERNs relative to children with low BI (McDermott et al., 2009). Additionally, children with a fearful temperament showed increased VLPFC source activation even in response to nonemotional stimuli (Lamm et al., 2012). Taken together, these studies suggest that high inhibitory control, as well as high self-monitoring, may result in negative social outcomes for children who are shy or have a more fearful temperament.

23.2.2 Cross-cultural Differences in the Development of Cognitive Control

Research on the development of cognitive control has mostly been conducted in Western cultures. However, an emerging body of cross-cultural studies suggests that Asian children may outperform Western children on measures of cognitive control (e.g., Lahat et al., 2010; Sabbagh et al., 2006).

Research comparing children from Western and Asian cultures has shown that Chinese children perform better on behavioral and neurophysiological measures of EFs than North American children (e.g., Chen et al., 1998; Ho, 1994; Lahat et al., 2010; Sabbagh et al., 2006; Wu, 1996). For example, Sabbagh et al. (2006) administered a battery of EF and theory of mind (ToM) tasks to preschoolers from China and the United States. ToM is the ability to attribute mental states – beliefs, intents, and desires – to oneself and others and to recognize that mental representations can differ across individuals (Premack and Woodruff, 1978). The Chinese preschoolers showed better performance than the US preschoolers on all measures of EF, but not on measures of ToM. However, individual differences in EF predicted ToM performance in both groups.

Chinese children's advanced performance on EF tasks may stem from the opportunities to exercise and practice these abilities that they encounter within their culture. For example, Chinese parents expect children to master impulse control at a much younger age than North American parents (Chen et al., 1998; Ho, 1994;

Wu, 1996). Compared with Western parents, Chinese parents are more controlling and protective in child rearing. For example, they often encourage their young children to stay close to and to be dependent on them. Indeed, most Chinese infants and toddlers sleep in the same bed or in the same room as their parents (Chen et al., 1998). In addition, impulse control is more highly valued in Chinese daycare settings than in North American daycare settings (Tobin et al., 1989).

Another possibility for Chinese children's superior cognitive control was suggested by Lahat et al. (2010) in a study that focused on the N2 component of ERP. Cultural differences in the importance that parents place on impulse control could affect children's motivation to succeed on a task such as the go/no-go task, resulting in greater PFC activation. The study compared 5-year-old children from a Chinese-Canadian ethnic background with children from a European-Canadian background on a go/no-go task. No behavioral differences between the two cultural groups were observed, but robust N2 amplitude differences were found. Chinese-Canadian children showed larger (i.e., more negative) N2 amplitudes than European-Canadian children on the right side of the scalp on no-go trials as well as on the left side of the scalp on go trials. Source analyses of the N2 showed greater modeled source activation for Chinese-Canadian children in dorsomedial, ventromedial, and (bilateral) ventrolateral PFC. These findings reveal that Chinese-Canadian children show greater hemispheric differentiation than European-Canadian children, suggesting more advanced cognitive control. Moreover, the asymmetrically lateralized N2 may be a reliable marker of both effortful inhibition (on the right) and effortful approach (on the left).

Behavioral cultural differences were not observed in the Lahat et al. cross-cultural study, despite cultural differences found in other research (e.g., Sabbagh et al., 2006). This discrepancy can stem from the different cognitive control tasks that were used or from the different age groups that were studied. Furthermore, the Chinese-Canadians in the Lahat et al. study grew up in Canada, whereas previous research examined Asian children living in Asia. In any case, this study demonstrates that neurophysiological techniques can provide a measure of neurocognitive function that is more sensitive than behavioral data alone.

In sum, individual differences in cognitive control have also been observed in cross-cultural variations. Specifically, an emerging body of research comparing children from Asian and Western cultures has shown behavioral (e.g., Sabbagh et al., 2006) as well as neurophysiological (Lahat et al., 2010) evidence, suggesting advanced cognitive control abilities among children from a Chinese cultural background compared with children from a Western cultural background. Although the reasons for these differences are not clear yet, it is possible that differences in socialization between the two cultures play a major role.

23.3 THE ROLE OF COGNITIVE CONTROL IN DECISION MAKING AND MOTIVATION

23.3.1 Motivation-related Decisions

Cognitive control has also been implicated in decision-making processes. Studies with adults support the idea of a frontostriatal network linking cognitive control and motivation during decision making (see Somerville and Casey, 2010). Fewer studies have examined the role of the development of cognitive control as it affects the emergence of decision-making skills.

A simple paradigm that has been used to assess basic decision making with young children is delay of gratification, which measures children's ability to give up an immediate reward in favor of a larger reward later. For example, participants are seated in front of a piece of candy while an experimenter leaves the room. If they wait for the experimenter to return, they get two treats; otherwise they get only one (Mischel et al., 1972). Variations of the standard delay of gratification paradigm have shown developmental differences throughout the preschool years. For example, in one study (Kochanska et al., 1996), children were asked to hold candy in their mouth without eating it until they were told to do so. In a second task, children were asked not to peek while they could hear that the experimenter was wrapping a gift for them. Children's ability to delay gratification increased significantly from 3 to 4 years of age. In a study linking delay of gratification and decision making, Prencipe and Zelazo (2005) examined children's delay of gratification for self and other (the experimenter). Three-year-olds typically chose an immediate reward for themselves and a delayed reward for other (the experimenter). According to Prencipe and Zelazo, these findings suggest that 3-year-olds are capable of adaptive decision making but still have difficulty regulating their own approach behavior in motivationally salient situations. According to these authors, it is possible that their behavior is driven by the relatively automatic processes rather than by more deliberate prefrontal networks. The findings can be explained in light of Barresi and Moore's (1996) model of the development of perspective taking. It is possible that 3-year-olds may have made impulsive choices in the self condition because they took an exclusively first-person perspective on their own behavior and had difficulty adopting a more objective, third-person perspective according to which delay would be preferred. In contrast, 3-year-olds may have chosen delayed rewards in the other condition because they

took an exclusively third-person perspective and had difficulty appreciating the experimenter's subjective perspective (i.e., his or her own desire for immediate gratification).

In more complex situations, individuals are often required to make approach-avoidance decisions in the face of uncertainty. One common measure of complex decision making in adults is the Iowa gambling task (IGT; Bechara et al., 1994). In this task, participants are asked to choose cards from four decks that contain a different number of cards that could lead to their winning or losing money. During the task, the participants learn that some decks are more advantageous than others. Kerr and Zelazo (2004) modified the IGT to create a version for children that included two decks of cards, one advantageous and one disadvantageous. Feedback on participants' decisions was provided in the form of happy (reward) and sad (loss) faces. Choosing cards from the disadvantageous deck resulted in more rewards on every trial but also with occasional (unpredictable) large losses. Three-year-olds failed to develop a preference for the advantageous deck. However, 4- and 5-year-olds were able to make advantageous decisions (Kerr and Zelazo, 2004).

Although these studies suggest a steady improvement in cognitive control and decision making with development, according to Somerville and Casey (2010), cognitive control and decision making can often be impaired in light of emotionally charged interactions. This impaired cognitive control is especially pronounced during adolescence when rates of risky behavior, such as drug use and risky sexual conduct, increase (Casey et al., 2005; Steinberg, 2008). Thus, although adolescents show improvements in cognitive control, their goal-oriented behavior can be diminished in light of motivational cues of potential reward (Cauffman et al., 2010; Figner et al., 2009; Steinberg et al., 2009). For example, Figner et al. (2009) used a gambling task in which reward feedback was given either during decision making or after decision making. The findings show that adolescents made riskier choices compared to adults, but only in the condition in which the reward was given during the decision. This condition is more emotionally charged and elicits greater arousal.

Another study examined participants between the ages of 10 and 30 years and used a delay discounting task (Steinberg et al., 2009) in which participants were asked to choose between an immediate reward of less value (e.g., $400 today) and a variety of delayed rewards of more value (e.g., $700 1 month from now or $800 6 months from now). The findings indicate that, before age 16, children showed a greater willingness to accept a smaller reward immediately than a large reward that was delayed. Cauffman et al. (2010) obtained similar results examining the same age range with a modified version of the IGT. Results indicate that approach behaviors

(a tendency to choose from the advantageous decks) display an inverted U-shape relation to age, peaking in mid- to late adolescence. In contrast, avoidance behaviors (a tendency to refrain from choosing from the disadvantageous decks) increase linearly with age, with adults avoiding disadvantageous decks at higher rates than both preadolescents and adolescents. Taken together, these studies show that risky choices tend to peak between 14 and 16 years of age, followed by a decline in risky behavior.

Casey et al. (2008) proposed a model describing the neurocircuitry of the development of control and motivational processes. According to this model, top-down prefrontal regions involved in cognitive control develop linearly with age, whereas bottom-up striatal regions, which are involved in processing of salient cues in the environment, develop in an inverted U-shaped function. Evidence for such a frontostriatal circuitry comes from studies using diffusion tensor imaging and fMRI. Casey and colleagues (Casey et al., 2007; Liston et al., 2006) have found that the strength of the connection between frontal and striatal regions is associated with effective cognitive control in typically and atypically developing individuals.

fMRI studies examining the role of the striatum in salient and motivational contexts support the idea that adolescents show enhanced sensitivity to incentives relative to children and adults (Ernst et al., 2005; Galvan et al., 2006; Geier et al., 2010; May et al., 2004). For example, Ernst et al. (2005) used a monetary reward task and found stronger activation among adolescents than adults in the left nucleus accumbens, a structure in the striatum thought to be involved in reward processing. In addition, a reduction in the fMRI blood oxygen level dependent (BOLD) signal in the amygdala in response to reward omission was larger for adults than for adolescents.

Few studies (e.g., Hardin et al., 2009; Jazbec et al., 2006) have examined the link between cognitive control and motivational processes. Recent research has shown that adolescents' cognitive control can be enhanced in light of incentives. For example, when participants were promised a financial reward for accurate performance on certain trials of an antisaccade task, cognitive control was improved for adolescents more than adults (Jazbec et al., 2006). This finding has also been obtained with social rewards, such as a happy face (Kohls et al., 2009). Geier et al. (2010) studied the neural underpinnings of reward processing and its influence on cognitive control in adolescence using a modified version of an antisaccade task. The results indicate that faster correct inhibitory responses were provided on reward trials than on neutral trials by both adolescents and adults. Additionally, fewer inhibitory errors were made by adolescents. For reward trials, the BOLD signal was attenuated in ventral striatum in adolescents during cue assessment.

This was followed by overactivation in adolescents during response preparation (i.e., during fixation after the reward cue) in the ventral striatum, as well as the precentral sulcus, which is important for controlling eye movements. These findings suggest enhanced activation in adolescents in control regions as a result of reward anticipation (Geier et al., 2010).

In sum, studies examining the development of cognitive control in decision making have pointed to an inverted U-shaped trend in development (see Somerville and Casey, 2010). Studies with young children show steady improvements in the ability to delay gratification (e.g., Prencipe and Zelazo, 2005) as well as more effective decision making (e.g., Kerr and Zelazo, 2004). However, studies have shown a greater propensity for risky decisions during adolescence in light of motivationally salient situations (e.g., Cauffman et al., 2010). fMRI studies examining the link between cognitive control processes and motivation have found enhanced activation during adolescence in brain regions associated with cognitive control during anticipation of reward (Geier et al., 2010).

23.3.2 Social and Moral Decisions and Behavior

Evidence for the role of cognitive control in influencing more specific types of decisions, such as social and moral decisions comes from behavioral, fMRI, and ERP studies (e.g., Greene et al., 2001, 2004; Lahat et al., in press, 2012b; Lahat and Zelazo, 2010). In these studies, participants are typically asked to make a decision about whether a social or moral violation is acceptable or unacceptable to perform. Moral violations involve intrinsic negative consequences for others, such as physical harm or issues of fairness (Nucci, 1981; Smetana, 2006; Turiel, 1983).

For example, Greene et al. (2001, 2004) found evidence for the role of cognitive conflict and inhibitory control in the moral judgments of adult participants. These authors distinguish between impersonal moral dilemmas and personal moral dilemmas. An example of an impersonal dilemma is the *trolley* dilemma (Thomson, 1986) in which one has to decide whether to allow an out-of-control trolley to continue down a track where it will kill five people or whether to push a switch diverting it to a track where it will kill only one person. However, in a variation of this dilemma, the *footbridge* dilemma, the only way to save the five people is to push a large person in front of the trolley, killing him but saving the others. This latter dilemma is a personal dilemma as it is introduced in an 'up-close-and-personal manner' (Greene et al., 2001) and the bystander witnessing the event now becomes a moral agent. Most individuals assert that it is acceptable to sacrifice one person in order to save five in the case of the trolley dilemma, but not in the case of the footbridge dilemma (Greene et al., 2001). Greene et al. (2001) found that RTs were longer when participants judged personal moral violations as acceptable than when they judged personal moral violations as unacceptable. This effect was not found for impersonal moral judgments. According to Greene et al. (2001), personal moral violations elicit a negative social–emotional prepotent response, which results in judging the moral violation as unacceptable. An individual must overcome this prepotent response in order to judge a personal moral violation as acceptable. Thus, according to Greene, making a utilitarian judgment to serve the greater good involves cognitive control in order to overcome prepotent responses elicited by personal dilemmas.

In a different study (Greene et al., 2004), the authors focused on personal moral dilemmas only and explored whether different patterns of neural activity in response to these dilemmas are correlated with differences in moral decision-making behavior. For this purpose, Greene et al. (2004) made a further distinction within the class of personal dilemmas. They differentiated between difficult personal moral dilemmas, which elicit high conflict, and easy personal moral dilemmas, which elicit low conflict. Difficult personal dilemmas are a class of dilemmas that create cognitive and emotional tension compared to easy dilemmas. In response to these dilemmas, participants tend to answer slowly, and they exhibit no consensus in their judgments. An example of a difficult dilemma is the *crying-baby* dilemma in which an individual and other townspeople have sought refuge in a cellar to escape from enemy soldiers who have taken over the village. The protagonist's baby begins to cry loudly, and this could summon the attention of the soldiers, who might kill the protagonist, his child, and the others hiding out in the cellar. To save himself and the others, the protagonist must smother his child to death. This case contrasts with easy, low-conflict, personal moral dilemmas that receive relatively rapid and uniform judgments. One such example is the *infanticide* dilemma, in which a teenage mother must decide whether or not to kill her unwanted newborn infant. The latter dilemma is considered easy in the sense that most participants tend to agree that an unwanted infant should not be killed.

Greene et al. (2004) examined whether different brain regions are involved in judgments of difficult versus easy moral dilemmas. The dilemmas were classified as either difficult or easy according to their RTs, with difficult dilemmas having longer RTs. The findings indicate that judgments of difficult dilemmas, as compared to easy dilemmas, involved increased activity bilaterally in both the DLPFC and the ACC. This contrast also revealed activity in the inferior parietal lobes and the posterior cingulate cortex. Greene et al. (2004) also compared the neural activity associated with utilitarian judgments (judging a personal moral violation as acceptable

in favor of the greater good, such as smothering the baby in the crying-baby dilemma) to that associated with non-utilitarian judgments (prohibiting a personal moral violation despite its utilitarian value, such as allowing the baby to live in the crying-baby dilemma). The authors found increased activity for utilitarian, as compared with nonutilitarian, moral judgments bilaterally in the anterior DLPFC and in the right inferior parietal lobe. In addition, they found increased activity for utilitarian moral judgments in the more anterior region of the posterior cingulate (Greene et al., 2004). These findings show that judgments of difficult dilemmas engage brain areas associated with the detection of conflict and the operation of inhibitory control. According to Greene et al. (2004), when participants respond in a utilitarian manner, such responses reflect not only the involvement of abstract reasoning but also the engagement of cognitive control in order to overcome prepotent social–emotional responses elicited by these dilemmas.

Evidence for the role of cognitive control in moral judgments has been found in children as young as 10 years of age (Lahat et al., 2012b, in press; Lahat and Zelazo, 2010). These authors obtained behavioral and neurophysiological data suggesting that the detection of cognitive conflict distinguishes between moral decisions and social conventional decisions. Social conventions are behavioral uniformities that serve to coordinate individuals' interactions in a social system (Nucci, 1981; Smetana, 1981, 2006; Turiel, 1983). These conventions, such as forms of address and modes of greeting, are symbolic elements of social organization. Social conventions, such as eating with one's fingers or wearing pyjamas to school, can vary across different social systems, are contingent on societal rules, and can be altered by authority or social consensus. This is in contrast to moral acts, such as hitting, lying, and stealing, which are considered universal, independent from rules and authority, and unalterable.

In a set of studies, Lahat et al. (2012b, in press) measured RTs and focused on the N2 component of ERP, which, as mentioned earlier, has been considered to be an index of cognitive control (e.g., Nieuwenhuis et al., 2003). Adults, children (10 years), and adolescents (12–14 years) were administered a moral–conventional judgments task while ERPs were being recorded and RTs were measured. The task included scenarios describing a social interaction and had three possible endings: a moral violation, a conventional violation, and a neutral act. Participants were to judge whether the act was acceptable or unacceptable to perform in a situation where a social rule was assumed or removed (i.e., "imagine that there is no rule against the act; is it okay or not okay to perform the act?"). The findings revealed that, at all ages, RTs were faster for moral rather than conventional violations when a rule was assumed (Lahat et al., 2012b).

ERP data indicated that adults', but not adolescents', N2 amplitudes were larger (i.e., more negative) for conventional rather than moral violations when a rule was assumed (Lahat and Zelazo, 2010). Taken together, these results suggest that judgments of conventional violations involve increased conflict detection compared to moral violations, and these two domains are processed differently across development. The findings were explained by the idea that judgments of conventional violations are more explicitly dependent on rules, and thus a violation of the rule results in increased conflict detection. However, judgments of moral violations are based more directly on the intrinsic negative consequences of the act and thus less cognitive conflict is detected in these trials. These findings inform theories of moral development and suggest that cognitive processing of moral judgments changes with age.

The role of cognitive control has also been found to be crucial for moral behavior, specifically that of lie-telling behavior in children and adolescents (Evans and Lee, 2011; Evans et al., 2011; Talwar and Lee, 2008). For example, Talwar and Lee (2008) studied children between the ages of 3 and 8 years. In this study, participants were told not to peek at a toy. However, most children could not resist the temptation and peeked and later lied about it. Children's conceptual moral understanding of lies, executive functioning, and theory-of-mind understanding were also assessed. Results indicated that children's initial denials about peeking were related to inhibitory control measured with a Stroop and whisper task (in which children are required to whisper their responses rather than say them aloud). Denials about peeking were also related to moral understanding and first-order false belief understanding; that is, telling a lie successfully required deliberately creating a false belief in the mind of another. Additionally, children's ability to maintain their lies was related to their second-order belief understanding (e.g., Ann knows that Sally thinks her toy is in the box), a finding in line with research showing that second-order beliefs begin to emerge around 6 years of age and undergo steady development well into adolescence (Sullivan et al., 1994). These findings suggest that social and cognitive factors may play an important role in children's lie-telling abilities.

In a similar paradigm, designed for older participants, Evans and Lee (2011) examined 8- to 16-year-old children's tendency to lie, the sophistication of their lies, and related cognitive factors. Participants were left alone and asked not to look at the answers to a test, but the majority of children peeked. The researcher then asked a series of questions to examine whether the participants would lie about their cheating and, if they did lie, evaluate the sophistication of their lies. Additionally, participants completed measures of EF, including inhibitory control measured with a Stroop task. Results revealed

that the sophistication of 8- to 16-year-old children's lies, but not their decision to lie, was significantly related to executive functioning skills and performance on the Stroop task. In these studies, participants with a better performance on the Stroop were better able to conceal incriminating knowledge they ought not to know. According to these authors, the Stroop task is thought to measure both inhibitory control and working memory. In the situation created in these studies, participants were required to hold in working memory their incriminating knowledge in order to create answers different from this knowledge. At the same time, they must inhibit reporting the truth. Taken together, these findings suggest that whether a person is a good liar who is able to, or a bad liar who is not able to, maintain his/her lie, is dependent on working memory in conjunction with inhibitory control.

In a different study (Evans et al., 2011), Chinese preschoolers' ability to tell a strategic lie by making it consistent with the physical evidence of their transgression was investigated. Participants in this study were left alone in a room and asked not to lift a cup to see its contents. If children lifted up the cup, the contents would be spilled and evidence of their transgression would be left behind. Upon returning to the room, the experimenter asked children whether they peeked and how the contents of the cup ended up on the table. The findings revealed that young children were able to tell strategic lies to be consistent with the physical evidence by about 4 or 5 years of age, and this ability increases in sophistication with age. Furthermore, the study revealed that children's theory-of-mind understanding and inhibitory control skills were significantly related to their ability to tell strategic lies in the face of physical evidence. Although this study was conducted in a non-Western culture, no cross-cultural comparison was made and, although research suggests that Chinese children are more advanced than Western children in cognitive control (e.g., Lahat et al., 2010; Sabbagh et al., 2006), it is not known if Chinese children are more advanced at telling strategic lies than Western children.

In sum, studies examining the neural correlates of moral judgments with adults have shown that certain classes of moral dilemmas (i.e., difficult dilemmas) involve inhibitory control and detection of conflict. These studies show increased activation in ACC and DLPFC during judgments of these dilemmas (Greene et al., 2004). The role of cognitive control in moral and social judgments has also been studied with a behavioral/ERP paradigm in children, adolescents, and adults (Lahat et al., 2012b; Lahat and Zelazo, 2010). Findings reveal larger N2 amplitudes for adults, but not children, in response to conventional rather than moral violations. This finding suggests that the morality–convention distinction continues to develop well into early adolescence. Finally, the role of inhibitory control has also been demonstrated in moral behavior (e.g., Evans and Lee, 2011).

23.4 CHAPTER SUMMARY AND FUTURE DIRECTIONS

In this chapter, the role of cognitive control across different social behaviors was reviewed. The chapter focused on the development of the neural correlates of two specific cognitive control functions: inhibitory control and self-monitoring (including conflict and error monitoring). As described earlier, these specific functions have been found to develop with the maturation of the PFC and patterns of activation increase with age (Zelazo et al., 2008).

Studies examining the neural correlates of the development of inhibitory control have shown that PFC activation not only increases with age, but also becomes more focalized (e.g., Bunge et al., 2002; Durston et al., 2006; Luna et al., 2001). As discussed, with development, brain regions not associated with task performance decrease in activation, while regions relevant to task performance increase in activation. With development, children also show improvements in self-monitoring abilities. For example, they are better able to detect and correct errors (e.g., Backen Jones et al., 2003; Bullock and Lutkenhaus, 1984). These behavioral data are in line with findings from neurophysiological studies, which show an increase in ERN amplitude with age (Davies et al., 2004). An additional form of self-monitoring that has been studied is conflict monitoring. Some argue that error monitoring is a specific type of conflict monitoring, which occurs postresponse and, although these abilities are distinct, there is an overlap in their functional activation, namely the ACC (Ridderinkhof et al., 2004). Even young children have been found to recruit the ACC in tasks that require self-monitoring (Casey et al., 1997a,b).

Inhibitory control and self-monitoring have been found to show associations with individual differences and their social–emotional outcomes (e.g., Fox and Henderson, 2000; Lamm et al., 2012; McDermott et al., 2009; White et al., 2011). This body of research has shown that children with a fearful temperament who are also high in inhibitory control or self-monitoring are at risk of developing negative social–emotional outcomes, such as social withdrawal and anxiety disorders. Evidence on individual differences associated with cognitive control come mostly from behavioral and electrophysiological studies. Future research should examine the association between temperament and cognitive control using neuroimaging in order to better localize differences in brain activation.

Individual differences relating to cultural variations have also been found, particularly when comparing Chinese children with children from Western cultures. These studies provide behavioral (Sabbagh et al., 2006) as well as neurophysiological (Lahat et al., 2010) evidence for advanced performance on cognitive control tasks among Chinese children. It is possible that socialization processes that differ across the two cultures contribute to these differences in cognitive control. The cross-cultural neurophysiological work has been conducted with Asian children who grew up in North America. Future research should compare Western children with Asian children who are raised in Asia. This would provide a more pure cross-cultural comparison.

In this chapter, the role of cognitive control in the development of decision making and motivation was also reviewed. Studies have shown that the development of decision making takes an inverted U-shaped form, with steady improvements during childhood (e.g., Kerr and Zelazo, 2004) and a propensity for risk taking during adolescence (Somerville and Casey, 2010). fMRI studies with adolescents (e.g., Geier et al., 2010) have shown increased activation in brain regions associated with cognitive control during anticipation of reward. Most of the work has focused on monetary or other types of nonsocial rewards. Future research should examine the relation between cognitive control and social reward, such as social acceptance.

Research has shown that cognitive control also plays a role in the development of moral and social decisions, as well as moral behavior. Specifically, the role of cognitive conflict has been demonstrated in studies with adults, in which increased activation has been found in the ACC and DLPFC (e.g., Greene et al., 2001, 2004). Cognitive conflict has also been found to play a role in adults', but not children's, distinction between moral and conventional judgments, as reflected in N2 amplitudes (Lahat and Zelazo, 2010). Finally, a role for the development of inhibitory control has been identified in children's and adolescents' moral behavior (Evans and Lee, 2011). Future research on the role of cognitive control in the development of moral judgment should examine direct relations between neurophysiological correlates of moral judgments and various types of cognitive control. This would allow to better pinpoint which cognitive control functions are involved in moral development.

Executive Function
Development, Individual Differences, and Clinical Insights

C. Hughes

University of Cambridge, Cambridge, UK

24.1 INTRODUCTION

Executive function (EF) is an umbrella term that encompasses the set of higher-order processes (such as inhibitory control, working memory, and attentional flexibility) that govern goal-directed action and adaptive responses to novel, complex, or ambiguous situations (Hughes et al., 2005). Research into the neural substrate for EF (Golden, 1981) has long focused on the prefrontal cortex (PFC), but this traditional view recently has been challenged for two reasons. First, positron emission tomography studies demonstrate that EF tasks activate parietal areas involved in basic attentional processes more strongly than the PFC (for a review, see Jurado and Rosselli, 2007); similar findings also have been reported in a recent magnetic resonance imaging (MRI) study of EF in children and adolescents (Tamnes et al., 2010). Second, clinical studies show that early pathology in any brain region leads to executive deficits, such that, for children at least, intact EF depends upon the integrity of the entire brain, not just the frontal regions (Anderson and Catroppa, 2005).

Research into EF in children has grown exponentially over the past few decades. A recent Scopus search using the terms *executive functions* and *children* showed just 5 studies prior to 1980; 26 studies between 1980 and 1990; 216 studies between 1990 and 2000; and 1092 studies between 2000 and 2010. This massive expansion of research reflects the growth of interest in childhood clinical groups, and EF deficits are apparent in a number of different developmental disorders – especially attention deficit hyperactivity disorder (ADHD) and autism spectrum disorder (ASD) (Pennington and Ozonoff, 1996; Sergeant et al., 2002). However, recent years also have seen a rapid growth in studies of normative age-related changes in EF and its neural substrates, enabling a valuable crossover between research on typical and atypical development. As Tau and Peterson (2010, p. 162) put it, documenting normative pathways of brain development "provides the Archimedean point from which to interpret and understand the aberrant pathways of brain development that produce disease," whereas studying atypical groups "informs our knowledge of normal brain

development by throwing into relief the developmental pathways that are most sensitive to perturbation."

Both the pervasiveness of EF deficits in childhood disorders and the salience of EF for studies of normal brain development can be understood in terms of the protracted nature of EF development. Thus, EF skills begin to emerge in infancy (Diamond, 1988), show marked improvements across toddlerhood and the preschool period (Carlson et al., 2004; Hughes and Ensor, 2007; Hughes et al., 2010), and continue to improve during the school-age years (e.g., Huizinga et al., 2006), with some aspects of EF continuing to develop throughout adolescence (Luciana et al., 2005; Luna et al., 2004). Interestingly, although several reviews of EF development are available (e.g., Anderson, 2002; Best et al., 2009; Blair et al., 2005; Blakemore and Choudhury, 2006; Garon et al., 2008; Hughes and Graham, 2002), few span the full period of development (for an exception, see Diamond, 2002). To address this gap, the first section of this chapter provides a synopsis of research findings on developmental trajectories for EF from infancy to adolescence in both typical and atypical populations.

Having a protracted developmental course also makes EF a focus of interest for researchers interested in exploring environmental influences. As noted by Garon (2008) and Hughes and Ensor (2009), this topic of environmental influence on EF is a promising new direction for research because the slow maturation of the frontal cortex and its networks makes it heavily dependent on the environment (e.g., Noble et al., 2005). However, until recently, the processes underpinning environmental influences on EF have been, in research terms, largely *terra incognita*. To rectify this gap, the second section of this chapter provides an overview of three strands of recent research that investigate (1) effects of training or intervention programs on children's emerging EF skills, (2) influences of parent–child interactions on EF, and (3) studies of environmental influence on EF in clinical groups.

Interwoven with perspectives on EF that emphasize typical or atypical development, the expansion of research in this field also mirrors the intensity of research into children's understanding of mind; numerous studies have reported a robust association between EF and children's theory-of-mind skills that is evident across a broad age range, independent of covariant effects of language ability and intelligence quotient, and applies to both typical and atypical populations. In addition, recent research has demonstrated that early emerging skills in both EF and theory of mind are strong predictors of children's readiness for school and their performance in academic subjects. The third section of this chapter aims to bring together the findings from research, tracing links between EF and children's academic, sociocognitive, and social success at school.

24.2 NORMATIVE DEVELOPMENTAL TRAJECTORIES FOR EF FROM INFANCY TO ADOLESCENCE

The past two decades have seen a massive increase in the availability of child-friendly EF tasks (for a useful summary, see Garon et al., 2008), leading to dramatic improvements in the understanding of the development of EF. For instance, it is now known that EF is a unitary construct with partially dissociable components (Garon et al., 2008) that begins to emerge in the first few years of life (e.g., Diamond, 1991) and continues to develop through to adulthood (Huizinga et al., 2006). However, most studies in this field have been cross-sectional in design and have not controlled for peripheral task demands. As a result, both cohort effects and developmental changes in how children cope with peripheral task demands may contribute to age-related contrasts in EF performance. In addition, simplifying adult tasks to make them age-appropriate for young children carries the danger of losing the critical EF component (Garon et al., 2008). These notes of caution need to be remembered when considering the summary review of findings from infants to adolescents given below.

24.2.1 Infancy

The first evidence that EF emerges in the first year of life (much earlier than previously believed) came from studies using Piaget's object permanence task in which babies are repeatedly allowed to retrieve an attractive object from one location (A) before seeing it hidden at a new location (B). Early studies indicated that while 8-month-olds and older babies typically search correctly at location B, 5-month-olds persist in searching for the object at location A (e.g., Harris, 1975). Although Piaget interpreted this 'A not B' error as a failure to recognize that objects have an independent existence in the world (i.e., a lack of 'object permanence'), later studies showed that when looking times rather than physical reaches are used to assess perceptual understanding, even 4-month-olds do well (e.g., Baillargeon et al., 1985). Thus, young babies who make the A not B error in their reaching responses may know that the object has been moved, but fail to inhibit their previously successful (and therefore prepotent) reach to A. Thus, success on this task can be seen as reflecting infants' growing cognitive flexibility and volitional control (Diamond and Goldman-Rakic, 1989). Other tasks that also demonstrate early executive skills in infancy include a detour-reaching task, in which infants are invited to retrieve an object that is visible behind a Perspex screen; success on this task depends on making a 'detour reach' around the side of the screen (Diamond et al., 1989). In short, a rudimentary ability

to inhibit prepotent responses is clearly evident by 7–12 months (Diamond, 2002).

More recent studies of infants also indicate an early emergence of other aspects of EF. In particular, building on the finding by Rothbart et al. (2003) that 2-year-olds' anticipatory looking (i.e., looking to the location of a target prior to its appearance) is associated with parental ratings of self-regulation, Sheese and colleagues (2008) have reported that 6- and 7-month-olds who display high levels of anticipatory looking also show more signs of self-regulation in their approach toward novel toys. Together, these two studies indicate that executive attention (indexed by anticipatory looking) is also evident very early in life. Interestingly, Sheese et al. (2008) found that anticipatory looking was also associated with looking away from disturbing stimuli (facemasks), supporting proposals (e.g., Aksan and Kochanska, 2004; Rothbart et al., 2000) for a link between early systems of emotional control (e.g., fear and caution) and later systems of cognitive control.

24.2.2 Preschoolers

Research into the preschool years accounts for the lion's share of studies of EF in childhood. As will be discussed in the third section of this chapter, this focus on preschoolers partly reflects the intensity of research into children's understanding of mind, which shows dramatic improvements in the preschool years (e.g., Wellman et al., 2001). Another reason for a research focus on preschoolers is that a wide variety of age-appropriate tasks have been developed in response to the previous dearth of tasks suitable for young children (e.g., Carlson, 2005; Diamond et al., 1997; Espy et al., 1999; Hughes, 1998; Zelazo and Muller, 2002).

However, even when these conceptual and methodological factors are taken into account, the growth of research on preschool EF remains remarkable and is difficult to summarize briefly. Fortunately, a recent comprehensive review by Garon et al. (2008) is helpful in at least three respects. First, adopting the 'unity and diversity' model proposed by Miyake and colleagues (2000) to account for the coherent yet fractionated nature of EF in adults, Garon et al. (2008) demonstrate that the three key components of EF (working memory, response inhibition, and set shifting) in adults are all evident before the age of 3 years. Second, Garon et al. (2008) address the question of how developmental changes in EF across the preschool years should be characterized, and, consistent with proposals from other theorists (e.g., Rothbart and Posner, 2005), highlight the importance of age-related improvements in attention and coordination of distinct EF components. As they observe, attention also appears central to theoretical accounts that

characterize EF development in terms of increased ability to overcome prepotent thoughts/acts (Diamond, 2002) or latent representations (Munakata, 2001) or to integrate conflicting rules (Zelazo et al., 2003).

Third, Garon et al. (2008) offer a number of suggestions for future research. One suggested direction (discussed more fully in the next section of this chapter) concerns the importance of studying environmental influences, as the slow maturation of the PFC and its networks make it heavily dependent on the environment (Noble et al., 2005). Another suggested direction is the use of longitudinal designs in order to examine developmental changes in EF. This is an important point as research into preschool EF (like so many fields within developmental psychology) is heavily dominated by cross-sectional studies that do not allow researchers to control for individual differences. In one exceptional longitudinal study, Hughes et al. (2010) applied latent-variable analyses to demonstrate that: (1) latent factors for EF in preschool and early school age show measurement invariance (supporting the validity of across-time comparisons of average EF performance); (2) individual differences in the preschool latent factor for EF are positively related to both maternal education and early verbal ability; and (3) rates of growth in EF are inversely related to verbal ability (such that preschoolers with low verbal ability begin to catch up with their peers following the transition to school) but are unrelated to maternal education (i.e., there is no independent catch-up effect for children with less-educated mothers). As these findings illustrate, adopting longitudinal study designs to examine developmental trajectories in early EF is valuable, both theoretically and for the development of educational policy.

24.2.3 School Age

Studies of EF in school-aged children often involve computerized tasks, which allow researchers to standardize administration, to include large numbers of trials, and to collect information on reaction times. One widely used battery of computerized EF tasks is the CANTAB (CAmbridge Neuropsychological Tests – Automated Battery), which was developed for work with adult clinical groups (Luciana, 2003) and was first administered to children in the Hughes et al. (1994) study of children with ASD; subsequent studies have confirmed that the CANTAB is sensitive to EF deficits in ASD across a wide range of ages and ability levels (Ozonoff et al., 2004). Normative data on age-related improvements in EF in typically developing children (screened to exclude children with learning or behavioral difficulties) have also been gathered (Luciana, 2003).

A key finding to emerge from studies of EF across the school years is that step-wise improvements are evident at different ages for different aspects of EF. Specifically (as noted earlier), the preschool years are characterized by dramatic improvements in inhibitory control, but studies of young school-aged children highlight improvements in cognitive flexibility and studies of preadolescents emphasize improvements in working memory and planning ability. For example, using the intradimensional/extradimensional (IDED) shift task from the CANTAB battery, Luciana (2003) reported a marked improvement in children's ability to shift their mental set around the age of 6 or 7 years. The IDED task is a multistage task that is based on the Wisconsin Card Sorting Task, which requires participants to work out a rule for sorting cards (e.g., sort by color, number, or shape of stimuli) and, then, when they receive negative feedback indicating that the rule has changed, to shift strategy in order to sort by a new rule. In the same study, Luciana (2003) showed that clear improvements on the Tower of London planning task or on a self-ordered search test of working memory were often not evident before the age of 11 or 12 years. Other studies using different tasks have reported a similar contrast in the developmental trajectories of different aspects of EF. For example, several studies report improvements in mental flexibility around age 8 years (e.g., Anderson, 2002; Anderson et al., 2001c), while planning, organizing, and strategic thinking are typically reported to emerge later and to show age-related improvements throughout adolescence (Anderson et al., 1996, 2001a; De Luca et al., 2003; Krikorian et al., 1994; Welsh et al., 1991).

At odds with this general pattern, however, are findings from another study that suggest a long developmental progression for cognitive flexibility, with 13-year-olds still not at adult levels (Davidson et al., 2006). A closer look at the specific tasks suggests that the contrast in these findings may be explained by Diamond's (2009) 'all or none' theory. According to this theory, the brain and mind work effortlessly (or under difficult conditions) at a gross level, but require effort (or more optimal conditions) to work in a more selective manner. Thus, it is easier to inhibit a dominant response all the time than only some of the time. As a result, even older children are likely to show frequent errors on task-switching paradigms, such as those used in the Davidson et al. (2006) study. This study also revealed several other interesting developmental contrasts. For example, adults slowed down on difficult trials to preserve accuracy, but children (and especially young children) were impulsive and so made errors on difficult trials. These contrasting speed accuracy trade-offs highlight the value of using computerized tasks to assess EF. At the same time, these advantages may be offset by a reduction in sensitivity. For example, children with ASD have been found to perform significantly better on a computerized set-shifting task than on a manual version (Ozonoff, 1995). In addition, computerized tasks are likely to have lower ecological validity, such that there is still a need for manual tasks that mimic everyday EF demands. Here, one task battery that deserves mention is the behavioral assessment of dysexecutive syndrome (Norris and Tate, 2000), which includes tasks that tap into abilities for multitasking, problem solving, and strategic thinking.

24.2.4 Adolescence

Consistent with the findings from younger samples described above, different aspects of EF have been reported to show distinct trajectories across the adolescent years. For example, in a study of Australian 11- to 17-year-olds that included a variety of EF tasks, Anderson et al. (2001b) found clear linear age-related improvements on tests of selective attention, working memory, and problem solving, but no age-related difference in planning performance.

Also echoing findings from studies of younger samples is an emerging theme from the adolescent literature regarding the importance of considering EF alongside other key brain systems. For example, Tau and Peterson (2010) note that adolescents and adults differ not just in the maturity of their EF functions, but also in the extent to which they avoid risk and respond to reward/peer influence (adolescents are less risk-averse, more driven by reward and more easily influenced by peers). As a result, accounts of developmental change in everyday behavior should consider not only top-down EF systems but also bottom-up motivational and emotional responses to situations of risk and reward.

Similar conclusions emerge from a recent community-based study of relations between EF, problem behaviors, and risk taking in 10- to 12-year-olds (Romer et al., 2009). In this study, the children's self-reported impulsivity was inversely related to both working memory and reversal learning and explained individual differences in both externalizing problems and performance on a risk-taking task. Noting that interventions to improve children's working memory have led to reductions in impulsive behaviors (e.g., Klingberg et al., 2005), the authors of this study concluded that young people who have difficulties in considering multiple (and potentially conflicting) goals will be less likely to either 'look before they leap' or temper their interest in novel or exciting experiences.

24.3 CLINICAL INSIGHTS, FROM INFANCY TO ADOLESCENCE

In parallel with, and perhaps fueling the growth of, research on normative development in EF, studies of EF in atypical child populations have grown dramatically and yielded several interesting findings that together emphasize the extent to which EF can be impaired by brain abnormalities or insults, especially if these occur early in life.

24.3.1 Infancy

The first clinical study of EF in infancy highlighted the importance of dopamine for EF. Specifically, Diamond et al. (1997) conducted a 4-year longitudinal study of children treated early and continuously for phenylketonuria (PKU), a metabolic disorder characterized by a failure to convert phenylalanine to tyrosine (the precursor of dopamine) that, if untreated, is the most common biochemical cause of intellectual disability. On tests of working memory and inhibitory control, children with PKU with high plasma levels of phenylalanine performed more poorly than all other control groups (including siblings and PKU children with lower levels of phenylalanine). Moreover, this impairment was specific to performance on EF tasks, directly related to levels of phenylalanine, and evident across the age groups, from the youngest (6–12 months) to the oldest (3½–7 years).

Long-term deficits in EF are also found in infants born prematurely and infants exposed prenatally to high levels of alcohol. In a recent meta-analysis, Mulder et al. (2009) showed that children born prematurely displayed a variety of EF impairments, with the degree of impairment predicted by: (1) gestational age (i.e., extremely premature infants show greater deficits), (2) age at test (group differences attenuate with age), and (3) aspect of EF under test (this 'catch-up' effect is evident for selective attention skills but not for attentional set-shifting skills). No corresponding systematic review of EF in children with prenatal alcohol exposure is yet available, but individual studies consistently report deficits in EF that are independent of IQ (e.g., Connor et al., 2000; Green et al., 2009; Mattson et al., 1999; Schonfeld et al., 2001) and somewhat distinct from EF deficits in other groups, such as children with ADHD (e.g., Vaurio et al., 2008). Moreover, a recent friendship training study involving primary-school-aged children with prenatal alcohol exposure showed that parental ratings of EF predicted gains in social skills, even when effects of IQ were taken into account (Schonfeld et al., 2009). In short, prenatal alcohol exposure has long-term adverse effects on children's emerging EF skills, which in turn not only underpin academic achievement (see later in this chapter) but also play a key role in these children's social competencies.

24.3.2 Preschoolers

From a clinical perspective, preschool milestones in EF have attracted considerable attention from researchers studying the cognitive profiles associated with ASD. For example, Hughes and Russell (1993) demonstrated that children with ASD (with a verbal mental age of at least 4 years) displayed significant difficulties on two tasks that most 4-year-olds passed with ease. The first of these was the 'Windows' task in which, for each of 20 trials, children could win a treat (visible through a window in a box) by choosing a visibly empty box. Children with ASD (and many 3-year-olds) chose the baited box, and often persisted in this incorrect response across all 20 trials. Moreover, administering the task in four different conditions (verbal/nonverbal; competitor present/absent) led to no change in the results. In the second task, to retrieve a large and attractive marble from inside a metal box, children needed to perform a simple but arbitrary means–end action (flicking a switch at the side of the box that turned off a simple circuit with an infrared beam that, if tripped, activated a small trapdoor on which the marble was resting). Once again, most older children with ASD and typically developing 3-year-olds (but not 4-year-olds) persisted in making a direct and unsuccessful attempt to reach into the box.

These findings added weight to reports of impaired performance by children with ASD on more traditional (and complex) EF tasks (e.g., Hughes et al., 1994; Ozonoff et al., 1991; Prior, 1979) and sparked a sustained program of research on EF deficits in ASD (for reviews, see Hill, 2004; Pennington and Ozonoff, 1996). The breadth and sophistication of current research in this field are nicely illustrated by a handful of recent findings that include: (1) evidence for associations between impaired inhibitory control and high-level repetitive behaviors (e.g., compulsions and preoccupations) in children with ASD (Mosconi et al., 2009); (2) imaging results that indicate reduced functional connectivity and network integration between the frontal, parietal, and occipital regions among individuals with ASD in completing EF tasks (Solomon et al., 2009); (3) longitudinal evidence for the importance of early EF in shaping the developmental trajectory of theory-of-mind skills in children with ASD (Pellicano, 2010); and (4) evidence for age-related improvements in EF from childhood to adolescence in ASD, indicating the presence of plasticity and suggesting a prolonged window for effective treatment (for a review, see O'Hearn et al., 2008).

24.3.3 School Age

Earlier, in the section on EF in typically developing school-aged children, concern was raised about the ecological validity of the computerized tasks that are often used with this age group. This issue of ecological validity is also salient from a clinical perspective, as EF deficits in children with ADHD (who, by definition, show marked problems of impulsivity/inattention/disorganization in their everyday lives) are often less pervasive and severe than the EF deficits shown by children with ASD (e.g., Geurts et al., 2004; Goldberg et al., 2005; but see also Happé et al., 2006), such that contemporary causal accounts of ADHD also include additional deficits in the signaling of delayed rewards (e.g., Sonuga-Barke, 2005).

In his review, Sonuga-Barke (2005) also argues for the importance of considering EF deficits alongside environmental influences, a view that is supported by the peak in diagnosis for ADHD at age 12 (Mandell et al., 2005); that is, just following the transition to secondary (or 'middle') school, which brings a significant increase in demands for self-controlled and planful behavior. Indeed, a recent longitudinal study that modeled trajectories for parent-rated ADHD symptoms confirms that the age-related decline in symptoms is at least transiently reversed following the transition to secondary school (Langberg et al., 2008). Likewise, in a study that involved carefully matched samples, Happé et al. (2006) found that children with ASD, but not children with ADHD, showed age-related improvements in EF performance. Together, these findings highlight the importance of adopting a developmental perspective when examining EF deficits in atypical groups.

24.3.4 Adolescence

Much of the clinical work on EF in adolescence has concerned risk taking and substance abuse. In particular, several researchers have reported a robust predictive association between poor EF and impulsivity in preadolescence and high levels of drug use in late adolescence (e.g., Aytaclar et al., 1999). Similarly, in a review of alcohol addiction in adolescence, Wiers et al. (2007) proposed a model in which repeated alcohol use leads to compromised EF development coupled with sensitization of a reward-based approach system. Note that this model adopts Tau and Peterson's (2010) recommended dual focus on top-down and bottom-up processes.

In the dual-focus study by Fairchild et al. (2009), there is a comparison between how adolescent boys with early- versus late-onset conduct disorder (CD) or controls perform on tests of EF (Wisconsin Card Sort Test) and decision making (Risky Choice task) under conditions of varying motivation and stress. Controlling for effects of IQ, they found nonsignificant group differences in EF, but more risky choices in both CD groups than in controls; adolescent boys with early-onset CD made risky choices even when the gains were relatively small. These findings suggest a shift in the balance between sensitivity to reward and punishment among boys with CD (particularly the early-onset form) that is similar to the imbalance proposed by Wiers et al. (2007) in top-down and bottom-up processes in addictive adolescents. Perhaps unsurprisingly then, CD is, as Fairchild et al. (2009) note, associated with a significantly increased susceptibility to substance-use disorders.

24.4 FROM BIOLOGICAL TO ENVIRONMENTAL PREDICTORS OF INDIVIDUAL DIFFERENCES IN EF

Biological studies have been hugely influential in research on EF in childhood. For example, the impact of Diamond and colleagues' (1989) EF account of age-related improvements in infants' performance on the A not B task was greatly increased by the convergent findings from parallel studies of: (1) rhesus monkeys (Diamond et al., 1989), which highlighted the dorsolateral PFC as pivotal to success on this task, and (2) children with PKU, which demonstrated the importance of dopamine for success on a wide battery of simple EF tasks (Diamond et al., 1997). More recently, in their review of studies using functional MRI, Tau and Peterson (2010) concluded that age-related improvements in EF in childhood are associated with increased activation of (dopamine-rich) frontal and striatal circuits.

Other seminal findings include the demonstration of Golden (1981) that myelination of the prefrontal cortex is associated with age-related improvements in EF in children. More recent technological advances have led to significant progress in documenting parallels between milestones in EF development and changes in brain myelination (e.g., Nagy et al., 2004). This progress is particularly evident in Giedd et al.'s (1999) large-scale longitudinal MRI work on adolescence, which has shown that this period is characterized by both a linear increase in white matter and a nonlinear decrease in gray matter. Gains in white matter have clear functional consequences, which include faster and more efficient sharing of information within the frontostriatal circuits and smoother communication between the frontal cortex and other brain regions (Paus, 2010). Peak periods of reduction in gray matter occur just after puberty and at the transition from adolescence to adulthood; although typically attributed to synaptic pruning, this 'loss' of gray matter may simply reflect gains in white matter (Paus, 2010). As noted in a recent review (Blakemore and Choudhury, 2006), structural changes in the adolescent brain are particularly evident in the frontal cortex

and are linked to age-related improvements in inhibitory control (Luna et al., 2004), working memory (e.g., Luciana et al., 2005), and decision making (e.g., Hooper et al., 2004).

The studies of EF in atypical groups summarized in the previous section provide a third strand of research with a clear biological perspective. In particular, impairments in EF are most pronounced among children with ADHD or ASD (Pennington and Ozonoff, 1996), two disorders that show substantial genetic influence (Kuntsi et al., 2004; Ronald et al., 2006). Indeed, EF has recently been implicated in the genetic basis for ADHD (e.g., Bidwell et al., 2007; Gau and Shang, 2010). More direct evidence for strong genetic influences on early EF comes from studies that include genotyping (e.g., Fossella et al., 2002; Rueda et al., 2005), which demonstrate that children with the homozygous long allele for the DAT1 gene (associated with high effortful control and low extroversion) outperform those with the heterozygous (long/short) allele on EF tests of conflict resolution (for a recent review of molecular genetic studies of EF in children, see Brocki et al., 2009).

However, none of the above findings precludes environmental factors also contributing to either developmental change or individual differences in EF. Indeed, genetic factors often show substantial interactions with environmental influences, such that genetic vulnerability is expressed only among individuals exposed to environmental stressors, such as harsh parenting or family chaos (Asbury et al., 2003, 2005). Moreover, as noted earlier, the development of EF has a very protracted course, which makes it particularly sensitive to environmental influence (Farah et al., 2006; Noble et al., 2005). In addition, current cognitive models of EF (e.g., Duncan, 2001) highlight the fluidity of relations between the prefrontal cortex and EF performance. Specifically, neurons within the PFC show a rapid adaptation to changing task demands (Freedman et al., 2001), making it difficult to map between behavioral and neuronal functions. In comparison with research on biological influences, studies of environmental influences on EF are largely *terra incognita*. Nevertheless, there is growing recognition that early experiences contribute to children's neurocognitive development. Specifically, unfavorable early environmental experiences adversely affect both brain structure (e.g., De Bellis, 2005) and function (e.g., Rutter and O'Connor, 2004); conversely, positive experiences (especially with caregivers) appear to have a positive impact on brain development (e.g., Nelson and Bloom, 1997; Schore, 2001). As Bierman et al. (2008, p. 823) put it, 'EF development depends, in part, upon sensitive responsive caregiving and opportunities for guided exploration of the social and physical environment, fostering sustained joint attention, emotional understanding, planning, and problem solving.'

Direct evidence for environmental effects on EF comes from intervention studies, which can be considered in two sets. The first set of studies involves direct training on task analogs. In the first of these studies, Kloo and Perner (2003) gave a simplified version of the Wisconsin Card Sort task to typically developing preschoolers and found that both card-sorting training and false-belief training (each delivered in two sessions on separate days) led to positive effects on EF at posttest. More recently, Rueda et al. (2005) gave 5 days of attention training to groups of 4- and 6-year-olds, and reported that children who performed poorly at pretest showed the greatest gains from this training program, with the overall improvements in executive attention and IQ performance being equivalent to half the difference between older and younger participants (i.e., to gains expected from 1 year's difference in age). Similarly, in a recent review, Klingberg (2010) reported that, across a wide variety of age groups, training leads to significant improvements in working memory. However, not all aspects of EF appear so malleable to training. For example, a 5-week preschool training program has been shown to produce significant improvements in working memory but not in inhibitory control (Thorell et al., 2009), raising interesting questions as to whether the distinct processes that underpin different aspects of EF lead to contrasts in the extent to which performance can be improved by training. The final study in this set of training interventions was conducted by Karbach and Kray (2009) and involved training on task switching, administered to both school-aged children (aged 8–10 years) and two groups of adults (aged 18–26 and 62–76 years). All three groups showed positive effects that transferred to other EF tasks and to tests of fluid intelligence (e.g., tests of abstract thinking and reasoning); however, when the training tasks were variable, improvements were reduced for children but increased for adults. This interaction effect highlights the importance of adopting a developmentally sensitive approach to the development of interventions.

The second set of intervention studies adopts a broader and more naturalistic approach and is thus perhaps of greater relevance for theories of how everyday social environments might impinge on children's EF development. At least three such interventions have been assessed using randomized control trials (RCTs). The first of these, Head Start REDI (REsearch based, Developmentally Informed), is integrated into the Head Start prekindergarten program for disadvantaged children and involves brief lessons, 'hands-on' extension activities, and specific teaching strategies linked empirically with the promotion of social–emotional competencies, language development, and emergent literacy skills. In their RCT, Bierman et al. (2008) reported that the REDI intervention led to significant improvements in

children's abilities to stay on task, coupled with marginally significant gains in set-shifting performance. Another well-recognized intervention is the Vygotskian 'Tools in the Mind' preschool curriculum (Bodrova and Leong, 1996; Diamond et al., 2007), which includes a variety of specially designed activities (e.g., sociodramatic play and shared reading) that enable children to progress from external to shared to self-regulation; teachers are also trained to foster early skills in literacy and mathematics by encouraging reflective thinking and metacognition. Interestingly, although language plays a pivotal role in Vygotskian accounts of cognitive development, the Tools curriculum appears to have positive effects on EF (as indexed by low problem behavior scores), but no significant impact on language development (Barnett et al., 2008). The third RCT focused on an 8-week school-based intervention for older children (7- to 9-year-olds) that aims to promote mindful awareness practices through twice-weekly half-hour sessions. Comparing teachers' and parents' pre- and post-program ratings of EF skills, Flook et al. (2010) reported that less well-regulated children showed particularly clear treatment-related gains (evident both at school and at home); note that this finding echoes earlier results from preschoolers (e.g., Rueda et al., 2005).

Together, the findings from these three RCTs support two of the three dimensions of adult–child interactions that Carlson (2003) has proposed as likely to favor EF in children: *scaffolding* (which provides children with successful experiences of problem-based learning) and *mind-mindedness* (which provides children with verbal tools for progressing from external to internal forms of self-regulation). Positive effects on EF of the third dimension of *sensitivity* (which provides infants with successful experiences of impacting on the environment) have been reported by Bernier et al. (2010) in their recent longitudinal study of 80 infants in which maternal sensitivity, mind-mindedness, and scaffolding (or 'autonomy support') were evaluated at 12–15 months of age, and EF was assessed at 18 and 26 months. All three measures of parenting predicted child EF; however, once the effects of maternal education and general cognitive ability were taken into account, scaffolding was the strongest predictor of EF at each age. Another recent study, conducted by Bibok et al. (2009), offers a refinement of how parental scaffolding may promote young children's EF skills (indexed by performance on an attention-switching task). Specifically, observations of parents scaffolding children's goal-directed activities revealed that the *timing* of parents' elaborative utterances was a key predictor of children's attention-switching skills.

In short, there is now good evidence that parents' deliberate efforts to scaffold children's goal-directed activities do indeed foster the development of early EF skills. However, as highlighted by research on children's developing social understanding, family influences are often incidental rather than deliberate. For example, young children are extremely acute observers of family life, paying particularly close attention to injustices such as parents' differential treatment of siblings (Dunn, 1993). This point can be applied to young children's observational skills more generally; most parents will be able to recall episodes in which their actions have been mimicked with uncanny accuracy. This attention to detail favors children's rapid mastery of complex action plans: while simple mimicry of adults' planful behavior does not constitute executive control, acquiring a repertoire of 'goal-directed' acts is likely to promote EF skills. Support for this view comes from a recent longitudinal observational study by Hughes and Ensor (2009) involving a socially diverse sample of 125 children. In this study, both maternal scaffolding (in structured play with jigsaws) and opportunities for observational learning (indexed by maternal strategic behavior in a multitasking paradigm and in a shared tidy-up task) predicted improvements between the ages of 2 and 4 in children's EF scores, even when effects of verbal ability were controlled. Note that including EF assessments at both time points enabled Hughes and Ensor (2009) to take the temporal stability of individual differences in EF into account and so minimize the confounding effects of genetic factors (Kovas et al., 2007).

Reinforcing the importance of incidental effects, Hughes and Ensor (2009) also found that EF development from age 2 to age 4 was *negatively* correlated with parental ratings of disorganized and unpredictable family life, suggesting that families can hinder as well as help young children's emerging EF skills. Here it is worth noting that the social diversity of Hughes and Ensor's (2009) study sample is important: just as socioeconomic (SES) effects appear strongest at the bottom end of the scale (e.g., Scarr, 2000), adverse environmental measures (e.g., ratings of family chaos) may only show significant variance if low SES families (who are most at risk of exposure to multiple stressors) are included. Using an expanded sample from the same longitudinal study (i.e., the target children, plus friends recruited at age 4; $N = 191$), Hughes et al. (in preparation) have applied latent-variable analyses to demonstrate that each of three distinct measures of maternal well-being (specifically, depression, parental efficacy, and satisfaction) showed independent associations with individual differences in EF. Interestingly, of these three factors, only maternal depression was also (negatively) related to individual differences in children's verbal ability; that is, while positive effects of favorable family environments appear specific to EF, unfavorable family environments appear to adversely affect cognitive development in general. Note also that the significant inverse relation between maternal depression and preschool EF

reported by Hughes et al. (in preparation) appears developmentally specific, as research on both older children and adolescents with depressed mothers has led to null findings (Klimes-Dougan et al., 2006; Micco et al., 2009). That said, the significant inverse relation between maternal depression and poor EF in preschoolers reported by Hughes et al. (in preparation) is supported by findings from a recent study of internationally adopted children, which demonstrate that, despite good catch-up in many specific areas of development, these young children (who were exposed to severe adverse early environments) showed persistent difficulties in EF and attentional regulation (Jacobs et al., 2010).

Clinical studies have also highlighted the importance of environmental influences. For example, studies of children who have experienced maltreatment or severe neglect highlight the impact of such extreme adverse environments on neuroendocrine and autonomic stress reactivity, which in turn leads to increased demands on EF systems of regulatory control (e.g., Bierman et al., 2008; Cicchetti, 2002). Moreover, findings from children with traumatic brain injury indicate that higher-order brain functions (such as EF) are particularly vulnerable while they are still emerging. Specifically, in their recent review of the effects of early brain injury on EF, Anderson et al. (2010) examined findings from children with focal brain pathology evident on MRI scans; they compared EF performance in late childhood/adolescence (assessed across a variety of domains) in children who sustained early brain injury at each of six developmental periods (congenital/perinatal/infancy/preschool/mid-childhood/late childhood), with these six groups being matched for gender, SES, lesion size, location, or laterality. Their findings clearly supported theoretical perspectives that emphasize vulnerability rather than plasticity in brain function. Specifically, children who experienced brain injury very early in life displayed markedly more severe deficits in EF (and IQ). In other words, while the development of EF can be disrupted, with either transient or more permanent consequences, EF skills, once established, are relatively robust (Johnson, 2005; Thomas and Johnson, 2008).

24.4.1 Early EF Predicts Academic, Sociocognitive, and Social Success at School

This third section aims to bring together the findings from research tracing links between EF and children's academic, sociocognitive, and social success at school. Interestingly, each of these research areas highlights different aspects of EF: working memory appears central in accounts of EF and academic performance; cognitive flexibility is highlighted by more than one account of EF and social cognition; and inhibitory control is central

to accounts of EF and social success. At the same time, overlapping associations are likely, as there is very close interplay between children's academic ability, social understanding, and social behavior at school.

24.4.1.1 EF and Academic Performance

Over the past two decades, research into the neurocognitive underpinnings of children's competence in core academic domains such as literacy and numeracy has expanded rapidly; interestingly, several accounts give EF (especially working memory) a prominent role (e.g., Blair and Razza, 2007; Gathercole and Pickering, 2000; Geary, 1990). Empirical research confirms the importance of working memory for academic achievement. For example, in a recent longitudinal study, Alloway and Alloway (2010) found that working memory at age 5 (i.e., at the start of formal education) eclipsed IQ as a predictor of academic success 6 years later. Likewise, accounts of academic failure among children and adolescents with ADHD highlight the importance of deficits in EF (e.g., Alloway et al., 2010; Clark et al., 2000), while Dahlin (2010) found that primary school children with special needs who completed a cognitive training program designed to enhance working memory also displayed accelerated reading development. That said, the role of working memory in mathematical competence is more complex than previously thought (Geary, 2010). In particular, echoing the finding (discussed in the first section of this chapter) that developmental timing is a stronger predictor of EF impairment than location of brain injury (Anderson et al., 2010), recent studies have shown significant changes in brain–mathematics relations as children develop and mature (Ansari, 2010; Meyer et al., 2010).

Working with younger children, and adopting a rather different theoretical perspective (in which early EF rather than academic performance is center stage), Blair and colleagues have shown that individual differences in EF in preschool predict both school readiness and children's success in numeracy and literacy (Blair and Diamond, 2008; Blair and Peters, 2003; Blair and Razza, 2007; Razza and Blair, 2009). In their review of this field, Blair and Diamond (2008) argue that early self-regulation reflects an emerging balance between emotional arousal and cognitive regulation, such that self-regulation (and hence children's school readiness) is likely to be enhanced by school interventions that link emotional/motivational arousal with activities designed to promote EF.

More recently, Hughes and Ensor (in press) have extended this research field in two ways: adopting a developmentally dynamic approach to examine *growth* of EF across the transition to school and considering

individual differences in EF trajectories in relation to children's own *perceptions* of their (academic and social) success at school. Research on children's self-perceived academic abilities has burgeoned over recent years, fueled by the finding that individual differences in IQ fail to account for up to 50% of the variance in academic performance (e.g., Chamorro-Premuzic and Furnham, 2005; Rhode and Thompson, 2007). Indeed, a meta-analytic review has shown that, even controlling for previous achievement, self-perceived abilities exert small but consistent effects on later achievement (Valentine et al., 2004). Conversely, poor self-perceptions in early childhood are associated with loneliness, withdrawal, and peer exclusion (Coplan et al., 2004). Together, these findings suggest that self-perceptions may be a key aspect of children's psychological (as opposed to practical) school readiness. In their study (in which 191 children were followed from ages 4 to 6), Hughes and Ensor (in press) found that, even with effects of concurrent verbal ability and EF controlled, children who had made rapid gains in EF across the transition to school reported higher levels of academic competence at age 6. Given that this is the first study to report an association between preschool EF and school-children's self-perceived abilities, it is worth noting that similar findings have been obtained from adult samples. In particular, Tangney and colleagues (2004) have reported that, among adults, individual differences in self-control (a construct that is closely related to EF) show robust associations with individual differences in self-esteem.

24.4.1.2 EF and Social Cognition

The finding that individual differences in EF trajectories predict children's self-perceived academic competence brings us to another hot topic, namely the robust association between variation in preschoolers' EF skills and in their understanding of mind. Interestingly, this link between EF and understanding of mind is evident at several different periods of development, from toddlerhood (e.g., Carlson et al., 2004; Hughes and Ensor, 2005) to adolescence (Dumontheil et al., 2010). Equally remarkable, the association between EF and theory of mind has been reported for a variety of clinical groups, including children with ASD (e.g., Pellicano, 2007), hyperactivity or conduct problems (Hughes et al., 1998), traumatic brain injuries (Dennis et al., 2009), and fetal alcohol syndrome (Rasmussen et al., 2009). Thus, the link between EF and theory of mind appears pervasive. How then should it be explained?

In an early review of the evidence for associations between EF and theory of mind, Perner and Lang (1999) offered five possible explanations: (1) *theory-of-mind skills are necessary for children to pass EF tasks* (e.g., in order to inhibit a particular response, children have to be able to represent it as maladaptive); (2) *EF is needed for children to develop their understanding of mental states* (e.g., experience of goal-directed action improves children's conceptual understanding of intentional states); (3) the relevant theory-of-mind tasks require EF (e.g., standard false-belief tasks place heavy demands on children's inhibitory control and/or working memory); (4) *tests of both EF and theory of mind require the same kind of embedded conditional reasoning*; and (5) the two systems are not functionally related, but have overlapping or neighboring *neural substrates*.

Having reviewed the evidence, Perner and Lang (1999) concluded that only a third of these proposals could be ruled out with confidence; in a subsequent study (see also Perner et al., 2002), the fourth account was also ruled out (as false-belief tasks appear as difficult as card-sorting tasks, despite requiring less complex conditional reasoning). Since then, evidence that similar brain regions are implicated in EF and theory of mind has grown (for reviews, see Perner and Aichhorn, 2008; Perner et al., 2006); thus, the fifth account (neuroanatomical proximity may well contribute to the association between the two domains) remains plausible. Indeed, very recent research demonstrates that dopamine, long recognized as pivotal to EF (e.g., see studies of PKU described in the first section of this chapter), also plays a key role in children's growing understanding of mind. For example, findings from a recent EEG study indicate that the dorsal medial PFC (which is rich in dopamine receptors and lies at the end of the mesocortical dopamine pathway) is a specific neurodevelopmental correlate of preschoolers' theory-of-mind development (Sabbagh et al., 2009). Likewise, using an archive of preschoolers' EEG recordings, Lackner et al. (2010) have reported that individual differences in eye-blink rate (an indirect but reliable measure of dopamine function) predicted theory-of-mind performance even controlling for several other related factors, including age, verbal ability, gender, and performance on a Stroop task (which taps the ability to inhibit a maladaptive response). Interestingly, as Lackner et al. (2010) note, dopamine provides a mechanism that may explain *both* neurobiological and experiential influences on theory-of-mind development. Specifically, dopamine promotes the neural plasticity needed to respond flexibly to environmental feedback by changing goals and expectations (e.g., Montague et al., 2004) and so may mediate the impact of family factors known to predict theory-of-mind development (e.g., frequencies of family conversations about mental states) (Ensor and Hughes, 2008) or of interactions with siblings (Perner et al., 1994) that depend on children's ability to reflect on (and revise) their own concepts of mind in order to accommodate new information from the environment.

Another area of progress in this research field has been the growth of longitudinal studies, including

microgenetic studies (e.g., Flynn, 2006) and studies of toddlers (Carlson et al., 2004; Hughes and Ensor, 2007). One consistent finding to emerge from these studies is that early EF predicts later mental-state awareness more strongly than early mental-state awareness predicts later EF. This asymmetry in predictive relationships challenges Perner and Lang's first account (namely that theory of mind provides a foundation for EF). Instead, without going as far as stipulating that EF is, in some sense, necessary for the emergence of mental-state awareness, it seems reasonable to argue that EF improvements in the preschool years help explain how children *make use* of their early intuitive understanding of mind.

It is also worth noting that the relationship between EF and theory of mind may well be developmentally dynamic. For example, in a critique of the original theory-of-mind account of ASD (which is often diagnosed long before children are expected to pass false-belief tasks), Tager-Flusberg (2001) proposed that early-onset 'socioperceptual' skills (or intuitive mentalizing) depend on modular cognitive processes, whereas later-onset 'sociocognitive' skills (or off-line mental-state reasoning) depend on other aspects of cognition, such as language and EF. This model of dual processes (e.g., Apperly et al., 2009; de Vignemont, 2009) also goes some way to explaining why typically developing young children can show quite sophisticated mentalizing skills in their everyday interactions and yet fail experimental false-belief tasks.

Note also that other models of theory-of-mind development also suggest a developmentally dynamic relationship with EF. For example, Wellman and colleagues (Wellman and Liu, 2004) have proposed that improvements in children's understanding of mind involve a series of distinct achievements, such that different aspects of EF may be particularly important for specific milestones. Conversely, the stage-like nature of development in EF outlined in the first section of this chapter also suggests the need for a more differentiated approach. For example, in their study of children with traumatic brain injuries, Dennis et al. (2009) used path analysis to elucidate the nature of relations between EF and theory of mind and argued that their findings support models of EF in which inhibitory control serves as a foundation for other aspects of EF, in particular working memory (Barkley, 1997). Specifically, Dennis et al. (2009) found that the relationship between impaired inhibitory control and theory of mind was mediated, at least among children with traumatic brain injury, by impairments in working memory.

24.4.1.3 EF and Social Competence

For adults, there is robust evidence that deficits in EF are associated with problems of antisocial behavior: in a meta-analytic review of this literature, Morgan and Lilienfeld (2000) reported that the average EF performance of antisocial groups fell 0.62 standard deviations below that of control groups. Building on this work, Raine (2002) reviewed evidence from neuropsychological, neurological, and brain imaging studies and concluded that prefrontal structural and functional deficits are implicated in antisocial or aggressive behavior throughout the lifespan. Most recently, Beauchamp and Anderson (2010) have conducted a theoretical review of the cognitive underpinnings of children's developing social skills and noted that, within EF, attentional control (i.e., self-monitoring, response inhibition, and self-regulation) is especially critical.

In one of the earliest studies to link EF to young children's social competence (and the first to use direct observational methods), Hughes et al. (2000) found that, in a socially diverse sample of preschoolers (half of whom had been rated by parents as 'hard to manage'), poor performance on a battery of EF tasks (but not on theory-of-mind tasks) was associated with higher frequencies of anger and antisocial behavior toward friends. In other words, the interpersonal problems of these hard-to-manage preschoolers appear not to reflect difficulties in social understanding *per se*, but rather failure of behavioral regulation. In a follow-up study with the same sample, Hughes et al. (2001) showed that poor EF at age 4 predicted negative behavior at age 5 and that this group of hard-to-manage children continued to show rule violations and perseverative errors at age 7 (Brophy et al., 2002).

In a further longitudinal observational study (for more details, see Hughes, 2011), Hughes and colleagues followed a socially diverse sample of 140 children from toddlerhood through to school age, recruiting best friends for each target child at age 4, such that their findings are best presented in two parts. In the first, Hughes and Ensor (2008) examined children's EF, verbal ability, and theory-of-mind scores at ages 2, 3, and 4 in relation to aggregate (multi-informant and multi-setting) measures of problem behaviors at each time point and made the following findings: (1) poor EF at age 2 predicted worsening problem behaviors from ages 2 to 4; (2) individual differences in EF at age 3 fully mediated the influence of age 2 language deficits upon age 4 problem behaviors; and (3) by age 4, individual differences in problem behaviors showed specific associations with individual differences in EF (but not theory of mind or verbal ability). Capitalizing on the expanded sample (N = 191), Hughes and Ensor applied latent growth models, which showed that high EF gains across the transition to school predicted low levels of teacher-rated emotional symptoms, hyperactivity, conduct problems, and peer problems at age 6 (as well as higher self-reported academic competence, as noted earlier). Together, these findings highlight the importance of

preschool EF for early social adjustment and demonstrate the value of examining developmental change in EF (gains in EF across the transition to school predicted social outcomes even when individual differences in concurrent EF were controlled).

Links between EF and social competence may also be indirect. For example, Razza and Blair (2009) have reported that false-belief understanding mediates the association between early individual differences in children's EF and later teacher ratings of children's social competence. On a related note, Maszk et al. (1999) found that 4- to 6-year-olds rated by peers and teachers as high in behavioral and emotional self-control became increasingly popular over the school year and so argued that individual differences in self-control may be meaningful for how children are viewed by others and hence for how they view themselves. This raises the interesting possibility with regard to Hughes and Ensor's findings. Specifically, children's awareness of their own gains in EF across the transition to school may shape both social behavior and self-concepts. If so, interventions to improve children's social adjustment might aim beyond increasing children's EF to ensuring that children are aware of their own progress in regulating and organizing their thoughts and behaviors.

At this point, it is worth noting that the findings reviewed in this chapter and elsewhere suggest that EF can act as a moderator, mediator, and outcome of interventions. For example, studies of both school-aged children (e.g., Flook et al., 2010) and preschoolers (e.g., Rueda et al., 2005) indicate that the effects of interventions are often particularly impressive for children with poor EF. Likewise, improvements in children's inhibitory control have been shown to at least partially mediate the positive effects of the PATHS curriculum on children's behavior (Riggs et al., 2006). Similarly, the three RCTs reviewed earlier in this chapter all demonstrated that positive effects on EF can be expected from enriched and structured curricula that promote scaffolding (and hence lead to experiences of successful problem-based learning) and adult mindmindedness (enabling a progression from external to internal forms of self-regulation). These multiple roles for EF in interventions to promote social behavior highlight the importance of adopting a broad and contextualized approach to identifying underlying mechanisms. The next step is to place research on interventions within a developmental perspective to identify whether different processes are pivotal for different age groups.

24.5 CONCLUSIONS

This chapter on EF in childhood has covered considerable ground, including development from infancy to adolescence in typically developing and atypical groups; positive and negative effects of environmental influences (from training on specific tasks to exposure to enriched and predictable environments); and academic, sociocognitive, and social outcomes associated with individual differences in early EF (or EF trajectories). Perhaps the main pair of conclusions to emerge from this review is that both continuities and contrasts in EF in children of different ages are striking. One striking commonality across studies of typically developing children of different ages is a close interplay between top-down systems of EF and bottom-up reward-oriented systems, such that, from infancy through to adolescence, poor EF appears associated with risk taking and sensation seeking. Indeed, research on several atypical groups, including children with ADHD, CD, or problems of substance abuse, also highlights this interplay between top-down and bottom-up processes. Although not yet evident in research on ASD, it is worth noting that the amygdala, which is a key substrate involved in reward processing, is central to at least one prominent account of ASD (Baron-Cohen et al., 2000). Thus, extending this dual focus on EF and reward processing to children with ASD would appear a fruitful direction for future research.

A second notable developmental continuity is that, across a wide age range, typically developing individuals with good EF are more likely than their peers to do well on tests of theory of mind and show positive self-concepts and less likely to display antisocial behaviors. Perhaps related to these stable correlates of EF, longitudinal studies support EF as a predictor of later academic achievement in both young children and adolescents. Finally, across a wide variety of ages, at least some aspects of EF (e.g., working memory) appear malleable to training effects.

Examples of age-related contrasts include differences in the nature of EF: improvements in some aspects of EF (such as inhibitory control) can be seen from a very early age, while other aspects (e.g., planning) do not show marked improvements until much later on in development. Another important contrast concerns the extent to which EF can be associated with a localized neural base: age-related improvements in EF appear hand in hand with an increase in frontostriatal activation, such that development is characterized by a progression from diffuse to specific neural substrate. Several age-related functional changes in children's performance on EF tasks suggest that this progressive localization of neural substrate may reflect increases in how strategic children and adolescents are when completing EF tasks. For example, adults and children differ markedly in how they respond to more challenging situations; while adults can reduce their speed of response to remain accurate, young children typically show a drop in accuracy. Similarly,

young children are particularly likely to show an 'all or none' effect, in that they can inhibit a response if this is consistently required of them, but find it much harder to cope with situations that place varying demands on this system of inhibitory control. Finally, related to these contrasts in strategy use, training studies indicate an age-related contrast in the optimal format of the training tasks, with task variability increasing training benefits in adults but reducing training benefits in children.

Together, the above age-related contrasts lead to a third key conclusion, namely the need to take developmental issues seriously when examining a construct such as EF that shows such a protracted developmental course. For example, if the differences noted above do indeed reflect an age-related contrast in strategy use on EF tasks, then the validity of across-age comparisons is in question, as different sets of skills may well underpin performance on the same task for children of different ages. An important first step in addressing this issue is to establish measurement invariance before comparing EF skills across different age groups (cf. Hughes et al., 2010). Developmental issues are also raised by findings from studies of atypical groups. Thus, studies comparing different clinical groups (e.g., children with ASD and children with ADHD) should be designed so that contrasts in developmental *trajectories* can be elucidated. The few existing studies that adopt a developmental perspective indicate that children with ASD may show greater progress than children with ADHD, but the reasons for this are not yet known.

The final conclusions to emerge from this review concern the interplay between EF and children's environments. First, although individual differences in EF have been viewed as almost entirely genetic in origin (e.g., Friedman et al., 2008), there is growing evidence that, for young children at least, environmental influences can be substantial. Thus, detailed longitudinal studies highlight the importance of family factors (e.g., maternal well-being, sensitivity, and consistency of parenting). In addition, at least three RCTs show that early educational interventions have positive effects on EF. These positive effects may be: (1) strongest for children with low levels of EF (i.e., EF moderates the impact of interventions); (2) pivotal to explaining the substantial improvement in children's behavior as a result of such interventions (i.e., EF is a mediator of intervention effects); and (3) achieved indirectly via improvements in children's theory-of-mind skills, or in how children are viewed by others, or how they view themselves. Clearly then, tracing out the mechanisms that underpin associations between family environments and children's growing EF skills as well as between interventions and children's social and cognitive achievements is an important challenge for future research.

The Effects of Stress on Early Brain and Behavioral Development

M.R. Gunnar[1], E.P. Davis[2,3]

[1]University of Minnesota, Minneapolis, MN, USA; [2]University of Denver, Denver, CO, USA; [3]University of California, Irvine, Orange, CA, USA

25.1 INTRODUCTION

Over a half century of research using animal models has documented the impact of early-life stress on neurobehavioral development (Sanchez et al., 2001). Both stress to the mother or more directly to the fetus during prenatal development and stressors that affect mother and infant during postnatal development have been shown to impact circuits that are developing during the period of stressor exposure, including the development of stress-mediating systems. Alterations in stress-mediating systems, in turn, influence how the organism responds to stressors throughout development, producing cascading effects that may result in significant physical and mental health problems later in life. Research on the neurobiological sequelae of stress during human pre- and postnatal development has a much shorter history. However, inroads are being made in understanding how exposure to stress early in life influences neurobehavioral development and lifelong health (Shonkoff et al., 2009).

Activity of the hypothalamic–pituitary–adrenocortical (HPA) axis, a stress-sensitive neuroendocrine system, has figured prominently in animal studies of early-life stress ever since it was noted in the 1950s that early experiences permanently altered its reactivity and regulation (Levine, 1957). Because the HPA axis produces hormones that function as gene transcription factors in numerous organs and tissues and because experience alters its activity as well as the activity of its receptors, research on early-life stress has continued to include a focus on the HPA axis. Attention to activity of this system in studies of human development has been promoted by the availability of assays that allow noninvasive measurement of cortisol, its end hormone, in small samples of saliva (Gunnar and Donzella, 2002). Consistent with the history of research in this area, a focus is maintained, although not exclusively, on the HPA axis in reviewing the research on early-life stress and human neurobehavioral development.

This chapter consists of four parts. First, it contains a brief review of the anatomy and physiology of the mature HPA axis and related stress-mediating systems and second, a discussion of prenatal stress and fetal programming. Third, there is a discussion on the postnatal development of the HPA system, the importance of social regulation of the HPA axis in early human development, and what is currently known about long-term impacts of early-life stress on later physical and mental health. Finally, issues that need to be addressed are considered as this field moves forward.

25.2 THE ANATOMY AND PHYSIOLOGY OF STRESS

Stressors are real or perceived threats to psychological or physical viability that are responded to by stressor-specific release of molecules termed stress mediators. These molecules bind to their receptor targets and orchestrate integrated responses that have evolved to increase survival in the immediate face of threat (Joels and Baram, 2009). Glucocorticoids (cortisol in humans) are steroid hormones that serve as a major mediator of the mammalian stress response. Glucocorticoids are produced by the cortex of the adrenal glands; the medulla of the adrenals produces adrenaline, a hormone that is central to the fight/flight response. Glucocorticoids serve multiple roles in defensive responding (Sapolsky et al., 2000). At basal levels they are permissive, in the sense that they maintain organs and tissues in a state that permits rapid and sustained mobilization by other neurotransmitters or hormones. At elevated levels they suppress the actions of other stress-mediating systems and, through negative feedback, return the HPA system to basal levels of activity. Via effects on gene transcription,

glucocorticoids also can have long-term effects on neural systems mediating perception and response to threat, both up- and down-regulating reactions to subsequent stressors. Critically, the effects of acute activations of the HPA system and those of chronic activation are markedly different, with chronic activation resulting in progressive changes in the expression of stress-mediating genes, alteration in neuronal systems that process signals of threat, and changes in neuronal firing patterns throughout the brain.

The cascade of events that produce changes in cortisol release by the adrenals begins with the release of corticotropin-releasing hormone (CRH) and arginine vasopressin (AVP) by cells in the paraventricular nuclei of the hypothalamus (see Figure 25.1, reviewed in Gunnar and Vazquez (2006)). CRH and AVP are released through small blood vessels to the anterior pituitary where they stimulate the release of adrenocorticotropic hormone (ACTH) into the bloodstream. Cells on the cortex of the adrenal glands respond to ACTH and start a cascade of enzymatic actions that convert cholesterol to cortisol (corticosterone in rodents). Activation of the adrenal cortex by ACTH also results in the production of dehydroepiandrosterone (DHEA), an adrenal androgen that because of its anabolic effects has antistress properties. Once released into the circulation, because of its lipid solubility, cortisol enters the cytoplasm of cells throughout the body and brain where it interacts with its receptors if they are present.

Cortisol has affinity to two receptors, mineralocorticoid receptors (MRs) and glucocorticoid receptors (GRs). Its affinity with MRs is many times greater than to GRs; hence, if both are present MRs will be occupied and activated first, followed by GRs. In most areas of the body, however, cortisol cannot access MRs because an enzyme is present (11 beta hydroxysteroid dehydrogenase or 11β-HSD) that converts cortisol to a form with low MR affinity. As discussed later, this enzyme is also present in the placenta where it serves to regulate impacts of maternal cortisol on the placenta and fetus. In the brain, however, the enzyme is not present, allowing the levels of cortisol in circulation to determine the balance between MR and GR activation. Under basal levels MRs tend to be almost wholly occupied; while when cortisol rises to stress levels and also at the peak of the diurnal rhythm, GRs become occupied as well. MRs tend to mediate many of the permissive effects of cortisol, while GRs mediate many of the more catabolic stress effects. GRs are also involved in negative feedback of the axis, functioning at the level of the pituitary, hypothalamus, hippocampus, and likely also the medial frontal cortex, to contain the HPA response and help return the axis to basal levels of activity.

While there is increasing evidence that under conditions of stress, rapid cell-membrane-mediated effects
FIGURE 25.1 The HPA system. (a) depicts the anatomy of the HPA system and structures important in its regulation. PFCtx, prefrontal cortex; AMY, amygdala; HYP, hypothalamus; HC, hippocampus; NTS, nucleus of the tractus solitarius. (b) depicts the activation (+) and negative feedback inhibition (−) pathways of the HPA system. Increases in GCs are initiated by the release of CRH/AVP from the medial parvocellular region of the paraventricular nucleus (mpPVN) in the hypothalamus. Negative feedback inhibition operates through GCs acting at the level of the pituitary, hypothalamus, and hippocampus. GABA, gamma animobutyric acid; CRH, corticotropin releasing hormone; AVP, arginine vasopressin; ACTH, adrenocorticotropic hormone. *Reproduced from Gunnar MR and Vazquez D (2006) Stress neurobiology and developmental psychopathology. of cortisol occur, most effects of cortisol involve translocation of the cortisol–receptor complex from the cytoplasm to the cell nucleus where cortisol interacts with glucocorticoid receptive elements (GREs) in the promotor region of many genes. Activation of GREs increases or decreases gene transcription in interaction with other gene transcription factors. Because many of cortisol's effects are produced via gene transcription, they take minutes to hours to be produced. This means that while acute threat may stimulate increases in cortisol production, cortisol itself is not a major factor in fight/flight responses that proceed on the basis of seconds to minutes.

Activation of the HPA axis is regulated by complex signals derived across a number of pathways that carry information about the state of the internal and external milieu (see Figure 25.2). Activation of the system in response to threats to internal homeostasis (e.g., blood volume loss), travel to the CRH-producing cells in the hypothalamus through brainstem pathways. Psychological threats that require integration of information about
FIGURE 25.2   Schematic representation of the activating (right side) and inhibiting (left side) circuits that contribute to the regulation of the HPA system. Catecholamines, *norepinephrine* (*NE*), *and epinephrine* (*E*) arising from medullary nuclei of the brainstem are the primary neurotransmitters providing activation of CRH synthesis and release from the mpPVN. *Serotonin* originating from dorsal raphe is weakly activating; it acts both directly on mpPVN and indirectly through *excitatory glutamate neurons* or *inhibitory gamma aminobutyric acid* (*GABA*) inputs. Paradoxically, the inhibitory GABA neurotransmitter activates the mpPVN to secrete CRH, as two GABA neurons activated in series leads to excitation and not inhibition. *Extrahypothalamic CRH also acts as a neurotransmitter to initiate autonomic and behavioral responses to stress.* The activation of the extrahypothalamic CRH system is initiated by *rising* glucocorticoid levels that operate on the amygdala to secrete CRH that, in turn, impacts on the locus cerouleus (LC). Through the activation of catecholaminergic brainstem nuclei there is also stimulation of descending pathways leading to NE/E release from the adrenal medulla that facilitates cardiovascular autonomic responses to stress. Inhibition of the HPA axis seen in the left side is provided by *glucocorticoids* acting on glucocorticoid receptors (GR) in the hypothalamus and pituitary where CRH and ACTH release is halted. The hippocampus serves to inhibit the stress response via multiple circuits, some of which are direct inhibitory GABA inputs; others are indirect through glutamate excitatory inputs to GABA neurons converging in the mpPVN. GABA neurons located in each of the structures further modify the stress reactivity and inhibition from other brain regions such as the thalamus, association cortex, cortical and limbic afferents. *Glucocorticoids provide positive stimulation to the amygdala for the synthesis and release of CRH, but negative to the pituitary, hypothalamus, and hippocampus. †Interaction is through glutamate outflow from these regions that synapse on local GABAergic neurons, producing inhibition of mpPVN. *Reproduced from Gunnar MR and Vazquez D (2006) Stress neurobiology and developmental psychopathology. In: Cicchetti D and Cohen D (eds.) Developmental Psychopathology: Developmental Neuroscience, 2nd edn., vol. 2, pp. 533–577. New York: Wiley, with permission.*

external events are mediated through pathways involving the amygdala and bed nucleus of the stria terminalis (BNST). Notably, neural systems involved in activating the axis in response to psychosocial threats either produce CRH or have receptors for CRH. The central nucleus of the amygdala is one region rich in CRH-producing neurons, activation of which plays a role not only on activating the HPA axis but also in stimulating increases in central norepinephrine and peripheral activation of the sympathetic nervous system. The extrahypothalamic CRH system is part of the fight/flight system and a key orchestrator of fear behavior (Rosen and Schulkin, 1998).

The expression of CRH and its receptors in the various brain regions involved in emotion and cognition is age-dependent and regulated by stress throughout the life span. Recent evidence indicates that effects of stress on neurodevelopment are mediated by CRH, as well as cortisol (Korosi and Baram, 2008).

25.3 PRENATAL STRESS AND NEUROBEHAVIORAL DEVELOPMENT

25.3.1 Fetal Programming

Fetal development proceeds at a more rapid pace than any later developmental stage (Barker, 1998a,b). For this reason, the human fetus is particularly vulnerable to both organizing and disorganizing influences, which have been described as programming. Programming is the process by which a stimulus or insult during a vulnerable developmental period has a long-lasting or permanent effect (Barker, 1998a,b; Kuzawa, 2005). The effects of programming are dependent on the timing (i.e., the developmental stage of organ systems and the changes in maternal and placental physiology) and the duration of exposure (Davis and Sandman, 2010; Nathanielsz, 1999). There is convincing support for fetal programming of adult health outcomes including heart disease, diabetes, and obesity; however, the evidence comes primarily from retrospective studies that rely on birth phenotype (e.g., small size at birth or preterm delivery) as an index of fetal development (e.g., Barker, 1998a,b). It is unlikely that birth phenotype alone is the cause of subsequent health outcomes. Birth phenotype, instead, reflects fetal adaptation to exposures that shape the structure and function of physiological systems that underlie health and disease risk (Gluckman and Hanson, 2004). Prenatal exposure to maternal stress signals is one of the primary pathways for prenatal programming of later health and development. In the first section, the role that prenatal maternal stress signals might play in preparing the fetus for adaptation to the postnatal world is discussed.

25.3.2 Stress Regulation and Pregnancy

During the prenatal period, signals from the maternal host environment influence the fetal developmental trajectory. Some of these effects may have evolved to help prepare the infant for the postnatal environment. The HPA axis participates in a surveillance and response system that is present in many species, from the desert-dwelling Western Spadefoot tadpole to the human fetus, and allows for the detection of threat so that development can be adjusted accordingly. For instance, rapidly evaporating pools of desert water result in the elevation of CRH in the tadpole, accelerating metamorphosis, and increasing the likelihood of survival. If the CRH response is blocked during environmental desiccation, then development is not accelerated and the tadpole's survival is compromised. There are long-term consequences for the tadpole that survives this early-life stress because its growth is stunted and it is at a disadvantage in the competition for food and reproduction (Denver, 1997). It has been argued that a similar signaling pathway participates in the regulation of human fetal development. Detection by the fetal/placental unit of stress signals from the maternal environment (e.g., cortisol) informs the fetus that there may be a threat to survival. This information may prime or advance the placental clock (McLean et al., 1995) by activating the promoter region of the CRH gene and increasing the placental synthesis of CRH (Sandman et al., 2006). The rapid increase in circulating CRH begins the cascade of events resulting in myometrial activation and in extreme cases, preterm birth. Early departure (i.e., preterm birth) from the inhospitable host environment may be essential for survival, but it also may have long-term consequences for the human fetus just as it does for the tadpole. The developmental trajectory of the fetus, whether born early or at term, is influenced by the maternal environment and adaptation of the developmental program to maternal stress signals may prepare the fetus for postnatal survival.

25.3.2.1 Changes in the Maternal HPA and Placental Axis Over the Course of Pregnancy

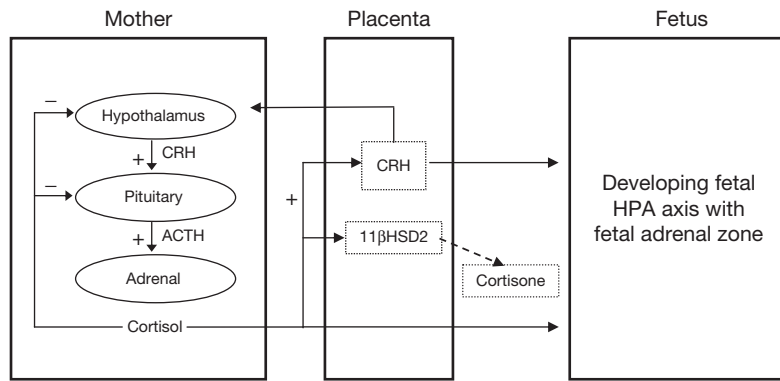
Regulation of the HPA axis is altered dramatically during pregnancy because the placenta expresses the genes for CRH (hCRHmRNA) and the precursor for ACTH and betaendorphin (proopiomelanocortin; see Figure 25.3). All of these stress-responsive hormones increase as pregnancy advances, but the exponential increase in placental CRH (pCRH) over the course of gestation in maternal plasma is remarkable, as by the latter half of gestation it reaches levels observed only in the hypothalamic portal system during physiological stress. pCRH is identical to hypothalamic CRH in structure, immunoreactivity, and bioactivity. There is, however, one crucial difference in its regulation. In contrast to the negative feedback regulation of hypothalamic CRH, cortisol stimulates the expression of hCRHmRNA in the placenta, establishing a positive feedback loop that allows for the simultaneous increase of pCRH, ACTH, and cortisol over the course of gestation (see for review, Sandman and Davis, 2010). The normative increase in stress-responsive hormones such as cortisol and pCRH plays an important role in the regulation of pregnancy as well as facilitating maturation of the fetus. However, because of the positive feedback between cortisol and pCRH, the effects of maternal stress on the fetus may


FIGURE 25.3   The regulation of the maternal HPA axis changes dramatically over the course of gestation with profound implications for the mother and the fetus. One of the most significant changes during pregnancy is the development of the placenta, a fetal organ with significant endocrine properties. In nonpregnant women, exposure to stress activates a cascade of events including the release of CRH, ACTH, and cortisol. This stress system is regulated by a negative feedback loop in which cortisol 'turns off' the HPA axis. During pregnancy, CRH is released from the placenta into both the maternal and fetal compartments. In contrast to the negative feedback regulation of hypothalamic CRH, cortisol *increases* the production of CRH from the placenta. Placental CRH (pCRH) concentrations rise exponentially over the course of gestation. Because of the positive feedback between cortisol and pCRH, the effects of maternal stress on the fetus may be amplified representing one pathway by which stress may exert influences on the fetus. In addition to its effects on pCRH, maternal cortisol passes through the placenta. However, the effects of maternal cortisol on the fetus are modulated by the presence of a placental enzyme 11βHSD2 which oxidizes it into an inactive form, cortisone. Activity of this enzyme increases as pregnancy advances, and then drops precipitously so that maternal cortisol is available to promote maturation of the fetal lungs and central nervous system as well as other organ systems. Structures of the HPA axis begin their development early in gestation and become increasingly functional with the progression toward term. See the text for description.

be amplified with potentially negative consequences for the developing fetus.

The effects of CRH and cortisol are modulated by the activities of binding proteins and enzymes. For example, in conjunction with the rapid acceleration of pCRH, CRH-binding protein levels decline sharply toward the end of gestation, increasing the availability of bioactive pCRH (McLean et al., 1995). Levels of binding protein have been associated with birth outcome (Hobel et al., 1999) and may moderate the activity and the effects of pCRH on the fetal nervous system. Maternal production of cortisol binding globulin (CBG) is stimulated by estrogen and thus levels increase progressively with advancing gestation, but then decline before term increasing fetal exposure to maternal cortisol in late gestation (Ho et al., 2007). Variations in CBG may contribute to individual differences in developmental outcomes because levels have been shown to be lower in women with growth-restricted fetuses (Ho et al., 2007). Another gestational timing effect may relate to the activity of the placental enzyme 11β-HSD2. This enzyme oxidizes maternal cortisol into cortisone, inactivating it and protecting the fetus from its direct and sometimes harmful effects during critical periods of development. The levels of placental 11β-HSD2 rise as gestation progresses before falling precipitously near term ensuring maturation of the fetal lungs, CNS and other organ systems in full-term births (Murphy and Clifton, 2003). Despite the presence of this protective enzyme early in gestation, maternal cortisol does reach the fetus and the amount varies with

circulating maternal levels (Gitau et al., 1998). In addition, maternal stress down-regulates 11β-HSD2 activity in the placenta allowing a greater proportion of maternal cortisol to cross the placenta to reach the fetus (Mairesse et al., 2007; O'Donnell et al., 2011) with negative consequences for fetal growth and development (Kajantie et al., 2003). This is another mechanism whereby the consequences of maternal stress for the developing fetus may be amplified. Because of the timetable of fetal development and the changes in maternal and placental physiology, the consequences of stress exposures will vary on the basis of the gestational period of exposure.

It is critical to acknowledge that the differences in reproductive and stress physiology, even in very closely related species such as humans and nonhuman primates, limit the validity of generalizing from animal models (Power et al., 2006). For these reasons, this review focuses on studies of gestational stress in humans.

25.3.3 Fetal Adrenal Development

The fetal adrenals make unique contributions to both the regulation of fetal development and the timing of parturition. Cortisol is thought to play critical roles in the promotion of fetal maturation in preparation for extrauterine life. Further, DHEA sulfate produced by the fetal adrenal is an obligate precursor for placental estrogen and is thought to contribute to the initiation of parturition.

Morphologically, the fetal adrenal gland is comprised of two zones: the outer, definitive zone, and the large, inner fetal zone. Between these two zones is the transitional zone. The fetal and definitive zones can be recognized after the eighth gestational week. The fetal adrenals grow rapidly until the third trimester so that at term the fetal adrenals are significantly larger, relative to body weight, than the adult adrenals. At the end of human pregnancy, the fetal zone begins to atrophy. The human fetal adrenal has steroidogenic enzymes as early as the seventh gestational week and cortisol secretion can be detected as early as the eighth week. Cortisol production from the fetal adrenal is regulated by ACTH and ACTH-containing cells can be seen in the pituitary by eight gestational weeks (Jaffe et al., 1998; Kempna and Fluck, 2008). There is evidence that the fetus responds to pain with an increase in cortisol during the latter half of gestation (Gitau et al., 2001).

25.3.3.1 Fetal Brain Development and Susceptibility to Stress and Stress Hormones

The rapid changes in the developing fetal brain render it particularly susceptible to organizing and disorganizing influences of stress-responsive hormones such as cortisol and pCRH. Between 8 and 16 gestational weeks migrating neurons form the subplate zone, awaiting connections from afferent neurons originating in the thalamus, basal forebrain, and brainstem. Once neurons reach their final destination, they arborize and branch in an attempt to establish appropriate connections (Sidman and Rakic, 1973). Cessation of neuronal proliferation and migration to the cortical plate occurs around 20–24 weeks. However, dramatic changes in the organization of the cerebral cortex continue through term (Bourgeois, 1997; Volpe, 2008). During the last third of human pregnancy the fetal brain is forming secondary and tertiary gyri, and exhibiting neuronal differentiation, dendritic arborization, axonal elongation, synapse formation and collateralization, and myelination (Bourgeois, 1997; Volpe, 2008). Synapse formation during this period accelerates to a rate of approximately 40 000 synapses per minute (Bourgeois, 1997). Linear increases in total gray matter volume of 1.4% per week are seen from 29 to 41 gestational weeks and approximately 50% of the increase in cortical volume occurs between 34 and 40 gestational weeks (Kinney, 2006).

Regions of the brain that are both integral to the regulation of stress responses and vulnerable to exposure to stress hormones, including the hippocampus and amygdala, develop rapidly throughout gestation. Both are identifiable between 6 and 8 gestational weeks and by term the basic neuroanatomical architecture of these regions is present. Limited information exists regarding the time course of prenatal development of cortisol receptors in humans. There is evidence that both types of cortisol receptors are present in the human hippocampus by 24 gestational weeks (Noorlander et al., 2006).

Data from animal models have documented that exposure to prenatal maternal biological and psychosocial stress influences the developing fetal brain and endocrine systems producing long-term effects on cognition, emotion, and physiology in the offspring (Kapoor et al., 2006). Evidence for persistent organizational changes or programming influences on the nervous system has been growing and may include changes in neurotransmitter levels, cell growth and survival, and adult neurogenesis. For instance, at high concentrations, the CRH and cortisol may inhibit growth and differentiation of the developing nervous system. Considerable evidence indicates that glucocorticoids, such as cortisol, are neurotoxic to hippocampal CA3 pyramidal cells, and fetal exposure to high levels of glucocorticoids produces irreversible damage to the hippocampus. Similar neurotoxic effects are observed with exposure to high levels of CRH. Exogenously administered CRH increases neuronal excitation leading to seizures in limbic areas associated with learning and memory and may participate in the mechanisms of neuronal injury. These data from animal models suggest mechanisms by which early-life stress may provoke long-term effects on stress, emotional regulation, and cognition (see Joels and Baram, 2009; Seckl, 2008 for reviews).

25.3.4 Gestational Stress Influences the Human Fetus

In humans, a compelling body of work has documented that both maternal report of elevated maternal stress or anxiety and exposure to traumatic events during pregnancy are associated with increased risk for preterm birth. These associations are independent of sociodemographic and obstetric risk factors. There are several pathways by which maternal stress may lead to preterm birth including accelerated production of pCRH and altered vascular and immune functioning (see Dunkel Schetter and Glynn, 2011 for review). Preterm birth is associated with pervasive developmental delays (Aarnoudse-Moens et al., 2009). It is believed, however, that intrauterine exposures, including stress, contribute to these impairments independently from birth outcomes. The study of human fetal development is important because it provides a direct test of the fetal programming hypothesis with the opportunity to assess the effects of gestational stress on development before the effects of external forces, such as birth outcome, parenting, and socialization, are exerted.

The idea that the fetus is responsive to maternal distress is not new and there are a number of reports suggesting that maternal exposure to trauma (e.g., earthquake)

during pregnancy has direct and profound implications for fetal physiology and behavior (Ianniruberto and Tajani, 1981). More direct tests of the effect of maternal psychological state on the fetus come from studies manipulating maternal stress or anxiety and evaluating the consequences for fetal behavior. Fetuses display a consistent response profile in response to maternal exposures to moderate laboratory challenges such as the Stroop color-word test or viewing videos of labor and delivery (DiPietro, 2004). The nature of these responses appears to be moderated by maternal psychological state (Kinsella and Monk, 2009). These laboratory studies provide compelling evidence that fetuses are responsive to maternal stress and anxiety and they raise the possibility that repeated exposures over the course of gestation may influence the developing fetal nervous system.

Direct measures of fetal responses to external stimulation provide an index of fetal nervous system development and have been used to assess the developmental consequences of exposure to physical or maternal psychological stress. The response to a vibroacoustic stimulus (VAS) is an indication of fetal maturity reflecting maturation and integrity of neural pathways through the cerebral cortex, midbrain, brainstem, vagus nerve, and the cardiac conduction system. Using the fetal response to VAS, it has been shown that stress signals, most clearly pCRH trajectories, influence the developing fetal nervous system. Low pCRH is associated with more mature or earlier development of the fetus' ability to mount a response to the VAS and with a more mature profile to a classic habituation/dishabituation paradigm (Class et al., 2008; Sandman et al., 1999). Other maternal stress signals including overexpression of beta-endorphin and underexpression of ACTH have additionally been linked to the fetal response to VAS (Sandman et al., 2003).

These studies provide evidence that signals of maternal stress during gestation exert programming influences on the nervous system that cannot be explained by postnatal experiences. Continuity between the fetal and infant periods in assessments of movement and heart rate indicate that maternal influences that shape developmental trajectories during the prenatal period will continue to influence functioning postnatally (DiPietro, 2004). It is additionally clear that consideration of sexually dimorphic profiles of fetal development is necessary, as discussed later in this chapter.

25.3.5 Prenatal Maternal Psychosocial Stress and Infant and Child Development

25.3.5.1 Socioemotional Development

A growing literature indicates that prenatal exposure to elevated levels of maternal psychosocial stress is associated with behavioral and emotional disturbances during infancy and childhood among healthy full-term infants that is independent of postpartum maternal psychosocial stress (Bergman et al., 2007; Blair et al., 2011; Davis et al., 2004, 2007). Both maternal report of psychosocial stress and report of stressful life events are associated with more fearful and reactive behaviors during infancy and toddlerhood. Effects on social and emotional development continue to be observed during childhood and adolescence. Maternal antenatal anxiety and depression predict reports of childhood behavioral and emotional problems, including attention deficit hyperactivity disorder and anxiety problems (Davis and Sandman, 2012; O'Connor et al., 2002; Van den Bergh and Marcoen, 2004). These associations remain significant after controlling for birth outcomes and postnatal maternal psychological state. This suggests that signals of maternal psychosocial stress influence the fetal developmental trajectory with implications for children's functioning after birth.

25.3.5.2 HPA Axis Functioning

Alterations to the fetal HPA axis are frequently proposed as the primary biological pathway underlying fetal programming of later health and development. Animal studies suggest that the fetal HPA axis may be particularly vulnerable to prenatal exposure to maternal stress (Kapoor et al., 2006); however, relatively little is known about the consequences of prenatal maternal stress for HPA axis functioning in humans. There is evidence for higher cortisol levels, during a laboratory challenge among infants and toddlers exposed prenatally to elevated maternal cortisol (Grant et al., 2009). Several studies have suggested that prenatal maternal psychosocial stress is associated with altered circadian regulation during childhood and adolescence, both on typical days (O'Connor et al., 2005; Van den Bergh et al., 2007) and on days when stressors such as the first day of school are experienced (Gutteling et al., 2005). These studies suggest that prenatal exposure to maternal psychosocial stress may influence the developing fetal HPA axis and that this has implications for the regulation of cortisol production during infancy, childhood, and adolescence.

The mechanism by which maternal psychosocial stress is communicated to the fetus is unknown. It is unlikely that maternal cortisol mediates the effect of maternal report of psychosocial stress on child outcomes, as the majority of published studies find that during gestation maternal cortisol and psychosocial distress are not correlated and they exert independent effects on child outcomes (e.g., Davis and Sandman, 2010; de Weerth and Buitelaar, 2005; Harville et al., 2009). Data from human and animal models indicate that an epigenetic mechanism may underlie both the maternal communication of adversity to the fetus and the persistent

influence of the exposure (Champagne and Curley, 2009; Oberlander et al., 2008; Szyf, 2011). Further, maternal psychosocial stress exerts widespread influences on a number of stress-sensitive systems other than the HPA axis including the immune and vascular systems (Dunkel Schetter and Glynn, 2011) indicating alternative pathways by which maternal psychological distress signals may impact the developing fetus.

25.3.5.3 Neurodevelopment

The influence of gestational exposure to maternal psychosocial stress on cognitive and motor development is less clear. There is evidence that maternal self-report of elevated stress and anxiety as well as exposure to traumatic life events, such as severe ice storms, during pregnancy are associated with delayed infant and child cognitive, language, and neuromotor development, and that these deficits may persist into adolescence. However, not all studies have demonstrated such associations and there is evidence that modest elevations in psychosocial stress during late gestation may actually increase cognitive maturation (Davis and Sandman, 2010; DiPietro et al., 2006).

Inconsistencies across studies may suggest that moderate exposure to prenatal maternal psychosocial stress does not negatively affect neurodevelopment. It is plausible, however, that generalized self-report measures of psychological distress do not adequately characterize stress that is unique during pregnancy. As reviewed in Davis and Sandman (2010), evidence is emerging that measures of pregnancy-specific stress (e.g., "I am fearful regarding the health of my baby," "I am concerned or worried about losing my baby") are better than measures of generalized psychological distress for predicting neurodevelopmental outcomes including fetal behavior, infant neurodevelopment, infant and toddler cognitive and motor development, and child brain development. It is important to note that these associations are not explained by actual medical risk associated with pregnancy and birth outcome. Support for the importance of pregnancy-specific stress for developmental outcomes comes from a recent study documenting associations between elevated pregnancy-specific anxiety and decreased gray matter density at 6–10 years of age (Buss et al., 2010). Elevations in pregnancy-specific anxiety, particularly early in gestation, are associated with gray matter volume reductions in the prefrontal cortex, the premotor cortex, the medial temporal lobe, the lateral temporal cortex, the postcentral gyrus as well as the cerebellum, extending to the middle occipital gyrus and the fusiform gyrus. These brain regions are associated with a variety of cognitive processes including reasoning, planning, attention, memory, and language, and raise the possibility that developmental alterations to these regions may underlie associations between elevated pregnancy-specific anxiety and cognitive performance observed in prior studies (Buss et al., 2011).

25.3.6 Prenatal Maternal Biological Stress Signals and Infant and Child Development

Alterations to the maternal HPA and placental axis are most frequently cited as the mechanisms that underlie fetal programming of later health and developmental outcomes. Although robust evidence exists from animal models, there are only a handful of studies that have evaluated the influence of biological stress signals during gestation on human development.

25.3.6.1 Social/emotional Development

Prenatal exposure to elevated maternal cortisol predicts increased fussiness, negative behavior, and fearfulness during infancy (Blair et al., 2011; Davis et al., 2007; de Weerth et al., 2003) and toddlerhood (Bergman et al., 2007). Further, there is evidence that elevations in pCRH contribute to the increased fearfulness observed during infancy (Davis et al., 2005). These studies suggest that maternal HPA and placental axis hormones contribute to the development of a fearful or reactive temperament. These data indicate that maternal and placental hormones contribute to the development of fearful temperament. New data from our prospective cohort suggest that this effect persists. Elevated gestational cortisol levels are associated with an increase in anxiety risk among preadolescent children (Davis and Sandman, 2012).

25.3.6.2 HPA Axis Functioning

Few studies have evaluated the consequences of prenatal maternal cortisol on HPA axis regulation in the offspring. In a prospective study with multiple prenatal assessments, it was documented that prenatal exposure to elevated levels of maternal cortisol is associated with a larger and more prolonged infant response to stress (Davis et al., 2011b). There is emerging, but as yet limited, evidence that this effect persists. In samples of 24 and 29 children, respectively, Gutteling et al. (2004) found that elevated maternal cortisol stress measured at one time during gestation (15–17 gestational weeks) independently predicted children's higher cortisol levels on the day of an inoculation and on the first day of a new school year. These studies provide evidence for effects of prenatal maternal cortisol on HPA axis functioning. Further prospective studies with multiple prenatal and postnatal measures are needed to address this question.

25.3.6.3 Neurodevelopment

Although little is known about the role of biological stress signals in shaping infant and child cognitive development, it is apparent that timing of exposure will be critical to understanding the developmental effects on outcome. Evidence suggests that the trajectory of maternal cortisol across gestation is the strongest predictor of child neurodevelopment. Elevated maternal cortisol during early and mid gestation has been associated with decreased neuromuscular maturity in the newborn (Ellman et al., 2008) and delayed cognitive development during toddlerhood (Bergman et al., 2010; Davis and Sandman, 2010). Conversely, elevated maternal cortisol late in gestation has been associated with significantly higher scores on measures of mental development at 1 year (Davis and Sandman, 2010).

These findings linking cortisol to neurodevelopment are remarkably consistent with its function in the maturation of the human fetus. Early in pregnancy, the fetus is protected from the naturally occurring increases in maternal cortisol by 11β-HSD2 (see Figure 25.3). However, because 11β-HSD2 is only a partial barrier, excessive increases in maternal cortisol early in gestation will expose the fetus to toxic levels with potentially detrimental consequences. In contrast, as pregnancy advances toward term, exposure to cortisol is necessary and beneficial for fetal maturation and exposure to increased cortisol is facilitated by the sharp drop in 11β-HSD2 activity, allowing a greater proportion of maternal cortisol to cross the placental barrier (Murphy and Clifton, 2003). The beneficial effects of modestly elevated cortisol during late gestation are consistent with animal models demonstrating that modest cortisol increases during the early postnatal period are associated with persisting beneficial effects for the developing brain (Catalani et al., 2000).

25.3.7 Is This Fetal Programming?

One concern that challenges research with humans is whether associations between maternal stress and anxiety and fetal outcomes should be interpreted as fetal programming, or alternatively, as a reflection of shared genetic factors. In the studies of naturally occurring variations in maternal cortisol or maternal self-reported stress, it is difficult to differentiate between these alternative explanations. The programming findings reported here, however, are consistent with animal models where random assignment is possible (Kapoor et al., 2006) and with human studies that evaluated the consequences of randomly occurring traumatic events, such as natural disasters (LaPlante et al., 2004; Yehuda et al., 2005) and with prenatal exposure to synthetic glucocorticoids (Davis et al., 2006, 2011a; French et al., 1999). More

convincingly, in a recent human study, similar effects of prenatal stress on child outcomes were documented among children conceived by *in vitro* fertilization in a model where mother and fetus were genetically unrelated (Rice et al., 2009). Thus, while in most human studies of prenatal stress, genetic mechanisms cannot be ruled out as a possible explanation, there is reasonable evidence to warrant the conclusion that maternal stress has effects on the neurodevelopment of the fetus.

25.3.8 Summary

Both psychosocial and biological maternal stress signals are associated with developmental consequences for the fetus. Further, these effects cannot be accounted for by birth outcome or postnatal maternal psychological distress. However, it is important to acknowledge that biological and psychosocial stress signals tend not to be correlated during pregnancy and have been shown to exert independent influences on developmental outcomes (Sandman and Davis, 2012). Future research will have to examine vascular or immune pathways that could be mechanisms by which increases in maternal psychosocial stress might also affect the fetus.

These studies emphasize the importance of performing prospective longitudinal studies in order to evaluate the trajectory of maternal stress signals across gestation and its association with infant and child developmental outcomes. Data indicate that the trajectory or profile biological and psychosocial stress signals may be more critical for determining developmental outcomes as compared to level at a given gestational interval (Davis and Sandman, 2010; Glynn et al., 2008). Both severity and timing of exposure must be considered in order to evaluate associations between prenatal stress measures and infant outcomes. The adaptive significance of these associations is yet to be determined and requires long-term follow-up evaluating the interaction between the prenatal and the postnatal environments.

25.4 POSTNATAL DEVELOPMENT

25.4.1 Postnatal Development of the HPA Axis

At birth, the HPA axis is not morphologically mature (Gunnar and Vazquez, 2006). The adrenal cortex still includes the fetal zone that involutes over the first six postnatal months. As the fetal zone involutes, the structure of the mature gland becomes more distinct. CBG is low in the neonate, increasing gradually over the initial postnatal months. As a result, small increases in total (bound and unbound) plasma cortisol concentrations in response to stressors in the neonatal period may index large increases in the biologically active unbound

fraction of the hormone. There is also some indication that adrenal sensitivity to ACTH decreases over the first postnatal months (Forest, 1978), being higher in months 1–4 than later in development. Thus for several months following birth, the human HPA axis is more highly reactive to stimulation than it is later in development. This is consistent with evidence that during the first 3 or 4 months even mild stimulation (e.g., being undressed, weighed, and measured) provokes significant elevations in cortisol, while by 4 months of age the same stimulation no longer elevates cortisol in most typically developing infants.

The pattern of diurnal cortisol production also changes over the first few years of life (Gunnar and Vazquez, 2006). At birth, basal levels of cortisol bear no relation to time-of-day, although they are associated with levels of behavioral arousal. By as early as 6 weeks of age, an early morning peak and evening nadir can be observed; however, because of marked day-to-day variability, observing these aspects of the diurnal rhythm requires analytical methods that isolate average patterns from variability. In the next months, the peak and nadir become more distinct; but, it is not until about 4 years of age as children give up their daily naps that a more fully mature pattern is noted from mid-morning to late afternoon. Throughout the first few years of life, napping is associated with decreases in cortisol over the nap periods and rebounds to prenap levels by about 30–45 min after the child awakens. Other normal daily events have also been associated with decreases and then rebounds in cortisol levels; the rebounds can be misinterpreted as a stress response. Such normal events include the car trip the child takes on the way to the laboratory for testing. Thus accurate assessment of HPA activity during infancy requires control of more than time-of-day.

Following infancy, there is little developmental change in cortisol levels or reactivity until puberty. Over the pubertal transition, basal cortisol levels increase, with the sharpest increase around Tanner stage 3 (Netherton et al., 2004). Reactivity of the axis to psychosocial stressors also appears to increase with puberty (Stroud et al., 2009). As there is evidence that pubertal maturation is associated with increased reactivity of emotion systems, researchers have speculated that increased HPA activity at puberty may contribute to the psychiatric vulnerability associated with this period of development (Spear, 2000). It may also be that the impacts of early experience on the development of HPA reactivity and regulation are not fully realized until the neurobiological changes associated with puberty and adolescent development have occurred.

Because the HPA axis is under multifactorial regulation (Ulrich-Lai and Herman, 2009), developmental changes in HPA reactivity and regulation are also dependent on the development of the many systems whose activity ultimately impinges on CRH-producing neurons in the hypothalamus. With regard to psychological stressors, the amygdala and BNST are critical in activation of the axis, while the hippocampus and medial prefrontal cortex (mPFC) are involved in constraining and terminating its response (see Figure 25.2). There is no information on how development of these extrahypothalamic structures affects reactivity and regulation of the human HPA response to stressors during childhood and adolescence. Furthermore, there is little information on the developmental changes in GRs in extrahypothalamic regions in humans. There is evidence that, unlike in the rodent, there is no developmental increase in GR in the hippocampus over development, suggesting that the capacity of the hippocampus to contain and terminate HPA responses to stressors is relatively mature at birth (Pryce, 2008). In contrast, GR mRNA expression levels do increase into adolescence in regions of the prefrontal cortex, consistent with evidence that GR expression is as high or higher in the neocortex in humans as it is in the hippocampus (Pryce, 2008). This latter finding suggests that in human development, activity of the HPA axis both impacts and is importantly affected by the ontogeny of prefrontal circuits. The protracted development of neural systems involved in and affected by activity of the HPA axis further suggests that postnatal experiences will shape the complex circuitry of what Joels and Baram (2009) termed the 'neurosymphony of stress.'

25.4.2 Social Regulation of the HPA Axis in Human Development

In rodents and nonhuman primates, there is considerable evidence that proximity and contact with the caregiver is critical to regulation of the HPA axis (Sanchez et al., 2001). This is also true in human development. As early as the first months of life, infants cared for by more sensitive and responsive caregivers show a more rapid return to baseline following activation of the axis (Blair et al., 2006), while those receiving insensitive care exhibit increases in cortisol during parent–infant play sessions (Spangler et al., 1994). The role of sensitive and responsive care in regulating the axis extends to infants' experiences with surrogate caregivers, including child care providers (Vermeer and van IJzendoorn, 2006). Indeed, throughout the preschool period there is evidence that, for children in out-of-home child care, elevations in cortisol over the child care day are larger for those who receive less sensitive and/or more intrusive/overcontrolling care than for those who are receiving more sensitive care.

Sensitive responsive caregiving is an important feature in the development of secure attachment

relationships. Attachment security is not a trait of the child but characterizes the relationship between a child and their adult caregiver. Children can be securely attached to one parent and insecurely attached to the other. Notably, all studies of the relations between attachment security and regulation of the HPA axis have been done examining mother–child relationships. Overall, children are able to use the presence and availability of their mother more effectively to regulate reactivity of the HPA axis if their relationship is secure rather than insecure (Gunnar and Donzella, 2002). This has been shown in studies using brief separations followed by reunions as the stressor, as well as in studies using physical stressors (i.e., inoculations). In studies of psychosocial threat (e.g., approach by strange objects, individuals), whether or not the effect is observed depends on whether the child exhibits fear behavior or not. For those exhibiting fear, the presence and availability of the attachment figure in secure relationships blocks elevations in cortisol, while in insecure relationships elevations are observed. What this suggests is that access to the mother in secure attachment relationships prevents fear and other negative emotions from stimulating elevations in cortisol. However, this is not the case when the mother is present but the attachment relationship is insecure. There is no understanding of the neurobiological processes underlying maternal buffering of the axis for frightened/distressed infants. One possibility is that secure relationships stimulate larger increases in oxytocin, a presumed antistress neuropeptide (Gouin et al., 2010). Among adults, intranasal infusions of oxytocin increase the stress-buffering effects of social support (Heinrichs et al., 2003). Thus greater productions of oxytocin among fearful infants when the mother is present in secure relationships may help to buffer or block cortisol increases.

While sensitive, responsive care and secure attachment relationships are expected to shape more regulated anxiety and stress responses over time, it is clear that early in life the actual presence of the attachment figure is needed to buffer activity of the HPA axis. A study of toddlers entering a new child care arrangement has shown that while toddlers in secure attachment relationships had lower cortisol levels during days when their mother accompanied them to child care (adaptation), as soon as she was no longer present, no differences in cortisol levels were observed as a function of attachment security (Ahnert et al., 2004). Furthermore, marked elevations in cortisol, relative to home levels, were noted for the first several weeks of child care, with these elevations decreasing but not eliminated after 5 months of experience in the care setting. Thus, however the buffering effect of attachment security is operating early in life, it is a characteristic of the relationship and requires the presence of the adult figure with whom the child is securely attached.

25.4.3 Early Care and HPA Axis Functioning

Given the powerful role of social relationships in regulating reactivity of the HPA axis early in life, one might expect that a child's early care history will shape the development of behavioral and HPA reactivity and regulation. That is, as in the animal literature, programming of threat reactive systems will extend into the postnatal period (Sanchez et al., 2001). While there is no question that early pathogenic care increases the risk of a variety of poor outcomes in human development, in every domain studied individual differences in susceptibility are substantial and numerous factors beyond early exposure to adverse care appear to be involved in predicting whether significant early experience effects are observed or not (Cicchetti and Rogosch, 1996).

The range of early care conditions examined in human studies is large, including not only normal variations in parental sensitivity and responsiveness but also neglect, physical and sexual abuse, exposure to interparental conflict and violence, global deprivation (as in orphanages/institutional care), parental loss, and conditions that often interfere with adequate caregiving (e.g., maternal depression, extreme poverty, homelessness). Some of the conditions involve repeated, acute experiences of threat (i.e., physical abuse), others more chronic experiences of the absence of supportive care (e.g., institutional rearing, neglect). Typically, these experiences do not occur in isolation from one another, and often their effects appear to be cumulative (Brown et al., 2009). With rare exceptions (e.g., children adopted from orphanages), care conditions early in life are more or less predictive of care conditions throughout childhood. Thus it is often challenging to isolate the impacts of early versus later experiences on activity of the HPA axis. Adding to the challenge of understanding the role of early care qualities is the fact that few studies of vulnerable children have examined reactivity and regulation of the HPA axis under conditions known to elicit stress responses. Most studies have either examined patterns of diurnal cortisol production and/or exposed children to mild challenges that do not activate the axis in most individuals (i.e., cognitive testing without feedback; Dickerson and Kemeny, 2004).

25.4.3.1 Diurnal Cortisol Patterns

As noted, the diurnal rhythm of the HPA axis is still maturing during the first years of life. It appears to be sensitive to adverse care, although alterations in diurnal patterns do not appear to be permanent, but rather associated with the more immediate contexts of early care. Effects of care context on diurnal patterns were first noted in research on 2- and 3-year-olds living in a Romanian institution. Of the 46 children studied, not one exhibited a typical diurnal pattern as sampled soon after wakeup,

at noon, and in the early evening. Compared to home-reared Romanian children, average levels were significantly lower in the early morning and tended to be higher, but not significantly so, in the early evening hours (Carlson and Earls, 1997). Similar results have been obtained in studies of preschool-aged children recently removed from maltreating homes and placed in foster homes (Bruce et al., 2009). It is not clear whether the child's age or type of adverse care influences associations with diurnal patterns. There is some evidence that among preschool-aged children emotional maltreatment may be associated with elevated early morning cortisol levels, while neglect is associated with abnormally low levels (Bruce et al., 2009). Studies of children adopted from institutions have noted similar low early morning levels, and hence a relatively flat pattern of cortisol production over the daytime hours. Nonetheless, when post-institutionalized children are studied several years after adoption they all exhibit the typical pattern of high morning and low evening cortisol production (e.g., Kertes et al., 2008). In addition, for children studied monthly for a year in foster care, increasingly flat diurnal patterns have been observed in the absence of interventions designed to help foster parents provide more supportive care, with lower early morning levels being associated with the degree of parenting stress reported by the foster parent (Fisher and Stoolmiller, 2008). Thus, it seems likely that the degree, and possibly the type of alteration in the diurnal rhythm in young children indexes stress in relation to the current context and is not a reflection of permanent alterations in the set point or regulation of the diurnal rhythm.

There are several caveats worth noting. First, although the results have focused on average patterns in cortisol production over the day, day-to-day variability may be just as important. Indeed, one of the impacts of providing support and training to foster parents is that over the course of a year, evening cortisol levels in the children become increasingly stable and low from day to day, while this is not the case for children in regular foster care. Second, in most studies, early morning samples were taken 30 or more minutes after awakening, and thus it is not clear whether the magnitude of the cortisol awakening response is what is reflected in the findings and not wakeup cortisol, which reflects the diurnal rhythm. Thus far, to our knowledge, there are no published studies of the cortisol awakening response during early childhood in children experiencing early adverse care.

25.4.4 Effects of Early Care on Cortisol Set Points and Reactivity

Animal models of early care lead to the prediction of unidirectional effects. That is, poorer quality care early in life shapes the set point of the HPA axis and increases behavioral and physiological reactivity to threat. Recently, Boyce and Ellis (2005) have argued for a U-shaped pattern whereby moderate parental support early in life reduces, while both extremely high and low supportive care results in heightened behavioral and physiological reactivity. Thus far, there have been few tests of the argument that extremely supportive care is associated with heightened behavioral and physiological reactivity to threat. There is more support for the argument that poorer care and/or conditions associated with poorer early-life care predict increases in HPA set points and reactivity or lability. Thus, children whose mothers reported significant economic stress and depressive symptoms during the children's infancy exhibited higher afternoon cortisol levels at age four if the family was still under economic stress at that time, and levels of cortisol at this age predicted heightened internalizing problems in first and second grade (Essex et al., 2002; Smider et al., 2002). Among extremely poor families in rural Mexico, a cash-transfer program instituted during the children's infancy was associated with lower cortisol levels, but not less HPA reactivity, when the children were 2 to 6 years old (Fernald and Gunnar, 2009). Likewise, after controlling for later depressive symptoms in the mother, offspring of women who suffered postnatal depression were found to exhibit higher and more labile early morning cortisol concentrations at age 13, which mediated the expression of depression in the children by age 16 (Halligan et al., 2007).

In contrast to these findings, studies of internationally adopted children who experienced severe neglect before adoption challenge the expectation of elevated set points and reactivity following lack of supportive care early in life. Among a small sample of preschool-aged children studied 3 years post adoption, severe preadoption neglect was associated with higher basal urinary cortisol levels and poorer cortisol regulation following a mother–child, but not stranger–child stressor task (Wismer Fries et al., 2008). Among a larger group of children studied in middle childhood, higher early morning levels were noted, but only as a function of physical growth delay at adoption (Kertes et al., 2008). Consistent with the possibility of continued programming of the axis during the postnatal period, this latter finding is very reminiscent of programming effects that have associated poorer intra-uterine growth with activity of the HPA axis later in life (Phillips et al., 2000).

Thus far, work on postinstitutionalized children has not revealed evidence of hyperresponsivity of the axis to psychosocial stress in the form of the Trier Social Stress Test (TSST), a public speaking stressor (Gunnar et al., 2009), although only one study has been reported thus far and the children were largely prepubertal. Notably, a recent study of teenage girls in child protective service examined cortisol and cardiac reactivity to the TSST and

noted blunted cortisol but not cardiac responses in these maltreated girls relative to nonmaltreated controls (MacMillan et al., 2009). It is not clear whether the difference between findings for postinstitutionalized and maltreated children reflect differences in the type and timing of early adversity, the timing of assessment (pre- versus postpubertal) or the concurrent life circumstances of the children (stable families versus foster care).

Adult studies of individuals maltreated as children have shown that patterns of HPA reactivity to psychosocial stressors depend on psychiatric diagnosis. For those suffering major depression, childhood maltreatment is associated with hyperreactivity and poor regulation of the axis, a pattern not seen among depressed adults without an early history of maltreatment (Heim et al., 2008). Conversely, among emotionally healthy adults, histories of more adverse family life conditions in childhood (i.e., maltreatment, interparental conflict, rejection) have been associated with a lower set point of the HPA axis and smaller cortisol responses to psychosocial stressor tasks (Carpenter et al., 2007). It has also been noted that among school-aged children, whether those who were sexually abused before age 5 exhibited altered cortisol production during a 5-day camp for maltreated children depended on whether the child exhibited internalizing behavior problems or not (Cicchetti et al., 2010). The confluence of internalizing problems and early sexual abuse predicted altered cortisol production, while neither factor alone appeared to have any association with cortisol levels (although for contradictory findings, see MacMillan et al., 2009).

The effects of trauma on the HPA axis also appear to depend on whether the individual develops posttraumatic stress disorder (PTSD) or not. Studied among adults, individuals with PTSD exhibit normal to low basal levels of cortisol; with varying evidence of hyper- or hyporeactivity to stressors, perhaps related to the extent that the stressor is reminicient of the original traumatizing experience (Yehuda, 2000). Among prepubertal children, PTSD appears to be associated with elevated levels of cortisol production (see review, Tarullo and Gunnar, 2006). Among sexually abused girls with PTSD assessed over time, elevated cortisol levels have been noted in childhood, with decreasing levels beginning in adolescence and levels lower than normal by adulthood (Trickett et al., 2010). It is still not clear whether puberty shifts the relation between PTSD and set points of the axis from hyper to hypo, or whether it is the time since trauma, which gradually alters the axis from hyper- to hypofunctioning.

25.4.5 Individual Differences

Numerous factors likely influence susceptibility to both pre- and postnatal programming of fear- and stress-response systems. Three factors are briefly mentioned here: sex differences, temperamental fearfulness or inhibition, and genes.

There is a developing literature suggesting that there are sexually dimorphic profiles of fetal development (Clifton, 2010). Compelling data from animal models document sex-specific consequences of stress hormone exposure (Goel and Bale, 2009). Further, there is growing appreciation that human fetal neurological development is different for males and females (Bernardes et al., 2008; Buss et al., 2009; DiPietro et al., 1998) and that gestational influences on fetal neurodevelopment may be associated with sex-specific postnatal developmental trajectories including risk for psychiatric disorders (Costello et al., 2007; Goel and Bale, 2009). The role of sex as a moderator of the effects of early postnatal care on fear- and stress-response systems is not clear (Gunnar and Vazquez, 2006). While there are some studies that indicate larger impacts of early parental care for boys than girls, many other studies have not indicated differential sensitivity by sex to variations in supportive early care.

Behavioral inhibition describes a temperament dimension defined by greater behavioral reactivity and inhibition of approach to novel, arousing, or unpredictable stimulation. Behaviorally inhibited infants often develop into children who are shy and prone to social anxiety (Chronis-Tuscano et al., 2009). While there is some evidence that extremely inhibited children have higher cortisol levels and reactivity (Kagan et al., 1987; Schmidt et al., 1997), this is not always found and likely depends on contextual factors, such as the degree of support the child has from attachment figures and whether inhibiting approach is an effective option for regulating stress (Gunnar, 2001; Gunnar and Donzella, 2002). The larger cortisol responses that fearful, inhibited children experience in the context of less supportive care may help mediate the greater vulnerability of these children to adverse early-life care (Phillips et al., 2011). However, their sensitivity may also allow them to excel in higher-quality care environments; a possibility proposed by Boyce and Ellis in their biological sensitivity to context theory (Boyce and Ellis, 2005).

As suggested by the work on behavioral inhibition, sensitivity to variations in the quality of early-life care may be influenced by genetic inheritance. For example, the type 1 CRH receptor mediates behavioral and physiological reactions to threat-provoking stimuli and there is now evidence that variants in the CRHR1 gene interact with early abuse histories to increase the risk of depression (Gillespie et al., 2009). A number of genetic polymorphisms have also been noted in genes that play key roles in the regulation of GR and thus the expression of glucocorticoid-responsive genes (Derijk and de Kloet, 2008). These too may influence risk and resilience to trauma and variations in the quality of early care environments (Derijk and de Kloet, 2008; Gillespie et al., 2009).

In the studies of children, variations in other genes, including those regulating major neurotransmitter systems, have been found to moderate relations between care experiences and reactivity of the HPA and sympathetic nervous system (Frigerio et al., 2009). Notably, although from a stress-diathesis perspective one might view genetic factors as increasing vulnerability to adverse early care, they may instead produce differential susceptibility to both the positive and negative qualities of early care (Belsky and Pluess, 2009).

25.4.6 Summary

Research on infants and children conducted over the last few decades has begun to illuminate the impact of postnatal experiences on the development of stress-mediating neurobiological systems. The human HPA axis continues to develop postnatally with significant changes in functioning over the first six postnatal months. Throughout infancy and early childhood the axis is under strong social regulation. Sensitive, responsive care maintains the axis in a relatively quiescent state and permits rapid returns to basal functioning following perturbations. There is increasing evidence that adverse care early in life impacts neurobehavioral development and impacts diurnal patterns of cortisol production assessed concurrently. There is emerging, but as yet sparse and sometimes conflicting, evidence that early neglect and abuse may be associated with long-term changes in the reactivity and regulation of the HPA axis and that effects on this neuroendocrine system may mediate some of the poor mental and physical outcomes of early maltreatment. In part, some of the conflicting findings appear related to the age at assessment as there may be changes in HPA functioning following early maltreatment or trauma that differ as a function of whether assessment is conducted before or after puberty. Some of the conflicting findings also appear to be related to whether or not the individual is suffering from an affective disorder or not, and if so, the nature of the disorder (i.e., depression, PTSD). Genetic variation likely contributes to the heterogeneity of outcomes noted both with regards to impacts on the HPA axis and on emotional functioning. Of particular note, however, are recent arguments that the same genes and/or emotional temperament that may result in heightened vulnerability to poor outcomes following early adverse care may also result in more optimal functioning, given positive early care experiences. Thus, while postnatal experiences appear to influence the developing neurobiology of stress reactivity and regulation, the role of individual differences and developmental timing are critical issues whose effects are still in need of a more complete explication.

25.5 FUTURE DIRECTIONS

The study of pre- and postnatal stress and its impact on neurodevelopment and health has thus far proceeded largely independently. It is time for this work to become integrated, both empirically and theoretically. While researchers studying prenatal stress have sometimes obtained measures of outcomes later in life, it is rare that postnatal experiences are examined as anything other than potential confounds to be controlled statistically. Yet, postnatal experiences have the potential to either ameliorate or exacerbate prenatal effects. In addition, alterations in infant functioning related to prenatal experiences may result in differential sensitivity to variations in early care experiences and/or behaviors that elicit different responses from caregivers. As noted, some researchers are beginning to address how the postnatal care interacts with prenatal stress exposure to influence cognitive, behavioral, and health outcomes. More of this work is needed.

From a fetal programming perspective, it is especially critical that conceptual models are examined via longitudinal studies that track postnatal development. Thus, if as some models posit, fetal programming via stress mediators prepares the fetus to survive in a harsh postnatal world (Gluckman and Hanson, 2004), then evidence is needed to support such a hypothesis. There is some evidence that this may be the case with regard to nutrition such that concordance in pre- and postnatal nutrition leads to more functional health outcomes than discordance (Armitage et al., 2005; Cleal et al., 2007). However, it is not known whether a similar adaptive advantage exists for other types of prenatal stressors and/or for other kinds of postnatal outcomes.

Consistent with early literature on outcomes for premature infants, it is also possible that a supportive postnatal environment may ameliorate and a harsh environment exacerbates the neurobehavioral sequelae of prenatal stress. In this case, discordance in the harshness of pre- and postnatal experience may predict better outcomes. Recent human studies have provided support for this possibility demonstrating that high-quality maternal care can compensate for the negative effects of prenatal stress exposures (Bergman et al., 2008, 2010). It remains likely that the effects of stress during the prenatal and postnatal periods will differ by developmental outcome and there is a clear need for prospective studies with multiple prenatal and postnatal assessments.

As noted earlier, there is an emerging literature that suggests that prenatal stress may operate on circuits that support enhanced behavioral inhibition or anxiety. If so, then an intriguing possibility is that prenatal stress may enhance the young child's sensitivity to its rearing context, resulting in more optimal outcomes under supportive conditions and poorer outcomes under harsh conditions than

may be noted for infants from nonstressed pregnancies. Whether this is the case has not been explored, but is an example of the need to integrate pre- and postnatal conceptual models.

Thus far, only these future direction comments on the value of incorporating research and theory on postnatal stress into models and research on prenatal stress have been focused upon. Perhaps a more critical need is for those studying postnatal stress to consider the role that prenatal stress may be playing in their findings. Certainly it seems likely that children who are abused, neglected, or abandoned to orphanage care may be the product of stressed pregnancies. It also is likely that they are the products of pregnancies complicated by poor nutrition and exposure to alcohol and drugs. Unfortunately, in many studies of postnatal stress there is meager information about prenatal conditions or even birth outcomes. Retrospective reports obtained from parents in studies, for example, of child maltreatment must be suspect. For children abandoned to orphanage care, often even the child's age at abandonment is unknown, let alone their gestational age and health at birth and any record of prenatal conditions. Nonetheless, despite the challenge of obtaining accurate information on prenatal conditions for children identified because of their poor postnatal care, studies are needed where such information can and has been obtained. This is particularly important in studies examining interventions to improve outcomes as prenatal conditions may moderate how the child responds.

Finally, one area that would seem ripe for integration into research on pre- and postnatal stress is the role that the dramatic hormonal changes that accompany pregnancy contribute to the quality of postnatal caregiving. Stress and reproductive hormones during pregnancy are associated with maternal cognitive functioning (Glynn, 2010), the development of postpartum depression (Yim et al., 2009), and the quality of maternal care (Feldman et al., 2007). The maternal hormonal milieu also impacts the developing fetus, as was discussed. Thus, to close the loop on the understanding of the ways in which stress impacts the developing fetus and young child, studies that incorporate the impacts of stress and maternal hormonal changes on the mother, her caregiving, and her response to her infant are needed.

Sex Differences in Brain and Behavioral Development

A.M. Beltz[1], J.E.O. Blakemore[2], S.A. Berenbaum[1]

[1]The Pennsylvania State University, University Park, PA, USA; [2]Indiana University – Purdue University Fort Wayne, Fort Wayne, IN, USA

26.1 INTRODUCTION

Psychological and neural sex differences are a topic of great interest for their relevance to both applied and basic science questions. From an applied perspective, they figure into discussions ranging from women's underrepresentation in science and math careers (Ceci and Williams, 2010; Halpern et al., 2007) to sex differences in incidences and forms of psychopathology (Hartung and Widiger, 1998; Zahn-Waxler et al., 2008). From a basic science perspective, sex represents an important dimension of individual difference, and factors that lead to differences between the sexes can help us to understand variation generally. The focus of this chapter is sex differences in the human brain and behavior, with an emphasis on cognitive abilities; our goal is to describe what is known and hypothesized about the differences, their development, and their etiology, and to begin to link brain differences to cognitive differences.

The chapter is organized into several sections. First, we summarize the evidence concerning psychological sex differences in human beings and the ways in which they develop across age, focusing on changes from infancy through young adulthood. Second, we consider the main theories that have been offered to explain the differences and the evidence that supports those perspectives. Third, we summarize the evidence concerning sex differences in the human brain and what (little) is known about their development. Fourth, we review the small body of research about the etiology and psychological correlates of brain sex differences. Fifth, we emphasize the gaps in our knowledge and provide suggestions for further research.

26.2 PSYCHOLOGICAL SEX DIFFERENCES: NATURE AND DEVELOPMENT

Sex differences are found in many psychological domains, from sensory thresholds to career choices. We focus here on cognitive sex differences but note other significant psychological domains in which the sexes differ. Our goal is not to provide an exhaustive review of the extensive literature in this area, but to provide a summary of the findings, highlighting the key differences and, in later sections, explanations of these differences, as well as the links between cognitive and brain sex differences. Detailed reviews, with supporting references, are available elsewhere, as cited throughout the chapter. Consistent with others, we describe sex differences in terms of *effect size*, *d* (Cohen, 1988): small ($d \sim 0.2$, 85% overlap in distributions of the sexes), moderate ($d \sim 0.5$, 67% overlap, probably noticeable), and large ($d \sim 0.8$, 53% overlap, very noticeable).

As a prelude to a description of the differences, we note that there is some controversy over the size of these differences, whether they have declined over time, and whether they even exist (Hyde, 2005). Some of the controversy relates to what is a meaningful difference, with some arguing that sex differences are too small to be worthwhile. But sex differences are among the largest effects in psychology; compare the effects described below with typical effects in psychology and medicine described elsewhere (e.g., Meyer et al., 2001). This is illustrated in Figure 26.1. Furthermore, there is not always a perfect mapping between the size of a difference and its significance.

26.2.1 Cognitive Abilities

The sexes do not differ in overall intelligence (discussed in Camarata and Woodcock, 2006; Halpern, 2012; Roivainen, 2011), but, as detailed below, they do differ in their pattern of abilities: on average, boys and men are better than girls and women in spatial and some mathematical skills, whereas girls and women are better than boys and men in many verbal abilities, memory, and processing speed (Halpern, 2012). One analysis of the structure of intelligence (Johnson and Bouchard, 2007) concludes that it consists of three dimensions: a rotation–verbal dimension (at one end of the dimension, tasks measuring mental rotation and other spatial skills, and at the other end, verbal tasks); a focus–diffusion dimension (at one end, attention focused on one main stimulus in the environment, and at the other end, attention focused diffusely on several cues simultaneously); and memory. Typically, men were found
FIGURE 26.1 Psychological sex differences in behavior compared to other health and psychological effects, described in standard deviation units, *d*. (data from Hyde, 2005; Meyer et al., 2001)
FIGURE 26.2 Sample sex differences in cognitive abilities: absolute value of the differences in standard deviation units, *d* (data from Blakemore et al., 2009); asterisks (*) indicate results from meta-analyses.

to be nearer the rotation and focus ends of those two dimensions, and women at the verbal and diffusion ends, and women to have better memory. Figure 26.2 provides a summary of the cognitive sex differences expressed in standard deviation units, *d*.

26.2.1.1 Spatial Abilities

One widely studied cognitive sex difference is spatial ability. There are several ways to parse the domain, but boys and men outperform girls and women in most aspects of spatial ability, with the size of the difference varying across abilities (Halpern, 2012; Lawton, 2010). The largest sex difference is in mental rotation, especially rotation of objects in three dimensions. This sex difference is apparent beginning in infancy (Moore and Johnson, 2008; Quinn and Liben, 2008), with boys and men having better ability than girls and women and with the difference increasing slightly from childhood to adulthood (Geiser et al., 2008).

There are moderately sized sex differences in spatial perception and the ability to identify spatial relations with respect to one's body in relation to external space

or to identify the true vertical or horizontal (Halpern, 2012). This ability is measured by tasks such as the 'rod and frame task' (Voyer and Bryden, 1993) and 'water level task' (Vasta and Liben, 1996).

There are also sex differences in abilities related to navigating in the real world (Lawton, 2010), an ability typically referred to as 'wayfinding.' Boys and men are better than girls and women at remembering and navigating to distant locations in large spaces; some of the difference results from sex differences in strategy, with men relying on cardinal (north, south, east, and west) directions and women relying on landmarks. Considering larger issues of the spatial environment, there is a huge sex disparity among National Geography Bee winners (despite equal participation from boys and girls); the sex ratio increases at each level of competition, so that in many years, all ten finalists are boys (Liben, 1995).

There is one aspect of spatial ability on which the sex difference is reversed: memory for spatial location. Girls and women are better than boys and men in remembering the location of objects (Voyer et al., 2007).

26.2.1.2 Mathematical Abilities

The sexes differ in quantitative abilities, with the differences again varying by type of ability and age (Halpern, 2012). In school, girls get better grades than do boys in arithmetic and mathematics classes (as they do in all classes), but they do not perform as well on standardized tests of math knowledge and skills (e.g., the SAT). The main math sex difference is in problem-solving tasks, with boys outperforming girls, especially at older ages. Recent data show the sex difference to be small (Lindberg et al., 2010), although the size of the difference is larger in some countries than in others, in ways that are sometimes, but not always, related to indices of gender equality in those countries (Else-Quest et al., 2010; Guiso et al., 2008). There are no sex differences in understanding mathematical concepts, and girls outperform boys in computation, especially before puberty.

The sexes also differ in their variability in spatial and mathematical abilities (Hedges and Nowell, 1995). For example, for the past 20 years, about four times as many seventh-grade boys as girls have scored in the high ranges of the SAT-Mathematics (Wai et al., 2010); before that time, there were even higher ratios of boys to girls at the top end.

26.2.1.3 Verbal Abilities

There are many different kinds of verbal and language-related skills, such as vocabulary size, use of correct grammar, reading, doing anagrams, and following verbal instructions. The sexes are similar on some skills. When there are differences, they are generally in the direction of girls and women having better skills than boys and men, although the size of the difference varies with ability and age (Halpern, 2012).

Language learning occurs earlier in girls than in boys, with boys catching up by age 6 (Bornstein et al., 2004; Wallentin, 2009). Language disorders are more common in boys than in girls (Wallentin, 2009). In terms of specific verbal skills, females have a small to moderate advantage over males in several skills, most prominently reading comprehension, verbal fluency, and phonological processing, but males have a small edge in analogies (Halpern, 2012). In terms of verbal abilities that are particularly important educationally, there is great concern about boys' lag in reading performance (Chudowsky and Chudowsky, 2010). Boys also write less well than girls, a difference that is especially notable at the highest ability levels (Hedges and Nowell, 1995; Wai et al., 2010).

Females also process verbal materials more rapidly than males, including intelligence scale subtests, verbal fluency tests asking for many words to be generated quickly, letters of the alphabet, and digits (Camarata and Woodcock, 2006; Roivainen, 2011). Females' faster processing speed may be one contributor to their superior reading and writing abilities.

26.2.1.4 Memory

As with other cognitive domains, there are several aspects of memory. In some, the sexes do not differ. But in several, girls and women are better than boys and men: they show more accurate recall for learning facts or material that they read, more readily learn lists of words, have better recall for lists of common objects such as animals, food, furniture, and appliances, and have better recognition memory (Halpern, 2012; Johnson and Bouchard, 2007). Women have better verbal memory in part because they use more efficient clustering strategies.

Sex differences in memory are especially consistent for episodic memory, that is, memory of specific events and episodes. For example, women are better than men at recognizing faces that they have seen before. Many episodic memories are verbally based, but women have better episodic memories even when the tasks are not verbal (e.g., face recognition) except when the memory tasks are clearly spatial, in which case men do better (Herlitz et al., 2010). Women also recall the identities and locations of objects better than men, although it has been suggested that this might be due to women's better memories overall (Voyer et al., 2007). Sex differences in memory are generally small to moderate in size.

26.2.1.5 Perceptual Speed

In addition to faster processing of verbally based cognitive tasks, girls and women are faster than boys and men in another type of speeded task, called perceptual

speed (Burns and Nettelbeck, 2005). Most intelligence tests have some subscales that measure this ability. In general, these tests involve the ability to perceive details and shift attention quickly, often while using fine motor skills such as finger movements (Halpern, 2012). The difference ranges from small to large, depending on the particular measure used.

26.2.2 Noncognitive Sex Differences

There are many other psychological domains in which the sexes differ, but we focus here on those that have received the most attention, that are relatively large in size, or that illustrate important points about studying sex differences (e.g., the importance of developmental status, measurement, and social context). Figure 26.3 provides a summary of the noncognitive sex differences expressed in standard deviation units, *d*.

26.2.2.1 Physical and Motor Skills

Sex differences in physical and motor skills vary by aspect and age (Blakemore et al., 2009). Boys are more active than girls (Eaton and Enns, 1986; Else-Quest et al., 2006), and activity level becomes increasingly sex-differentiated with age, with the differences largest in familiar, nonthreatening settings and when peers are present. There are few sex differences in early milestones of reaching, sitting, crawling, and walking, but differences in motor skills begin to appear in the second year (Mondschein et al., 2000). The earlier neurological development of girls compared to boys results in

early development of some abilities, such as eye–hand coordination. Overall, girls develop sooner than and are superior to boys with respect to fine motor skills, whereas boys have better gross motor skills and are stronger than girls (Largo et al., 2001a,b), which combine with boys' advantage in spatial skills to result in large sex differences in targeting (hitting a target with a ball) (Kimura, 1999). Sex differences in many (but not all) physical and motor abilities increase with age, although the patterns vary considerably depending on the particular skill (Dorfberger et al., 2009; Thomas and French, 1985).

26.2.2.2 Activity Interests

One of the largest and most important sex differences concerns interests (Blakemore et al., 2009; Ruble et al., 2006). In childhood, boys and girls prefer and engage with different toys (e.g., trucks and dolls) and participate in different activities (e.g., playing sports and playing dress-up). In adolescence, boys and girls continue to prefer and participate in different leisure activities (e.g., building things and dance), household chores (e.g., taking out the garbage and preparing food), and academic pursuits (e.g., math and language arts). In adulthood, men and women continue to prefer and participate in different activities, and are differentially represented in different occupations; for example, men prefer occupations that involve working with things, and women prefer occupations that involve working with people (Su et al., 2009). Although the sexes overlap in their interests and activity participation, the average differences
FIGURE 26.3 Sample sex differences in noncognitive characteristics (not including play or sex partners): absolute value of the differences in standard deviation units, *d* (*data from Blakemore et al., 2009*); asterisks (*) indicate results from meta-analyses.

are large to very large. Interests are important because they are reasonably stable, and shape future career choices, especially with respect to domains such as mathematics and the physical sciences (Diekman et al., 2010).

26.2.2.3 Temperament and Personality

Overall, most aspects of temperament show small or no sex differences (Else-Quest et al., 2006). The main exception is effortful control, which shows a moderate advantage for girls, and has been suggested to be consistent with the greater incidence of externalizing disorders in boys, which are characterized by inattentive, antisocial, and aggressive behaviors. In addition, boys have higher levels of surgency than girls, reflecting their greater activity and high-intensity pleasure.

Research on 'the big five' personality factors shows small differences between adult men and women. Costa and colleagues (2001) reported that women were higher than men in neuroticism, agreeableness, and extroversion. They also found cross-cultural similarities in the patterns of sex differences, but the differences between men and women were found to be largest in European and North American countries, and smallest in African and Asian countries.

There are also small sex differences favoring boys and men in global self-esteem, especially after childhood (Kling et al., 1999). Sex differences vary across the different domains of self-esteem, with males having consistently higher appearance-related, personal self, self-satisfaction, and athletic self-esteem, and females having higher ethical and behavioral conduct self-esteem (Gentile et al., 2009).

26.2.2.4 Social Behaviors

The stereotypes about sex differences in social behavior – that girls and women are emotionally expressive and perceptive, and more attuned to babies, and that boys and men take risks and are aggressive – have some basis in evidence, but the differences are not large and depend on context. Consider some examples (for details, see Blakemore et al., 2009). Regarding emotional expression, there is some suggestion that boys and men express more anger and less fear and sadness than girls, but more convincing is evidence that boys come to hide emotions like sadness and fear purposefully, especially in the presence of peers (Kyratzis, 2001). Regarding perceiving emotion in others, girls and women are somewhat more sympathetic, empathic, and accurate at decoding emotions than are boys and men, but the differences are small and depend on how they are measured (larger on self-report than on physiological response) (Eisenberg et al., 2006; McClure, 2000). Girls show more interest in and nurturant interaction with babies than boys do, although the size of the sex difference varies across the particular situations measured in various studies (summarized in Blakemore et al., 2009). Regarding risk-taking, boys are more likely than girls to take risks and to be injured (Byrnes et al., 1999; Morrongiello and Matheis, 2007).

Aggression is one social behavior where sex differences are well known. Aggression is defined as behavior intended to harm others and includes physical, verbal, and indirect aggression. Males are more physically and verbally aggressive than females (Card et al., 2008; Dodge et al., 2006) from childhood through adulthood. Although the social context affects aggression, and the size of the difference varies across age and culture, there are no instances in which females are more directly aggressive than males.

Sometimes physical aggression moves into the domain of seriously antisocial or criminal behavior. Although few people show the type of high levels of physical aggression that would be called violent or antisocial, or at the very extreme, commit murder, the majority of those who do are male, in childhood, adolescence, and adulthood (Archer, 2004; Dodge et al., 2006; Moffitt et al., 2001; Rutter et al., 1998).

Another form of aggression is often called indirect, social, or relational aggression (e.g., Crick, 1995). This form of aggression involves such things as manipulating social relationships or purposefully excluding others. It has been seen as the 'feminine' form of aggression and often (but not always) reported to be more common in girls (see discussion in Blakemore et al., 2009). However, a recent meta-analysis (Card et al., 2008) found no significant differences between boys and girls in indirect aggression from childhood through adolescence.

26.2.2.5 Psychological Disorders

Many forms of serious behavioral problems and mental illness occur at different rates in the two sexes (Hartung and Widiger, 1998). Psychological problems are often described as being internalizing (e.g., anxiety and depression) or externalizing (e.g., conduct disorder, antisocial behavior, including, among other things, criminal acts and excessive aggression, and attention-deficit hyperactivity disorder). The incidence of internalizing problems is higher in girls and women, whereas the incidence of externalizing problems is higher in boys and men (Zahn-Waxler, 1993; Zahn-Waxler et al., 2008); boys are also more likely than girls to have learning and reading disabilities (Blakemore et al., 2009). Disorders that are predominant in males tend to have their onset in childhood (Hartung and Widiger, 1998), whereas the female preponderance of depression and eating disorders begins at puberty (Nolen-Hoeksema and Hilt, 2009).

26.3 EXPLANATIONS FOR PSYCHOLOGICAL SEX DIFFERENCES

Hypothesized causes of psychological sex differences tend to focus on either genetic and biological factors or social and cultural factors. We highlight the key theoretical perspectives focusing on proximal processes; we refer readers elsewhere for discussion and critiques of evolutionary explanations of cognitive and neural sex differences (e.g., Eagly and Wood, 1999; Geary, 1998; Hannagan, 2008; Wood and Eagly, 2002).

26.3.1 Socialization Perspectives

Most work on psychological sex differences comes from a socialization perspective, that is, that sex differences develop as an individual navigates, observes others, is socialized, and internalizes information about the social world. There are several types of socialization theories, differing in the extent to which they emphasize the role of basic social learning mechanisms, subtle socialization practices, social identity (as male or female), cognitive schemas derived from gender identity that guide behavior, and the role of sex-typed social roles and resulting stereotypes and expectancies.

26.3.1.1 Socialization of Noncognitive Sex Differences

Most studies of gender socialization have focused on social behaviors. This literature has been reviewed elsewhere (Blakemore et al., 2009; Martin and Ruble, 2010; Ruble et al., 2006), so we provide a brief summary. In essence, boys and girls are socialized differently in ways that affect a variety of psychological outcomes, with this gendered socialization coming from a variety of sources. Much of the focus has been on socialization by peers and parents, but there are powerful influences from other social forces, including other adults such as teachers, coaches, and clergy, and information received via the many forms of media.

Peers are a key enforcer of sex-typing. Children have strong preferences for interaction with members of their own sex, with these preferences maintained by children themselves and resistant to change by adults (Maccoby, 1998; Ruble et al., 2006). The more children play with others of the same sex, the more they engage in sex-typed activities and play styles (Martin and Fabes, 2001).

Parents also shape sex-typing, as seen in two examples. First, parents influence the career choices of their offspring in several ways: by differential encouragement of sex-appropriate activities, by the attitudes they espouse regarding what is appropriate for boys versus girls, and by the resources they provide to their children (e.g., paying for and providing computer-related materials and encouraging extracurricular involvement in math and science for sons, but not for daughters) (Simpkins et al., 2005). Second, parents socialize emotion differently in their sons and their daughters, through their conversations (e.g., Fivush, 1998; Fivush and Buckner, 2000): With daughters as compared to with sons, parents use more emotion-related words, elaborate their discussion of emotion more extensively, and focus these conversations on the emotional aspects of interpersonal relationships; over time, girls' own discussions include more extensive focus on emotion and emotional issues than do boys' own discussions.

Children also help to socialize themselves through their use of gender schemas. Children are motivated to be like others of their own sex and form cognitive constructions or networks of associations about the sexes that influence their behavior and thinking (Martin et al., 2002). These gender schemas direct children's attention, influence how information is interpreted, organized, and remembered, and guide behavior with objects and people; specifically, children selectively attend to and remember sex-typed information and show biases towards members of their own group (for review, see Martin et al., 2002). Many studies confirm the power of gender schemas to influence many aspects of behavior and thinking, including children's toy play, play partners, the ability to learn about activities that are traditionally sex-typed for the other sex, and impressions of others (reviewed in Blakemore et al., 2009; Martin et al., 2002; Ruble et al., 2006).

26.3.1.2 Socialization of Cognitive Sex Differences

Socialization perspectives have been applied less to cognitive abilities than to other sex-typed characteristics. Nevertheless, there are several types of evidence confirming the importance of social influences on sex-typed abilities.

Sex-typed academic skills, such as math and language, are influenced by family socialization. For example, although parents think that academic achievement is equally important for sons and daughters, they provide support for extracurricular involvement in math and science more for sons than for daughters (Simpkins et al., 2005), and parents' subtle beliefs about the inherent superiority of boys in such domains appears to undermine girls' subsequent academic performance, especially in math (Eccles et al., 2000).

Sex differences in spatial ability have been seen to depend on socioeconomic status (SES), with differences apparent in children from middle and high SES backgrounds, but not in children from low SES backgrounds (Levine et al., 2005). Such SES effects were suggested to result in part from access to experiences that facilitate spatial ability.

Spatial abilities have been suggested to develop from childhood sex-typed activities (e.g., Connor and Serbin, 1977, reviewed in Lawton, 2010). In particular, boy-typed toys and activities (such as building with Lego) are seen to encourage manipulation and exploration of the environment, and some have claimed that sex differences in spatial abilities would be reduced or even eliminated if girls were encouraged to play more with boys' toys (Halpern, 1986; Tracy, 1990). Evidence does show a weak-to-moderate link between spatial ability and aspects of sex-typed activities (e.g., Newcombe et al., 1983), but there is some variability and inconsistency that likely reflects methodological and conceptual issues (Baenninger and Newcombe, 1989; Voyer et al., 2000). It is important to note that these associations are not evidence of causation: engagement in boy-typed activities might enhance spatial ability or instead reflect that ability, that is, children with high spatial ability might be attracted to toys that allow manipulation and exploration. Some longitudinal data suggest that the causal path is from abilities to activities rather than the reverse (Newcombe and Dubas, 1992).

It is therefore important to note direct experimental evidence that spatial ability can be enhanced by experience. In particular, spatial ability can be improved through practice and training, with generalization beyond training stimuli. For example, playing an action video game was seen to improve both spatial attention and mental rotation ability (Feng et al., 2007). Training benefits both sexes, with women sometimes benefiting more than men, so that training may eliminate a sex difference in this domain (Lawton, 2010; Uttal et al., 2012).

Finally, stereotypes that emphasize women's cognitive inferiority appear to impair their performance (Steele, 1997). This has been demonstrated in studies that involve experimental manipulations, as illustrated for both math and spatial ability. Women who were told that sex differences in math have genetic causes performed worse on math tests than those who were told that the differences have experiential causes (Dar-Nimrod and Heine, 2006). Women who were told that men outperform women on spatial tasks performed worse on a mental rotations test than women who received neutral information, and the poorer performance of the group given negative stereotypes appeared to reflect increased emotional load (Wraga et al., 2007).

26.3.2 Genetic Perspectives

It is reasonable to expect that sex-related characteristics would be influenced by genes on the sex chromosomes, reflecting sex differences in sex chromosome composition (XX for typical females, XY for typical males). Work in individuals with sex chromosome abnormalities using sophisticated approaches has provided intriguing evidence that genes on the X chromosome

may influence aspects of cognition, including aspects of spatial ability (Ross et al., 2006). Evidence in rodents suggests that genes on the Y chromosome influence sex-typed behavior, including spatial ability and parenting (Arnold, 2009; Arnold and Chen, 2009). There are very limited human data on this topic, but they do not currently show direct effects of genes on the Y chromosome: Women with complete androgen insensitivity syndrome, who have a Y chromosome but no effective androgen exposure, reported similar childhood and adulthood gender role behavior to unaffected women (Hines et al., 2003a).

26.3.3 Hormonal Perspectives

26.3.3.1 Principles

Most of the research on biological mechanisms underlying gendered characteristics has focused on sex hormones, primarily androgens (including testosterone) and estrogens. This research is rooted in the work of Phoenix, Goy, and colleagues (Gibber and Goy, 1985; Phoenix et al., 1959, 1973), showing the long-lasting effects of early sex hormones on sex differences in behavior in rodents and primates, and in the subsequent work of Money and Ehrhardt (1972) in human beings. Hormones affect behavior in two ways (Becker et al., 2008; Goy and McEwen, 1980). First, sex hormones produce permanent changes to brain structures and the behaviors they subserve ('organizational' effects). Such effects usually occur early in life (during the prenatal period in human beings), although adolescence may also be an important organizational period (Schulz et al., 2009; Sisk and Zehr, 2005). Second, sex hormones produce temporary alterations to the brain and behavior (through ongoing changes to neural circuitry) as the hormones circulate in the body throughout adolescence and adulthood ('activational' effects). The main distinctions between organizational and activational effects concern timing and permanence, although these distinctions are not absolute (Arnold and Breedlove, 1985).

26.3.3.2 Evidence for Hormonal Influences on Nonhuman Sex-typed Behavior

Studies in many nonhuman animal species show that sex hormones are crucial for behavioral sex differences. Much work has confirmed and extended the early work of Phoenix, Goy, and colleagues, showing that hormones present during early life organize the brain so that they have long-lasting effects (Becker et al., 2002, 2008; Ryan and Vandenbergh, 2002; Wallen, 2005, 2009). These studies generally involve experimental manipulations of hormones (e.g., injecting females with testosterone, castrating males), but behavior has also been seen to be influenced by naturally occurring variations in hormones,

such as those that result from an animal's position in the uterus, particularly the sex of its littermates (for reviews, see Clark and Galef, 1998; Ryan and Vandenbergh, 2002).

Even in nonhuman animals, however, the effects are complex. For example, studies in monkeys highlight two aspects of this complexity: (a) there are several sensitive periods for androgen effects on behavior, even during the prenatal period, with some behaviors masculinized by exposure early (but not late) in gestation, and other behaviors masculinized by exposure late (but not early) in gestation (Goy et al., 1988); and (b) environmental context modifies behavioral effects of hormones (Wallen, 1996).

Further, sex hormones may continue to exert organizational effects well beyond early life. Evidence from rodents indicates that puberty is another organizational period, with sex hormones at puberty producing permanent changes to the brain and behavior (Schulz et al., 2009; Sisk and Zehr, 2005).

There is also an extensive literature showing that sex hormones are necessary for the expression of sex-typed behaviors in adulthood (activational effects). Much work has focused on the importance for sexual behavior of testosterone in males and estradiol in females, but these hormones also play a role in the expression of nonsexual behaviors in adult animals, such as maternal behavior and aggression (Becker et al., 2002, 2008).

26.3.3.3 *Methods for Studying Early Hormonal Influences on Human Behavior*

Studies in people cannot involve experimental manipulations of hormones, but have taken considerable advantage of natural experiments, individuals whose hormone levels were atypical for their sex during early development as a result of a genetic disease or maternal ingestion of drugs during pregnancy to prevent miscarriage (for details, see Blakemore et al., 2009). The most extensively studied natural experiment is congenital adrenal hyperplasia (CAH), a genetic disease resulting in exposure to high levels of androgens beginning early in gestation because of an enzyme defect affecting cortisol production. If human psychological sex differences are affected by androgens present during critical periods of development (as occurs in nonhuman animals), then females with CAH should be behaviorally more male-typed and less female-typed than a comparison group of females without CAH.

Because CAH is not a perfect experiment (e.g., high levels of prenatal androgen also lead to masculinized genitalia, which might affect socialization, and CAH requires lifelong treatment with cortisone), it is important to seek converging evidence from other sources. Such evidence has been obtained for a number of behavioral domains from other natural experiments and from normal individuals with typical variations in hormones. The latter includes those whose hormones have been directly measured (in amniotic fluid) and those whose hormones have been inferred (by virtue of sharing a uterine environment with an opposite-sex twin).

We briefly summarize the evidence that prenatal hormones – particularly androgens – influence human psychological sex differences and highlight key findings and issues. This evidence has been discussed in detail elsewhere (Berenbaum, 2006; Berenbaum and Beltz, 2011; Blakemore et al., 2009; Cohen-Bendahan et al., 2005; Hines, 2010).

26.3.3.4 *Prenatal Hormone Influences on Human Behavior: Noncognitive Sex Differences*

Data from several groups and countries with a variety of sound methods (including observations, tests, self-reports, and parent-reports) make clear that girls and women with CAH are more male-typed and less female-typed in aspects of their feelings, preferences, and behavior than are girls and women without CAH (in most studies, their unaffected sisters; reviewed in Berenbaum and Beltz, 2011; Blakemore et al., 2009; Hines, 2010). The largest difference between females with and without CAH is in sex-typed activity interests and engagement: girls and women with CAH prefer and are more likely to participate in male-typed activities from childhood through adulthood. They also have male-typed occupational interests; for example, females with CAH reported more interest in occupations that involve working with things (versus people) than unaffected female siblings (Beltz et al., 2011). The male-typed activity preferences and engagement in girls with CAH are directly associated with prenatal androgen and have not been shown to be influenced by parents' behavior (Meyer-Bahlburg et al., 2006; Nordenström et al., 2002; Pasterski et al., 2005). Females with CAH are sex-atypical in other domains (reviewed in Berenbaum and Beltz, 2011; Blakemore et al., 2009; Hines, 2010). Compared to typical females, females with CAH are more aggressive and less interested in babies and are more likely to have bisexual or homosexual orientation (although most are exclusively heterosexual). These masculinized characteristics stand in contrast to female-typical identity in the overwhelming majority of females with CAH (Dessens et al., 2005).

Data from other natural experiments also show that male-typical prenatal androgen levels are associated with male-typed activity interests and nonheterosexual orientation (e.g., Meyer-Bahlburg, 2005, reviewed in Berenbaum and Beltz, 2011; Blakemore et al., 2009). But the most compelling converging evidence comes from a study linking amniotic testosterone levels to activity interests in boys and girls at ages 6–10 (Auyeung et al., 2009): the most male-typed interests

and characteristics (as reported by parents on a widely used measure) were found in children who had had high levels (for their sex) of naturally occurring prenatal testosterone. Unfortunately, there is little other good evidence about links between amniotic testosterone and other sex-typed characteristics in typical samples; the few existing studies had small samples and other methodological limitations.

There has also been interest in effects of early hormones on sex differences in psychopathology. Early organizational androgens have been hypothesized to contribute to the male vulnerability for childhood disorders (e.g., Baron-Cohen et al., 2004; Martel et al., 2009); however, there has been little consideration of the ways that different disorders would be affected by hormones. For example, autism has been claimed to reflect 'the extreme male brain' and therefore result from exposure to high prenatal androgens (Baron-Cohen et al., 2004), but many other disorders show similar male predominance and have been suggested by others to also result from high prenatal androgens (e.g., Martel et al., 2009).

26.3.3.5 Prenatal Hormone Influences on Human Behavior: Cognitive Sex Differences

Evidence from multiple sources provides moderate support for the notion that prenatal androgens influence later spatial and related abilities. Nothing is known about prenatal hormonal effects on mathematical abilities or on abilities that show a female advantage, because the sex differences are small to moderate, and it has been hard to accrue large enough samples.

Females with CAH have been found to have higher spatial ability than their sisters in childhood, adolescence, and adulthood (Berenbaum et al., 2012; Hampson et al., 1998; Hines et al., 2003b; Mueller et al., 2008; Resnick et al., 1986), with a meta-analysis suggesting that the effect is small to moderate (Puts et al., 2008). The relatively small size of the effect may explain why the effect is not always seen (e.g., Hines et al., 2003b; Malouf et al., 2006).

Confirming evidence for the effects of androgen on spatial ability comes from individuals at the other end of androgen levels: males with low early androgen levels due to idiopathic hypogonadotropic hypogonadism (IHH) have lower spatial ability than controls (Hier and Crowley, 1982). Importantly, the external genitals of males with IHH appear typical, suggesting that enhanced spatial ability in females with CAH is not due to social responses to their genitals.

There are now several studies of androgen effects on spatial ability in typical samples that provide converging evidence for prenatal androgen effects on spatial ability. In three studies of opposite-sex twins, females with a male co-twin (who are thought to have above-average prenatal exposure to testosterone) have been shown to have higher spatial ability than females with a female

co-twin (Cole-Harding et al., 1988; Heil et al., 2011; Vuoksimaa et al., 2010). But, prenatal hormone influences are confounded with postnatal socialization in some of these findings because females with a male co-twin are reared with a male sibling of the same age. Evidence against socialization effects comes from women with slightly older siblings: those with a brother did not have better spatial ability than those with a sister (Heil et al., 2011). In one study of amniotic hormones, testosterone was associated with some indices of spatial ability in girls at age 7: compared to girls who had low amniotic testosterone, girls with high levels showed faster, but not more accurate, mental rotation; the effect was seen only in girls who showed evidence of using a mental rotation strategy (Grimshaw et al., 1995b).

26.3.3.6 Adolescent Hormone Influences on Human Behavior

In light of the recent animal evidence on the behavioral importance of organizational hormones at puberty, there has been increased attention to the effects of pubertal hormones on the human brain and behavior (see also Section 26.5). With respect to behavior, there is considerable speculation – but not a lot of data – about the ways in which changes at adolescence are triggered by the surge in sex hormones at that time, including girls' increased vulnerability to depression and eating disorders (Crick and Zahn-Waxler, 2003; Martel et al., 2009) and boys' increased risk taking and substance use (Forbes and Dahl, 2010; Steinberg, 2008). This is an area of active investigation, thus it is likely we will know much more about pubertal hormone effects on the brain and behavior within the next decade.

26.3.3.7 Circulating Hormone Influences on Human Behavior

There is an extensive literature (primarily in adolescents and adults) linking circulating levels of sex hormones (especially estradiol and testosterone) to sex-typed characteristics, primarily aggression, mood, and cognitive abilities (reviewed in Buchanan et al., 1992; Hampson, 2007; Maki and Sundermann, 2009; Puts et al., 2010). This work focuses on activational (transient) effects of hormones, so that behavior changes when hormone levels change. Findings are complex and difficult to summarize briefly (see reviews above for details). Much of the complexity reflects small effects, reliance on observational studies in adults, and bidirectional effects of behavior and hormones (e.g., aggressive behavior can increase testosterone). Hormones do not produce simple changes in behavior, and the most valuable studies are those that examine the ways in which hormones act indirectly and interact with social factors to change sex-related characteristics.

There is some consistency in the findings regarding cognitive effects of circulating sex hormones, with data coming from studies of natural variations in hormones across individuals and within individuals (e.g., in association with the menstrual cycle) and effects of hormone replacement (in association with aging or surgical removal of the ovaries). Findings are complex (for reviews, see Hampson, 2007; Maki and Sundermann, 2009), but generally suggest that spatial ability is facilitated by testosterone in the moderate range (levels that are high for females and low for males) and verbal memory is facilitated by estradiol, especially in postmenopausal women who are relatively young or recently menopausal. Nevertheless, links between cognition and hormones are not always found, probably due to factors that modify the effects of both hormones (e.g., diet) and cognition (e.g., experiences).

26.3.4 Integrated Perspectives

It is clear that sex-typed characteristics are influenced by multiple factors, and it is unfortunate that most studies focus on a single set of factors, rather than examining them in concert. As we have argued elsewhere (Berenbaum et al., 2011), sex differences can best be understood by integrating the different perspectives; focusing on only one set of causes (either social or biological) can lead to a distorted or even misleading understanding of sex-typed processes.

Consider spatial ability as an example of the ways in which an understanding of sex differences could be enhanced by attention to both biology *and* social experiences (for detailed discussion and other examples, see Berenbaum et al., 2011). As discussed above, evidence makes it clear that spatial ability depends on social experiences, genes on the X chromosome, and sex hormones during prenatal development and again in adult life. But spatial ability almost certainly develops from *joint* influences of biology and social experiences, as illustrated in two ways. First, biological influences on spatial ability are likely mediated through experience. As noted above, girls who are exposed to high levels of androgen during prenatal life (because of normal variation or CAH) are more likely than girls with low levels to play with boys' toys, and those toys may facilitate the development of spatial ability (e.g., Newcombe et al., 1983). Preliminary evidence from females with CAH does indeed indicate that their enhanced spatial abilities are in part mediated by their masculinized activity interests (Berenbaum et al., 2012). Second, biological predispositions likely facilitate learning. Although existing training studies are not compelling in this regard (men, who have high androgen levels, do not appear to be more likely to benefit from practice than women, who have low androgen

levels), the situation might differ in childhood, when abilities are developing, and on tests that do not show ceiling effects. This question can be studied in girls with CAH and in typical children, by examining the effects of practice at varying ages and with varying environmental experiences (e.g., as a function of SES).

26.4 BRAIN SEX DIFFERENCES: NATURE, DEVELOPMENT, AND CONSEQUENCES

The brains of men and women, and of boys and girls, are similar in many ways, but there are some systematic differences in anatomical structure, physiological functioning, and development. An understanding of these differences – and what causes them – should provide insight into the mechanisms underlying sex differences in human health, disease, and behavior, including the characteristics discussed above (Cosgrove et al., 2007; McCarthy and Arnold, 2011).

In this section, we review the work on human brain sex differences. We focus on topics where there is converging evidence for brain sex differences, but we also present some exciting new findings that will likely spark future research. Most of the work reviewed comes from studies using magnetic resonance imaging (MRI), as it is the dominant research tool in human developmental neuroscience (Casey et al., 2005; Luna et al., 2010), but we also consider work using other techniques, such as positron emission tomography (PET), perceptual asymmetries, and post mortem examinations.

26.4.1 Issues in Studying Brain Sex Differences

MRI is widely used as a measure of brain anatomy and physiology. Structural MRI (sMRI) provides measures of brain morphology and architecture (e.g., volumes of gray matter, white matter, and subcortical structures). Blood oxygen level-dependent (BOLD) functional MRI (fMRI) is a measure of change in blood oxygenation thought to reflect neural activity. Diffusion tensor imaging (DTI) is the most frequently used assessment of water diffusion in the brain, thought to reflect white matter microstructure and thus information transmission among brain regions. All MRI measures – sMRI, fMRI, and DTI – are indirect measures of brain structure and function, involving multiple assumptions and inferences, and each reflects multiple dynamic processes occurring at cellular and subcelluar levels (for discussion relevant to developmental science, see Casey et al., 2005; Paus, 2010).

The analysis of MRI data, particularly functional data, is complex and based on multiple assumptions, partly

because assessments are indirect. The brain is typically partitioned into volumetric pixels, or voxels, and statistics are conducted on each voxel as if it were independent of all others. This 'mass univariate approach' can result in a score of false positives unless appropriate corrections to *p*-values are made for multiple comparisons (Friston, 2004). In studies linking behavior to brain activation, findings may be spurious if only voxels exceeding some preset threshold are examined (Vul et al., 2009). This is essentially a selection bias: only data from voxels reflecting significant brain activation are examined in relation to behavior. This problem can be avoided through *a priori* selection of brain regions of interest (ROIs) for analyses (Poldrack, 2000; Vul et al., 2009).

Concerns have been expressed about the interpretations of findings of brain sex differences (Fine, 2010; Jordan-Young, 2010). Such problems appear to result from the inappropriate use of data, rather than from the data themselves. First, people may over-interpret brain images because they are compelling; research containing irrelevant neuroscience explanations and brain images is rated by nonexperts as more satisfying or reasonable than accurate work without such information (Beck, 2010; McCabe and Castel, 2008; Weisberg et al., 2008). Second, brain sex differences are often interpreted in simplistic ways. For example, a bigger brain is not necessarily a better brain (see Section 26.4.2.1), and brain sex differences are not indicators of predetermined behavioral inequalities (see also McCarthy and Arnold, 2011; Poldrack, 2000). Third, brain sex differences need to be considered in conjunction with behavioral sex differences (see Sections 26.4.2.5 and 26.4.3).

As we discuss below, there is much careful and important work demonstrating brain sex differences. Research questions developed from a clear conceptual framework are often investigated using sound methodology and a careful approach to examining brain–behavior relations. Inferences are often balanced and appropriate, and there is considerable convergence of evidence. Of course, as in any area of science, not all studies are perfect, but limitations in methodology and inference are no more prevalent or problematic in this field than elsewhere (Fiedler, 2011).

26.4.2 Sex Differences in Brain Structure and Their Development

An understanding of brain sex differences requires consideration of development. Some of the most compelling work on brain–behavior relations has shown both a change in structural sex differences across development and the importance of considering developmental trajectories (pattern of brain changes over time), not just a single measurement (see Rubenstein and Rakic, 2013). For example, general intelligence has been shown to relate to changes in cortical thickness across childhood and adolescence, but not to absolute measures of cortical thickness at a given age (Shaw et al., 2006); compared to typical children, children with attention-deficit hyperactivity disorder have delayed trajectories of cortical thickness maturation (Shaw et al., 2010). Thus, sex differences in brain development are best examined in longitudinal neuroimaging studies; however, there are many more studies of sex differences at a single point in time, so we review those studies (typically done in adults) as well as the longitudinal neuroimaging data. We first review findings of sex differences in brain structure and then examine how structural differences relate to behavioral sex differences.

26.4.2.1 Brain Volume

There are sex differences in intracranial and cerebral volume, with both approximately 10% larger in males than in females. These differences are seen in measurements made on postmortem brains (Holloway, 1980) and in live ones (using MRI) (De Bellis et al., 2001; Giedd and Rapoport, 2010; Giedd et al., 1997; Goldstein et al., 2001; Lenroot and Giedd, 2010; Lenroot et al., 2007; Nopoulos et al., 2000; Sowell et al., 2002); they are also seen in several nonhuman primate species (Falk et al., 1999; Holloway, 1980). The human differences appear to be primarily due to the larger occipital and frontal poles of men compared to women (Sowell et al., 2007). The differences in brain size are due in part to sex differences in body size, reflecting overall growth differences (Halpern, 2012; Holloway, 1980; Peters, 1991; Peters et al., 1998).

The brain reaches about 95% of its adult size by age 6, but the relative proportions of gray matter and white matter continue to change throughout childhood and adolescence. The peak cerebral volume occurs about 4 years earlier in girls than in boys, but boys have a larger absolute cerebrum size than girls throughout development (Giedd and Rapoport, 2010; Lenroot et al., 2007).

The implications of brain size sex differences for brain function or behavior, however, are not clear (see also Section 26.4.2.5). Sex differences in the size of other body structures (e.g., men's larger hearts and noses) do not translate into sex differences in function. Further, a larger brain does not necessarily mean a smarter brain. Although there is a moderate association between brain size and intelligence (Flashman et al., 1997; Luders et al., 2009b), there are no sex differences in general intelligence, and neural connectivity (rather than size) is key to understanding the brain substrates of intelligence (Song et al., 2008; van den Heuvel et al., 2009). Interpretations of structural size differences are complicated for several reasons: normal brain maturation involves cell death and synaptic pruning, reducing brain size; brain

size may be larger in individuals with developmental disorders, such as autism (Shaw et al., 2010; Sowell et al., 2001, 2002); there are dynamic relations between experiences and brain anatomy (e.g., taxi driving experience is associated with hippocampal shape) (Maguire et al., 2000, 2003).

The sex difference in body size creates difficulties in studying sex differences in brain size, which, in turn, creates difficulties in studying other aspects of brain sex differences, leading to controversies over whether to correct for body size and overall brain size. Some have argued that sex differences in brain size are best corrected by body weight or height (Halpern, 2012; Holloway, 1980). Others have claimed that the relation between body height or weight and brain size is weak (Peters, 1991), particularly because there is great variation in human body size and type (Peters et al., 1998). Further, the relation between brain and body size changes across development (Giedd and Rapoport, 2010; Lenroot and Giedd, 2010), suggesting that brain–body size corrections should only be made in adult samples.

There are several ways to correct for sex differences in intracranial or cerebral volume in order to examine sex differences in specific brain structures (see Bishop and Wahlsten, 1997). First, brain volume can be covaried. This approach is most appropriate if there is a linear relationship between brain size and the size of the brain structure or region being investigated, and it can misrepresent sex differences if the relation is present in only one sex. Second, a ratio can be computed, reflecting the volume of the structure or regions being investigated as a proportion of brain size; this approach is easy to understand, but its anatomical interpretation is unclear. Finally, recent innovative approaches have been suggested, including the use of different numerical scaling factors for different characteristics of brain anatomy because larger brains are not uniform expansions of smaller brains; for example, there is greater relative increase in cortical surface area than cortical thickness with brain size increases (Im et al., 2008). Longitudinal studies overcome the problem by allowing examination of within-individual change across time and subsequent comparison of rates of change between the sexes (e.g., Thambisetty et al., 2010).

26.4.2.2 Regional Structure Volume

There are several consistently replicated sex differences in the size of human regional brain structures. But these effects are not always detected, likely because they are small and approaches to correcting for sex differences in brain size vary across studies. Generally, as detailed below, some key regions of the brain implicated in interhemispheric communication and memory (e.g.,

hippocampus and caudate nuclei) are larger in women than men, and other subcortical regions implicated in affective and sexual behaviors (e.g., amygdala and hypothalamus) are larger in men than women.

26.4.2.2.1 SEX DIFFERENCES IN INTERHEMISPHERIC COMMISSURES

Several studies have investigated sex differences in interhemispheric commissures (fiber bundles spanning the two halves of the brain). Commissures are important for facilitating information flow across hemispheres and thus for promoting cognitive function (Bryden, 1982; Kimura, 1999).

There has been particular focus on sex differences in the most posterior portion of the corpus callosum (CC), the splenium, following an early histological report of a sex difference in this region (De Lacoste-Utamsing and Holloway, 1982). A meta-analysis of 49 studies concluded that there are no systematic sex differences in this structure when appropriate corrections are made for the sex difference in brain size (Bishop and Wahlsten, 1997), and recent MRI studies support this finding (Leonard et al., 2008; Luders et al., 2006b). Nonetheless, research with large, adult samples using a sophisticated analysis technique (in which derivations of an individual's CC from a template CC are captured at many points), indicates that women do, in fact, have larger splenia than men (Davatzikos and Resnick, 1998; Dubb et al., 2003). Other research has positively linked the size of the splenium in women (but not men) to cognitive abilities, such as verbal fluency, two-dimensional mental rotations, and memory (Davatzikos and Resnick, 1998; Hines et al., 1992); however, these links are not consistently seen in children and adolescents (e.g., Luders et al., 2011).

The CC develops in a rostral-to-caudal direction throughout childhood and early adolescence, and the rate of growth may be greater in girls than in boys (Luders et al., 2010; Thompson et al., 2000). This sex difference is particularly striking because boys have faster overall rates of white matter development than girls (Section 26.4.2.4). Even from late adolescence through late adulthood, the splenium appears to increase in size in women more than in men (Dubb et al., 2003).

There are sex differences in the anterior commissure (connecting the right and left temporal lobes) and massa intermedia (connecting the right and left thalamus), but less is known about their functional significance than that of the CC. Both structures are generally found to be larger in women than men (Allen and Gorski, 1991, 1992; Kimura, 1999). The massa intermedia is also more frequently absent in men than in women (Rabl, 1958), and absence of this structure is linked to greater performance IQ scores for men, but not for women (Lansdell and Davie, 1972).

26.4.2.2.2 SEX DIFFERENCES IN STRUCTURES INVOLVED IN LEARNING AND MEMORY

Several brain structures implicated in learning and memory are also larger in females than males, consistent with the female advantage in memory (Section 26.2.1.4). The hippocampus, which is important for memory formation, retention, and recall, is larger in women than men (Cahill, 2005; Filipek et al., 1994; Goldstein et al., 2001; Halpern, 2012; Lenroot and Giedd, 2010), though this difference is most consistently reported in children and adolescents, perhaps because the hippocampus is generally found to grow at a faster rate and thus to mature earlier in girls than boys (Giedd et al., 1997; Lenroot and Giedd, 2010). The caudate nuclei, which are part of the basal ganglia and implicated in learning and memory, are also larger in females than males; this finding has been reported in both children (Giedd et al., 1997; Sowell et al., 2002) and adults (Filipek et al., 1994; Goldstein et al., 2001). Caution must be used when interpreting the implications of these findings because the sex difference in verbal memory remained in a sample of men and women who had left anterior temporal lobectomy, suggesting that other brain regions and sex differences in strategy are also important for sex differences in memory (Berenbaum et al., 1997).

26.4.2.2.3 SEX DIFFERENCES IN SUBCORTICAL STRUCTURES INVOLVED IN AFFECTIVE AND SEXUAL BEHAVIORS

Brain structures consistently found to be larger in men than women include regions of the hypothalamus and the amygdala. Sex differences in the human hypothalamus parallel early studies showing a very large sex difference in the rodent preoptic hypothalamus (Gorski et al., 1978). In particular, one of the four interstitial nuclei of the anterior hypothalamus (INAH-3) is larger in men than women (reviewed in Halpern, 2012; Kimura, 1999; LeVay, 1991). There are also reports that some regions of the bed nucleus of the stria terminalis (BNST), the central portion of the connection between the hypothalamus and amygdala, are larger in men than women (Allen and Gorski, 1990; Zhou et al., 1995). Although the functional implications of these sex differences are unclear, there is some suggestion that the INAH and BNST play a role in gender identity and sexual orientation (for discussion, see Hines, 2011; Savic et al., 2010).

The amygdalae, a pair of bilateral structures in the medial temporal lobe, are also larger in boys and men than in girls and women (Cahill, 2005; Goldstein et al., 2001; Halpern, 2012; Lenroot and Giedd, 2010) and develop faster in boys than in girls (Giedd et al., 1997; Lenroot and Giedd, 2010). They are thought to be important for the detection of and behavioral response to affective visual cues, perhaps because of their connectivity to many cortical and subcortical regions (Pessoa and Adolphs, 2010).

26.4.2.3 Gray Matter

There are sex differences in gray matter, with girls and women having relatively more gray matter than boys and men across the lifespan, particularly in parts of the frontal, temporal, and parietal lobes (Gur et al., 1999; Lenroot et al., 2007; Leonard et al., 2008; Luders and Toga, 2010; Luders et al., 2002; Paus, 2010). Relatedly, women have greater cortical thickness than do men in some areas of the brain, particularly in the frontal and parietal lobes. Supporting evidence comes from several different samples and research methodologies, including MRI combined with surface morphometry (Im et al., 2006; Lv et al., 2010), pattern algorithms (Luders et al., 2006a; Sowell et al., 2007), and tissue segmentation (Koscik et al., 2009). Some histological findings are inconsistent, but their interpretation is complicated by small sample sizes (e.g., Rabinowicz et al., 1999).

There are parallel differences in cortical complexity, or patterning of cerebral convolutions, with women showing greater complexity than men, particularly in the frontal and parietal lobes (Luders et al., 2004, 2006c). Findings of sex differences appear to vary with method: differences favoring females have been found using a new mesh-based approach (in which the convolutions at several thousand surface points are estimated from three-dimensional brain scans), but not when using the gyrification index (ratio of cortical surface to visible gyral surface, calculated from two-dimensional postmortem brain slices) (Zilles et al., 1988).

Gray matter develops in an inverted U-shaped trajectory across childhood and adolescence, increasing until puberty and then decreasing through early adulthood (Giedd and Rapoport, 2010; Giedd et al., 1999; Lenroot and Giedd, 2010; Lenroot et al., 2007). The shape and timing of the peak in gray matter trajectories differ across brain regions: parietal lobe volumes peak first, followed by frontal and temporal lobe volumes. Relatedly, cortical maturity, marked by decreases in cortical density, occurs in a specified pattern: the medial sensorimotor cortex matures first, with development proceeding in rostral and lateral directions, such that the prefrontal and lateral temporal cortices are the last regions to mature (Gogtay et al., 2004). This reduction in gray matter density, which occurs after pubertal onset, likely reflects the elimination of irrelevant brain connections and strengthening of relevant ones (i.e., pruning). The sexes have similarly shaped trajectories of gray matter development across all brain regions, but girls have an earlier average peak than boys, consistent with their earlier pubertal maturation. Generally, girls show a peak in regional gray matter between 8 and 10 years of age, whereas boys show a peak between 9 and 11 years of age (Lenroot et al., 2007).

26.4.2.4 White Matter

There is not clear consistency from MRI studies regarding sex differences in overall brain proportions of white matter. Some evidence indicates that men have a greater proportion of white matter than do women (Allen et al., 2003; Gur et al., 1999), but the difference is not always found and inconsistencies are not explained by differential corrections for the sex difference in brain size (Luders et al., 2002; Nopoulos et al., 2000). Women are rarely found to have greater white matter volume than men, suggesting that small samples make it difficult to consistently detect the increased white matter in men compared to women. Inconsistencies may also reflect age differences; sex differences in the proportion of brain white matter generally emerge in adolescence and persist through adulthood (Paus, 2010).

Converging evidence from MRI also suggests no sex differences in fractional anisotropy (FA), which is thought to reflect directed information transmission along white matter paths. This evidence comes from large, cross-sectional DTI studies (Eluvathingal et al., 2007; Giorgio et al., 2008; Lebel et al., 2008).

White matter volume increases linearly through childhood and into adulthood, and this pattern is consistent across brain regions (Giedd et al., 1999; Lenroot et al., 2007). Girls and boys both experience linear increases in white matter volume, but boys have a more rapid rate of increase compared to girls, particularly in adolescence (Lenroot et al., 2007). FA similarly increases across early childhood and into adulthood in an inferior-to-superior and posterior-to-anterior fashion (Colby et al., 2011); white matter connections around subcortical structures and in the CC undergo the greatest change across development, and frontal–temporal tracts are the last to mature (Eluvathingal et al., 2007; Giorgio et al., 2008; Lebel et al., 2008). Increases in FA may mark a transition from functional localization to distributed neural network functioning in the developing brain. For example, adolescents show a decrease in frontal gray matter density as FA increases in pathways connecting frontal regions to other brain areas (Giorgio et al., 2008). The ways in which sex interacts with age changes in FA are still unclear (for a review, see Schmithorst and Yuan, 2010): there are few patterns among the observed sex differences, and inconsistent findings likely reflect samples of varying age, the sex difference in white matter development, differences in FA measurement across studies (e.g., analyses at the level of voxels versus ROIs), and problems inherent in FA methodology (e.g., measurement of perpendicular fiber tracts within a voxel).

26.4.2.5 Implications of Sex Differences in Brain Structure

Some – but not all (e.g., Luders et al., 2009a) – of the sex differences in brain morphology might result from the different shaping of larger versus smaller brains (Allen et al., 2003; Im et al., 2008; Luders et al., 2002, 2010; Seldon, 2005; Zhang and Sejnowski, 2000). In larger as compared to smaller brains, the cortex tends to be flatter and thinner because it fills a larger intracranial space; this is consistent with reports of greater cortical thickness and complexity in women than men. There is also more white matter in larger brains because longer axonal connections are made to cortical regions that are farther apart than in smaller brains. This is consistent with evidence that men have greater white matter volumes than women.

What do sex differences in brain structure mean for cognitive sex differences? Compared to women, men appear to have larger regions of the parietal lobe, which is the primary brain area implicated in spatial ability (Brun et al., 2009). Parietal lobe surface area is, in fact, positively related to mental rotations performance in men, whereas parietal lobe gray matter volume is negatively related to mental rotations performance in women (Koscik et al., 2009); this suggests that different parietal lobe morphology subserves mental rotations performance in men and women, but it does not indicate whether men and women equally engage parietal regions during mental rotations tasks (this requires data on brain activation). There is also evidence from structural studies that some brain regions implicated in language, especially the temporal lobe, are larger in women than men (Brun et al., 2009; Harasty et al., 1997). But, these studies are difficult to interpret because verbal ability was not assessed. Sex differences in brain activation during spatial and language tasks are reviewed below (Sections 26.4.3.1 and 26.4.3.2, respectively).

It is probable that not all structural sex differences have behavioral significance, as there are likely multiple paths to the same outcome (De Vries, 2004; McCarthy and Arnold, 2011); this also appears to be the case for other bodily organs (e.g., the heart). Despite large variations in structure, brain function is remarkably similar and stable across people (Sporns, 2011). If this 'functional homeostasis' is maintained, then links between brain structure and behavior will not always exist.

26.4.3 Sex Differences in Brain Function (Activation)

There is a considerable literature examining sex differences in brain function as measured by task-specific activation (fMRI). The most meaningful work relates brain activation to task performance. An important issue concerns the sex difference on the behavioral outcome of interest. If men and women perform at different levels, brain activation differences might tell us about the neural substrates of the performance difference. If men and women perform at similar levels, brain activation

patterns might tell us about the (potentially different) processes or strategies they use to arrive at the same outcome.

26.4.3.1 Spatial Abilities

There has been interest in finding the neural correlates of the male advantage in spatial ability described in Section 26.2.1.1. Generally, in both sexes, spatial processing is associated with activation of the parietal lobes as well as temporal, premotor, and extrastriate areas (Butler et al., 2006; Christova et al., 2008; Halari et al., 2006; Hugdahl et al., 2006; Thomsen et al., 2000; Weiss et al., 2003a; see also Chapter 15). There is also some evidence that right hemisphere regions are more engaged in spatial tasks than left hemisphere regions, particularly for men (see Section 26.4.3.4).

The brain regions activated by men and women during mental rotations tasks are largely overlapping when there are no sex differences in behavioral performance, but some brain differences have been reported. Women engage portions of the frontal lobe, in particular the right inferior frontal gyrus, that men generally do not (Hugdahl et al., 2006; Jordan et al., 2002; Weiss et al., 2003a). For women, it is the activation of these frontal regions (as well as some temporal and parietal regions) that positively predicts task performance accuracy, whereas activation of parietal regions (e.g., postcentral gyrus and precuneus) positively predicts accuracy for men (Butler et al., 2006). The different patterns of task-related brain activation for women and men might reflect women's use of top-down processing and men's use of bottom-up processing to complete mental rotations tasks (Butler et al., 2006).

Functional brain sex differences during mental rotations tasks when the sexes differ in performance may tell us about the neural substrates of the cognitive difference, although the performance differences may complicate interpretation. Most behavioral tests of mental rotations involve comparisons among multiple figures, whereas most neuroimaging studies of mental rotations involve a pairwise comparison because of scanner space constraints; the sex difference in mental rotations performance is likely reduced in the latter compared to the former (Peters and Battista, 2008). In one fMRI study in which men outperformed women, there were no sex differences in brain regions activated by the task, but women had significantly greater activation of those regions than men (Halari et al., 2006); this is consistent with the notion that increased activation reflects the need to work harder (e.g., Gur et al., 2000).

There are also sex differences in brain activation during other visuospatial tasks. When matching the orientation of angled lines, men were reported to have greater activation than women of left occipital and cingulate regions, and this effect increased with age (Clements

et al., 2006; Clements-Stephens et al., 2009); in contrast, no regional brain sex differences were found in a similar task in which a joystick was used to move a cursor in a specified angle away from a central stimulus (Christova et al., 2008). During spatial navigation, men were seen to engage more left temporal regions than women, and women to engage more right frontal, parietal, and hippocampal regions than men (Grön et al., 2000), although sex differences in related tasks have not always been found (Ohnishi et al., 2006). During spatial attention tasks, men appear to activate left parietal regions more than women, whereas women engage more right frontal regions than men (Rubia et al., 2010), although this difference is not always found (Bell et al., 2006). These studies converge to indicate that visuospatial tasks engage different brain systems in the two sexes: men recruit left hemisphere regions to a greater degree than women, and women recruit frontal lobe regions that men generally do not. Unfortunately, it is difficult to review these findings in relation to behavioral performance because of the limited number of studies available and differences across studies in the tasks used.

26.4.3.2 Language

Several studies have focused on finding the neural substrates of the female advantage in verbal ability described in Section 26.2.1.3. Generally, in both sexes, activity in regions of the left hemisphere, including the temporal lobe, prefrontal cortex, inferior frontal gyrus, cingulate, and regions of the parietal lobe is associated with the performance of most language tasks, including verbal fluency, rhyming, and comprehension (Allendorfer et al., 2012; Buckner et al., 1995; Burman et al., 2008; Clements et al., 2006; Frost et al., 1999; Gauthier et al., 2009; Halari et al., 2006; Plante et al., 2006; Shaywitz et al., 1995; Weiss et al., 2003b).

As for spatial ability, findings of sex differences in brain activation for language tasks using fMRI depend upon whether the sexes are matched on behavioral performance. When they are matched on task performance, most studies do not find differences in brain activation (Allendorfer et al., 2012; Clements et al., 2006; Donnelly et al., 2011; Frost et al., 1999; Weiss et al., 2003b). Nonetheless, differences favoring both sexes have also been reported: men have been seen to have greater activation than women in language-related regions (Buckner et al., 1995; Gauthier et al., 2009); the reverse has also been found, with women having greater activation than men, particularly in right hemisphere regions (Plante et al., 2006; Shaywitz et al., 1995). When the sexes are not matched on task performance, women behaviorally outperform and display greater brain activation than men, especially in right hemisphere regions (Burman et al., 2008; Halari et al., 2006; Plante et al., 2006), consistent with other data discussed in Section 26.4.3.4 suggesting

bilateral representation of language in women. (This argument might appear inconsistent with that presented in Section 26.4.3.1, that is, that the greater frontal lobe activity of women during spatial tasks reflected their need to work harder than men. Issues pertaining to the interpretation of sex differences in brain function are complicated, however, as we discuss in Section 26.4.3.6.) Furthermore, the link between performance accuracy and brain activation differs for men and women: in women, accuracy is strongly linked to primary language areas in the bilateral frontal and left temporal lobes; in men, accuracy is weakly linked to primary left hemisphere language regions and also to secondary language areas, such as the left caudate and cingulate and right parietal lobe (Allendorfer et al., 2012; Burman et al., 2008; Donnelly et al., 2011).

26.4.3.3 Emotional Recognition

Much imaging work has concerned the neural substrates of sex differences in the processing of emotions, enough for reviews of sex differences in brain activity during the processing of emotional information, with a focus on amygdala engagement during the viewing of emotional human faces (Fusar-Poli et al., 2009; Sergerie et al., 2008). (It is interesting that most studies on emotion have focused on faces, rather than voices or prosody. See Chapter 18 for further reading on the neurobiology of face processing.) The viewing of emotional faces generally elicits activation in several brain regions, including the amygdala, frontal and prefrontal cortices, anterior cingulate cortex, insula, as well as areas in the temporal, parietal, and occipital lobes (Fusar-Poli et al., 2009; Sergerie et al., 2008). The amygdala is typically engaged in the viewing of all emotions, in particular happy, sad, and fearful faces (Fusar-Poli et al., 2009); this is likely a reflection of its central connectivity to visual, subcortical, and cortical regions of the brain, all of which are engaged in the detection of emotional cues and subsequent planning of behavioral responses (Pessoa and Adolphs, 2010).

There are sex differences in amygdala volume (larger in men than in women) and amygdala activation during the viewing of emotional faces (men have greater activation than do women). Two meta-analyses of over 100 empirical studies each have confirmed the sex differences in brain activation during emotion recognition tasks: men have greater bilateral activity than women in limbic areas, including the amygdala, and in prefrontal regions (Fusar-Poli et al., 2009; Sergerie et al., 2008), perhaps reflecting their need to work harder on the task, since women typically outperform men in the decoding of emotions (Section 26.2.2.4). Task performance was not explicitly considered in the meta-analyses, and studies varied in their measurement and reporting of behavioral sex differences. Few studies have, in fact, investigated sex differences in the link between amygdala

activation and performance on emotion recognition tasks: the frontal lobe inhibits amygdala activation during explicit identification of emotions versus the passive viewing of emotions (Critchley et al., 2000; Hariri et al., 2000), so most emotion recognition tasks do not require explicit behavioral responses. The limited available data suggest that bilateral amygdala activity is positively linked to emotion recognition accuracy for both men and women (Derntl et al., 2009; Habel et al., 2007).

There are also sex differences in amygdala activation during other emotion-related tasks. In a manner consistent with findings on facial emotion recognition, men show more amygdala activity than women during the viewing of sexual stimuli (reviewed in Hamann, 2005). During emotional memory tasks, the amygdala is activated in both sexes, but activation is greater in the left amygdala in women and in the right amygdala in men. This finding is not easy to interpret, but it has been suggested that sex differences in internalizing psychopathology arise in part through differences in memory for the gist of (right hemisphere) versus the details of (left hemisphere) negative emotional episodes (reviewed in Cahill, 2010; Hamann, 2005) (See Chapter 16 for further reading on the neurobiology of memory development.) Compared to emotional memory tasks, which emphasize emotions with a negative valence and have dominated the literature, tasks that emphasize emotions with a positive valence elicit different patterns of brain sex differences, with women showing more frontal and temporal activity than men, and men showing more left amygdala activity than women (Stevens and Hamann, 2012).

26.4.3.4 Lateralized Functions

Lateralization, also referred to as hemispheric specialization or functional asymmetry, has been a popular explanation for cognitive sex differences, particularly for language and spatial abilities. Typically, the left hemisphere, which houses both Broca's and Wernicke's areas, is dominant for sequential processing, including language, and the right hemisphere is dominant for simultaneous processing, including spatial abilities (for reviews, see Bryden, 1982; Hall et al., 2008; Kansaku and Kitazawa, 2001; Kimura, 1999). Data going back several decades, derived from patients with brain damage and behavioral tasks in typical individuals (such as split-field visual tasks, dichotic listening, and electroencephalogram asymmetry), suggest that women are less lateralized than men, especially for language (Bryden, 1982; McGlone, 1980). The topic has also been studied using fMRI, but results are often task- and method-dependent and subject to misinterpretation. For example, evidence reviewed above suggests that women have more right hemisphere activation than men for language tasks, and men have more left hemisphere activation than women for spatial tasks, but this does not mean that men are left-lateralized for

language and women are right-lateralized for spatial tasks. Lateralization must be explicitly tested by comparing activation in the two hemispheres; it is not sufficient to show that the activity of only one hemisphere is above baseline or that there are significant sex differences in specific regions of a single hemisphere. When the correct analyses are conducted, women show less lateralization than men. Women's reduced lateralization has been suggested to be linked to greater interhemispheric communication facilitated by their larger interhemispheric commissures (e.g., CC and anterior commissure) (Halpern, 2012; Hines et al., 1992).

There is some evidence for sex differences in functional lateralization of spatial ability, although findings from neuroimaging (PET and fMRI) are not always consistent with those from perceptual asymmetry assessments (e.g., split visual field and dichotic listening tasks), suggesting that the methods are measuring different aspects of lateralization. A meta-analysis of sex differences in lateralization of spatial tasks measured by a variety of methods (e.g., fMRI, PET, split visual field, brain damage) found that men primarily engage the right hemisphere and women engage both hemispheres when solving spatial tasks (Vogel et al., 2003). However, the findings from the fMRI studies on spatial ability reviewed above (Section 26.4.2.1) in which lateralization was explicitly examined are mixed: some reported greater right than left hemisphere activity for both men and women (Halari et al., 2006; Hugdahl et al., 2006), others reported more right-lateralized activity in men than women (e.g., Christova et al., 2008) or in women than men (e.g., Clements et al., 2006), and still others reported no lateralization effects (e.g., Weiss et al., 2003a).

Women have somewhat greater bilateral representation for language than men. Two recent meta-analyses of fMRI and PET studies on language lateralization reported weak support for left-lateralization in men but not women in several domains (Sommer et al., 2004, 2008), and meta-analyses using other behavioral methods (e.g., dichotic listening) reveal similar differences (Bryden, 1982; Sommer et al., 2008; Voyer, 2011). Findings from the fMRI studies on language reviewed above (Section 26.4.3.2) are consistent with these meta-analyses, with some reporting greater left than right hemisphere activity in both sexes (Frost et al., 1999; Plante et al., 2006; Weiss et al., 2003b), and others reporting this effect only for men (Clements et al., 2006; Shaywitz et al., 1995).

Sex differences in amygdala lateralization during emotion-related tasks are task-dependent. Studies on emotion recognition reviewed above (Section 26.4.3.3), in which task performance and lateralization effects were explicitly examined, found no support for sex differences (Derntl et al., 2009; Habel et al., 2007). This bilateral pattern of activation may depend on development, though: recent work shows right-lateralized amygdala

activity during facial emotion recognition for adolescent boys (but not girls) (Schneider et al., 2011). There is also evidence for sex differences in amygdala lateralization during other emotion tasks in adults: men have right-lateralized and women have left-lateralized amygdala activity for emotion-related memories (Cahill, 2010; Hamann, 2005). A meta-analysis of fMRI and PET studies on a combination of emotion-related tasks found that men had more right-lateralized activity than women (Wager et al., 2003), but other work suggests that sex differences disappear with improved meta-analytic methodology (e.g., incorporating effect sizes of original findings into the analysis) (Sergerie et al., 2008).

There are few studies directly examining the link between sex differences in lateralized activation and sex differences in cognitive performance. For spatial ability, greater (usually right) lateralization is thought to be linked to better performance because the processing of spatial information is unhindered by language circuitry. For language, the lateralization-performance link is unclear: greater lateralization has been associated with poorer language skills in typical males (compared to females), and incomplete lateralization has been hypothesized to be a risk factor for language disorders (Hall et al., 2008). Interestingly, the limited data on the association between lateralization and performance concern language tasks. As expected, results are largely inconsistent, likely due to study variations in task designs and the poor temporal resolution of PET and fMRI – a general limitation of the techniques that is particularly critical in examinations of the speed and timing of interhemispheric processing (for discussion, see Hall et al., 2008; Kansaku and Kitazawa, 2001; Kitazawa and Kansaku, 2005; Ortigue et al., 2005). It is important to note that rarely are women reported to be more lateralized than men, so inconsistencies likely reflect differential measurement sensitivity and small sex differences. Given the relatively small sex differences in brain lateralization and the relatively large sex differences in some abilities, it is very unlikely that lateralization differences completely account for cognitive sex differences.

26.4.3.5 Development of Sex Differences in Brain Function

There are fewer studies of functional brain development than structural brain development, although structure and function are certainly interdependent. Typically, brain activity related to cognitive task performance becomes less diffuse and more fine-tuned with age, probably related to increasing connectivity among brain regions (Casey et al., 2005; Giorgio et al., 2008). For example, brain function in children is driven by short-range connections among anatomically close regions; in adults, many local connections are replaced

by long-range ones, reflecting greater neural integration with development (Fair et al., 2007, 2009).

Brain function in adolescence is likely affected by the different trajectories of gray and white matter development, and these brain changes may underlie the increased risk-taking behavior characteristic of this developmental period. Limbic regions, which are implicated in affective processing, mature in early-to-mid adolescence, whereas the prefrontal cortex, which is thought to subserve cognitive control functions, is among the last brain region to undergo cortical thinning and myelination. The discordant maturational timing between these affective and cognitive neural processing networks is thought to result in limited top-down control of responses to appetitive stimuli such as peers and addictive substances (Casey et al., 2011; Steinberg, 2008). Because girls have faster brain development compared to boys, they are thought to experience a shorter period of discordance between limbic and prefrontal regions and therefore to be less likely to engage in the type of risk-taking behavior that emerges in adolescence (e.g., risky sex, substance use).

26.4.3.6 Implications of Sex Differences in Brain Function

There are several conclusions that emerge from the studies reviewed; a simplified summary of sex differences in neural activation to spatial, language, and emotion-related tasks is provided in Figure 26.4. First, with respect to visuospatial tasks, particularly mental rotations, both men and women engage parietal regions, but women engage frontal regions that men typically do not, and men engage some left-hemisphere regions that women typically do not (Figure 26.4(a)). Second, with respect to language tasks, women recruit more bilateral frontal and temporal regions than do men (Figure 26.4(b)). Third, with respect to the processing of emotional faces, men show greater bilateral amygdala activity than do women (Figure 26.4(c), right), perhaps reflecting their need to work harder than women to decode emotions. Fourth, with respect to negative emotional memory, women show greater left amygdala activity than men, and men show greater right amygdala activity than women (Figure 26.4(c), left); this difference is considered to have implications for sex differences in psychopathology (Cahill, 2010; Hamann, 2005; Stevens and Hamann, 2012).

We can also draw some general conclusions regarding sex differences in the lateralization of brain function for cognition and the link between brain activation and performance on cognitive tasks. With respect to lateralization, although the evidence is mixed, it appears that women are more likely than men to process material in both hemispheres; the lateralized activity of men appears to contribute to some cognitive advantages (e.g., in spatial ability) and disadvantages (e.g. in language).

With respect to brain activation–task performance links, performance accuracy is associated with activation of different brain regions for men and women for both visuospatial and language tasks, perhaps reflecting the use of sex-specific strategies.

Thus, the sexes engage similar brain regions to solve cognitive tasks, but they also appear to diverge in some notable ways. The sex differences primarily reflect two brain processes: efficiency and integration. Greater brain activity in the sex that typically performs worse on a behavioral task than the sex that performs better can be understood in terms of neural efficiency. When performance is poor, the task is seen to be difficult, and thus more neural resources are recruited to solve it. This interpretation is consistent with findings from studies in which task difficulty was manipulated: the neural substrates of a task become more widely distributed as task difficulty increases (e.g., Gur et al., 2000). Greater brain activity in the sex that typically performs better on a behavioral task than the sex that performs worse can be understood in terms of neural integration. When performance is good, the task elicits a diverse set of associations, subserved by greater neural engagement. This interpretation is consistent with findings on the neural systems underlying intelligence: functional connectivity among brain regions is positively associated with intelligence (Song et al., 2008). Whether efficiency or integration is invoked as an explanation for functional brain sex differences is likely dependent upon the nature of the task (e.g., complexity) and methodology (e.g., sample characteristics, task design, data analysis procedures); they are not mutually exclusive explanations, as evidenced by recent work on the efficiency of small-world networks (Fair et al., 2009; Sporns, 2011).

It is important to note that evidence regarding sex differences in brain function during performance of spatial, language, and emotion-related tasks is not completely consistent, for several reasons. First, results regarding sex differences in brain activation depend upon whether or not sex differences in task performance occurred and how they were considered. Second, samples are small in many neuroimaging studies, leading to low statistical power (and difficulty in detecting sex differences). Third, tasks and stimulus presentation methods vary across studies, so brain activation patterns are difficult to compare across studies. Fourth, participants vary across studies in sample characteristics, such as age; given sex differences in developmental trajectories (McClure et al., 2004; Plante et al., 2006; Rubia et al., 2010), it is important to be sure that findings reflect sex rather than developmental status. Fifth, the scanning environment constrains behavioral assessments in several ways (e.g., space, stimulus presentation), so the behavior measured in the scanner likely differs from the behavior that shows a sex difference outside the scanner (e.g., Peters and Battista, 2008).
FIGURE 26.4 Summary of sex differences in neural activation to sex-typed tasks. Colors indicate areas of brain activation: Men in blue, women in red, overlap in purple. (a) Spatial tasks; right: right hemisphere, left: left hemisphere. (b) Language tasks; right: right hemisphere, left: left hemisphere. (c) Amygdala during emotion-related tasks depicted on coronal slice; right: facial recognition, left: emotional memories (see text for details).

26.5 CAUSES OF BRAIN SEX DIFFERENCES

The brain is plastic, and its development is influenced by a combination of genetic, epigenetic, hormonal, and experiential effects throughout the lifespan. Most aspects of brain development reflect a dynamic interplay among these factors and are therefore difficult to isolate and investigate (Cosgrove et al., 2007; McCarthy and Arnold, 2011; Poldrack, 2000).

Animal models are important for informing examinations of human neural processes. Many brain regions that show sex differences in human beings correspond to sexually dimorphic brain regions in nonhuman animals (Goldstein et al., 2001), and animal studies have helped to guide many human studies; however, the degree to which animal findings generalize to human beings is not always clear, particularly with respect to cognitive domains that are species-specific, such as language.

Research on the causes of human brain sex differences is relatively new; thus, the studies we review below must be interpreted critically and require replication. Parallel to our discussion of the causes of psychological sex differences (Section 26.3), we consider influences on brain sex differences of socialization, genes, and focus on hormones (prenatal, adolescent, and circulating).

26.5.1 Socialization Contributions to Brain Sex Differences

Brain sex differences are usually considered to be innate, but the brain changes in response to experiences, so it is important to consider socialization (Cosgrove et al., 2007). Although sex-differential experiences were not measured in most studies reviewed above (Section 26.4), socialization effects could account for variability in findings and inconsistencies across reports. For example, studies failing to find sex differences in white matter volume (as discussed in Section 26.4.2.4) could reflect effects of sex-differential experiences; perhaps certain male-typed experiences (e.g., engaging in spatial activities) facilitate white matter growth, so girls who have these experiences have more 'male-typical' white matter than girls who do not have these experiences.

There is much interesting work to be done regarding socialization influences on brain sex differences, particularly examining the ways in which training on cognitive tasks might differentially mediate (or be mediated by) brain sex differences. For example, we suggest above (Section 26.4.3.1) that sex differences in brain activation during the performance of spatial tasks might reflect sex-differential strategy use during task completion (see also Butler et al., 2006; Clements-Stephens et al., 2009; Jordan et al., 2002; Thomsen et al., 2000). We also review above evidence for the potential elimination of the behavioral sex difference in spatial tasks through training (Section 26.3.1.2). Thus, the sex difference in brain activation during spatial task performance might be partially explained by sex-differential experiences with spatial stimuli, and consequently, learned strategies for manipulation of those stimuli. Investigations of cognitive training effects on brain function of males and females are warranted.

26.5.2 Genetic Contributions to Brain Sex Differences

There is little conclusive evidence regarding sex chromosome contributions to human brain development and the ways in which genes and the environment interact to influence the brain in sex-differential ways. Recent twin data show greater genetic influences on white matter development in boys than girls (Chiang et al., 2011). Consistent with this, intriguing preliminary evidence indicates that several genes on the Y chromosome are expressed in the human male prenatal brain at midgestation (Reinius and Jazin, 2009) and the adult male brain (Vawter et al., 2004); however, development of the external genitalia is underway by midgestation and complete maturation has occurred by adulthood, so these findings might also reflect hormone (e.g., androgens from the testes) or experiential effects on the brain.

Some insight into the role of the X chromosome in brain sex differences is also provided by studies of girls and women with Turner syndrome (TS), who have a single (X) sex chromosome. Compared to unaffected controls, girls and women with TS have decreased parietal lobe volume and decreased activation in parietal lobe regions during a variety of visuospatial tasks; they also have increased amygdala volume and increased amygdala activation during the recognition of fearful faces. These findings are consistent with their cognitive profile, which is characterized, in part, by visuospatial and emotion recognition deficits (reviewed in Knickmeyer and Davenport, 2011). The implications of these findings for brain sex differences in the unaffected population are unclear for several reasons. First, brain differences are confounded by cognitive performance differences: TS and unaffected control groups generally differ on task performance in functional imaging studies. Second, sex hormone production is low in individuals with TS; thus, differential patterns of brain structure and function in individuals with TS as compared to those in unaffected girls and women might reflect sex hormone influences instead of X-chromosome influences on the brain. This is consistent with evidence showing that estradiol

replacement in adolescents with TS reduces differences between girls with TS and control girls (Lepage et al., 2012). Third, it is unclear whether findings in individuals with TS reflect effects of the X chromosome, having a single (be it X or Y) sex chromosome, or X-chromosome dosage. Effects of X-chromosome dosage have been investigated by comparing brain structure in men with Klinefelter Syndrome (XXY) to unaffected men and women. Unfortunately, results from these studies are not easy to interpret because (as in studies in women with TS) X-dosage effects are confounded with effects of sex hormones (for discussion, see Bryant et al., 2011; Lentini et al., 2012). There is clearly much opportunity for future work on sex chromosome influences on brain sex differences.

26.5.3 Hormonal Contributions to Brain Sex Differences

Sex hormones, particularly androgens, are the most investigated cause of sex differences in the human brain. There is evidence from clinical and typical samples for prenatal, adolescent, and circulating sex hormone influences on the brain, but this research area is relatively new, and conclusions must be tentative.

26.5.3.1 Prenatal Hormone Links to Brain Sex Differences

The influence of androgens present during early development on structural brain sex differences has been examined in individuals with CAH and in typical boys whose amniotic testosterone levels were assessed. As discussed above (Section 26.3.4), androgens masculinize a variety of characteristics in girls and women with CAH (including activity interests, some social behaviors, and spatial ability). Structural imaging studies reveal effects that are generally more consistent with the disease process than with prenatal hormone effects on the brain; smaller amygdala volumes were reported in both males and females with CAH than in unaffected males and females (Merke et al., 2003), likely reflecting effects of postnatal cortisone treatment in individuals with CAH. In typical boys aged 8 to 11 years, testosterone levels from amniotic fluid have been linked to gray matter volumes in brain regions that show sex differences. Specifically, testosterone was positively linked to gray matter volumes in temporal regions, but negatively linked to volumes in occipital and frontal regions (Lombardo et al., 2012). More research is necessary to determine if this pattern of results is also seen in girls and if it changes with development.

Findings regarding prenatal androgen influences on brain function suggest altered amygdala and hippocampal activity in individuals with CAH, but interpretation is not straightforward. Consider findings from one set of studies in which images of emotional faces were viewed, rated, and recalled (Ernst et al., 2007; Mazzone et al., 2011). Brain activation findings showed that girls with CAH had greater amygdala activation while viewing negative facial emotions and less hippocampal activation while recalling emotional faces compared to unaffected girls; however, there were also group differences in behavioral ratings and task performance, complicating interpretation of brain activation differences. In a separate PET functional imaging study, women with CAH were not seen to differ from unaffected women in their neural response to olfactory stimuli: both groups displayed increased amygdala activation to a masculine pheromone and increased hypothalamus activation to a feminine pheromone, compared to men who showed the reciprocal pattern of brain activity (Ciumas et al., 2009).

Information about prenatal androgen effects on brain function also comes from typical samples, in which testosterone levels have been measured in amniotic fluid and linked to performance on dichotic listening tasks in childhood. Amniotic testosterone levels were positively associated with left-lateralized language processing in one sample of 6-year-old girls and boys (Lust et al., 2010) and another sample of 10-year-old girls (Grimshaw et al., 1995a). This is consistent with the sex difference in language lateralization reported in adults and children (Section 26.4.3.4). Amniotic testosterone levels have also been associated with right-lateralized emotion processing (measured with an emotion–word dichotic listening task) in 10-year-old boys (Grimshaw et al., 1995a), consistent with meta-analytic findings on right-lateralized amygdala activation in men (but not women) during emotion-related tasks (Wager et al., 2003).

26.5.3.2 Adolescent Hormone Links to Brain Sex Differences

There is considerable interest in the ways that brain changes in adolescence reflect the direct effects of pubertal sex hormones, although most work has not been able to differentiate permanent (organizational) effects of hormones from transient (activational) effects. Generally, pubertal increases in sex-specific gonadal hormones (estrogen in girls and testosterone in boys) are associated with decreases in cortical gray matter volume (reviewed in Peper et al., 2011). When boys and girls are matched on pubertal development, however, sex differences in links between testosterone and regional gray matter volumes are more difficult to interpret, with boys showing fewer significant associations than girls (Bramen et al., 2012). This apparent discrepancy may be explained by androgen sensitivity. The efficiency of the androgen receptor gene has been suggested to moderate the influence of sex hormones on cortical thinning: fewer repeats

of a functional polymorphism within the gene predicted more 'masculinized' patterns of maturation (Paus et al., 2010; Raznahan et al., 2010).

There is stronger evidence for a link between pubertal hormones and white matter development in boys than in girls. In boys, increases in testosterone at puberty have been linked to increases in white matter volume (reviewed in Peper et al., 2011), with the efficiency of the androgen receptor gene moderating this association (Paus et al., 2010; Perrin et al., 2008). Testosterone levels – but not pubertal stage – have also been linked to FA increases in boys (Bava et al., 2011; Herting et al., 2012). Findings are inconsistent for girls: advanced pubertal stage has been positively linked to increases in white matter volume (Peper et al., 2011), but estradiol levels have been negatively associated with FA in girls (Herting et al., 2012). Differences in brain links with hormone levels versus pubertal stage may reflect limitations in self-reports of pubertal stage for both sexes (discussed in Dorn et al., 2006).

Pubertal hormone effects on brain function have been studied less than effects on brain structure, but some insight is provided by a study on the neural substrates of a monetary reward task (Forbes et al., 2010). Girls and boys with more advanced pubertal development (compared to same-age peers with less advanced development) showed less striatum and more prefrontal cortex activation at reward *presentation*, consistent with evidence for the discordant maturation of affective and cognitive neural processing networks in adolescence (Section 26.4.3.5). For boys only, testosterone levels were positively linked with striatum activity during reward *anticipation*, perhaps reflecting a sex difference in the neural substrates of consummatory anticipation that emerges at puberty. Estradiol links to brain function were not examined in this study, presumably because the measurement of this hormone is problematic, particularly during puberty (Dorn and Biro, 2011).

The influence of pubertal hormones on brain sex differences has also been investigated in boys with extremely early (disordered) puberty (Mueller et al., 2009, 2011a,b). Results are difficult to interpret, however, because of age and performance differences between clinical and control groups. Nonetheless, this research illustrates a valuable approach (i.e., neuroimaging individuals with atypical pubertal timing) to understanding hormonal influences on brain development.

26.5.3.3 Circulating Hormone Links to Brain Sex Differences

Relations between regional volumes and circulating hormone levels in adults provide evidence for transient (activational) effects of sex hormones on sex-related brain structure, as seen in both clinical and typical samples. Changes in overall brain volume were observed in a sample of transsexuals after 4 months of hormone treatment (antiandrogens + estrogens for male-to-female, and androgens for female-to-male) (Hulshoff Pol et al., 2006). Compared to untreated controls, male-to-female transsexuals showed decreases in overall brain volume, and female-to-male transsexuals showed increases in overall brain and hypothalamus volumes. These findings are consistent with the sex differences reported above (Sections 26.4.2.1. and 26.4.2.2.3) and suggest that androgens increase overall and some regional brain volumes. Nonetheless, the results regarding circulating androgen influences on overall brain volume are surprising, given that the sex difference in brain volume is apparent in childhood (Section 26.4.2.1). Regional specificity of hormone effects has been seen in samples of typical adults, but results differ across studies, likely due to differences in sample characteristics (e.g., age) and methods (e.g., how sex differences were accounted for in brain-hormone links). Circulating estrogen levels were positively linked to gray matter volume in the left superior parietal gyrus, but results differ across studies, likely due to differences in sample characteristics (e.g., age) and methods (e.g., how sex differences were accounted for in brain-hormone links). Circulating testosterone levels were negatively linked to gray matter volume in the left inferior frontal gyrus (Witte et al., 2010) and positively linked to gray matter volumes in the hippocampus, amygdala, insula, and occiptial regions (Lentini et al., 2012)

Examinations of structural and functional brain changes at menopause and during different phases of the menstrual cycle provide indirect evidence for activational effects of estrogens on the brain. Generally, the hippocampus and frontal lobes are implicated as the primary sites for estrogen effects on brain structure in humans; thus, estrogen effects on brain function are most evident in verbal memory tasks, which show a sex difference that favors females (Section 26.2.1.4), and are subserved by the hippocampus and frontal lobes (Maki, 2005; Maki and Resnick, 2001). At menopause, there is evidence for decreases in whole brain, frontal lobe, and hippocampal volumes (Goto et al., 2011; Robertson et al., 2009). Further, estrogen therapy begun around the onset of menopause and of a relatively short duration (about 5 years) offsets these volume reductions (Erickson et al., 2010; Lord et al., 2008; Resnick et al., 2009). Postmenopausal women undergoing estrogen therapy have also been shown to have greater activation of frontal, parietal, and hippocampal regions during verbal and working memory tasks in comparison to postmenopausal women who never used estrogen therapy (Berent-Spillson et al., 2010; Dumas et al., 2010; Persad et al., 2009; Shaywitz et al., 1999). Interestingly, the increased activation with hormone therapy did not predict

better memory in these studies; there were no performance differences between estrogen therapy users and nonusers on the memory tasks. Estrogen therapy users, however, had greater cerebral blood flow and better memory task performance than nonusers in research using PET; thus, cerebral blow flood may be one mechanism through which estrogen influences cognition (and is best measured by PET; Maki and Resnick, 2000; Resnick et al., 1998). This is a promising area for future research.

Indirect evidence for estrogen influences on the structure and function of the brain is also provided by research with women at different phases of their menstrual cycle. In high-estrogen phases of the menstrual cycle as compared to low-estrogen phases, women generally show more hippocampal volume as well as left frontal and temporal activation during the completion of verbal and mental rotation tasks (Dietrich et al., 2001; Fernández et al., 2003; Konrad et al., 2008; Protopopescu et al., 2008; Schöning et al., 2007). As with findings from studies on estrogen therapy at menopause, the implications of this research are not clear, because there is currently little evidence for a relation between estrogen-influenced brain activation and task performance: in the functional studies reviewed above, increased left frontal lobe activation in the high-estrogen phase of the cycle did not predict differential task performance (Dietrich et al., 2001; Fernández et al., 2003; Konrad et al., 2008). Similarly, during the high-estrogen phase of the menstrual cycle as compared to the low-estrogen phase, estradiol levels predicted greater left frontal lobe activation during a verbal memory task, but they did not predict better task performance (Craig et al., 2008).

In summary, there is little conclusive evidence regarding social, genetic, or hormonal contributions to sex differences in human brain structure and function, but this research area is growing. Most of the available data concern hormones. Preliminary findings suggest that prenatal androgen influences the activity of the hippocampus, amygdala, and lateralization of the brain for language- and emotion-related tasks. There is also some indication that sex-specific hormones at puberty are linked to the reduction of gray matter volume in adolescence, and that testosterone in boys is linked to the adolescent increase in white matter. Finally, there is evidence for activational effects of sex hormones on the adult brain, particularly for estrogen influences on hippocampal and frontal lobe function. Unfortunately, there are few data linking sex hormone influences on the brain with behavior. There are also few data regarding sex chromosome expression in the human brain, and no data regarding socialization influences on brain sex differences. Thus, there is much opportunity for future research.

26.6 CONCLUSIONS AND FUTURE DIRECTIONS

As reviewed above, the sexes differ in significant ways in both behavior and the brain (including structure and function), although there is still much to be learned regarding sex differences and their development and causes. It is important to be aware of the ways in which age and sample size can affect conclusions regarding the existence – or not – of sex differences.

There is good evidence that both sex hormones and social factors influence the development of human sex-related psychological characteristics, although little is currently known about the pathways by which socialization acts on and modifies biological predispositions. Determinants of brain sex differences are still largely unknown, but it is important to remember that the brain is plastic and that sex differences likely emerge from the interplay of genes, sex hormones, and social experiences. Brain sex differences cannot be assumed to be innate.

There are several opportunities to study the etiology of sex differences in brain and behavior. First, sex differences in early brain development can be studied in natural experiments in which prenatal hormone exposure is sex-atypical, such as CAH. These conditions help us to separate the relative influences of early (prenatal and neonatal) hormones and postnatal socialization, and, more important, allow the study of their interplay. Examples of the information that can be gained from these conditions have been reviewed in this chapter and elsewhere (Berenbaum and Beltz, 2011; Blakemore et al., 2009). Second, sex differences in adolescent brain development can be studied in individuals with disordered pubertal development. This provides an opportunity to test hypotheses about permanent changes to the brain induced by sex hormones (Sisk and Zehr, 2005, reviewed in Berenbaum and Beltz, 2011; Giedd et al., 2006). Third, sex differences in adolescent brain development can also be studied in typical individuals, by linking variations in pubertal development to changes in behavior and in the brain. There is some intriguing recent cross-sectional work in this area (reviewed in Berenbaum and Beltz, 2011; Peper et al., 2011), but longitudinal studies are optimal for learning how hormones and socialization at puberty influence brain changes and for examining the permanence of the changes.

The links between neural and behavioral sex differences are beginning to be understood, but they must be directly tested. It is not sufficient to find sex differences in regions of the brain known to subserve specific sex-related behavioral characteristics; sex differences in those regions of the brain must be shown to *explain* the behavioral sex differences.

There are several opportunities to understand direct links between sex differences in the brain and behavior. First, the meaning of sex differences in brain activation – when they reflect strategy use (when the sexes perform similarly) or behavioral differences (when the sexes differ in performance) – can be understood by manipulating task difficulty during functional brain scanning. Such types of designs are rare in examinations of sex differences, but they are typical in other research areas (e.g., Poldrack, 2000). Second, causal inferences about links between brain and behavior can be strengthened by using effective connectivity mapping which takes advantage of the time series nature of functional neuro-imaging data. Work on functional and structural connectivity reviewed in this chapter has identified brain regions with related functional activity (e.g., Fair et al., 2007, 2009) and structural connections (e.g., Schmithorst and Yuan, 2010), but effective connectivity mapping would allow prediction of regional brain activity from activity in other brain regions or task performance (e.g., Gates et al., 2010, 2011; Kim et al., 2007). For example, effective connectivity mapping enables inferences regarding the direction of a connection between two brain regions: the connection might go from region A to region B for women, but from region B to region A for men. Third, neural effects of sex-differential experiences can be studied using longitudinal neuroimaging designs. For example, studies of cognitive training effects on changes in brain structure or function can reveal the plasticity of the brain and indicate how sex differences arise and how they might be modified (and the within-subject design avoids the confounding influence of sex differences in brain size) (e.g., Thambisetty et al., 2010).

In sum, the sexes are similar in many ways, but there are notable differences in their brain and behavior (including cognitive abilities). An understanding of sex differences has implications for discussions about women's underrepresentation in science and mathematics careers as well as for the differences in the etiology, appearance, and treatment of psychopathology between boys and men as compared to girls and women. Studying sex differences can also tell us about individual differences generally. By identifying the differences, delineating their development, and investigating their causes, we begin to uncover the mechanisms underlying variation in human health, disease, and behavior.

Neural-Tube Defects

C. Pyrgaki[1], L. Niswander[1,2]

[1]University of Colorado Denver, Aurora, CO, USA; [2]Howard Hughes Medical Institute, Aurora, CO, USA

27.1 NEURAL-TUBE DEFECTS

After heart defects, neural-tube defects (NTDs) are the second most common birth defect, occurring in approximately 300 000 newborns worldwide (∼1:1000 live births) (Botto et al., 1999). The prevalence of NTDs varies considerably between different racial and ethnic groups (Carmichael et al., 2004; Feldman et al., 1982; Feuchtbaum et al., 1999). In the United States, the two most common types of NTDs, spina bifida and anencephaly, are estimated to affect ∼3000 pregnancies each year, with caudal NTDs occurring at a higher rate than cranial NTDs (Canfield et al., 2009; CDC, 2004). Both cranial and caudal NTDs can be associated with craniofacial defects (Rittler et al., 2008), but the majority of NTDs are nonsyndromic (Hall et al., 1988). NTDs, especially those of the cranial region, seem to have a higher prevalence among females (Rogers and Morris, 1973; Seller, 1987), although the reason for this sex difference is not well understood.

27.1.1 Types of NTDs

NTDs are divided into two major groups, cranial NTDs and spinal NTDs, and the nomenclature and classification of NTDs in humans are based on position and severity of the NTDs. Cranial NTDs result from failure of the neural tube to close in the cranial region and are classified as follows:

1. Encephalocele, defined as herniation of the cranial vault. Encephalocele can be either a meningocele,

if the herniation contains only cerebral spinal fluid (CSF) and meninges, or a meningoencephalocele, if it also contains neural tissue (McComb, 1997).

2. Anencephaly, where the cranial vault is absent and the neural tissue degenerates by week 8 of gestation (Calzolari et al., 2004).

Spinal NTDs also are referred to as spinal dysraphisms. This term was coined by Lichtenstein in 1940 to describe incomplete fusion or malformations of structures in the dorsal midline of the back, particularly congenital abnormalities of the vertebral column and spinal cord (Tavafoghi et al., 1978). These can be further divided into three groups:

1. Spina bifida occulta, which in its strict definition refers only to bone-fusion defects in the spine.
2. Spina bifida cystica, which refers to meningocele and myelomeningocele, where the herniation contains not only CSF, but also neuronal tissue.
3. Spina bifida aperta (SBA), in which the neural tissue is exposed to the environment (Kaufman, 2004).

A relatively rare form of dysraphism that is open or exposed results from the failure of closure of the neural tube throughout its entire length and is called craniorachischisis (Coskun et al., 2009). The term *spina bifida* has become commonly associated with the open spinal dysraphism of a myelomeningocele.

27.1.2 Clinical Aspects and Prognosis of NTDs

NTDs can be fatal; all exencephalic embryos are stillborn or die shortly after birth, whereas the mortality rate of babies with spina bifida is especially high over the first year of life. Individuals with less severe myelomeningocele suffer from lifelong disabilities, including reduced mobility, little or no bowel and bladder control, and urological infections, and they often require surgical interventions to control the effect of hydrocephalus, the build-up of fluid inside the skull caused by obstruction of CSF circulation (Simeonsson et al., 2002). NTDs pose a considerable monetary burden on the health care system (Kinsman and Doehring, 1996), as well as a significant emotional burden on the affected individual and his/her family. Therefore, understanding neural-tube development and the causes of NTDs are among the most important health-related studies today.

27.1.3 Etiology of NTDs

The etiology of NTDs is complex and involves both genetic and environmental factors, which makes NTDs a classic example of a multifactorial disorder.

27.1.3.1 Genetics of NTDs

The genetic risk of a recurrent NTD in a family with one child with an NTD is 2–5%, a 50-fold increase compared with the rest of the population (Forrester and Merz, 2005). Despite the evidence that genetics plays a pivotal role in the occurrence of NTDs, there are few data on single-gene defects directly associated with NTDs in humans. A number of chromosome rearrangements, such as trisomies 13 and 18, and known genetic syndromes, for example, Meckel syndrome, are associated with NTDs (Lynch, 2005). Chromosomal abnormalities, such as aneuploidy, are present in 5–17% of cases with NTDs (Kennedy et al., 1998), and a 13q deletion, with a critical region at 13q33-34, is strongly correlated with the occurrence of NTDs (Luo et al., 2000). These data can be used to extract clues in an effort to determine the identity of genes involved in neural-tube closure. Clues as to candidate genes for association studies of human NTDs also have been derived from research in animal models of NTD, as described below and as outlined in comprehensive reviews by Harris and Juriloff in 2007 and 2010.

27.1.3.1.1 ENVIRONMENT AND NTDS

Maternal diabetes during pregnancy is a key environmental factor, as there is a greater than tenfold increase in NTD frequency in the offspring of diabetic mothers as compared to the general population (Milunsky et al., 1982). The mechanism by which diabetes contributes to failure of neural-tube closure in humans remains unclear. However, a mouse model of diabetes showed a correlation between elevated blood glucose in the mother, increased apoptosis of neural cells, and reduced levels of Pax3, a gene required for neural-tube (NT) formation (Fine et al., 1999; Phelan et al., 1997). Genomics studies show that maternal diabetes can alter transcriptional programs in the developing mouse embryo, potentially affecting genes that directly and indirectly control NT formation (Pavlinkova et al., 2009). Maternal hyperthermia during pregnancy can increase the risk of NTDs up to twofold, although the mechanism responsible for this increase is unknown (Lynberg et al., 1994). Pharmacological agents, among them valproic acid (Nau et al., 1991) and antiepileptic drugs, are associated with an increased incidence of NTDs. For example, antiepileptic drugs can increase NTD risk by 10- to 20-fold (Lindhout et al., 1992). Lifestyle choices such as drinking, smoking, and recreational drugs also increase the risk of NTDs through unknown mechanisms (Suarez et al., 2008). Finally, studies have provided a link between dietary choices and risk for NTDs. In general, vitamin intake is not correlated with reduced risk for NTDs (Carmichael et al., 2003); however, there is one dietary supplement, folic acid, which can reduce the risk

for NTDs when added to the maternal diet periconceptionally. Folic acid is the environmental factor that has attracted the most attention from developmental biologists, epidemiologists, and the general public due to the view that it has a protective effect against NTDs (Honein et al., 2001). Epidemiological studies started in the early 1980s showed that maternal folic-acid supplementation led to a significant reduction in NTD incidence (Laurence, 1985). This evidence dramatically influenced public-health policies and led to food-fortification programs in the United States and a number of other countries. The mechanism by which folic acid affects the incidence of NTDs remains largely unknown, despite the investigative efforts of a number of laboratories worldwide concerning its effect on the developing embryo.

As noted, there is a gap in knowledge of the mechanisms that lead to NTDs with respect to both genetic and environmental causes. This lack of knowledge significantly limits efforts of the scientific and medical communities toward the prevention of NTDs, both through genetic counseling and through control of the embryonic environment before and during NT formation.

27.2 VERTEBRATE NEURULATION

27.2.1 Animal Models for Vertebrate Neurulation Studies

Neural-tube development requires the coordination of multiple tissues (neural ectoderm, the neighboring mesenchyme, and the overlying ectoderm) in both space and time. For over 50 years, a number of animal systems have been used to study NT development. Model systems such as birds (Averbuch-Heller et al., 1994; Bel-Vialar et al., 2002; Schoenwolf et al., 1989) and amphibians (Clarke et al., 1991; Davidson and Keller, 1999; Roffers-Agarwal et al., 2008) and zebrafish (Nyholm et al., 2009; Puschel et al., 1992; Sumanas

et al., 2005) have contributed considerable insight into neurulation. The mouse is the most extensively studied mammalian experimental model for neurulation and NTD, and it most closely recapitulates human neurulation. However, even mice have limitations as a model of human NT development. For example, there are thought to be differences between mice and humans in the number of closure initiation sites, the sites where the neural folds first meet. Moreover, very few mouse models of NTD are representative of nonsyndromic human NTDs (Juriloff and Harris, 2000). Despite these differences, the mouse undergoes neurulation in a manner that is closer to human than to other animal models used to study neurulation to date. Moreover, similar genes are likely responsible for NT closure in humans as in mice (Harris and Juriloff, 2007, 2010). Finally, the great number of mouse NTD mutants provides an invaluable tool for understanding the underlying genetic, molecular, and cellular basis of NTD.

27.2.2 Primary and Secondary Neurulation

The process that forms the primordium of the central nervous system, the neural tube, is called neurulation. Modes of neurulation vary across vertebrate species; however, cellular comparisons reveal conserved mechanisms. This reinforces the idea that study of neurulation in different animal systems can contribute to our understanding of the molecular basis of NT formation and NTDs in humans.

There are two different modes of neurulation: primary and secondary neurulation (Figure 27.1). During primary neurulation, the flat and thickened epithelial layer on the dorsal surface of the embryo called the neural plate bends, and the neural folds seal together to form a hollow neural tube. Secondary neurulation occurs in the most caudal region of the embryo. During secondary neurulation, a cluster of mesenchymal cells condenses below the surface ectoderm to form a cord-like structure. A central lumen forms in this compact structure through
FIGURE 27.1   Primary and secondary neurulation. (a) Primary neurulation and (b) secondary neurulation in amniotes. Organization of cells from onset (*left*) to completion (*right*) of neurulation.

a process known as cavitation, giving rise to the NT (Griffith et al., 1992; Schoenwolf, 1979; Schoenwolf and Delongo, 1980). All amniotes studied to date, including humans (Saitsu et al., 2004), undergo both primary and secondary neurulation.

Although anamniotes have provided considerable information on how neurulation occurs and have furthered our understanding of neurulation in mammals, for the purposes of this chapter, we will focus on amniotes and more specifically mice due to their similarity in development and genetics to human neurulation.

27.2.3 Neurulation in Amniote Model Systems

Amniote neurulation occurs in at least four stages: (i) the acquisition of a neural fate, (ii) the elevation of the neural folds, (iii) the bending of the neural plate, and (iv) the meeting of the neural folds at the midline and fusion that forms the closed neural tube (Figure 27.2).

These four stages occur concurrently along the rostral–caudal axis and in coordination with movements of the primitive streak. Following neural induction, the neuroectoderm becomes morphologically distinct from the non-neural ectoderm through apicobasal thickening of the neuroectoderm to form a tall and thick epithelial sheet that is relatively wide along the medial–lateral axis and short along the anterior–posterior (AP) axis (Figure 27.2(a)). Subsequently, the neural plate undergoes convergent extension (see below) to narrow along the medial–lateral axis and elongate along the AP axis.

Bending of the neural plate at the lateral edges forms the neural folds, which continue to elevate and converge to meet in the midline and form a closed tube. Forces from the neural ectoderm, the mesenchyme and the adjacent non-neural ectoderm promote elevation of the neural folds (Moury and Schoenwolf, 1995). Further bending of the neural folds is driven by formation of "hinge" points involving apical constriction of a limited number of cells in three positions along the neural plate. The first hinge point, called the floor plate or medial hinge point (MHP), forms in the middle of the neural plate above the notochord (posterior) or prechordal mesoderm (anterior). The next two hinge points form in pairs on the dorsolateral sides of the elevating neural folds and are called dorsolateral hinge points (DLHPs; Figure 27.2(b) and 27.2(c)) (Colas and Schoenwolf, 2001; Shum and Copp, 1996). The inductive signal for MHP formation comes from the notochord/prechordal mesoderm and is the secreted protein Sonic Hedgehog (Shh) (Smith and Schoenwolf, 1989; van Straaten et al., 1988). Shh, in a dose-dependent manner, also participates in positioning of the DLHPs (Ybot-Gonzalez et al., 2002). Bending the neural folds is critically important in bringing the neural folds in close proximity to the midline and thus facilitates closure.

The final step of neurulation is when the neural folds meet in the midline, the non-neural ectoderm separates from the neural ectoderm, and each tissue layer seals together to form a continuous sheet of ectoderm overlying the closed neural tube (Figure 27.2(d)). This closure is traditionally called fusion, although the cells do not actually fuse. Very little is known about this last step of neurulation in any organism. For instance, in the mammalian embryo, it has been debated whether the neural or non-neural ectoderm initiates closure. Recent live imaging of the mouse embryo during neurulation showed that the non-neural ectoderm cells are highly dynamic and extend thin, long, and fast-moving cellular extensions that connect the two folds as they approach each other, indicating that the non-neural ectoderm initiates and possibly drives neural-fold fusion (Pyrgaki, 2010b). A role for adhesion molecules is hypothesized in fusion. For example, mutations in adhesion molecules, such as ephrinA5 and ephrinA7, can cause NTDs in mice (Holmberg et al., 2000). However, a direct involvement of these molecules in neural-fold fusion has not been demonstrated.

The fusion of the neural folds starts from one or more initial closure points, depending on the species examined. The classical view has been of a zipper-like closure that proceeds rostrally and caudally from these initial closure points. Recent live imaging of the mouse embryo cranial
FIGURE 27.2 Four distinct steps of neural-tube formation in amniotes. (a) Acquisition of a neural fate and shaping of the neural plate. (b) Elevation of the neural folds. The non-neural ectoderm exerts force on the neural folds to contribute to neural-fold elevation. (c) Bending of the neural plate and formation of hinge points. In three positions, the neural ectoderm cells change their shape from cuboidal to wedge-shaped to form the medial hinge point and dorsolateral hinge points. These cellular changes facilitate further bending of neuroectoderm to bring the neural folds close together along the midline. (d) Meeting of the neural folds at the midline and fusion to form the closed neural tube and the overlying ectodermal sheet.

region supports a zipper-like closure in the hindbrain. However, closure in the mouse midbrain suggests a different mechanism in which intermediate closure points facilitate closure of the folds in a "buttoning-up" manner (Pyrgaki et al., 2010b).

Migration of the neural crest cells, which form at the boundary between the neural and non-neural ectoderm and then migrate laterally to different parts of the body, occurs concurrently with neural-tube closure in some rostral–caudal regions or after neural-tube closure in other regions.

27.2.4 Neurulation in Humans

Practical and ethical considerations limit our ability to study neurulation in humans, and animal models are therefore needed to provide insight into the cellular and molecular bases of human neurulation. However, there is sufficient information regarding neurulation in humans to suggest that some of the principles of neurulation in amniotes also apply to the human embryo.

Neural-tube formation and closure in humans occurs within the first month of pregnancy, between weeks 3–4 of gestation. In humans, primary neurulation is responsible for generating most of the neural tube. The caudal eminence of the human embryo is formed via secondary neurulation, which will be the point of origin of the terminal parts of the spinal cord, notochord, somites, vertebrae, hindgut, nerves, and blood vessels. This ectoderm-covered mass of pluripotent tissue is a continuation of the primitive streak (at stages 9–12), and it gradually replaces the streak (at stages 12 and 13 of the development of the human embryo, at about 4 weeks post fertilization) and forms a solid cellular mass called the neural cord. The neural cord forms the lower sacral and coccygeal parts of the spinal cord (Muller and O'Rahilly, 1987). The rostral and caudal neuropores close when approximately 20 and 25 pairs of somites are visible, respectively.

One potential difference between human and mouse neural-tube formation may be the number of initial closure points. The mouse has three initial fusion points. In humans, there is an ongoing debate about the number of fusion points. Clinical studies of human embryos with NTDs have argued for 3–5 closure points (Martinez-Frias et al., 1996; Nakatsu et al., 2000; Srinivas et al., 2008). These data are disputed in a study published in 2002 that supports the idea that the human embryo has only two initial closure sites and two neuropores (O'Rahilly and Muller, 2002). It is unclear whether the question of the number of closure points in the human embryo can be answered by case reports. Therefore, one cannot be sure that animal models fully represent the human condition, and it is very likely they do not. We need to be aware that, despite their usefulness, animal models do have limitations, and one needs to be

careful when using them to infer analogies to human neurulation.

27.3 GENETIC APPROACHES USED TO UNCOVER REGULATORS OF NEURAL-TUBE CLOSURE IN MICE

Genetic approaches in model organisms are powerful tools for elucidating the biological bases of NTDs and NT development. The mouse provides an excellent model for studies of mammalian neurulation, as the technology of genetic manipulation is very advanced, allowing for a specific gene to be altered and studied with respect to its effect on the organism (Sedivy and Joyner, 1992).

Targeted mutagenesis approaches in the mouse have dramatically assisted efforts to understand better the processes underlying human disease. A great number of mouse models of human conditions are used in research to provide insight into the mechanisms of disease and to explore novel treatments for these conditions.

Phenotype-driven approaches (also referred to as forward genetic screens) start from animals that have been selected for a phenotype of interest and then move to identifying the gene that has been mutated. Many of the forward genetic screens utilize mutagenic agents, ENU being the agent most widely used, that create point mutations and hence can result not only in the inactivation of genes, but also in the generation of novel alleles (i.e., neomorphic, hypomorphic, and alteration of a conserved protein domain). These novel alleles may better represent a disease phenotype than a complete loss-of-function allele.

Over the past decade, forward genetic screens in mice from a number of laboratories worldwide have provided a new resource for the study of multiple biological systems, including neural-tube closure (Nishimura et al., 2003; Zohn et al., 2005). Additional studies to determine the molecular and cellular processes regulated by these key developmental genes have promoted new levels of understanding of the mechanisms that underlie embryonic development. In terms of neural-tube development, forward genetic approaches in the mouse have revealed a number of novel genes that oftentimes had not been functionally analyzed in any system, thus highlighting the effectiveness of phenotype-based screens in elucidating novel aspects of NT development.

27.4 MOLECULAR BASIS OF NTDs

The following sections will describe the molecular mechanisms that control normal neurulation and how these can be disturbed and subsequently lead to NTDs, with the focus on mice and humans.

Following neural induction, the early neural plate is initially specified to give rise to rostral brain tissues (i.e., the forebrain). Posterior character is then imparted to the neural tissue such that it acquires more caudal fates (midbrain, hindbrain, and spinal cord). Further rostrocaudal patterning of the neural plate then begins to take place, as well as patterning in the dorsoventral axis. As the process of neural induction, patterning, and formation of the neural tube is covered in detail in Rubenstein and Rakic, 2013. We will focus here on how disruptions of genes that regulate these processes lead to NTDs both in mice and humans.

27.4.1 Genes Controlling Convergent Extension/ PCP Pathway and NTDs

After neural induction, the neural plate narrows and elongates along the embryo's medial–lateral and AP axes, respectively. This shaping of the neural plate is achieved mainly via the morphogenetic process called convergent extension: a medially directed movement and intercalation of the neural-plate cells toward the midline resulting in the lengthening and narrowing of the neural plate (Figure 27.3(a) and 27.3(b)).

It is well established that the planar cell polarity (PCP) pathway controls convergent extension of both neural and mesodermal tissues in vertebrates (reviewed in Wallingford et al., 2002). Vertebrate cognates of the PCP cascade are required for neural-tube closure in frog, zebrafish, and mouse embryos. In the mouse embryo, mutations in five different genes of the PCP pathway lead to the most severe form of NTD, in which the NT remains open throughout its length and mimics the human condition known as craniorachischisis. These embryos have an abnormally wide neural plate, and the two folds are physically too far apart to be joined to each other, due to defects in convergent extension.

The *loop tail* (*Lp*) mouse is the oldest mouse model of craniorachischisis, first described in 1949 by Strong and Hollander. Heterozygous *Lp* mice are viable with a characteristic looped tail, whereas homozygotes exhibit craniorachischisis (Strong and Hollander, 1949). The neural folds of *Lp* homozygous embryos at 8.5 days after fertilization (E8.5) are elevated, but the MHP is absent and the midline region assumes a U shape, in contrast to the normal "V" shape. The gene mutated in *Lp* is homologous to *Drosophila strabismus* and is called *Vangl2* (also *Lpp1* or *Lptap*) (Murdoch
FIGURE 27.3 Convergent extension and apical constriction. (a) Convergent extension cell movements result in tissue elongation via intercalation of adjacent cells (depicted by *dark* and *light squares*) in an epithelial sheet to form a narrower, longer strip of tissue. (b) Convergent extension facilitates the narrowing of the neural plate and brings the neural folds in closer proximity. (c) Apical constriction. Contraction on the apical side of neural cells leads to formation of hinge points and bending of the neural tube.

et al., 2001a). *Vangl2* encodes a transmembrane protein with a C-terminal PDZ-binding motif and is expressed broadly in the early neuroectoderm (Jessen and Solnica-Krezel, 2004). Mice null for *Vangl1*, another Vangl family member in mammals, show subtle alterations in the polarity of inner-hair cells of the cochlea (another manifestation of a PCP defect), but trans-heterozygotes for *Vangl1* and *Vangl2* exhibit craniorachischisis, similar to *Vangl2* null mice (Torban et al., 2008). Genetic interactions have been also observed between *Lp* and *circletail* (*Crc*) mice (Murdoch et al., 2001b). Mice heterozygous for both *Lp* and *Crc*, though not allelic, display the same phenotype of craniorachichis that each of these mice displays when homozygous for each individual gene. The *Crc* mouse harbors a stop mutation in the cell polarity gene *Scribble*, which is the mouse orthologue of *Scribble* in flies (Murdoch et al., 2003). *Lp* also genetically interacts with a regulator of the PCP pathway, PTK7. PTK7 is highly conserved among species and encodes a transmembrane tyrosine kinase protein that, when mutated, leads to NTD and defects in stereociliary bundle orientation in mice (Lu et al., 2004). Two other mouse mutant lines, *Crash* and *Spin cycle*, display NTD and inner-ear defects that result from disruption of the PCP gene *Celsr1*, a large protocadherin seven-pass transmembrane molecule, orthologous to *Flamingo*, a *Drosophila* gene also known as *Starry night* (Curtin et al., 2003). Finally, double mutants of mouse *Disheveled1* and *Disheveled2* (*Dsh1* and *Dsh2*) exhibit NTDs very similar to the craniorachischisis observed in other PCP mutants. *Dsh1* and *Dsh2* share 65% sequence identity, and the fact that *Dsh1* null mice have a far less severe phenotype (Hamblet et al., 2002) than the double mutant indicates functional redundancy between the two proteins.

Recent studies indicate another role for the PCP proteins in cilia biogenesis. In *Xenopus*, loss of function of *Fuzzy* or *Inturned*, two orthologues of fly PCP effector proteins, results in NTD and failure of ciliogenesis due to incorrect microtubule orientation (Park et al., 2006). Disruption of *Fuz* in mice also causes NTDs, apparently due to disrupted ciliogenesis that in turn leads to defective Shh signaling (Gray et al., 2009). Furthermore, *inturned* in mammals is an important regulator of cilia formation, NT closure, and embryonic development, and *inturned* mutations affect Shh signaling (Zeng et al., 2010). A connection between ciliary function and NT closure has also been identified in humans. Meckel syndrome, the most frequently identified syndromic NTD, is associated with disruption of *MKS1* and *MKS3* (Kyttala et al., 2006; Smith et al., 2006). Mks1 is required for ciliogenesis and Hedgehog signaling in mice (Weatherbee et al., 2009). Genes involved in Bardet–Biedl syndrome (BBS), a human ciliary defect, have been disrupted in mice, leading to phenotypes shared with PCP mutants, including NTDs (exencephaly), open

eyelids, and disrupted cochlear stereociliary bundles. BBS genes interact with *Vangl2* in mice and zebrafish and Vangl2, like BBS proteins, is localized to the basal body and axoneme of the cilia (Ross et al., 2005). Within the PCP pathway genes, the coding region and splice sites of *Vangl1* and 2 have been analyzed in a population of 66 human patients with NTDs, and only one variant in *Vangl1* was identified, which is predicted to result in a nonsynonymous change that is unlikely to have functional significance (Doudney et al., 2005). More recently, however, three patients with NTD were found to be heterozygotes for mutated VANGL1 alleles and five novel mutations in VANGL1 have also been found in patients with NTDs (Kibar et al., 2007, 2009). Moreover in a 2010 study, three novel missense mutations in VANGL2 were found in three different human fetuses with severe NTDs (Lei et al., 2010). Recent studies took advantage of this PCP pathway-specific knowledge generated from animal models to interrogate a larger set of PCP genes for mutations in samples from patients with craniorachischisis. This identified eight potentially causative mutations in CELSR1 and SCRIB. Overall, these studies make a strong case for a connection between PCP genes and NTDs.

27.4.2 Neural-Tube Patterning

Patterning of the neural tube along the AP and dorsal–ventral (DV) axes relies on tightly regulated molecular cascades. The patterning centers of the early embryo as well as their mechanisms of actions are described in Rubenstein and Rakic, 2013. Here, we will describe how disruption of patterning-related genes alters NT development and leads to NTDs in humans and mice.

27.4.2.1 Anterior–posterior Patterning Genes and NTDs

The major players of AP patterning include graded signals from fibroblast growth factors (FGFs), Wnt, and retinoic acid (RA). FGFs are key players in caudal transformation of anterior neural tissue to a more posterior fate (Kudoh et al., 2004; Rentzsch et al., 2004). FGFs are expressed in the regressing primitive streak, which continues to promote the progressive caudal patterning of the neural tissue (Dasen et al., 2003; Liu et al., 2001).

Along with FGFs, a number of other molecules, such as Wnts, Nodal, and RA, are present in the posterior of the embryo, and they refine the AP fate of the neural tissue (reviewed in Gamse and Sive, 2000). RA signaling acts to promote the neural character of the hindbrain and the anterior spinal cord (Bel-Vialar et al., 2002; Liu et al., 2001). RA and FGF act in opposition to each other to impart AP fates along the spinal cord. Studies in *Xenopus* embryos indicate a requirement for RA

signaling for expression of posterior markers (Hoxb9, N-tubulin, and Xlim1) and for establishment of posterior fate (Blumberg et al., 1996), and overexpression of Cyp26, an enzyme that mediates the degradation of RA, causes anterior structures to develop where normally there should be posterior structures (de Roos et al., 1999; Hollemann et al., 1998). The mammalian homologue, Cyp26A1, when ablated in mice, causes embryonic lethality, spina bifida, and truncation of the tail and lumbrosacral region. A higher risk for NTDs in humans has been associated with polymorphisms in RALDH2, an enzyme in the biosynthetic pathway of RA. Other enzymes which function in RA synthesis or metabolism, such as ALDH1, CYP26A1, CYP26B1, and CYP26C1, as well as cellular RA-binding proteins, such as CRABP1 and CRABP2, have been examined as potential NTD risk factors, but none of these genes has so far shown significant correlation with NTD risk in humans (Deak et al., 2005b).

Graded activity of Wnt signaling is also required for proper positioning of the midbrain–hindbrain border. The mechanism by which Wnt leads to posteriorization of the neural tissue is indirect and requires FGF signaling (Domingos et al., 2001). Mutations in components of the Wnt pathway can lead to NTDs. For example, a missense mutation of a highly conserved amino acid in the low-density, lipoprotein-receptor-related protein 6 (Lrp6), a co-receptor required for Wnt canonical signaling, causes exencephaly in homozygous mutant mice. Mice heterozygous for this mutation display the characteristic phenotype of a crooked tail (Carter et al., 2005).

27.4.2.2 Dorsal–ventral Patterning Genes and NTDs

Dorsoventral patterning largely utilizes a common mechanism throughout the length of the embryonic body. Four different classes of secreted factors influence DV patterning: Shh, bone morphogenetic proteins (BMPs), FGFs, and RA.

Correct patterning of the ventral half of the NT largely relies on the activity of Shh, whereas the dorsal half requires the inductive activities of the transforming growth factor-beta superfamily, which includes the BMPs, expressed in the overlying ectoderm and the roof plate. The roof plate is the dorsal equivalent of the floor plate, and it expresses BMP4, 5, and 7, which in turn induce dorsal genes, such as the transcription factors Pax3 and Msx (Liem et al., 1995, 1997). BMPs also act to set the borders of expression of bHLH (*Math*, *Mash*, and *Ngn*) and LIM (*Lbx* and *Lmx*) transcription factors (Helms and Johnson, 2003).

Tissues from humans with SBA have been evaluated for mutations in Bmp4 or the BMP inhibitor Noggin. Four heterozygous missense mutations in Bmp4 inherited from unaffected heterozygous parents in four different patients have been identified (Felder et al., 2002). Three out of the four missense mutations in Bmp4 (S91C, T225A, and R226W) are in the protein region responsible for dimerization, and the sequence alterations in this region have been proposed to influence the stability of the mature protein. The fourth missense mutation (S367T) was found within the C-terminal region that is physiologically important and hence might disrupt the function of the mature BMP4 protein. Moreover, one missense mutation (G92E) was found in Noggin, which replaces a highly conserved glycine in a region essential for proper structure and function of the Noggin protein. The sequence variants in these SBA patients may cause changes in protein stability and/or activity and therefore contribute to the failure of NT development (Felder et al., 2002).

Shh signaling, from the notochord and floor plate, acts on the surrounding neural cells to regulate the expression of transcription factors that control the formation of ventral cell types, such as motor neurons and ventral interneurons. As described above, genes involved in ciliogenesis are also needed for Hedgehog signaling and disruptions in this process are associated with NTD in mice and humans.

The Pax family of patterning molecules has been extensively studied for association with NTD. Many Pax genes are tightly regulated in both space and time during NT development (Stoykova and Gruss, 1994), and BMPs act in conjunction with Shh to set the correct expression boundaries of Pax genes. Mutations of *Pax3* in mice cause the *splotch* (*sp*) phenotype, which includes NTD (exencephaly and spina bifida) and dysgenesis of spinal ganglia, limb, and heart structures (reviewed in Gruss and Walther, 1992). *Pax3* mutations are associated with the Waardenburg syndrome in humans (pigmentation, limb, and enteric nervous-system defects and deafness) (Baldwin et al., 1994; Tassabehji et al., 1993). Attempts have been made to associate NTD in humans with mutations in *PAX 1*, *3*, *7*, or *9*. In two studies of 79 and 38 familial cases of NTDs, one mutation in the paired domain of *Pax1* was found in a patient with spina bifida (Hol et al., 1996); however, no further Pax mutations have been detected. Thus, the data to date do not show a strong association between Pax gene mutations and human NTDs.

27.4.2.3 Bending of the Neural Plate and NTDs

Another crucial step during NT formation is the bending of the neural plate in order to elevate and bring the two folds into close proximity along the midline. The MHP and two DLHPs are differentially used at different axial levels. Moreover, their formation is differentially controlled at a molecular level. For example, lack of *Zic2* function in mice causes loss of DLHP, although the MHP forms properly (Ybot-Gonzalez et al., 2007), and this results in extensive spina bifida (Elms et al.,

2003; Nagai et al., 2000). In mouse, the posterior neuropore completes NT formation, although it lacks a MHP; thus, the presence of the DLHP is sufficient for closure. The MHP may be dispensable for spinal neural-tube closure, as mice that lack Shh, HNF3β, Gli2, or Gli1 and Gli2 do not develop spinal NTD, despite failure to form the MHP, although less-acute bending still occurs by an unknown mechanism (Ang and Rossant, 1994; Chiang et al., 1996; Ding et al., 1998; Matise et al., 1998; Park et al., 2000; Weinstein et al., 1994).

The Shh pathway is critical in the bending of the neural plate. High Shh levels suppress DLHP formation (Ybot-Gonzalez et al., 2002), and low Shh levels induce their formation (Echelard et al., 1993), thus helping to set the position of DLHP formation. Loss of Patched, the Shh receptor that keeps the Shh pathway in an "off" state when a ligand is absent, causes both cranial and spinal NTDs in mice (Goodrich et al., 1997). One aspect of the phenotype could be that loss of Ptch constitutively actives the pathway and, like Shh overexpression, prevents DLHP formation. Loss of PKA, a protein kinase that downregulates Shh signaling, leads to spinal NTD (Huang et al., 2002). Mutation of Rab23, another negative regulator of the Shh pathway, disrupts DLHP formation and neural patterning leading to cranial NTD (Gunther et al., 1994).

The cellular basis for NT bending is apical constriction. The neuroepithelium, a pseudostratified epithelium of a single-layer thickness, begins to change its shape from columnar to wedge, first in the medial region and then at dorsolateral positions, where the hinge points will form (Figures 27.2(b), 27.2(c), and 27.3(c)). Our understanding of the cellular basis of this highly regulated constriction is limited. Two molecules, Shroom3 and p190RhoGAP, regulate apical constriction in the NT. Shroom3 belongs in the Shroom family but to date only Shroom3 has been associated with NTDs in mice. Shroom3 controls apical constriction via binding of filamentous actin. Mice null for *Shroom3* display exencephaly and loss of actin that would normally be localized on the apical-cell surface (Hildebrand and Soriano, 1999). P190RhoGAP is a negative regulator of Rho GTPase, which regulates actin microfilaments. Mice lacking p190RhoGAP have a number of defects, including NTD, and an excessive accumulation of polymerized actin in cells of the neural plate (Brouns et al., 2000). In addition to apical constriction, basal expansion, a process that is potentially also relying on cytoskeletal rearrangements, has been thought to assist NT bending (Smith and Schoenwolf, 1987); however, no mutants that disrupt this process have been identified.

Like *Shroom3*, other genes that regulate actin rearrangement at the cell surface are associated with NTDs. For example, cranial NTDs result from the disruption of protein kinase C, which targets a number of cytoskeletal regulators including the actin-binding protein vinculin, the cytoskeleton-related genes *mena* (*Enah*)/*profilin1* (*pfn1*), and *Macs* and *Mlp* (Koleske et al., 1998; Lanier et al., 1999; Stumpo et al., 1995; Xu et al., 1998). These data support the involvement of actin in NT formation. However, both older (Schoenwolf et al., 1988) and more recent (Ybot-Gonzalez and Copp, 1999) studies indicate that the MHP and DLHP are not affected by cytochalasin treatment, which blocks actin polymerization and elongation. This suggests that actin microfilaments may act to stabilize the hinge points after their formation, rather than to drive their formation.

Some of the genes involved in apical constriction and bending of the neural plate have been examined in human NTDs. In the Shh pathway, GLI3 mutations cause two different syndromes, the Greig cephalopolydactyly syndrome and the Pallister–Hall syndrome (Johnston et al., 2005, Radhakrishna et al., 1997), but neither syndrome presents with NTD. The lack of NTD is perhaps not surprising, given that the *Gli3* mutant mouse (*extratoes*) shows cranial NTDs with low penetrance and only in homozygous mutant embryos, and this also results in perinatal lethality (Winter and Huson, 1988). Mutations in *Shh* (Nanni et al., 1999) and in its receptor, *patched-1*, are associated with holoprosencephaly (Ming et al., 2002), a structural forebrain anomaly found with high frequency in humans. In studies conducted on human embryos with craniorachischisis, abnormal *Shh* expression was found (Kirillova et al., 2000), similar to altered expression of *Shh* in *Lp* mice (Murdoch et al., 2001a). However, the primary event leading to abnormal *Shh* expression was not identified. Variations in the *Shh* gene have not been correlated with other human NTDs, although these studies have largely been limited to the N-terminus part of the Shh protein, but not the C-terminus, which contains the autocatalytic cleavage site (Zhu et al., 2003). Variations in genes such as *PKA*, *Zic1*, *2*, *3* also failed to show correlation with human NTDs. In terms of apical constriction, only *MLP* and *MACS* have been examined as potential candidates for NTDs, but no correlation was found at least in 43 Caucasian simplex families in which the affected child had a lumbrosacral myelomeningocele (Stumpo et al., 1998).

27.4.2.4 NTDs due to Disruption of Neural-fold Fusion

The last step of NT closure, the joining of the two folds along the midline, also called fusion, is the least studied and least understood. It has been hypothesized that adhesion molecules facilitate neural-fold joining. However, whether such molecules play a direct role in fusion is unknown, although as outlined below, a few adhesion molecules are required for NT closure. In addition, it has been suggested that components of the extracellular matrix (ECM) might play a role in fusion (Moran and

Rice, 1975; Sadler, 1978), although it is unclear which ECM components may be involved.

Defects in a few adhesion molecules have been linked to NTDs. For example, in mice, inactivation of the ephrin receptor subfamily members *Eph-A5* or *Eph-A7* causes NTDs (Holmberg et al., 2000). Both ephrin receptors are expressed in the cranial, but not spinal, neuroepithelium. Ephrin signaling is thought to act through components of the PCP pathway. According to Lee et al. (2006), ephrinB1, a cell-surface-ephrin ligand, controls migration of cells during frog development by acting through PCP-pathway components and clustering of Dishevelled proteins. Two members of the cadherin family of adhesion molecules, N-cadherin and E-cadherin, have complementary expression patterns during neurulation, with N-cadherin expressed in the neural plate and E-cadherin expressed in the non-neural ectoderm (Detrick et al., 1990). Mice null for *N-cadherin* (*Cdh2*) undergo normal neurulation, showing that N-cadherin is not essential for NT formation (Radice et al., 1997). A role for E-cadherin has been more difficult to discern, as loss of E-cadherin results in embryonic lethality prior to neurulation. However, two pieces of evidence support a role for E-cadherin in NT closure. First, the culture of rat embryos with an antisense oligonucleotide against E-cadherin leads to cranial NT malformations (Chen and Hales, 1995). Secondly, when E-cadherin is downregulated in the non-neural ectoderm as occurs in Grhl2 mutants, the neural folds, face, and body wall fail to fuse (Pyrgaki et al., 2010a; Werth et al., 2010). NCAM1 is another adhesion molecule expressed in the neuroectoderm. Although *NCAM1* null mice do not display NTD (Cremer et al., 1994), NCAM1 has been studied in 132 families with spina bifida, and variations in this molecule may contribute to NTD risk (Deak et al., 2005a). Finally, NTD is observed in mouse embryos lacking protease activator receptor 1 and 2 (PAR1 and PAR2), which are expressed in the non-neural ectoderm during NT formation (Camerer et al., 2010). Thus, both cellular and molecular evidence support the idea that the non-neural ectoderm is involved in initiating and perhaps driving neural-fold fusion.

27.4.2.5 NTD due to Disruption of Apoptosis

During NT development, as during embryonic development in general, apoptosis and cell proliferation must be tightly regulated for development to proceed normally. Apoptosis or programmed cell death occurs in the neuroepithelium during neurulation. This was first documented by ultrastructural studies (Geelen and Langman, 1979; Schluter, 1973) and subsequently shown to be apoptotic cell death (Lawson et al., 1999). Either an increased or decreased rate of apoptosis has been associated with NTDs in mice. For example, NTDs in embryos lacking *ApoB* (Homanics et al., 1995), *Bcl10* (Ruland et al., 2001) or *Mdm4* are associated with increased apoptosis. In these cases, the phenotype is attributed to insufficient numbers of cells participating in neurulation.

Conversely, mutations in genes such as *Trp-53* (Sah et al., 1995), *Casp3* (Kuida et al., 1998), and *Apaf1* (Cecconi et al., 1998) lead to NTDs associated with reduced levels of apoptosis. In these cases, excessive numbers of cells that would otherwise be reduced by apoptosis are thought to prevent the normal morphogenesis of the neural plate. Despite the dramatic phenotypes caused by misregulation of apoptosis, experimental studies to block apoptosis with pharmacological agents during mouse neurulation indicates that apoptosis facilitates NT closure but is not necessary for its completion (Massa et al., 2009; Yamaguchi et al., 2011). To date, there have been no studies that attempt to correlate the risk for human NTDs with molecules of the apoptotic pathway.

27.4.2.6 NTD due to Disruption of Proliferation

Proliferation must be tightly controlled, as either increased or decreased rates of proliferation can lead to NTDs. During cranial neural closure, proliferation is differentially regulated along the dorsoventral axis of the NT, with the dorsal half displaying more proliferation than the ventral half (Copp et al., 2003). As proliferation and differentiation are inversely correlated, this difference is reflected by a greater number of differentiated cells in the ventral NT at this early stage of neurulation.

Changes in expression of genes that control proliferation often lead to abnormal NT development. For example, overexpression of *Notch3* results in exencephaly, and these mice have increased numbers of neuronal progenitors (Lardelli et al., 1996). Tumor-suppressor genes, when mutated in mice, can cause abnormal neural-cell proliferation and lead to exencephaly. Examples include loss of function of *p53* (Sah et al., 1995) and a hypomorphic mutation in *Brca1* (Gowen et al., 1996). A study of an Irish population showed that two noncoding variants of *p53* are associated with NTD risk and two different variants with maternal risk (Pangilinan et al., 2008). In addition, variations in *Brca1* in a family-based association study correlate with spina bifida, although this may not be causative (King et al., 2007). Mutations in *Tsc2*, another tumor-suppressor gene, cause exencephaly and embryonic lethality in mice (Kobayashi et al., 1999). Mice with heterozygous mutations for genes of the chromatin-remodeling complex, such as *Brg1* and *Srg1*, are predisposed to exencephaly, and they often get tumors of the nervous system (Kim et al., 2001). Hyperproliferation also causes exencephaly in the mouse *Phactr4*^{humdy} mutant, which indirectly regulates the

tumor-suppressor protein Rb (Kim et al., 2007). Hyperproliferation of the neuroepithelium before and during closure creates excess tissue, which inhibits bending of the NT and/or prevents the two folds from reaching each other. Reduced proliferation, on the other hand, leads to a number of cells inadequate to complete NT closure. Loss of mLin41 causes cranial NTD due to reduced proliferation and premature differentiation of the neuroectoderm, thus acting as a temporal regulator of neural progenitor maintenance (Chen et al., 2012).

Changes in cell number in tissues that surround the neuroepithelium can indirectly have a deleterious effect on NT formation. One example is reduced proliferation in the hindgut of *curly tail* mice, which likely carry a mutation in *Grhl3* (reviewed in Brouns et al., 2005). This hypoproliferation causes growth imbalance between the ventral and dorsal tissue, which in turn leads to excessive curvature within the caudal region and the failure of the posterior neuropore to close (Gustavsson et al., 2007; van Straaten and Copp, 2001). To date, the connection between the disruption of *Grhl3* and the proliferation defect remains elusive. Another example is the *open mind* mutation, which disrupts Hectd1 ubiquitin ligase, and results in inappropriate numbers of head-mesoderm cells and exencephaly (Zohn et al., 2007). Finally, *Twist1* mutant mice display exencephaly and severe craniofacial defects (Soo et al., 2002). *Twist1* is expressed in the head mesenchyme, where it regulates both proliferation (Ota et al., 2004) and apoptosis (Hjiantoniou et al., 2003), as well as neural-crest delamination and migration (Vincentz et al., 2008). The Saethre–Chotzen syndrome (SCS) in humans is due to TWIST1 mutations (Elanko et al., 2001; Kress et al., 2006). The SCS phenotype includes craniofacial defects but not NTD, although these phenotypes are thought to be due to haploinsufficiency rather than complete loss of TWIST1 function (el Ghouzzi et al., 1997).

27.5 FUTURE DIRECTIONS

In mice, there are currently >200 genes that are known to be required for neural-tube closure. However, surprisingly few of these models have been used to go beyond the question of the function of an individual gene. An interesting next level of exploration will be to determine the interplay between these genes. NTD in humans is largely thought to be a multigenic disease in which small changes in multiple genes may combine to lead to NTDs. Although the analysis of model organisms with homozygous mutations or severe loss-of-function phenotypes has been extremely useful, these models do not adequately reflect the complex genetics of human NTD. Therefore, it will be of interest to probe the phenotypic interplay between different gene mutations further, including that between genes that do not obviously fit within a particular pathway or cellular process.

The genetic complexity of human NTD leads to a cautionary note with respect to genetic counseling. Based on the already large number of gene candidates identified from animal NTD models and the fact that a significant portion of the genome is still not functionally analyzed, there will likely be on the order of 500–1000 genes required for NT closure and which, when mutated, can lead to NTD. This highlights the difficulty in trying to identify causative single-gene mutations in human NTD. Moreover, it becomes a daunting task to conceive of a comprehensive genetic screen. Ultimately, advances in personalized medicine and whole-genome analysis will open this field of research to a more comprehensive overview. Studies are underway to determine whether genome copy-number variations are associated with NTD, but these data are currently lacking. The potential to identify a large number of polymorphisms leads to the next question, namely, how to determine whether a polymorphism identified from association studies in humans may create a meaningful change in gene expression or protein function. This question can now be quite readily addressed by techniques that allow sophisticated manipulation of the mouse genome such that specific polymorphisms can be created and tested *in vivo* for changes in phenotype and/or protein function.

Another area ripe for exploration lies in determining the interplay between mouse NTD models and known environmental factors. For example, would NTD risk increase in mice heterozygous for a mutation in a gene required for NT closure when gestation occurs in a mother that is a model for diabetes or obesity? If so, this would greatly aid research in determining the molecular basis of NTD risk defined by epidemiological studies.

Epidemiological research lies at the heart of one of the most profoundly influential studies that has changed our approach to NTD risk. Epidemiological studies have clearly shown a decreased incidence of NTD as diets across the world have improved, and this positive response has been strongly correlated with a higher level of folic acid in the diet. Although the preventative effect of folic acid on NTD incidence has been recognized since the 1980s, surprisingly little basic research has been done to understand the mechanistic basis for this effect. To date, only 18 mouse NTD models have been tested for their responsiveness to folic acid. Of these, FA supplementation reduced the incidence of NTDs in six cases, was not beneficial in nine cases, and, contrary to expectations, exacerbated NTDs in three cases (Gray et al., 2010; Harris 2009; Marean et al., 2011). Testing of many more of these mouse models will provide critical information for understanding the molecular logic that may underlie responsiveness to folic-acid

supplementation. For example, are there particular pathways or cellular processes that are associated with responsiveness to folic-acid supplementation? Is the response allele-specific, or can a null allele be rescued, the latter perhaps suggesting that folic acid may bypass the defect? Folic acid provides the building blocks for many cellular reactions, including cell proliferation, gene expression, and genome stability, through its effects on nucleotide biosynthesis and as a methyl donor. Mouse NTD models can be used to tease out the complex function of folic acid, for instance, by targeting one arm of the biosynthetic pathway (i.e., supplementation with purines or biasing the diet toward methyl donors) in order to determine the mechanisms of folic-acid responsiveness better. Furthermore, there is a need to reconsider the treatment traditionally done in the mouse studies, which consists of short-term (days) exposure to folic-acid supplementation. This is not reflective of the trend in long-term folic-acid exposure in the U.S. population, as mandatory FA fortification began in 1998 and periconceptual use has been strongly recommended since the early 1990s. Indeed, recent long-term and multigenerational studies in mice indicate that the incidence of NTD for a given genetic allele can differ between short- and long-term folic acid diets and that the epigenetic profile can vary widely in wild-type mice fed a methyl diet for six generations (Li et al., 2011; Marean et al., 2011). These unexpected findings highlight the need to understand how FA influences NT closure and the mechanisms and genetics underlying the response to FA. Finally, in both mice and humans, there are a relatively large proportion of folate-resistant NTDs. One goal will be to utilize the knowledge gained from understanding the normal function of the mutated gene and its downstream pathways to determine whether other periconceptual therapies can be designed based on this insight. The types of studies outlined above will be critical to a better understanding of the complex genetic interplay that likely represents non-syndromic NTD in humans, as well as the intriguing but poorly understood intersection between genes and environmental influences in the highly complicated process of neural-tube closure.

Fetal Alcohol Spectrum Disorder
Targeted Effects of Ethanol on Cell Proliferation and Survival

28.1 INTRODUCTION

Developmental disorders arise from genetic and environmental causes. Often, either the genetic or environmental factor takes precedence and defines the disorder, for example, as in Huntington's chorea or mercury poisoning, respectively. In other situations, the effects of the two contributors are not mutually exclusive. In fact, the effect of a genetic or environmental alteration alone may be masked, and a disorder may result only when a genetically susceptible organism is exposed to an environmental factor. One such developmental disorder is fetal alcohol spectrum disorder (FASD).

Besides genetic and environmental contributions, another major factor defining developmental disorders such as FASD is fetal programming. On the basis of this concept, nutrition or exposure to a substance during fetal development can cause alterations over the lifespan. These consequences often can be quiescent for years and then have powerful effects that shape the behavior of adolescent or adult humans; for example, fetal exposure to substances can shape lifelong mental health status (Salisbury et al., 2009; Schlotz and Phillips, 2009). Taken more broadly, fetal programming can be part of a cycle that promotes the continued pathological situation. In the case of alcohol use, this has been referred to as the "alcoholism generator" (Miller and Spear, 2006). Accordingly, fetal exposure increases the likelihood of alcohol use in adolescents and reduces the age of initiation of alcohol consumption. These behaviors contribute to an increased incidence of alcoholism/alcohol abuse in adults, which in turn begets children who are exposed to alcohol *in utero*.

28.2 CLINICAL CONSEQUENCES OF ALCOHOL EXPOSURE

The effects of ethanol on a fetus are extensive, devastating, often permanent, and when clustered, are referred to as FASD. Depending upon the population, 2% or more of all neonates have FASD (Centers for Disease Control and Prevention, 2009). Defects can include a stereotypical set of craniofacial malformations such as narrow palpebral fissures, a deficient philtrum, and a flattened nasal bridge (Jones et al., 1973; Lemoine et al., 1968). Based on rodent studies, these features occur when the exposure is restricted to or includes the period of gastrulation (Sulik, 2005; Sulik et al., 1981).

Prenatal alcohol exposure has profound effects on the nervous system in humans, including learning/memory deficits and hyperactivity (Coles, 2006; Fryer et al., 2006). In fact, prenatal alcohol exposure is the leading known cause of mental retardation (Abel and Sokol, 1992; Stratton et al., 1996). Careful examination of the brains of children with FASD shows profound changes. Postmortem and imaging studies show that their brains are smaller, can be covered with sheets of neuroglial heterotopias, and exhibit abnormal gyral patterns and dysmorphic corpora callosa (e.g., Bookstein et al., 2002; Clarren et al., 1978; Jellinger et al., 1981; Pfeiffer et al., 1979; Riley et al., 1995; Swayze et al., 1997; Wisniewski et al., 1983). Quantitative magnetic resonance imaging studies show that ethanol induces microencephaly, as evidenced by the reduced size of specific nuclei, for example, the basal ganglia (Mattson et al., 1996) and cerebellum (Sowell et al., 1996).

28.3 ANIMAL MODELS OF ETHANOL INTAKE

When interpreting the data on fetal ethanol effects, it is important to appreciate the various animal models of FASD because each has strengths and weaknesses, as discussed in a number of excellent reviews (e.g., Cudd, 2005; Kelly et al., 2009; Schneider et al., 2011). For the purposes of this review, it is important to consider three features of a chosen model when determining its utility and appropriateness: the timing, duration, and amount of ethanol exposure. That is, the method of choice is based on the focus of the study and on determining the variables that require controls.

The timing and duration of ethanol exposure are critical because neural development is a constantly changing and asynchronous process among the multitude of brain components. Grossly, the brain increases in size steadily during gestation and then transiently exhibits a relative burst during what is described as the brain growth spurt (Dobbing and Sands, 1979). In primates, this spurt occurs during the third trimester of gestation, and in rodents, it occurs during the first 2 postnatal weeks. Much of this growth results from the early morphogenesis of neuronal processes and the production of glia. Another major event that contributes to early brain growth and can shape the response to ethanol neurotoxicity is the timing and duration of neuronal production. Neurons in most components of the rodent brain are generated prenatally, but in some brain regions (e.g., the hippocampus, thalamus, and cerebellum), some neurons are produced postnatally (e.g., Altman and Bayer, 1990; Altman and Das, 1965, 1966; Mooney and Miller, 2007a; Rao and Jacobson, 2005). The complexity of the effect of ethanol on select brain structures results from the incidence and different length periods of this neuronogenesis. These periods may be discrete or may overlap; thus, individual or multiple brain structures may be vulnerable to ethanol at a particular time during gestation.

The amount of exposure, that is, the dose of ethanol, is also a critical variable (Bonthius and West, 1988a,b, 1990). Dose can be defined by the peak exposure and the time over which this exposure is maintained. For example, the size of the cerebellum and the density of Purkinje neurons are adversely affected by ethanol when ethanol is administered in a larger bolus over a short period of time than when it is delivered more slowly over a more protracted period, even if the total amount of ethanol exposure is equalized.

Prenatal administration of ethanol has generally relied on one of three methods: (1) pair-feeding of a liquid diet, (2) intragastric gavage of the dam, and (3) delivery via intraperitoneal injection of the dam. Integral to these models is the use of controls that account for caloric and nutritional intake and for stress. (1) In the pair-feeding approach, animals in the ethanol-exposed group are given an ethanol-containing liquid diet at the same time each day, and the same volume as an isocaloric, non-ethanol-containing diet is given to the pair-fed control animal. The pair-feeding model is the most biologically relevant to the human situation; however, it leads to variability in blood ethanol concentrations over the diurnal cycle (Miller, 1992). Often, changes in pair-fed controls have been compared with animals fed chow and water *ad libitum*, but this diet differs from the liquid ethanol-containing and control diets. Therefore, it is advisable to provide the controls fed *ad libitum* free access to the liquid control diets (Eade et al., 2010; Youngentob et al., 2007). (2) In the gavage model, an ethanol-containing liquid is delivered to pregnant dams directly into their stomachs (Kelly and Lawrence, 2008). This can lead to stress, the effects of which can be minimized by frequent and equivalent handling of all the subjects. (3) In the injection model (usually used with mice), pregnant dams are administered a diluted

solution of ethanol or an equivalent volume of saline. This can produce quick increases in peak ethanol exposure; however, it also has the complication of stress. The latter two models should include careful monitoring of nutritional intake.

Administration of ethanol in the early postnatal period is a bit more complicated. Using one approach, referred to as the pup-in-a-cup method (Diaz and Samson, 1980; West et al., 1981), each 4-day-old rat pup has a permanent gavage tube implanted directly into its stomach and an ethanol-containing solution of artificial milk or a non-ethanol control solution is delivered directly. The liquid is usually provided every 2 h, but this schedule can be manipulated. This method allows for careful delivery and monitoring of the ethanol, but the pups are stressed and do not have maternal interactions. Comparisons to suckling control pups can partially obviate these confounding variables. An alternative method is to provide the ethanol or control solution via intragastric gavage (Kelly and Lawrence, 2008). Following gavage, the pups are returned to their dam. This method minimizes the stress inherent in the pup-in-a-cup method, but it does have some inherent stress that can affect maternal–pup interactions, and it is labor intensive.

28.4 CELL NUMBERS

Research on the effects of ethanol on the rodent brain, specifically the cerebral cortex, is more advanced than similar research on humans (Miller, 2006a). The rat cerebral cortex has been extensively studied and is profoundly affected by prenatal ethanol exposure. It is smaller and exhibits multiple abnormalities such as neurons that are in the wrong place (i.e., ectopic neurons), dysmorphic and dysfunctional neurons, and alterations in synaptogenesis and myelinogenesis. These developmental problems lead to permanent alterations. For example, (1) the numbers of neurons in cortex and other structures in the mature brain are reduced (e.g., Bonthius et al., 1992; Marcussen et al., 1994; Miller, 1995a,b, 1999; Miller and Muller, 1989; Miller and Potempa, 1990; Mooney and Miller, 2007a), (2) surviving neurons form aberrant connections (e.g., Al-Rabiai and Miller, 1989; Clamp and Lindsley, 1998; Miller, 1987, 1997; Miller and Al-Rabiai, 1994; Miller et al., 1990; West et al., 1981), and (3) cortical metabolism is reduced (e.g., Miller and Dow-Edwards, 1988, 1993; Vingan et al., 1986). These changes are downstream from primary defects in early development, for example, in neuronal production and survival. This review focuses on these two processes, which are primary determinants of the numbers of neurons in a specific brain structure.

28.4.1 Cell Proliferation

In the rodent, the proliferation of most central nervous system (CNS) neurons occurs prenatally and, in some structures (e.g., the cerebellum, thalamus, and hippocampus), it extends into the first couple of weeks postnatally. In most cases, this proliferation takes place within zones that line or are proximal to the ventricles. The principal exceptions to this pattern are the external granule layer (EGL) of the cerebellum and the subgranular zone (SGZ) of the dentate gyrus, which are seeded by cells lining the fourth and lateral ventricles, respectively (Chizhikov et al., 2006; Rao and Jacobson, 2005). Cell proliferation is defined by the cycling behavior of the cells (i.e., how quickly cells pass through the four phases of the cell cycle) and the numbers of cells that are actively cycling, which is known as the growth fraction.

28.4.1.1 Cell Cycle

28.4.1.1.1 CEREBRAL CORTEX

Ethanol has a profound effect on the cell cycle kinetics and growth fraction for proliferating populations. *Ad libitum* consumption of ethanol by pregnant rat dams during the last 2 weeks of gestation (achieving peak blood ethanol concentrations of $\sim150 \text{ mg dl}^{-1}$) affects cell proliferation in the brains of the developing fetuses. The cycling of cells in the cortical ventricular zone (VZ) is retarded (Kennedy and Elliott, 1985; Miller, 1989; Miller and Nowakowski, 1991). On the other hand, ethanol has no effect on the numbers of cells that are actively cycling. Ethanol has a similar effect on VZ cells in organotypic slices of the dorsal telencephalon (Siegenthaler and Miller, 2005a) and cultures of dissociated neuroblastoma cells (Luo and Miller, 1999a) and neural stem cells (Hicks et al., 2010). In each of these cases, ethanol has a consistent effect of prolonging the length of the cell cycle. This occurs principally through lengthening of the G1 phase of the cell cycle, though other phases, notably S, are also vulnerable.

The changes in the cell cycle kinetics appear to result from activation of specific cell cycle checkpoints. Ethanol induces a strong genomic response, which leads to the down- or upregulation of many transcripts associated with passage through G1 (Hicks et al., 2010). Inhibition of the G1/S checkpoint is a consequence of the silencing of genes that are necessary for the progression of cells through G2 and M. Methylation and another epigenetic event, acetylation, are key mechanisms underlying gene silencing and are targets of ethanol (Haycock, 2009; Hicks et al., 2010; Liu et al., 2009; Moonat et al., 2010; Oberlander et al., 2008; Pandey et al., 2008; Zhou et al., 2011). The occurrence of methylation is environmentally affected by the presence of an ambient growth factor (Hicks et al., 2010). Such findings are consistent with

evidence that ethanol toxicity can be offset by choline supplementation (Thomas et al., 2004, 2010).

The response of VZ cells to ethanol differs from that of cycling cells in non-VZ proliferative populations, for example, the subventricular zone (SZ). The SZ gives rise to cortical neurons largely in the superficial cortex (Miller, 1989; Nieto et al., 2004; Pontious et al., 2008; Tarabykin et al., 2001) and neurons in the olfactory bulb (Lledo et al., 2008; Whitman and Greer, 2009). Exposure to moderate amounts of ethanol *in vivo* (wherein the blood ethanol concentration is ~150 mg dl^{-1}) increases SZ cell proliferation (Miller and Nowakowski, 1991). This results from an increase in the growth fraction and not from a change in the cell cycle kinetics of SZ cells. The net outcome is that there is a latent surge in the generation of cortical neurons, particularly those that are normally destined for the superficial cortex (Miller, 1986, 1988a, 1997). A similar growth-promoting effect is also evident for neural progenitors in the SGZ of the dentate gyrus; however, this effect is dose-dependent, with high doses of ethanol depressing neural production (Miller, 1995a).

28.4.1.1.2 THALAMUS

The ventrobasal (VB) nucleus of the thalamus is a special CNS site; it has two nonoverlapping periods of neuronal generation (Altman and Bayer, 1979, 1989; Mooney and Miller, 2007b). The second (postnatal) period of neuronogenesis uniquely occurs within the brain parenchyma *per se.* This second period is even more intriguing because it occurs concurrent with a number of desynchronous developmental events within the VB. Such events include the elaboration of neurites particularly by the prenatally generated neurons, the formation of synapses, the generation of projections to the cortex, and the innervation of the VB by cortical axons.

Prenatal exposure to ethanol has a latent effect on the proliferating cells in the VB of young pups (Mooney and Miller, 2010). Specifically, the length of the cell cycle is shorter in ethanol-exposed animals than in controls, and this has a direct, albeit transient, effect on the number of neurons generated daily. This change is consistent with the notion that ethanol exposure initiates a sequence of fetal programming, that is, ethanol causes effects in the fetus that have long-term consequences, which become evident in the more mature animal. The proliferation and survival of the postnatally generated VB neurons are regulated by neurotrophins, for example, nerve growth factor (NGF) and brain-derived neurotrophic factor (BDNF; Mooney and Miller, 2011). Prenatal exposure to ethanol affects the expression of NGF, and it only alters postnatal VB neuronogenesis in the presence of the dyadic effector NGF.

28.4.1.1.3 BRAINSTEM

Early exposure to ethanol also affects the generation of neurons in the brainstem. This includes neurons in the trigeminal brainstem nuclear complex (Miller, 1999; Miller and Muller, 1989), which are derived from cells lining the fourth ventricle. This effect has been refined by restricting the exposure to ethanol to a single episode on a single day. As might be predicted, exposure on a day of neuronogenesis (when neuronal precursors pass through their last mitotic division) is sufficient to reduce the neuronal number in some cranial nerve nuclei (Mooney and Miller, 2007c). It is surprising, however, that these nuclei are equally vulnerable to exposure on a day of gastrulation [e.g., gestational day (G) 7 or G8] and refractile to ethanol toxicity during the 3–4 days between gastrulation and neuronogenesis. These patterns are consistent with the notion that cycling stem cells are vulnerable to ethanol and that these effects are programmed at an early time.

Most cerebellar neurons are derived from an auxiliary proliferative zone, EGL (Rao and Jacobson, 2005). The EGL gives rise to the granule neurons that populate the internal granular layer. The generation of cerebellar granule neurons is negatively affected by ethanol (Bauer-Moffett and Altman, 1977; Kornguth et al., 1979). This alteration results from an ethanol-induced lengthening of the cell cycle of their precursors in the external granule layer (Borges and Lewis, 1983) and by the dysregulation of cyclins and cyclin-dependent kinases (Li et al., 2002).

28.4.1.2 Fetal Programming

Prenatal exposure to ethanol has many long-term consequences, and at least two of them can be attributed to fetal programming. They relate to the two systems that exhibit postnatal neurogenesis: (1) the SGZ of the dentate gyrus and (2) the anterior SZ and olfactory system. Postnatal neurogenesis is highly responsive to environmental perturbations.

28.4.1.2.1 DENTATE GYRUS

The dentate gyrus has captured the interest of neuroscientists because of its apparent role in learning and memory, notably spatial navigation. Increased neuronogenesis (the production of new neurons) correlates with improved learning and memory (Deng et al., 2010; Eisch et al., 2008; Leuner and Gould, 2010). For example, rats that exercise on a running wheel have increased neuronal production and improved learning in a spatial learning task in a Morris water maze (van Praag et al., 2005). The numbers of neurons generated and the behavioral improvement are positively correlated to the amount of running. Furthermore, training on hippocampal-dependent associative learning tasks doubles the number of neurons in the rat dentate gyrus (Gould et al., 1999). This contrasts with training on hippocampal-independent tasks wherein there is no

effect on the number of neurons in the dentate gyrus. Some pathological situations, such as traumatic brain injury (e.g., stroke), can stimulate neuronal production (Dash et al., 2001). This can lead to improved recovery and learning outcome (Chang et al., 2005; Chou et al., 2006; Kleindienst et al., 2005; Lu et al., 2005; Nakatomi et al., 2002; Wang et al., 2004).

SGZ neuronogenesis is reduced in a number of situations. The antiproliferative agent methylazoxymethanol (MAM) can eliminate the postnatal generation of neural cells in the dentate gyrus. Animals treated with MAM have impaired performance in hippocampal-dependent memory tasks, for example, conditioned fear (Shors et al., 2001). Recovery of neuronogenesis correlates with a return in ability to acquire trace memories. Postnatal neuronogenesis is highly responsive to environmental perturbations. Inflammation and stress can cause a decrease in neuronogenesis and degradation in memory (Ekdahl et al., 2003; Monje et al., 2002, 2003). Different psychiatric states can affect neural stem cell proliferation in the adult dentate gyrus. Postmortem samples from schizophrenic patients reveal depressed proliferation, whereas proliferation in patients with bipolar disorder is unaffected (Reif et al., 2006). Furthermore, SGZ neurogenesis decreases with aging (Jin et al., 2005; Kuhn et al., 1996) as does the ability to learn new tasks and to recall memories. Ablation of proliferating SGZ cells by irradiation compromises spatial discrimination, navigation, and learning (Clelland et al., 2009).

Ethanol exposure has fascinating effects on neuronal generation in the dentate gyrus in rats of all ages. Exposure of adolescents and adults to high doses of ethanol reduces SGZ neurogenesis (Crews et al., 2006; Nixon and Crews, 2002). This corresponds to ethanol-induced reductions in learning and memory. Moreover, at least in nursing rats, the effects of ethanol are dose-dependent (Miller, 1995a). Whereas exposure to high doses reduces neuronogenesis, low doses can promote neuronal production. Exposure to other substances of abuse (e.g., opiates and cocaine) also depresses neuronal generation and reduces the ability to learn and remember new behaviors (Domínguez-Escribà et al., 2006; Eisch et al., 2000). Note that all of these substances of abuse appear to target the proliferation of new cells rather than their differentiation and survival. Possibly the most intriguing findings are that prenatal exposure to ethanol alters SGZ neurogenesis in adolescents and adults (Domínguez-Escribà et al., 2006; Klintsova et al., 2007; Redila et al., 2006). The implication is that such fetal programming is transmitted via proliferating neural stem cells.

28.4.1.2.2 OLFACTORY SYSTEM

The olfactory system is affected by ethanol. Exposure to ethanol during the first 2 postnatal weeks leads to a reduction in the numbers of granule and mitral cells in the olfactory bulb (Bonthius et al., 1992). This reduction persists into adulthood despite replacement from cells generated in the anterior SZ. There is no direct evidence that ethanol affects the proliferation of cells in the anterior SZ; however, studies do show that prenatal exposure to ethanol can shape the olfactory behavior of adolescents (Eade et al., 2009, 2010; Eade and Youngentob, 2009; Youngentob et al., 2007). Not only is there an enhanced neurophysiological response to ethanol odor among rats exposed to ethanol *in utero*, but such animals are also more likely to follow an ethanol-exposed peer than a water-exposed rat. In addition, ethanol-exposed animals show an increased avidity for bitter-tasting substances including ethanol and quinine (Youngentob and Glendinning, 2009; Youngentob et al., 2007). Together, these findings show that animals exposed to ethanol prenatally are programmed to prefer the odor and taste of ethanol. Human studies also show a link between prenatal exposure to ethanol and later use/abuse of the drug (Molina et al., 2007; Pepino and Mennella, 2007). Indeed, this is the basis for the 'alcoholism generator' (Miller and Spear, 2006).

28.4.1.3 Cell Fate

Cell fate is defined by many events; one appears to be cell migration. Prenatal exposure to ethanol disrupts the migration of cortical neurons *in vivo* (Miller, 1986, 1988a, 1993) and *in situ* (Siegenthaler and Miller, 2004). *In vivo* studies show that late-generated neurons that normally reside in layer II/III of the cortex often terminate their migration in layers V and VI after ethanol exposure (Miller, 1986, 1988a, 1997). Some early-generated neurons destined for layer V end up in the superficial cortex (Miller, 1986, 1987, 1988a; Miller et al., 1990). Despite these defects, the neurons retain their connectional phenotype. That is, many of the late- and early-generated neurons are callosal or corticospinal projection neurons, respectively, regardless of whether they are distributed in their correct position or in an ectopic location. Interestingly, this disruption is remarkably similar to the pattern that occurs when cortical precursors from a later time in cortical neuronogenesis are transplanted into the proliferative zones of younger fetuses (McConnell, 1988). The implication from this heterochronic transplantation experiment is that cells that are generated late in cortical histogenesis are predominantly neuronal progenitors, and the fates of these cells are largely immutable regardless of their ultimate laminar residence. By extension, it also appears that ethanol does not affect cell fate when the exposure includes the time when cells pass through their final mitotic cycle, that is, their birth date (Miller, 1987, 1997). Note that a study of cultured neural stem cells also shows that ethanol has no effect on the diversity or numbers of progeny (Hicks et al., 2010).

Some *in vivo* data support the notion that cell fate can be altered by ethanol exposure. Prenatal exposure to ethanol alters the fates of hematopoietic progenitors in the bone marrow of mouse neonates, and lymphocyte development is delayed (Wang et al., 2006, 2009). Presumably, this contributes to the immunosuppression and vulnerability of children with FASD (Sliwowska et al., 2006; Zhang et al., 2005).

Numerous studies of cultured precursors concur that ethanol can affect cell fate. For example, the diversity of cells generated by precursors in neurospheres can be reduced by ethanol (Santillano et al., 2005), and the differentiation of cultured neural stem cells is affected by ethanol (Tateno et al., 2005). Accordingly, ethanol induces precursors to become glia (astrocytes and oligodendrocytes) and reduces neuronal differentiation. This occurs in the absence of an effect on cell viability. A study of human brain-derived neural stem and progenitor cells shows that ethanol alters the expression profile of glia- and neuron-committed precursors (Vangipuram and Lyman, 2010). The concept of ethanol-induced cell fate switching is also addressed by the cell and *in ovo* culture studies by Vernadakis and colleagues. The embryonic chick telencephalic wall contains proliferating pluripotential cells, that is, neural stem cells (Kentroti and Vernadakis, 1992, 1995). Ethanol can cause the selective elimination of cells with a particular lineage (i.e., after lineages are determined Kentroti and Vernadakis, 1996); however, other evidence shows that ethanol causes cells to switch their neurochemical phenotypic lineage (Brodie and Vernadakis, 1992; Kentroti and Vernadakis, 1992).

Ethanol can affect the differentiation of cycling and recently postmitotic cells via targeted alterations of genetic expression (Hashimoto-Torii et al., 2011; Hicks et al., 2010; Liu et al., 2009; Miller et al., 2006; Zhou et al., 2011). This is exemplified by altered expression of genes associated with cell proliferation (e.g., cyclins and cyclin-dependent kinases), growth factor function (e.g., transforming growth factor (TGF) β1, insulin-like growth factor (IGF) I, epidermal growth factor (EGF) receptor), and extracellular matrix molecules (e.g., integrins, L1, and neural cell adhesion molecule), as well as mRNAs underlying cell determination and morphogenesis such as *Wasf1*, *SatB2*, *Bhlhb5*, *ID2*, *NR4A3*, *FoxP1*, neurogenin, *Sox5*, and *Bhlhe22*. One mechanism by which the profile of expressed transcripts is altered is the ethanol-induced selective hyper- and hypomethylation of CpG islands of genes associated with neural development such as *Bub1*; cyclins A2, B1, and F; securin; IGF-I; and EGF-containing fibulin-like extracellular matrix protein I (Hicks et al., 2010; Liu et al., 2009; Zhou et al., 2011). The changes in methylation are particularly notable for cells treated with TGFβ1.

28.4.1.4 Growth Factor Regulation of Cell Proliferation

28.4.1.4.1 INSULIN-LIKE GROWTH FACTOR I

The behavior of neural stem cells can be affected by pro- and antimitogenic growth factors. IGF-I is a key promitogenic player in brain development (Rubin and Baserga, 1995). Reduction or elimination of IGF-I (e.g., via pharmacological blockade or gene knockout or knockdown) leads to smaller fetuses and microencephaly. One of the contributing effects of IGF-I toward brain growth is its ability to promote cell proliferation as exemplified by a shortened doubling time for cultured neural cells (Resnicoff et al., 1994). IGF-I initiates its action by binding to and activating specific membrane-bound receptors that sequentially lead to the activation of extracellular signal-regulated kinase (ERK) 1/2.

Microencephaly and reductions in overall body growth caused by prenatal exposure to ethanol correlate with reductions in plasma IGF-I (Breese et al., 1993; de la Monte et al., 2005; Lynch et al., 2001; Mauceri et al., 1993; Singh et al., 1994; Soscia et al., 2006). Some studies also show that IGF-2 is altered (Singh et al., 1994), whereas others show that IGF-2 expression is unchanged (Breese and Sonntag, 1995). A further contributor to the brain and body growth reduction is a decrease in IGF-I transcript and protein in pregnant dams. The acute changes during gestation have long-term consequences (Breese et al., 1993). Despite being normal during the first 3 postnatal weeks, IGF-I concentrations eventually fall in weanling and adolescent rats. The dynamism of ethanol-induced changes has also been examined in the chick (Lynch et al., 2001). IGF-I expression is unaffected before day 6, drops transiently on day 6, and then rises 2 days later. This increase appears to be a response to a reduction in the availability of IGF-binding protein. Supplementation of IGF-I in the rat can partially offset ethanol-induced alterations (McGough et al., 2009) and alleviate the behavioral effects of ethanol such as on motor coordination. On the other hand, IGF-I does not mitigate ethanol-induced hyperactivity and spatial learning deficits.

Ethanol inhibits the effects of IGF-I to promote cell proliferation (Resnicoff et al., 1994). This is associated with a reduction in receptor phosphorylation and the association of phosphatidylinositol-3 kinase (PI3K) with insulin receptor substrate 1. Thus, central IGF signaling mechanisms are altered by ethanol. Apparently, these changes lead to altered feedback regulation. Impaired insulin and IGF-I signaling leads to a general depression of the transcription of genes for insulin, IGF-I and IGF receptors (de la Monte et al., 2005). The outcome of these changes is the inhibition of glucose transport and the associated production of ATP.

28.4.1.4.2 PLATELET-DERIVED GROWTH FACTOR

Like IGF, platelet-derived growth factor (PDGF) is a potent promitogenic factor. PDGF ligands and receptors are expressed by cells in the immature brain (Reddy and Pleasure, 1992; Valenzuela et al., 1997) and cycling neural cells (Luo and Miller, 1997, 1999b). Moreover, PDGF ligands affect the behavior of cycling neural cells (Luo and Miller, 1997, 1999b). This is mediated by an acceleration of the cell cycle, presumably by shortening the G1 phase.

Of the two high-affinity receptors for PDGF, ethanol targets the α isoform (Luo and Miller, 1999b). It upregulates the expression and inhibits the activation of the PDGFα receptor. PDGF signals through a receptor-activated Ras-Raf-ERK1/2 pathway in proliferating neural cells. Ethanol affects the PDGF-initiated activation of each mediator in the Ras-Raf-ERK1/2 cascade with the ultimate effect being a change in the pattern of ERK1/2 phosphorylation. Interestingly, ethanol causes the upregulation of ERK1/2, which changes the PDGF-promoted phasic stimulation into a tonic activation.

28.4.1.4.3 TRANSFORMING GROWTH FACTOR β1

Antimitogenic factors are a counterbalancing set of proteins. They are critical for limiting cell proliferation and restraining the expansion of neural precursor populations. A prime example of an antimitogenic factor is TGFβ1. TGFβ1 reduces neural generation, not by slowing the cell cycle, but by moving cells out of a proliferative population (Hicks et al., 2010; Siegenthaler and Miller, 2005b). That is, TGFβ1 reduces the growth fraction by promoting cell cycle exit. This is transduced through a p21-mediated mechanism. Furthermore, TGFβ1 facilitates this cell cycle exit and promotes the migration of postmitotic cells away from the proliferative populations (Siegenthaler and Miller, 2004).

TGFβ1 binds to a heterodimerized receptor with serine/threonine kinase activity (Danielpour and Song, 2006; ten Dijke and Hill, 2004). When activated, the receptor phosphorylates Smad2/3, which translocates to the nucleus and promotes transcription. In cortical proliferative zones, TGFβ1 also activates ERK1/2 either directly or through crosstalk with activated Smad2/3 (Powrozek and Miller, 2009). TGFβ1 activation of ERK1/2 is a sustained (tonic) response, not unlike that initiated by ethanol (Luo and Miller, 1999a).

Ethanol inhibits the TGFβ1-mediated inhibition of cell proliferation in various populations of neural precursors: astrocytes and C6 glioma cells (Miller and Luo, 2002a), B104 neuroblastoma cells (Luo and Miller, 1999a), and neuronal progenitors (Miller and Luo, 2002b). The principal mechanism involves ethanol-mediated interference with the TGFβ1-induced reduction in the growth fraction. Concomitantly, it may cause the death of neural cells through a TGFβ1-mediated mechanism (Hicks and Miller, 2011; Kuhn and Sarkar, 2008). Prenatal exposure to ethanol affects the expression of TGFβ receptors in the fetal cerebral wall (Miller, 2003), which has downstream effects on the two signaling pathways triggered by TGFβ1 (Powrozek and Miller, 2009). These two pathways rely on Smad2/3 and ERK1/2. Not only do these pathways interact, but ethanol can affect this interplay. In fact, it appears that ethanol mimics, and presumably acts through, TGFβ1.

28.4.2 Neuronal Death/Survival

Neuronal death is a normal process of neural development. Neurons can die via a number of processes: apoptosis, necrosis, excitotoxicity, and autophagy. Apoptosis is the most common mode during development; it is characterized by morphological and biochemical changes (Danial and Korsmeyer, 2004; Kerr, 2002; Kerr et al., 1972; Mooney and Henderson, 2006; Wyllie, 1997). Morphological changes include chromatin condensation, membrane blebbing, endonucleolytic DNA cleavage, and formation of apoptotic bodies. Biochemical changes include activation of caspase 3, fragmentation of the nuclear DNA, and the consequent generation of polyadenylated strands of DNA.

Neuronal death is time dependent, and it can affect proliferating and postproliferative cells. Though the proliferative behavior of both stem and progenitor cells can be affected by ethanol (Miller, 2006b; Zawada and Das, 2006), there is an apparent difference in the susceptibility of these two types of precursors to ethanol-induced death. Stem cells (which are commonly in the VZ) may be vulnerable to ethanol; however, neural progenitors (e.g., those in the SZ) appear to be impervious to ethanol-induced death (Camarillo and Miranda, 2008; Hicks and Miller, 2011; Prock and Miranda, 2007; Santillano et al., 2005). Interestingly, these data run counter to studies showing that ethanol has no apparent effect on the survival of stem cells (Tateno et al., 2005). Such findings are in accord with the evidence that hypoxic ischemia has little effect on stem cells but compromises the viability of progenitors (Romanko et al., 2004).

The survival of postproliferative cells has most thoroughly been studied in the cerebral cortex. In the cortex, the period of naturally occurring neuronal death (NOND) takes place primarily during the second postnatal week (e.g., Ferrer et al., 1990; Finlay and Slattery, 1983; Heumann and Leuba, 1983; Heumann et al., 1978; Miller, 1995c). Indeed, the pattern of NOND follows the inside-to-outside sequence of cortical neuronal

generation. That is, it is defined by the neuronal time of origin so that neurons in the deep cortex (e.g., layer V) die before those in the superficial cortex (layer II/III; Miller, 1988b, 1995c).

Developmental exposure to ethanol can induce neuronal death in various brain regions, and this death appears to be generalized. For example, in the principal sensory nucleus of the trigeminal nerve, all constituent neurons appear to be equally vulnerable (Miller, 1995b, 1999). Likewise, there is no discernible pattern to the incidence of death among Purkinje and granule neurons within a cerebellar lobule (Pierce et al., 1999). Patterns of biochemical changes indicate that ethanol-induced neuronal death also occurs in neocortex (Kuhn and Miller, 1998; Miller, 1996; Mooney and Miller, 2001; Olney et al., 2002a,b). Based on anatomical studies of the expression of 'death markers' (e.g., caspase 3 immunolabeling and terminal uridylated nick-end labeling), it appears that the cerebral cortex is different in that select subpopulations are particularly vulnerable to ethanol exposure during the period of NOND, notably neurons in layers II/III and V (Ikonomidou et al., 2000; Olney et al., 2002a,b; Young et al., 2003).

Ethanol can affect multiple mechanisms of neuronal death (Mooney and Henderson, 2006). Three are described here: (1) intrinsic, (2) extrinsic, and (3) caspase 3-independent pathways.

28.4.2.1 Intrinsic Pathway

The intrinsic pathway is a mitochondrial-dependent pathway that is typically activated in response to an apoptotic signal such as DNA damage or reactive oxygen species (ROS; Green and Reed, 1998; Miller et al., 2000; Mooney and Henderson, 2006; Soengas et al., 1999). Proapoptotic proteins are released from the mitochondrial intermembrane space. Permeabilization of the mitochondrial outer membrane is mediated by Bcl proteins and promotes binding of p53 to proapoptotic proteins, for example, Bcl-XS or Bax (Chipuk et al., 2004). Bax upregulation may allow insertion of Bax homodimers into the mitochondrial membrane, thereby altering its permeability and permitting intermembrane substances to leak into the cytoplasm. These substances cause activation of caspase 3, which represses DNA repair and initiates DNA fragmentation and cell death.

Exposure to ethanol alters the *in vivo* expression of Bcl proteins (Mooney and Miller, 2003). Changes may be rapid, as in the case of the transcripts (Inoue et al., 2002; Moore et al., 1999), or delayed, as detected by changes in protein expression (Mooney and Miller, 2001; Heaton et al., 2003b). Ethanol also increases the expression of active caspase 3 (Carloni et al., 2004; Han et al., 2005; Ikonomidou et al., 2000; Mooney and Miller, 2003; Nowoslawski et al., 2005; Olney et al., 2002a,b) and induces production of ROS, which then

causes DNA damage (Heaton et al., 2003a,b; Kotch et al., 1995; Maffi et al., 2008; Ramachandran et al., 2001, 2003). Interestingly, Bax is apparently required for ethanol-induced cell death, but caspase 3 is not (Young et al., 2003, 2005). Mice deficient in *Bax* do not exhibit argyrophilic (degenerating) cells in response to acute ethanol exposure, whereas caspase 3-null animals do.

28.4.2.2 Extrinsic Pathway

The extrinsic pathway is activated by binding the Fas ligand (FasL) to its cell surface receptor Fas. This binding causes receptor oligomerization, and the recruitment of the Fas-associated death domain (Fadd) and its association with procaspases 8 and 10 (Benn and Wolff, 2004). The Fadd-caspase 8/10 complex forms the death-inducing signaling complex, which cleaves and activates caspase 3. As with the intrinsic pathway, active caspase 3 inactivates poly-ADP-ribose polymerase (PARP) and allows DNA fragmentation. In addition, active caspase 8 cleaves the Bcl family protein, Bid. Truncated Bid (tBid) translocates to the mitochondria where it can activate the intrinsic pathway by promoting insertion of Bax homodimers into the mitochondrial membrane. Ethanol alters expression of FasL and Fas (Cheema et al., 2000; de la Monte and Wands, 2002; Hicks and Miller, 2011) and can increase caspase 8 activity (Vaudry et al., 2002).

28.4.2.3 Caspase 3-Independent Pathway

As with the intrinsic pathway, the caspase 3-independent pathway is mitochondria-dependent. Following its release from the mitochondrial intermembrane space, apoptosis-inducing factor can either directly upregulate DNase activity or can cleave and inactivate PARP. The effect of this is the repression of DNA repair and promotion of cell degeneration. Although there is little direct evidence that ethanol activates the caspase 3-independent pathway, inhibiting caspase activity does not prevent ethanol-induced cell death (D'Mello et al., 2000; Keramaris et al., 2000; Miller et al., 1997; Selznick et al., 2000; Stefanis et al., 1999). This implies that a caspase 3-independent pathway is able to be activated, regardless of whether it is the main pathway affected by ethanol. It is noteworthy that both the intrinsic and extrinsic pathways are upstream of p53 activation (Mooney and Henderson, 2006); ethanol affects p53 expression (Kuhn and Miller, 1998) and p53-mediated cell death (Miller et al., 2003).

28.4.2.4 Growth Factor Targets

Neurotrophins play critical roles in normal brain development (e.g., Bibel and Barde, 2000). Developmental expression of neurotrophins is necessary for neuronal survival, process outgrowth, and synaptogenesis. Two neurotrophins particularly important for brain

development are NGF and BDNF. Although NGF is not expressed by cortical progenitors *in vitro* or in the VZ *in vivo*, which suggests that it is not required for cell proliferation or the initiation of migration (Barnabé-Heider and Miller, 2003; Fukumitsu et al., 1998; Maisonpierre et al., 1990), it is highly expressed in the early postnatal period, suggesting a role in postmitotic development (Das et al., 2001; Heaton et al., 2003b).

BDNF is present in cortical progenitor cells *in vivo* and *in vitro* (Barnabé-Heider and Miller, 2003; Fukumitsu et al., 1998; Maisonpierre et al., 1990) and remains evident in the cerebral cortex through adulthood (Climent et al., 2002; Das et al., 2001; Heaton et al., 2003b; Itami et al., 2000; Pitts and Miller, 2000; Vitalis et al., 2002).

Developmental exposure to ethanol alters the expression of neurotrophins and their receptors, although there is no consensus as to the effect (e.g., Climent et al., 2002; Heaton et al., 1999, 2000b, 2003a,b; Light et al., 2001; Seabold et al., 1998). Prenatal and postnatal exposure to ethanol increases NGF expression in the cortex and striatum (Heaton et al., 2000a, 2003a,b). Cortical BDNF expression (Climent et al., 2002) is reduced during the first 2 postnatal weeks by prenatal exposure to ethanol, whereas postnatal exposure to ethanol increases cortical BDNF expression (Heaton et al., 2003b).

For neurotrophins to have an effect on brain development, they must bind to and activate receptors. Thus, the expression, both the amount and location, of receptors may provide greater insight into the role of the neurotrophin systems in development. Cortical expression of trkA and trkB is upregulated following prenatal exposure to ethanol (Climent et al., 2002; Gottesfeld et al., 1990; Valles et al., 1994). Exposure to ethanol in the early postnatal period also upregulates cortical p75 expression (Toesca et al., 2003) as does ethanol treatment of cultured cortical neurons (Seabold et al., 1998). Evidence suggests that p75 can mediate apoptotic death or mediate the protective effect of a neurotrophin (Blochl and Blochl, 2007; Casaccia-Bonnefil et al., 1996, 1999; Seabold et al., 1998). Thus, the changes in receptor expression may be in response to ethanol-induced reductions in neurotrophin concentrations and subserve a protective mechanism.

Exogenous neurotrophins can ameliorate ethanol-induced cell death. Animals that overexpress NGF are less vulnerable to ethanol-induced neurotoxicity (Heaton et al., 2000a). The addition of NGF or BDNF to cultured cells reduces ethanol-induced cell death (Bhave et al., 1999; de la Monte et al., 2000, Heaton et al., 1992, 1993, 1994; Miller et al., 2003; Seabold et al., 1998). The ability of NGF to protect cortical neurons against ethanol-induced death is both site-specific and age-dependent. NGF fails to protect against ethanol-induced death in cultures of cortical neurons (Seabold et al., 1998), or in slice cultures from 16-day-old rat fetuses (Mooney and Miller, 2007a). In contrast, NGF is neuroprotective in slice cultures taken from a 3-day-old rat brain. This neuroprotection is seen only in the more mature lower cortical plate and not in the upper cortical plate, which largely contains migrating neurons. The implication is that the neuroprotection depends upon the maturity of the neurons.

NGF-induced neuroprotection is correlated with receptor activity. Ethanol inhibits the NGF-induced phosphorylation of trkA in the primary neurons taken from 16-day-old fetuses but does not affect p-trk expression in slices from 3-day-old pups. Activation, that is, phosphorylation, of trkA is generally associated with neuronal survival. Thus, an ethanol-induced reduction in p-trk expression may be predictive of an inability of NGF to protect against ethanol-induced death.

In addition to altering the expression of neurotrophin ligands and receptors, exposure to ethanol alters downstream signaling. Trk receptors can signal survival via the ERK1/2 and PI3K pathways, and p75 may also signal survival via PI3K. Activation of both pathways is age-dependent. Growth factor-dependent activation is downregulated in the presence of ethanol (Climent et al., 2002; Kalluri and Ticku, 2002). Ethanol inhibits endogenous phospho-ERK1/2 expression (Kalluri and Ticku, 2002). Ethanol also alters growth factor-induced phosphorylation of the ERK1/2 pathway in cortical cells (Climent et al., 2002; Luo and Miller, 1999a,b) and PI3K/Akt in cerebellar cells (de la Monte and Wands, 2002; Li et al., 2004). Interestingly, the ethanol-induced reduction in growth factor-stimulated PI3K/Akt activation in cerebellar neurons occurs in the absence of a change in receptor or ligand expression (de la Monte and Wands, 2002). The effect of ethanol on pathway activation is cell type dependent. For example, ethanol inhibits the BDNF-mediated increase in expression of phosphorylated jun-*N*-terminal kinase (p-JNK) and phosphorylated Akt (p-Akt) in cultured mouse cerebellar granule cells (Li et al., 2004). In contrast, in a human neuroblastoma cell line (TB8 cells), ethanol inhibits the BDNF-mediated increase in p-Akt but not p-JNK expression, suggesting that different pathways are activated by BDNF in these cells.

28.5 BEHAVIORAL CONSEQUENCES

Social interactions are crucial for the survival of humans and other mammalian species. In humans, peer relationships are sources of knowledge about behavioral patterns, attitudes, values, and consequences in different situations (Deutsch and Gerard, 1955). In the same way, peer-directed social activity of rodents seems crucial for establishing social organization in a group or between partners and for developing the ability to express and understand intraspecific communication signals (Vanderschuren et al., 1997).

A secure and consistent social milieu is important not only for humans, but for laboratory rodents as well, with social deprivation being stressful (Hall, 1998). Rats exhibit numerous social behaviors including play fighting, contact behavior, and social investigation. Abnormal social behaviors have been reported in rats following a number of developmental insults, including neonatal lesions of the amygdala (Daenen et al., 2002), neonatal exposure to Borna disease virus (Lancaster et al., 2007), and ethanol exposure during development (Kelly et al., 2000; Thomas et al., 1998). Developmental exposure to ethanol alters play-fighting behavior (Lawrence et al., 2008; Lugli et al., 2003; Meyer and Riley, 1986; Royalty, 1990), as well as the amount and type of active social interactions in adolescents and adults (Kelly and Dillingham, 1994; Lugli et al., 2003). Prenatal exposure to ethanol alters social behavior in a sex-dependent fashion (Meyer and Riley, 1986), with males showing less play behavior and females demonstrating more play fighting. Interestingly, a single exposure to ethanol on G12 alters the social behavior of adolescent and adult rats, and many of the changes are sex-specific, that is, they are detected only in males (Mooney and Varlinskaya, 2011; Mooney et al., 2009).

28.6 SUMMARY

Early developmental exposure to ethanol has multiple consequences including targeted effects on cell proliferation and survival. In general, ethanol reduces cell proliferation and compromises neuronal survival, but the scope of the changes are defined by the site, the exposure, the maturity of the cells, and the growth factor availability and receptivity. The culmination of these changes affects the total numbers of neurons in the brain. Interestingly, the numbers of neurons in structures within a particular system (e.g., the somatosensory system) may be differentially altered. For example, the numbers of neurons in the rat trigeminal brainstem nuclei (Miller, 1999; Miller and Muller, 1989) and the somatosensory cortex (Miller and Potempa, 1990; Powrozek and Zhou, 2005) are 30–50% fewer in ethanol-exposed animals; however, no detectable effect is evident in the thalamus (Livy et al., 2001; Mooney and Miller, 1999, 2010). This breakdown in the numerical matching of neuronal populations within a system of interconnected structures implies that the assemblage of neurons within each structure occurs either autonomously or asynchronously. The consequences of such differential effects are functional changes (Miller and Dow-Edwards, 1993; Vingan et al., 1986; Xie et al., 2010) that likely underlie ethanol-induced dysfunction such as motor incoordination and cognitive deficits (Coles, 2006; Fryer et al., 2006).

Two intriguing contributors to postnatal responses and responsivity are genetic–environmental interactions and fetal programming. It is becoming clearer that ethanol has targeted effects on genomic expression and epigenetic modifications (e.g., Haycock, 2009; Hicks et al., 2010; Pandey et al., 2008). Overlying these interactions, and possibly a result of them, is the effect of early exposure to ethanol on fetal programming (Miller and Spear, 2006). Such programming may be mediated through neural stem cells. The mechanism and the scope of this programming are at present unknown. Understanding them will not only provide key insights into normal brain ontogeny, but it is also likely critical for developing strategies to modify neural development and outcome and ultimately preventing or offsetting developmental disorders such as FASD.

Azetidine-2-Carboxylic Acid and Other Nonprotein Amino Acids in the Pathogenesis of Neurodevelopmental Disorders

E. Rubenstein

Stanford University School of Medicine, Stanford, CA, USA

29.1 INTRODUCTION

There are approximately 900 naturally occurring amino acids, of which only 22 have been evolutionarily selected for inclusion as subunits in the structure of proteins (Rosenthal and Bell, 1979; Rubenstein, 2000). The others, nonprotein amino acids, are found principally in plants and lower marine forms in which they participate in metabolism and provide a means of nitrogen storage. In addition, many are deployed as toxic weapons, deterring intruding vegetation and marauding predators.

Some amino acids have entered the food chain. Notable among this group is azetidine-2-carboxylic acid (Aze), which is the lower homolog of the protein amino acid proline. It readily escapes the gate-keeping function of prolyl aminoacyl-tRNA synthetases and replaces proline in proteins, corrupting their structure, function, and antigenicity. Aze may be an environmental agent that contributes to susceptibility to a wide range of disorders, especially those involving the central nervous system (Rubenstein, 2008).

Proline is an anomalous amino acid (Figure 29.1(c)). Its nitrogen atom is linked to only one hydrogen atom instead of two. It cannot act as a hydrogen bond donor but can serve as an acceptor. The nitrogen is covalently bound to the ring structure, constraining its mobility in peptide bond formation. The φ backbone dihedral angle is about $-75°$, and proline displays conformational rigidity. Unlike other amino acids, which prefer the *trans* configuration of the hydrogen and oxygen atoms in the peptide bond, proline readily shifts to the *cis* architecture in response to regional changes in spatial charge distribution. Lacking a hydrogen atom, the proline molecule isomerizes by swinging its entire ring into the *cis* position, a conformational change that realigns the local peptide sequence, resulting in folding of the protein (Baldwin, 2008; Smith et al., 2012).
FIGURE 29.1 Small-ring molecules. This figure shows the structures of four-membered rings as free molecules: β-lactam (a), L-azetidine-2-carboxylic acid (Aze) (b), and as constituents of the two plant chelator molecules, nicotianamine (d) and mugineic acid (e). Note the similarity of β-lactam (a) and L-azetidine-2-carboxylic acid (Aze) (b). Proline (c) is the five-membered ring higher homologue of Aze (b). The four-membered rings are red, the ring acyl group is green, and the ring carboxyl groups are blue.

Because of its idiosyncrasies as an amino acid, proline is not found within alpha helices or beta sheets. It can take a position at the ends of these structures and in turns. Repeating prolyl residues may fold into a left-handed helix (PPII), with backbone dihedral angles of about $-75°$, $150°$, and a *trans* configuration of their peptide bonds. A right-handed helix (PPI) forms with dihedral angles of about $-75°$ and $160°$ when there is a *cis* configuration of their peptide bonds.

Aze, bearing a ring that contains four members instead of five, is otherwise nearly identical to proline (Figure 29.1(b)). There are, of course, subtle differences in bond angles, including those that determine the degree of ring puckering. Azetidine changes its *cis–trans* configuration under slightly different conditions of local charge, and its presence can thus cause misfolding (Tsai et al., 1990).

29.1.1 Ring Strain and Reactivity

Biomolecules comprise atoms in chains that tend to adopt a linear configuration in which their mutually repelling electron clouds maintain maximal distance from each other. This is not possible in small-ring compounds. The conformation of such cyclic molecules subjects them to various forms of strain or structural stress. The increased internal energy acquired during synthesis is released during chemical transactions (Hassner, 1983). Crowding can result in narrowing of preferred bond angles, compression of electron orbitals, and malpositioning of ring members. For these reasons, strain energy is exceedingly high in small cyclic molecules, increasing their chemical reactivity.

Molecules with five or more rings abound in biochemistry, but there appear to be only two four-membered ring compounds that have entered human life, and both have done so as exogenous substances: beta-lactam and Aze.

Beta-lactam closely resembles Aze. It is a cyclic amide with an acyl group on a carbon adjacent to the nitrogen (Figure 29.1(a)). It is the central component of the penicillins. The penicillin molecule binds to and inactivates the bacterial cell wall transpeptidase enzyme that forms an acyl intermediate with a D-alanyl-D-alanyl terminal peptide residue. Penicillin intrudes into the active site of the enzyme, where its beta-lactam impersonates the structure of the normal substrate. It irreversibly inhibits the enzyme, thus preventing cross-linking of the bacterial cell wall (Stryer, 1988). The ring strain of the four-membered beta-lactam contributes to its remarkable reactivity (Hassner, 1983).

Aze is strikingly similar to beta-lactam. Instead of an acyl group, it contains a carboxyl group on ring atom number 2. Like beta-lactam, Aze is highly strained and is thus highly reactive.

29.1.2 The Aminoacyl-tRNA Prolyl Synthetases

There are two aminoacyl-tRNA synthetases that recognize proline, EPRS (cytoplasmic) and PARS2 (nucleus encoded but mitochondrial). EPRS is multifunctional, recognizing glutamic acid as well as proline. The human forms of these synthetases lack editing domains. The chromosomal location of the gene *EPRS* is 1q41-q42 and that of *PARS2* is 1p32.2 (Antonellis and Green, 2008). Certain nonprotein amino acids escape the gate-keeping function of aminoacyl-tRNA synthetases and gain entry into proteins, replacing their homologs and changing the structure, function, and antigenicity of the misassembled molecule. The large number of disorders associated with synthetase dysfunction include the Charcot-Marie-Tooth disease, amyotrophic lateral sclerosis (ALS), leukoencephalopathy, Parkinson's disease, various neoplasms, autoimmune polymyositis, dermatomyositis, rheumatoid and erosive arthritis, and type 2 diabetes (Antonellis and Green, 2008; Beebe et al., 2008; Park et al., 2008).

29.1.3 Azetidine-2-Carboxylic Acid

Notable among nonprotein amino acids with disease-causing potential is azetidine-2-carboxylic acid (Aze), the lower homolog of proline that is identical to proline except in that it contains four instead of five members in its ring (Fowden, 1956). Aze is ubiquitously present in low concentrations in vegetation, where it is a central component of the chelating molecules, nicotianamine and mugineic acid, which capture metals from the soil and transfer them to various parts of the plants (Figure 29.1(d) and 29.1(e)) (Curie et al., 2009; von Wiren et al., 1999).

In certain species, Aze accumulates to exceedingly high levels, notably in the bulbous roots of table beets and sugar beets (*Beta vulgaris*). Such plants deploy the toxic Aze to deter the intrusion of competing vegetation and to poison infecting microorganisms and predating animals. Thus, Aze is present in the food chain via small concentrations in vegetables. However, it is in high concentrations in certain foods, especially in dairy products derived from livestock fed sugar beet by-products (Rubenstein, 2008).

29.1.4 Aze in the Food Chain

The entry of Aze into the food chain is a consequence of geopolitical events of the 19th and 20th centuries (Rubenstein, 2008). Previously sugar beets were not cultivated or used for human consumption. They grew wildly and were foraged by animals, notably red deer in Europe. The sugar beet is an unattractive, large, bulbous plant with a flavor offensive to humans. The root was occasionally used as a therapeutic agent for various illnesses. In 1747, the German apothecary chemist Andreas Margraff discovered low concentrations of sucrose in the root. During the following 50 years, his student and research associate, Franz Achard, succeeded in increasing the concentration of sugar several times over, and at present the sucrose concentration can be as high as 18%. The Napoleonic wars resulted in the blockades of Europe, which severed the supply of Caribbean sugar. The entire continent was deprived of its principal source of sweets for nearly a decade.

To quell unrest, Napoleon issued a decree in 1810 allotting 8000 acres of land near Paris to sugar beet production. He also ordered the construction of facilities to process sugar beets and organized schools to teach sugar beet agronomy. After a slow start, the sugar beet industry grew rapidly, and by the middle of the century it was flourishing. Since then, it has become the fourth leading agricultural enterprise in Europe and a major farming activity in both Canada and the United States. Sugar beets are now grown and processed virtually worldwide, including in Asia, the Middle East, and the Far East. At present, about one-third of the world's sucrose supply comes from sugar beets.

Sugar beet processing involves washing the plants, dicing them, and then boiling them in alkali. The sucrose is extracted after several rounds of distillation. The residue, consisting of plant parts and thick molasses and rich in Aze, is fed to farm animals, especially to dairy cattle, which savor its unusually sweet flavor. A dairy cow may be fed as much as 10 pounds of sugar beet molasses per day. This increases its consumption of grasses and grains so that its daily food intake supports the required volume of its milk production. The health and milk production of dairy cattle begin to falter after about 5 years, at which time they are slaughtered. It is this association between sugar beets and milk and meat production that has led to the introduction of Aze into milk, other dairy products, and, notably, gelatin (Rubenstein et al., 2009).

Aze is also present in high concentrations in table (garden) beets, which are a staple food in Central and Eastern Europe. They are the principal constituent of beet soup (borscht). Sliced beets are also a popular offering in salad bars in the United States (Rubenstein et al., 2006).

29.1.5 The Multiple Sclerosis/Aze Hypothesis

Five independent lines of evidence suggest an association between Aze consumption and the pathogenesis of multiple sclerosis. The central concept is that Aze intrusion into the proline-laden consensual epitope of myelin basic protein leads to the molecule's architectural modification, functional impairment, and eventual emergence as an antigen. Thereafter, immune mechanisms are triggered and progressively damage the myelin sheath.

Correlation does not establish causation; however, the chronologic, geographic, migrational, enzootic, biochemical, and genetic associations warrant further investigation (Bessonov et al., 2010a,b; Rubenstein, 2008; Sobel, 2008).

29.1.6 Chronologic and Geographic Evidence

The emergence of dietary Aze in high concentrations closely preceded in time and place Charcot's description of what appeared to be a new disease, multiple sclerosis. This was in Paris in 1868 (Talley, 2005). The geographic distribution of the disease thereafter coincided with that of sugar beet agriculture, extending at higher latitudes across Europe, North America, and then virtually worldwide, including Sardinia, the Middle East, Scandinavia, and the Orkney and Faroe Islands. Micro hot-spots, such as those in Alberta, Canada, and the Tokachi Province in Japan, add support to the geographical evidence.

Alberta is the epicenter of sugar beet production in Canada and has the highest prevalence of multiple sclerosis in that country. Tokachi province, a small region in northern Japan, produces half of that nation's sugar beet crop and has the highest prevalence of multiple sclerosis among any Asian population (Rubenstein, 2008).

29.1.7 Migrational Evidence

Myelination of the central nervous system begins in early life and continues through adolescence, a fact pertinent to the effect of population migration on the occurrence of multiple sclerosis (Kennedy et al., 2006). An example is the abrupt appearance of the disease in the French West Indies during the 1990s among returning West Indians who had emigrated to France during the 1950s and 1960s (Cabre et al., 2005).

The risk was highest for those who arrived in France before the age of 15. Their mean duration of stay was 12.3 years, and the mean interval between their arrival in France and the appearance of the disease was 19.1 years. This epidemiology recapitulates in mirror image the original emergence and spread of the disease (Rubenstein, 2008).

29.1.8 Enzootic Evidence

Swayback is an enzootic disease closely mimicking multiple sclerosis in clinical and histological characteristics. An outbreak in Alberta in 1972 killed 60 of 100 newborn lambs. An investigation into the circumstances surrounding this event led to the conclusion that the only unique feature was that the ewes and their offspring were fed an unusual diet containing large amounts of sugar beet silage (Cancilla and Barlow, 1969; Chalmers, 1974).

29.1.9 Biochemical Evidence

As already described, the misincorporation of Aze into a protein can result in alteration of protein structure, function, and immunogenicity (Bessonov et al., 2010a,b; Rubenstein, 2008). In the case of multiple sclerosis, the putative site of the misincorporation lies in the myelin basic protein (Boggs, 2006; Harauz et al., 2009). Specifically, the misincorporation would occur in the position of one or more of the four prolyls in the consensual epitopic sequence, which embraces the hexapeptide stretch PRTPPP (residues 96–101, human numbering). This highly conserved proline-rich motif is stochastically vulnerable to the deleterious effects of Aze replacement of proline.

Aze may intrude within other proline-rich molecules involved in myelination. An enormous body of meticulous research has contributed to our knowledge of myelin basic protein, its posttranslational modification, and its roles in signaling and protein–protein binding (Boggs, 2006; Harauz et al., 2009).

The random incursion of Aze into myelin basic protein and related ensemble myelin proteins may account for some of the anatomic, pathologic, and clinical heterogeneity of the disorder. Such misassembly could ultimately ignite or contribute to the progression of immune responses, which can have dire clinical consequences.

The metabolic burdens caused by the inherently error-prone processes of translation are compounded by exposure to an alien amino acid and by an impaired aminoacyl-tRNA synthetase mechanism. Defective editing causes the myriad pathologic effects already listed. The presence of extensive oligodendrocyte apoptosis, together with the absence of lymphocyte and myelin phagocytosis in newly formed multiple sclerosis lesions, supports the concept that autoimmunity plays a critical role in demyelination.

29.1.10 Genetic Evidence

The important role of genetics in the pathogenesis of multiple sclerosis has been authoritatively reviewed by Oksenberg et al. (2008). These considerations have led to a targeted genomic search for SNPs involving genes related to Aze. The work, conducted in collaboration with the laboratory of Dr. Ronald Davis at Stanford, is currently in progress.

29.1.11 Alternative Splicing and Amplification

Alien amino acids ordinarily affect only the molecule that has been misincorporated; however, the misassembly of molecules involved in alternative splicing can alter hundreds of different kinds of 'downstream' proteins that undergo the splicing process. Therefore, the misassembly of alternative splicing proteins can greatly amplify the molecular pathology induced by Aze.

A growing body of evidence has implicated the role of disordered alternative splicing in disease pathogenesis. This mechanism has been identified in a number of developmental disorders, especially those involving the nervous system. Recent reports have focused on the A2BP1 protein, which binds to the C-terminus of ataxin-2.

Ataxin-2 has been found to act as a coregulator of zinc-finger transcriptional activity (Hallen et al., 2011). Defective function of this molecular mechanism can lead to amplified abnormal splicing of a large number of proteins and thus to an exceptionally diverse group of disorders.

Prominent among the diseases associated with abnormal splicing are multiple abnormalities caused by

defective neurodevelopment, including various forms of autism (Abrahams and Geschwind, 2008; Geschwind and Levitt, 2007; Hammock and Levitt, 2011; Martin et al., 2007; Sakai et al., 2011; Voineagu et al., 2011). Exposure to Aze-containing milk and other dairy products early in life may be of relevance, serving as an environmental susceptibility factor in autism spectrum disorders (see Chapter 34 and Rubenstein and Rakic, 2013).

Another neurodegenerative disorder that may be related to ataxin-2 and A2BP1 is ALS (Bonini and Gitler, 2011; Daoud et al., 2011; Lee et al., 2011; Van Damme et al., 2011). It is relevant to point out that the nonprotein amino acid β-N-methyl-amino-L-alanine (BMAA) has long been suspected to be an environmental susceptibility factor in ALS, initially in several Western Pacific islands. β-N-oxalylamino-L-alanine (BOAA) has been implicated in neurolathyrism endemic in certain regions of East Africa and Southern Asia. Canavanine, a homolog of arginine, is present in hundreds of legumes and in high concentrations in alfalfa seeds and sprouts. It has been suspected of playing a role in the pathogenesis of autoimmune disorders, including systemic lupus erythematosus (Cox et al., 2005; Rubenstein, 2000).

Other nonneurologic disorders associated with ataxin-2/A2BP1 include type 2 diabetes (Lehtinen et al., 2011). Similarly, obesity has been linked to the alternative splicing proteins (Ma et al., 2010). Biliary cirrhosis has also been associated with the same protein (Joshita et al., 2010).

29.1.12 Toxicity of Aze

A large number of early reports confirmed that Aze causes biochemical, morphological, and clinical defects. Among the biochemical abnormalities are misincorporation into vasopressin, hemoglobin, ovalbumin, and proline peptides. Inadvertent administration of Aze has resulted in butyric aminoaciduria. Morphologic abnormalities include abnormalities of somite formation, Golgi structure, osteoblasts, epithelial buds, cartilage, thyroid tissue, cleft palate, vertebral ossification, testes, keratin, hair, collagen, teeth, renal ducts, and mammary epithelium (Rubenstein, 2000; Tsai et al., 1990). Aze has recently been shown to be toxic to neurons and astrocytes in cell cultures, with associated increases in oxidized and ubiquitinated proteins (Dasuri et al., 2011).

Recent studies conducted by the Azetidine Group of collaborating investigators at the Stanford Medical Center have focused on the molecular details of misincorporation. This group includes M. Albertelli, M.J. Butte, R. Davis, J.E. Elias, M. Fontaine, K.V. Grimes, S. Krishnakumar, M. Mindrinos, G. Sonderstrup, R. Sobel, and E. Rubenstein. Some of this work has been summarized in the report by R.A. Sobel et al.

Aze has been found in milk samples from Boulder, CO. The use of sugar beets for dairy cattle feeding ceased in California about 3 years ago, and milk samples from California are currently free of Aze.

The administration (by oral gavage or intraperitoneal injection) of Aze in doses of 300 or 600 mg/kg to newborn CD-1 mice resulted in oligodendrocyte nuclear swelling and hepatic injury. Three of the five mice fed the larger dose by gavage were found dead or euthanized at 12–15 days. Three of the five mice in the 600-mg intraperitoneal group were euthanized or found dead after 20–24 days of Aze administration. The remaining mice in the 600-mg group and all the mice in the 300-mg group and control groups remained healthy. Mice that were euthanized early or found dead showed lethargy and weight loss; two also had tail paresis or paralysis. Some of the livers displayed mottled pale areas of hepatocyte vacuolization (Sobel et al., 2011).

Our collaborator in Canada, G. Harauz, has reported studies of myelin basic protein in recombinant *Escherichia coli*. These showed that Aze resulted in severe diminution in growth rate and that Aze was misincorporated in 3 of 11 possible sites in myelin basic protein. Molecular modeling led to the conclusion that Aze could cause a severe bend in the polypeptide chain and could disrupt a polyproline II structure (Bessonov et al., 2010a,b).

29.1.13 ATAXIN-2 and A2BP1 as Proline-Rich Proteins

These considerations have led to an analysis of compositional bias among the amino acids within ataxin-2 and A2BP1. The study revealed that ataxin-2 is exceptionally proline rich. Of its 1313 residues, a total of 177 are prolyls (13.4%). Positions 47–158 contain 30 prolyls among its 112 amino acids (26.8%), and within this sequence, prolyls comprise 7 of the 10 amino acids in positions 55–64. Among the 184 amino acids in positions 561–734, there are 44 prolyls (23.9%). Finally, there are 34 prolyls (21.7%) among the 157 amino acids in the sequence 929–1085 (UniProt ID Q 99700).

A2BP1 is less proline-rich, containing 40 prolyls among its 370 amino acids (10.8%). Noteworthy is the sequence PPPPIP, which occupies positions 281–286 (GenBank AA143817.1).

29.2 DISCUSSION

It is clear that Aze can displace proline in proteins and that such misassembly can have deleterious effects on protein structure, function, and immunogenicity. Whether Aze, introduced into the diet or into medicinal agents, has contributed to the shifting prevalence and

incidence of clinical disorders is unknown. The complexities associated with an ever-changing biosphere and with population shifts constitute nearly chaotic conditions that challenge epidemiology.

Caution is required before inferences are drawn.

Is it possible that a simple compound, a small and apparently innocent amino acid found in plants, has become a susceptibility factor in the pathogenesis of a broad spectrum of diseases in which genetic predisposition plays a critically important role? Well-planned studies will be required to address this question. These must take into account such confounding factors as dose and time and duration of exposure, from early embryonic life through adulthood.

Some supporting evidence can be accumulated by demonstrating that Aze is in the environment of those affected and that Aze is in their tissues and in the specific cells that are damaged, for instance, in central nervous system cells in the case of neurologic disease. In most instances, this would require examination of autopsy material from patients and from controls. If a suitable animal model exists, the administration of Aze in appropriate doses at appropriate states of development should reproduce illness. Finally, the removal of Aze, perhaps by washout with pure proline, might prove beneficial.

The group at Stanford is testing the reactivity of fresh T cells from patients with various diseases to synthetic proteins in which Aze has replaced proline in differing combinations and permutations.

It is important to proceed with great caution in forming conclusions. It is essential to avoid the needlessly damaging consequences of inappropriate disclosures disseminated by the popular media. The public needs to be reminded periodically about the significance of environmental hazards and that even sunlight, oxygen, and water can be detrimental. It will require ingenuity, collaborative effort, and persistence to identify the environmental agent that may underlie the suffering experienced by millions.

Down Syndrome

A.B. Bowman[1], K.C. Ess[1], K.K. Kumar[1], K.L. Summar[2]

[1]Vanderbilt University, Nashville, TN, USA; [2]George Washington University, Washington, DC, USA

OUTLINE

30.1 INTRODUCTION

Trisomy of human chromosome 21 (HSA21) is the genetic basis of Down syndrome (DS). DS is associated with a spectrum of developmental disabilities and physiological and health disturbances of varying penetrance. Despite the variability of DS-associated phenotypes, all individuals express some degree of intellectual disability.

Triplication of a large number of genes on one human chromosome has made basic research into the molecular genetics and the cellular and neuropathological basis quite challenging. Yet advancing our understanding of DS pathophysiology as well as identifying new interventional strategies requires living animal and cellular models. Herein lies the challenge; how can one most accurately model a disease caused by trisomy of an entire

human chromosome containing more than 400 individual genes? The best solution to date has been to duplicate large segments of syntenic regions of mouse chromosomes that carry subsets of genes located on HSA21. Alternatively, the insertion of segments of HSA21 into the mouse has also been employed to define specific genes that underlie aspects of the DS phenotype. Mouse models are, therefore, immensely valuable in deciphering genetic interactions of conserved human disease genes. But as the number of genes being studied grows, so does the risk of species-specific differences confounding the application of what can be learned in the mouse to the human disease. The recent advent of induced pluripotent stem cell (iPSC) technology offers the promise of human cellular models of DS that have full trisomy 21.

This chapter begins in Section 30.2 with a description of the DS genetic and clinical phenotypes, with an emphasis on neurological features. Section 30.3 details the experimental models of DS, with an emphasis on their utility and accuracy for translation to the human condition. Section 30.4 describes our current understanding of the neuroanatomical and functional correlates of the DS phenotype, with an emphasis on comparing research from experimental models with what is known about the human phenotype. These DS endophenotypes span both time (from embryonic neurodevelopment to adult aging) and scale (from molecular and cellular aspects up to local circuits and systems neuroscience). Section 30.5 outlines genotype–phenotype correlations in DS and the contribution of specific HSA21 genes as well as other genetic interactions with the DS endophenotypes. The chapter concludes with a discussion of directions for future research using iPSCs and consideration of potential therapeutic interventions.

30.2 DS MOLECULAR GENETICS AND CLINICAL PHENOTYPE

30.2.1 Trisomy of Human Chromosome 21 and the Molecular Genetics of DS

Euploid human cells contain 46 chromosomes (2N), including 22 pairs of autosomes and one pair of sex chromosomes (46,XX [female] and 46,XY [male]). Haploid human cells contain 23 chromosomes (N), which is characteristic of normal ovum and spermatozoa. Typical development is dependent upon the gene content of these chromosomes as well as chromosomal balance. Cells that do not contain an exact multiple of the haploid number of chromosomes are termed *aneuploid cells*. This abnormal chromosomal distribution is the most common and clinically significant type of human chromosome abnormality, occurring in 3–4% of all pregnancies (Lee and Summar, 2009). Human aneuploidies include

monosomies (one copy of a particular chromosome) and polysomies (more than two copies of a particular chromosome). The majority of aneuploid conceptuses are spontaneously lost during the first trimester of pregnancy. Nondisjunction is the most common mechanism of aneuploidy. When nondisjunction occurs, during meiosis I or meiosis II, gametes are created that either contain an extra chromosome or lack a copy of a chromosome. During conception, these abnormal cells combine with haploid gametes and result in monosomic or trisomic zygotes (Figure 30.1). Nondisjunction occurring later during mitosis results in a mosaic cell line. In addition to nondisjunction, chromosomal rearrangement such as translocation, partial duplication, and ring chromosome formation can result in aneuploidy.

Trisomy 21 is the quintessential example of aneuploidy in humans and results in the clinical phenotype of DS. This mechanism is responsible for the most common genetic cause of intellectual disability, occurring in 1 in 833 live births and making DS an excellent model for studying the relationship of genetics to neural function (http://www.cdc.gov/features/dsdownsyndrome). Individuals with DS have variations in neurodevelopment and neurodegeneration as well as disorders involving the central nervous system and other systems of the body. To further explore the complex relationship between aneuploidy, human development, and the clinical phenotype of DS, many researchers from diverse disciplines, including biologists, educators, physicians, and psychologists, have investigated pieces of the puzzle. A comprehensive review of all of these areas is beyond the scope of this text. The focus of this discussion is the influence of molecular genetics on the neurological phenotype of DS.

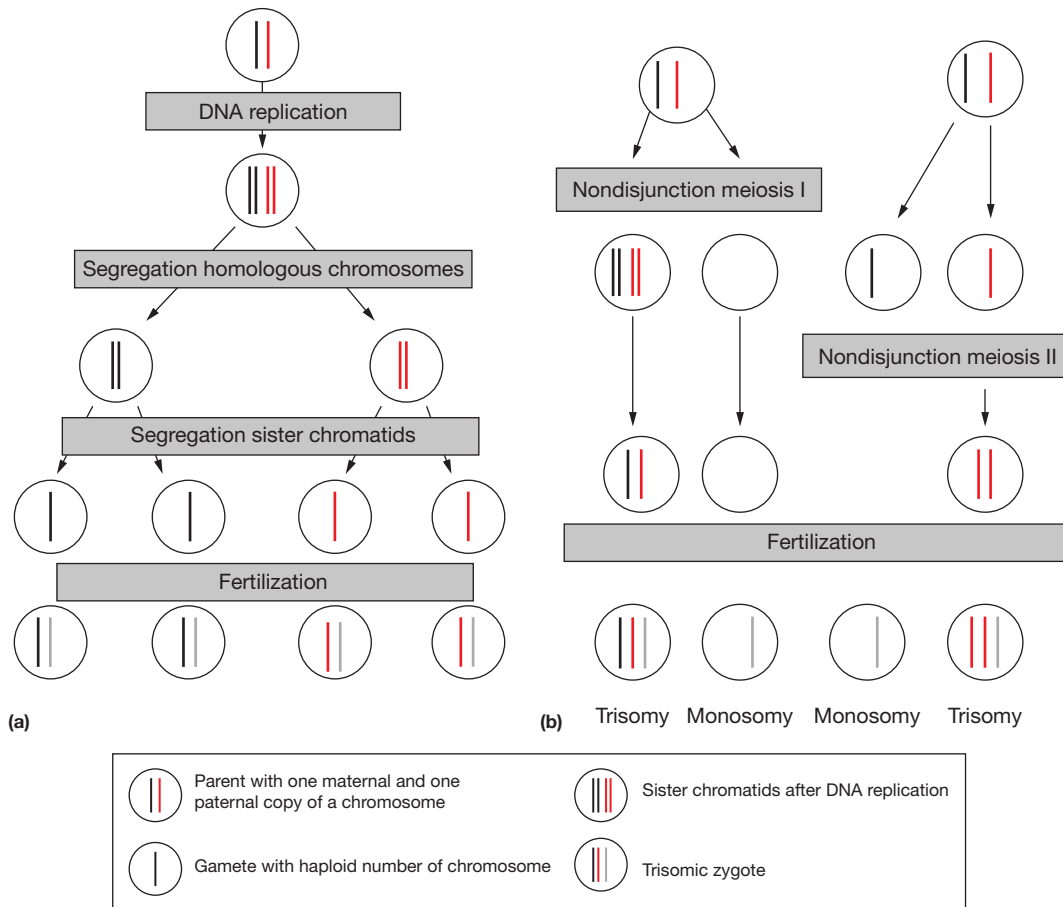
To elucidate the origins of the phenotypic features, scientists have approached aneuploidy and DS with the assumption that if a gene is present in three copies, the expression of that gene will be increased. The gene dosage hypothesis states that the increased expression of multiple trisomic genes directly leads to the features of DS (Antonarakis et al., 2004; Korbel et al., 2009). The amplified developmental instability hypothesis states that the phenotype is not directly due to specific genes on chromosome 21 but rather to a change in genetic balance and regulation (Patterson and Costa, 2005). Evidence of globally increased expression of genes on chromosome 21 in human fetal material has been documented by measuring mRNA levels (Mao et al., 2003). These same transcriptome studies failed to document the increased expression of genes not found on chromosome 21 in the same tissues. Proteomic studies have documented that mRNA from genes mapped to chromosome 21 translates into increased protein production in transgenic mice as well as in human tissues (Gulesserian et al., 2001; Tan et al., 1973; Wang et al.,


FIGURE 30.1 Meiotic nondisjunction. (a) Normal meiosis results in gametes with a haploid number of chromosomes. When fertilized with other normal gametes, a normal diploid state is reestablished. (b) In meiotic nondisjunction, two chromosomes migrate to the same daughter cell resulting in gametes with a diploid (or null) number of chromosomes. When fertilized with other normal gametes, abnormal trisomic or monosomic states are established. (a, b) Symbol key is provided in the box at the bottom of the figure.

1998). Recently, posttranscriptional regulators, including miRNAs, have been found to be overexpressed in DS brain and heart tissue specimens, resulting in a decreased expression of target genes, which very likely contributes to the DS phenotype (Kuhn et al., 2008).

Not only gene dosage, a factor in the phenotype of DS, but also gene content plays a crucial role. In 2000, through the collaborative work of many investigators, the complete DNA sequence of human chromosome 21 was published. This landmark work showed that human chromosome 21 is a relatively gene-poor chromosome, with 225 genes embedded in 33.8 Mb of genomic DNA compared with the 545 genes embedded in 33.4 MB of chromosome 22 (Hattori et al., 2000). With new sequencing technology, the number of genes on the human chromosome is now thought to be between 300 and 500 (http://www.ensembl.org). This finding of comparatively few genes on chromosome 21 offers a possible explanation of why trisomy 21 is compatible with postnatal survival and longevity whereas trisomy of HSA13, HSA15, and HSA22 are not. Finally, allelic variation of

chromosome 21, epigenetic factors, mosaic status, and environmental effects must be taken into consideration when studying the correlations between the genotype and phenotype of DS. There are some aspects of the phenotype of trisomy 21 that appear consistently in every individual with DS (i.e., facial appearance, intellectual disability, and generalized hypotonia). However, each of these common phenotypic features exhibits a great deal of variability in expression from one individual to another (e.g., intellectual disability ranges from mild to moderate cognitive impairment). Clearly, more work is needed to fully understand all the factors involved in these variations.

30.2.2 Neurodevelopmental and Neurodegenerative Features of the DS Phenotype

Historically, DS has been the prototypical intellectual disability disorder in research as well as in societal portrayals and thus implies a nonspecific alteration in brain

development and pathology. However, DS is associated with distinct neuroanatomic and neuropathologic findings that in turn present with specific cognitive deficits. Postmortem observations (Crome et al., 1966; Davidson, 1928; Wisniewski et al., 1985) and volumetric magnetic resonance imaging (MRI) studies (Aylward et al., 1997b, 1999; Emerson et al., 1995; Pearlson et al., 1998; Raz et al., 1995) indicate that people with DS have reduced total brain volumes, most notably in the frontal and temporal areas as well as the cerebellum. Altered temporal volume, architecture, and function in DS (particularly of the hippocampal area) are considered to be responsible, in part, for the cognitive deficits associated with DS (Pennington et al., 2003). Disturbances in cerebellar volume and architecture are associated with the generalized hypotonia of DS as well as the inability to learn new skills (Daum and Ackermann, 1995; Konczak and Timmann, 2007). A similar finding of reduced hippocampal volume in children with DS suggests that these are neurodevelopmental findings rather than neurodegenerative findings of an aging brain (Pinter et al., 2001a). By contrast, people with DS have normal volumes of subcortical areas, including the lenticular nuclei and posterior parietal and occipital gray matter.

Interest in the neuropathology of DS existed long before the genetic etiology was delineated. Pathologic findings characteristic of those seen in dementia of the Alzheimer's type were described in the brains of individuals with DS long before the normal number of human chromosomes was even determined (Jervis, 1948; Struwe, 1929). It is now known that virtually all adults with DS who have come to autopsy have the hallmark neuropathology of Alzheimer disease (AD), with prominent β-amyloid plaques and neurofibrillary tangles (NFTs). Furthermore, decreased numbers of apical dendritic spines of pyramidal neurons in the hippocampus and cingulate gyrus were noted when comparing the brains of people with DS to those of normal controls (Becker et al., 1986; Takashima et al., 1994). Significantly reduced dendritic spines, increased β-amyloid plaques, and increased NFTss in DS are considered to be specific findings that are not seen in other types of intellectual disability (Suetsugu and Mehraein, 1980).

Like the gross anatomical and histological findings, the cognitive phenotype found in individuals with DS is specific (Silverman, 2007). Cognitive deficits in DS are not uniform across all domains. Particular deficits exist in learning, memory, and language that lead to difficulty with intellectual functioning. To further complicate this issue, a great deal of variability exists between individuals. People with DS have difficulty with verbal short-term memory and explicit (episodic or conscious) long-term memory (Lott and Dierssen, 2010; Silverman, 2007). The function of explicit memory has been linked to the hippocampus (Squire, 1992), which has been shown to function abnormally in DS (Pennington et al., 2003).

Implicit memory – the ability to use previous experience to assist with the performance of a task without conscious awareness – is preserved in DS (Carlesimo et al., 1997). Prefrontal cortex function also affects explicit and working memory and has been shown to have deficits in DS (Nadel, 1999). This impairment seems to involve verbal information with sparing of visuospatial domains, offering a potential explanation of why people with DS learn better in an environment that includes visual materials in addition to verbal presentation (Frenkel and Bourdin, 2009; Lanfranchi et al., 2009). Morphology of grammar (internal structure of words) and syntax (how words are put together in phrases) are impaired in people with DS. The communication difficulties are specific to DS when compared to others with intellectual disabilities and mental age-matched controls. Communication is further complicated for people with DS because intelligibility is negatively affected by poor oral motor tone and anatomic factors of the mouth and pharynx (Abbeduto et al., 2001). New technologies, including functional imaging techniques such as functional MRI (fMRI) and spectroscopy, should allow for further studies of correlations between described cognitive and language deficits and brain function in humans with DS.

Longitudinal studies with adults with DS reveal the onset of cognitive decline (from baseline) in middle age similar to that seen in much older individuals without intellectual disability (Devenny et al., 1996, 2000). These observations along with the knowledge of the ubiquitous presence of amyloid plaques and NFTs in postmortem trisomy 21 specimens have led to many investigations into the risk of Alzheimer's type dementia in people with DS. Multiple studies of varying design have established that approximately 50–70% of adults with DS will develop dementia by age 60–70 years. Importantly, an alternative statement of these data is that some individuals with DS will survive dementia-free into old age (Devenny et al., 1996).

Understanding the genotype–phenotype relationship in DS may lead to a greater understanding of neurodevelopment and neurodegeneration through mechanisms involved in the gene dosage effect as well as gene balance and regulation. This has obvious application to the continued improvement of the lives of people with DS, but it may also lead to novel therapies for the general population that suffers from neurodevelopmental as well as neurodegenerative disorders of the central nervous system.

30.2.3 Other CNS Features of DS

As noted in Table 30.1, people with DS have increased risk for seizures, psychiatric disorders, and Alzheimer dementia. Alzheimer dementia was discussed in the

TABLE 30.1 Common medical comorbidities in children with Down syndrome

System	Finding
Ears, eyes, nose	Hearing loss (conductive and sensorineural), frequent and chronic otitis media, obstructive sleep apnea, glaucoma, cataracts (congenital and acquired), refractive errors, strabismus, nystagmus, amblyopia
Cardiovascular	Atrioventricular septal defect, ventricular septal defect, atrial septal defect, patent ductus arteriosus, tetralogy of Fallot, and persistent pulmonary hypertension; adolescents and young adults – mitral valve prolapse and aortic regurgitation
Endocrine	Diabetes mellitus, hypothyroidism, hyperthyroidism
Gastrointestinal	Constipation, celiac sprue (25%)
Hematological	Transient myeloproliferative disorder, leukemia
Neurological	Intellectual disability (mental retardation); hypotonia, seizures; psychiatric disorders, autism spectrum disorder
Orthopedic	Atlantooccipital instability, pes planus, subluxation of patella, developmental hip dysplasia
Dermatological	Hyperkeratosis, seborrhea, cutis marmorata, xerosis, folliculitis

previous section and will not be addressed here. Seizures have a bimodal distribution in DS with 40% of seizure disorders presenting in the first year of life and another 40% present in the third decade or later (Pueschel et al., 1991). Epilepsy in the very young can manifest as infantile spasms or generalized tonic clonic ('grand mal') seizures. Infantile spasms due to any etiology are associated with hypsarrhythmia, a specific electroencephalographic finding, and infants with DS and infantile spasms have more frequent diagnoses of an autism spectrum disorder later in life (Eisermann et al., 2003). Seizures presenting in adolescents and adults can be generalized tonic clonic or partial ('petit mal'). Both types of seizures are usually accompanied by some alteration of mental status that can be brief. This has led to missed diagnoses in people with DS as the seizures may be ascribed to a lack of focus or attention. Finally, age of seizure onset appears to be important in DS as adults older than 45 years are more likely to develop dementia, whereas early onset of seizures is not associated with dementia (Lott and Dierssen, 2010; Puri et al., 2001).

Behavioral and psychiatric disorders are more common in people with all intellectual disabilities when compared to the general population. However, people with DS score significantly lower on maladaptive behaviors when compared to people with other cognitive disabilities (Dykens and Kasari, 1997). Children with DS, for example, are frequently diagnosed with disruptive behaviors including attention deficit hyperactivity disorder, oppositional defiant disorder, or aggression (Myers and Pueschel, 1991). Less is known about behavioral and psychiatric problems in adolescents with DS. Preliminary data show that they may have fewer externalizing (disruptive) behaviors than their younger cohorts (Dykens et al., 2002). Adults with DS are more prone to depression when compared to the typical population and to others with intellectual disabilities (6–11% compared to 1–2%; Collacott et al., 1992). Historically, 'diagnostic overshadowing' has led to a failure to recognize co-occurrence of psychiatric illness in individuals with intellectual disability (Reiss et al., 1982). With improved recognition of these secondary disorders in this population, prompt treatment and eventually even more effective therapies may be discovered.

30.2.4 Non-CNS Features of DS

Some medical comorbidities occur more often in people with DS as compared to their typically developing peers, including congenital heart disease (100-fold increase; Ferencz et al., 1985), leukemia (30-fold; Hasle et al., 2000), and Alzheimer dementia (10-fold increase in DS; Zigman and Lott, 2007). Of the congenital heart lesions, the most common lesions are atrioventricular septal defects (45% of newborns with DS), ventricular septal defects (35%), atrial septal defects (8%), patent ductus arteriosus (7%), tetralogy of Fallot (4%), and others (1%) (Roizen and Patterson, 2003). Due to the prevalence of congenital heart disease in DS, the American Academy of Pediatrics recommends an echocardiogram and pediatric cardiology evaluation in every newborn with DS regardless of the presence of symptoms or physical findings (American Academy of Pediatrics and Committee on Genetics, 2011). Hearing loss (both conductive and sensorineural) and visual disturbances (glaucoma, cataracts, strabismus, myopia, astigmatism) occur with much more frequency in people with DS and can present in infancy through adulthood. For these reasons, vigilant screening of vision and hearing is recommended to prevent further deleterious effects on intellectual and adaptive functioning (American Academy of Pediatrics and Committee on Genetics, 2011; Roizen, 2002; Smith, 2001).

Advances in medical care have improved survival for people with DS (increasing from an average of 12 years in the 1940s to an average of 57.8 years for women and 61.1 years for men) (Bittles et al., 2007; Glasson et al., 2003). Despite this improved survival, there are many physical problems involving every organ system of the body that can affect people with DS. Additional studies are needed to better understand the impact of these

comorbidities on the intellectual and adaptive functioning of people with DS.

Just as secondary medical conditions can occur with increased frequency in DS, there are comorbidities that appear to be less common in DS than in the general population. For example, analysis of the causes of deaths between these groups revealed that mortality due to ischemic heart disease is less than one half and deaths due to solid tumors less than one tenth in DS patients compared to the general population (standardized mortality odds ratio of 0.42 and 0.07, respectively, for causes of death; Yang et al., 2002). Review of cancer registries has confirmed that people with DS have fewer solid tumors even though they have an increased risk of leukemia (Hasle et al., 2000). Two candidate genes from HSA21 have provided potential mechanisms for this 'protective factor' against solid tumors. The first gene is the Down syndrome candidate region 1 (DSCR1/RCAN1), which is a calcineurin inhibitor. DSCR1 is modestly overexpressed in transgenic mice, and this overexpression is sufficient to provide suppression of tumor growth by inhibiting angiogenesis by attenuation of calcineurin activity (Baek et al., 2009). Other mouse studies have implicated the upregulation of the oncogene Ets 2 as a possible factor in the prophylactic effect of trisomy 21 on solid tumor development (Sussan et al., 2008). Further studies need to be done to clarify this apparent advantage in cancer among people with DS and distinguish genetic from environmental differences. Potentially, novel therapeutic interventions for cancer in the general population could be designed by a better understanding of DS.

30.3 EXPERIMENTAL MODELS OF DS

30.3.1 Overview of DS Mouse Models

The need for animal models to study human development and disease has been recognized for millennia dating back to at least the time of Aristotle and Galen (Guerrini, 2003). The incredible pace of research during the last half century has allowed the creation of increasingly sophisticated and relevant animal models of many diseases. The mouse has become the favored model system given the well-defined anatomy and physiology of this species; completely sequenced genome; availability of robust quantitative assays of learning, memory, and anxiety; as well as a huge inventory of available tools including specific antibodies and genetic engineering to modify the mouse genome. This latter development continues to improve with refined and subtle manipulations now routine. However, modeling the complexity of a chromosomal human disease such as DS in the mouse has proven to be very difficult. This is due largely to evolutionary differences between mice and humans in the sequence, expression patterns, and function of many genes. Furthermore, HSA21 is not present in a direct orthologous fashion in mice as genetic material corresponding to that found on HSA21 is found mainly on mouse chromosomes 16 (Mmu16) but also on Mmu10 and Mmu17. Conversely, additional genes on Mmu16, Mmu10, and Mmu17 are not found on HSA21 and thus are likely not relevant to the study of DS. These evolutionary changes have made a 'simple' mouse model of DS very challenging. However, recent advances to allow complex genomic engineering have recently been achieved, leading to the recent creation of a mouse with trisomy of almost all the genetic information that is normally found on HSA21 (Yu et al., 2010). These models will likely be most informative when combined with single-gene knockouts to test whether three copies of specific genes contribute to the pathogenesis of DS and whether decreasing gene dosage can reverse the clinical features. Such findings would provide a clear rationale to selectively target identified pathways pharmacologically (Table 30.2).

30.3.2 DS Mouse Models with Mouse Additional Segments

Initial attempts to model DS reasoned that most HSA21 genes are found on a syntenic region of mouse chromosome 16. Animals with balanced chromosomal translocations were identified and then selectively bred to generate an Mmu16 trisomy mouse. These mice died *in utero*, likely because of cardiac and placental abnormalities (Miyabara et al., 1982). Additional relevant phenotypes include generalized edema and delayed development of the cerebral cortex. While these results strongly support that genes present on a syntenic region of HSA21 in the mouse are required for normal development, their lack of viability severely hampered further progress and determination of the relevance to DS. Furthermore, Mmu16 trisomy is unable to provide any information about the role of HSA21 orthologs found on Mmu10 and Mmu17. Finally, as Mmu16 contains multiple genes not found on HSA21, any results from these mice have to be interpreted with caution.

A major advance in DS research was the generation of a mouse with a balanced translocation of Mmu16 that corresponded closely to the syntenic region of HSA21 (Figure 30.2). Selective breeding of these animals allowed the generation of Ts65Dn mice that are trisomic for about 14 Mb of mouse DNA and contain the majority (at least 132) of the genes on HSA21 (Holtzman et al., 1996). Ts65Dn mice, however, have significant limitations including some mortality during early postnatal life and phenotypic variability. In addition, males are infertile, complicating the maintenance of this mouse

TABLE 30.2 Mouse models of DS

	Triplication	Abnormalities	Limitations	Reference
Mouse chromosome				
Mmu16	Entire Mmu16	Edema, abnormal cerebral cortex, heart defects, thymic hypoplasia	Lethal *in utero*, no Mmu10 and Mmu17 genes	Miyabara et al. (1982)
Ts65Dn	Partial Mmu16	Some perinatal death, cerebellar hypoplasia, cortical and hippocampal spine alterations, craniofacial dysmorphology	Perinatal death, no cardiac abnormalities, hyperactive, no Mmu10 and Mmu17 genes	Holtzman et al. (1996)
Ts1Cje	Partial Mmu16	Cerebellar hypoplasia, craniofacial dysmorphology, hippocampal spine alterations	No cardiac abnormalities, hypoactive, no Mmu10 and Mmu17 genes	Sago et al. (1998)
Ts1Rhr	Partial Mmu16	Increased size of mandible	Lack of CNS and cardiac phenotypes??	Olson et al. (2004)
Ms1Rhr	Deletion partial Mmu16	None	Lack of CNS phenotype	Olson et al. (2007)
Duplication of human chromosome				
Tc1	Extra copy of HSA21	Decreased density of cerebellar granule neurons, cardiac defects	Variable penetrance likely due to mosaicism	O'Doherty et al. (2005)
Chromosomal engineering				
Ts1Yah	Mmu17	Impaired working memory, enhanced spatial memory	No Mmu16 genes	Pereira et al. (2009)
Dp(10, 16, 17)	Mmu10, Mmu16, Mmu17	Impaired cognition, hippocampal-mediated deficits, hydrocephalus	Only initial characterization to date	Yu et al. (2010)

colony. While Ts65Dn mice exhibit no cardiac defects, over the years they have proven invaluable because of CNS and craniofacial abnormalities (Kurt et al., 2000; Roper et al., 2006b). The brain abnormalities include a small cerebellum with decreased numbers of granule neurons and Purkinje cells (Baxter et al., 2000). In addition, decreased spine density was seen on dendrites from hippocampal dentate granule neurons (Belichenko et al., 2004). The failure of Ts65Dn mice to more closely phenocopy DS should not be too surprising given the complexity of this syndrome and the lack of triplication of many additional orthologous genes that reside on Mmu10 and Mmu17. The Ts1Cje model (Figure 30.2) has also been used by many investigators and features a partial trisomy of Mmu16 though the region is smaller than in Ts65Dn containing approximately 85 orthologous genes (Sago et al., 1998). These mice have CNS abnormalities similar to those seen in Ts65Dn, including small cerebellums and abnormalities in the number of cerebellar granule cells, but not Purkinje neurons. Similar to Ts65Dn, decreased spine density with dendritic spine enlargement was seen in this model (Belichenko et al., 2007). Multiple histogenic and physiological processes have been examined in these mouse models, revealing important insights into a spectrum of DS-relevant phenotypes (see Sections 30.3.3 and 30.4 for more details).

While models with triplication of Mmu16 continue to provide important information about global DS phenotypes and preclinical testing, additional mouse models are clearly needed to more finely define genetic requirements for the pathogenesis of DS. Also, other models were needed to test the emerging hypothesis that trisomy of a 'critical region' of HSA21 (Down syndrome critical region, DSCR) is sufficient or required for the phenotypes seen in DS. This hypothesis was based on the identification of rare patients with DS that appeared to have trisomy of a relatively discrete region of HSA21. This hypothesis has been more rigorously tested in mice using Cre/LoxP technology to duplicate (Ts1Rhr) or delete (Ms1Rhr) an approximately 4-Mb region of Mmu16 containing the approximately 33 orthologous genes found in the DSCR (Olson et al., 2004). Interbreeding with wild-type mice then allows the production of animals with one or three copies of the mouse DSCR. A particularly elegant application of this technique was to breed Ms1Rhr mice to Ts65Dn or Ts1Cje mice. This allowed the generation of mice that were trisomic for genes within Ts65Dn or Ts1Cje but disomic within the DSCR. These Ms1Rhr/Ts65Dn mice did not reverse abnormalities of cranial morphology, and Ts1Rhr mice that were trisomic for just the DSCR also did not exhibit cranial abnormalities (Olson et al., 2004). CNS
FIGURE 30.2   Schematic of human and mouse chromosomes relevant to DS and comparison of the most commonly used mouse models. The majority of HSA21 orthologous genes are located on Mmu16 but they can also be found on Mmu10 and Mmu17. The commonly used Ts65Dn, Ts1Cje, Ts1Rhr, and Ms1Rhr/T65Dn mouse models of DS feature triplication of variable segments of Mmu16 as shown. The Ts1Rhr region contains the 'Down syndrome critical region' (DSCR). The names of specific genes are listed to denote the approximate beginning and end of each Mmu16 segment.

manifestations have not been extensively studied though trisomy of the DSCR in Ts1Rhr mice was insufficient to produce abnormalities of spatial learning (Olson et al., 2007). However, removing the DSCR region with Ms1Rhr/Ts65Dn mice reversed hippocampal-dependent memory deficits. In addition, detailed analyses of Ts1Rhr mice revealed an increased size of dendritic spines and decreased spine density as seen in Ts65Dn or Ts1Cje mice (Belichenko et al., 2009a,b). These models demonstrate that despite its name, genes within the DSCR are not sufficient for the craniofacial abnormalities and some of the CNS manifestations seen in DS. This approach again underscores a complex interplay of genes in the DSCR with non-DSCR genes located on Mmu16 as well as Mmu10 and Mmu17. A further study of the DSCR was recently reported with overexpression of RCAN1 (Dierssen et al., 2011). These mice have disruptions in visual–spatial learning similar to that seen in people with DS.

A similar technique of chromosomal engineering was used to make Ts1Yah mice that are trisomic for the syntenic region of Mmu17 including 12 orthologous genes found on HSA21 (Pereira et al., 2009). These mice have learning and behavioral abnormalities but enhanced spatial learning, which is typically a hippocampal-dependent process. These somewhat contradictory results firmly support the need for animal models that have genetic alterations of genes outside of Mmu16 and further underscore the complexity inherent to DS.

The most exciting recent advance using chromosomal engineering was the creation of a mouse model that is trisomic for essentially all the relevant portions of Mmu16, Mmu10, and Mmu17 that correspond to HSA21 (Yu et al., 2010). These Dp(10)1Yey/+, Dp(16)1Yey/+, and Dp(17)1Yey/+ mice (Dp(10, 16, 17)) exhibit impaired hippocampal-dependent learning and hippocampal long-term potentiation (LTP). In addition, a few Dp(10, 16, 17) mice had aqueductal stenosis and hydrocephalus. No potential abnormalities of the cerebral cortex or craniofacial or cardiac defects relevant to DS have been reported to date.

30.3.3 Transchromosomic DS Mouse Model Using Human DNA

While the new Dp(10, 16, 17) mouse described previously is very promising, alterations in DS may require increased expression of *human* genes and/or functional changes in *human* proteins. To address this possibility, mice have been generated using microcell-mediated chromosomal transfer (Shinohara et al., 2001). These Tc1 animals contain an approximately 42-Mb portion of HSA21 (O'Doherty et al., 2005). However, these animals are limited as a DS model because of loss of the human chromosome in a variable fashion in different organs and tissues. This mosaicism may be broadly similar to that seen in people with DS but significantly hampers the use of Tc1 mice for biomedical research.

30.3.4 Nonmouse Models of DS

While mouse models have dominated the field of DS research, additional models have been developed in *Drosophila*, *Caenorhabditis elegans*, and even yeast by modifying orthologous genes found within HSA21 (Guipponi et al., 2000; Moldrich, 2007; Tejedor et al., 1995). As discussed below, these additional model systems have allowed the testing of individual genes relevant to DS and the study of conserved gene expression and protein function (Chang and Min, 2005; Raich et al., 2003; Yu et al., 2009). *Drosophila* has been a particularly valuable and experimentally tractable system. For example, overexpression of any of the three HSA21 orthologs *dap160* (*ITSN1*), *synj* (*SYNJ1*), and *nla* (*DSCR1*) produced abnormalities in brain synaptic connections, but overexpression of all three genes impaired synaptic vesicle recycling and motor function (Chang and Min, 2009). Such 'simpler' model systems can complement existing

TABLE 30.3 Nonmouse models of DS

Organism	Gene alteration	Abnormalities	Limitations	Reference
Drosophila melanogaster	Overexpression of *dap160* or *synj* or *nla1*	Reduced recycling of neurotransmitter vesicles	Divergent evolution, lack of interactions with other DS-related genes	Chang and Min (2009)
Drosophila melanogaster	Overexpression of *dap160* and *synj* and *nla1*	Reduced recycling of neurotransmitter vesicles and impaired locomotion	Divergent evolution, studies limited to three overexpressed genes	Chang and Min (2009)
Drosophila melanogaster	Loss of *Dscam* exon 19	Impaired neural development and axonogenesis	Divergent evolution, unable to study interactions with other DS-related genes, unclear relevance to DS	Yu et al. (2009)
Caenorhabditis elegans	Overexpression of *mbk-1 (DYRK1A)*	Impaired odortaxis	Divergent evolution, unable to study interactions with other DS-related genes	Raich et al. (2003)
Homo sapiens	iPSC with trisomy 21	None reported	*In vitro* studies only	Park et al. (2008)

mouse models and test single and multiple gene function and interaction within the developing brain. Furthermore, these additional model systems may be well positioned to identify and test new therapies to ameliorate various brain phenotypes relevant to DS (Table 30.3).

30.3.5 Human Cellular Models of DS: Stem Cells and Patient-Specific Models of Disease

Mouse models of DS described above were generated with the express intent of identifying biological pathways altered by the trisomy of genes found on HSA21. As described above, these models include Ts65Dn, Ts1Cje, Ts1Rhr, Ms1Rhr, Tc1, Ts1Yah, and Dp(10, 16, 17). They have all contributed to our knowledge in defining genomic regions required for subsets of DS phenotypes including craniofacial and age-related neurodegeneration, cardiovascular phenotypes, learning and memory deficits, cerebellar hypoplasia, and partial penetrance neonatal lethality. These models may have served best by reaffirming the complexity of DS and the ongoing challenges in modeling a 'simple' trisomic disease. In addition, these mouse models have focused attention on a subset of HSA21 genes (e.g., *DSCR1*, *DYRK1A*, *APP*, and *SOD1*) and biological pathways (nuclear factor of activated T cells (NFAT) activation, Hedgehog signaling, and microtubule-based intracellular transport) that appear to play an important role in the generation of these phenotypes in the mouse models (see Section 30.4). The existing mouse models and other model organisms as described earlier suffer from limitations that are important to consider when applying research findings to DS. First, most of the models are trisomic for only a subset (one or more) of the homologous genes on HSA21 and as such fail to account for the impact of these other genes in the processes and phenotypes being studied. The generation of

the Tc1 model carrying an almost intact HSA21 largely overcame this problem. However, as described above, the mosaic loss of HSA21 from a significant portion of cells in these animals complicates the interpretation of the phenotypes in this model. Second, regulatory control of exogenous human genes may differ from that of their endogenous mouse counterparts; thus, the degree of overexpression of trisomic genes may not accurately model the expression of these genes in patients. Indeed, the lack of DS-like anatomical and morphological phenotypes in the Tc1 model may be due to differences in expression of human genes in the mouse. Third, genetic interactions with genes not found on HSA21 may show species-specific differences; thus, pathways identified in the mouse may play a stronger or weaker role in the human condition. Finally, there are several discrepancies between the mouse models and human patients including differences in skeletal modifications, absence of comparable gastrointestinal abnormalities, failure to observe cortical lamination defects, and hypoplasia of the cerebrum in the mouse models (Delabar et al., 2006). The recent creation of Dp(10, 16, 17) mice may circumvent many of these concerns though it remains possible that human genes and proteins have different pathological roles leading to the phenotypes seen in people with DS. Much more extensive evaluations of Dp(10, 16, 17) mice will be required to see if they will become the preeminent animal model for DS. Despite these shortcomings, trisomy mouse models are currently the best available research tool for studying the molecular pathophysiology of DS in a whole animal. However, a human-based neuronal/glial model of DS would address many of the caveats discussed here, facilitate the translation of research findings between human and animal research, and speed the discovery and testing of therapeutic targets.

At the end of 2007, three independent laboratories, headed by Shinya Yamanaka (Kyoto University), George Daley (Harvard Medical School), and James Thomson

(University of Wisconsin–Madison), generated pluripotent stem cells from adult human dermal cells with the developmental potential seemingly equivalent to that of human embryonic stem cells (Park et al., 2008; Takahashi et al., 2007; Yu et al., 2007). These iPSCs were found to be competent to generate all three major cell type lineages and resemble embryonic stem cells in their pluripotency and other important characteristics. Human iPSCs can be differentiated into embryoid bodies as has been done with human embryonic stem cells (Takahashi et al., 2007; Yu et al., 2007). Neural progenitor cells can be harvested from embryoid bodies and cultured prior to differentiation into neurons and glia (Yeo et al., 2007, 2008). The ability to generate iPSCs from human patients is anticipated to open up a new frontier of research into human disease. The study of the pathogenesis of DS represents an almost ideal application of this technology given the challenges of modeling trisomy of HSA21 in other model systems, as discussed earlier. Furthermore, the ability to differentiate neurons and glia from DS iPSCs offers a chance to examine in detail changes in both the development and maintenance of neural function caused by trisomy HSA21 in the context of human cells. Finally, the relative ease to expand, maintain, culture, and differentiate iPSCs will enable this resource to be utilized by a broader range of research laboratories around the world, expanding both the scope and depth of DS research being pursued. To date, there has been a single report of iPSCs being generated from trisomy 21 fibroblasts (Park et al., 2008). This is an important 'proof of principle' and establishes that trisomy of HSA21 does not prevent the reprogramming process required to make iPSCs and that this exciting new technology can be effectively applied to the study of DS.

30.4 NEUROLOGICAL AND FUNCTIONAL CORRELATES OF THE DS PHENOTYPE

Research efforts to better understand the cellular and functional basis of the DS phenotype have followed a two-pronged strategy. The first strategy is to characterize and define the neurological, functional, and neuroanatomical correlates of the DS genotype in human patients. This enables understanding of the specific neurological phenotypes associated with DS. The second strategy seeks to refine this knowledge by a detailed study of the molecular, cellular, and functional correlates of the DS genotype using experimental model systems. Under this approach, researchers have sought to understand the pathophysiological basis of the DS phenotype by characterizing and identifying the myriad observable differences between DS and control groups and developing a hierarchy of potential cause–effect relationships between biomarkers of the disease and the behavioral, cognitive, and neurological challenges facing patients. Thus, phenotypes in DS animal and cellular models are consistently compared and contrasted to the clinical phenotypes of the DS patient. This approach seeks to increase scientific confidence in the accuracy of DS model systems to recapitulate the pathophysiology of trisomy HSA21. Here, we examine known DS model phenotypes and their possible relationships with known DS phenotypes. Studies on phenotypic correlates of the DS genotype fall under two broad categories: (1) studies examining the influence of specific trisomic genes to particular DS phenotypes and (2) studies using models with multiple trisomic genes (from several genes up to near-complete representation of HSA21 genes) to better understand the cellular, behavioral, and functional correlates of the DS genotype.

30.4.1 Behavioral, Motor, and Cognitive Alterations

Mouse models of DS have been carefully examined for cognitive, motor, and behavioral deficits consistent with the intellectual disability, motor, and behavioral features associated with DS. The specific nature of the DS phenotype has been extensively characterized as well as compared and contrasted with other developmental disorders. The intellectual quotient of individuals with DS averages about 50 (Contestabile et al., 2010; Vicari, 2004; Vicari et al., 2000, 2005). However, mental retardation is insufficient to explain the specific pattern of neuronal functional domains affected in DS. For example, despite similar or even less severe mental retardation, the distinctive characteristics of children with DS, compared to children with other developmental and intellectual disabilities, have been recognized as advantageous for their rearing and social integration (Corrice and Glidden, 2009). Individuals with DS exhibit a decreased risk for maladaptive behaviors, psychopathology, or emotional disturbance compared to others having a similar degree of mental retardation (Dykens, 2007). However, DS individuals carry a tenfold larger risk for a comorbid diagnosis of autism than the general population (Molloy et al., 2009). Despite this, social interactions and repetitive movements are not considered a part of the core DS phenotype (Corrice and Glidden, 2009; Dykens, 2007; Molloy et al., 2009; Zigler and Hodapp, 1991). Instead, speech and language difficulties, along with learning and memory deficits, are the principal phenotypic features of DS (Contestabile et al., 2010). In addition, individuals with DS show elevated gaze fixation and decreased scanning for novel stimuli in the environment, as well as subdued emotional responsiveness (Zigler and Hodapp, 1991). Also, significant delays

in the development of cognitive and neurological milestones are reported for DS (Nadel, 2003). Hippocampal and prefrontal cortical dysfunction appears to be at the core of these deficits (Nadel, 2003). Declines in both short- and long-term memory as well as in memory consolidation have been reported, with deficits in both visual–spatial as well as verbal memory. Finally, a large portion of patients with DS exhibit a progressive cognitive decline with aging and the pathological features of AD.

Several recent reviews summarize the behavioral phenotypes of DS mouse models (Contestabile et al., 2010; Rachidi and Lopes, 2007). Common behavioral abnormalities in these models include decreased fear conditioning, decreased novel object recognition and long-term memory, decreased spatial learning and memory, hypoactivity and decreased exploratory behavior, and delayed acquisition of sensorimotor skills. These behavioral phenotypes are consistent with the human DS phenotype and arguably validate these models for mechanistic study and detailed characterization. By far the most widely used and extensively characterized of these models is the Ts65Dn segmental trisomy mouse model (Figure 30.2). Characterization of these mice revealed a significant developmental delay in acquisition of sensorimotor behaviors (Holtzman et al., 1996). Of particular note was a delay in the pattern of ultrasonic vocalizations, possibly similar to the delay in speech seen in human DS children (Holtzman et al., 1996). The newest and most complete mouse segmental trisomic DS genetic model, Dp(10, 16, 17), exhibits deficits in hippocampal-dependent learning and memory by the Morris water maze test, in which trisomic animals spent significantly less time searching for a hidden platform in the target quadrant as well as the contextual fear conditioning test (Yu et al., 2010). Analysis of the HSA21 'transchromosomic' mouse model, Tc1, also revealed spatial learning and memory deficits by Morris water maze and novel object memory deficits (Morice et al., 2008; O'Doherty et al., 2005). However, while defects in short-term spatial and novel object memory were detected, long-term memory appeared to be intact. This is in contrast to the Ts65Dn model, which exhibits deficits in long-term memory of novel objects (Fernandez and Garner, 2008), or the Ts1Cje model, which has normal performance in short- and long-term novel object memory tests (Fernandez and Garner, 2007). The basis for these discrepancies in DS mouse models is unresolved. Possible explanations include (1) the inclusion of different partially overlapping sets of HSA21 gene or related genes in the various models, (2) difficulties in modeling the influence of human trisomy in a rodent model, and (3) environmental factors or experimental differences that may influence mouse behavior experiments.

Genetic dissection of DS mouse phenotypes, to attribute specific HSA21 genes or chromosomal regions to the DS phenotype, has received considerable attention in the field. Approaches to asking questions on the role of genes specific to the DS phenotype take advantage of various mouse models with partially overlapping sets of triplicated genes, for example, the analysis of novel object memory in the Ts65Dn and Ts1Cje lines mentioned earlier (Fernandez and Garner, 2007), as the Ts65Dn line contains additional genetic material homologous to HSA21 not found in the Ts1Cje line. Comparison of partially overlapping segmental trisomic mouse models can provide insight into the genetic basis of the DS behavioral phenotypes. For example, the work of Epstein and colleagues with the Ts65Dn, Ts1Cje, and Ms1Ts65 lines examined correlations between motor activity and learning and memory by Morris water maze between the *App* to *Sod1*, *Sod1* to *Mx11*, and *App* to *Mx1* genetic intervals (Sago et al., 2000). However, complexities and differences in phenotypic penetrance have made clear genotype–phenotype correlations challenging. This complexity is further exemplified by work on a segmental trisomic model (Ts1Yah) that contains genes found in the subtelomeric region of HSA21 (*Abcg1* to *U2af1*) from Mmu17 and genes that are excluded from the widely used Ts65Dn, Ts1Cje, and Ms1Ts65 mice, which include only HSA21 homologous genes found on Mmu16 (Pereira et al., 2009). The Ts1Yah line exhibits deficits in novel object recognition, but improvements above control lines for spatial memory (Pereira et al., 2009). This work again revealed additional complexity in the combinatorial genotype–phenotype correlations that could contribute to the overall DS phenotype.

A complementary approach to genetic dissection of HSA21 genes and their contribution to the DS phenotype is to perform detailed phenotypic characterization in single-locus genetic models. For example, a BAC transgenic model of the *Abcg1* locus found no alterations in behavioral tests for anxiety or working memory (Parkinson et al., 2009). While these results suggest that the *Abcg1* locus does not contribute to the cognitive deficits in DS, caution must be taken in drawing this conclusion, given that the potential influence of other HSA21 loci cannot be ruled out. A *Dyrk1a* BAC transgenic model, in contrast, exhibited profound learning and memory deficits on the Morris water maze test (Ahn et al., 2006). While these results strongly suggest that *Dyrk1a* contributes to learning and memory deficits in DS, caution must also be taken concerning this conclusion as its relative contribution in the context of full trisomy HSA21 is unknown. Another example is the *Sim2* transgenic lines that display anxiety-related behaviors similar to those found in segmental trisomy models that include *Sim2* such as Ts65Dn (Chrast et al., 2000). In addition to overexpression models, genetic knockout of

HSA21 homologous genes may also inform us about the role of genes in the DS phenotype. For example, the *RCAN1* null mouse exhibits deficits in spatial learning and memory as well as contextual learning (Hoeffer et al., 2007). The phenotype is similar to lines with elevated calcineurin activity. Closer study revealed the *RCAN1* null mouse has elevated activity in this pathway (Hoeffer et al., 2007). Functional analysis of HSA21 genes can provide mechanistic insight into the neural pathways underlying behavioral phenotypes.

30.4.2 Neurogenesis

DS is associated with reduced brain size (∼80% of typically developing humans) from very early in development (∼5-month fetuses) through adulthood (Pinter et al., 2001b; Schmidt-Sidor et al., 1990; Winter et al., 2000). Both hypocellularity and hypoplasia likely contribute to this phenotype (Contestabile et al., 2010). Several regions of the brain are affected including the neocortex (entorhinal, frontal, prefrontal, and temporal cortices), hippocampus, amygdala, cerebellum, hypothalamus, and brainstem (Aylward et al., 1997a, 1999; Contestabile et al., 2010; Kesslak et al., 1994; Pine et al., 1997; Raz et al., 1995; Sylvester, 1983; Teipel and Hampel, 2006; Teipel et al., 2003, 2004). Several studies converge upon particularly substantial decreases in brain volume for the hippocampus and temporal lobe. Indeed, behavioral- and neural activity-based animal studies have focused upon phenotypic abnormalities of the hippocampus in part for this reason. Neurogenesis defects, reductions in the numbers of neurons generated in development, are likely to substantially contribute to reduced brain size in DS and have been observed in both DS fetuses and children (Contestabile et al., 2010; Guidi et al., 2008; Larsen et al., 2008; Wisniewski, 1990; Wisniewski et al., 1984). Schmidt-Sidor and colleagues examined brains of fetuses of 15–22 weeks gestational age and from birth to 60 months of age and reported that initial defects occur sometime between 22 weeks of age and birth (Schmidt-Sidor et al., 1990). Thus neurogenesis defects likely represent the earliest neurological phenotypic evidence of the DS genotype. Indeed, some of the earliest descriptions of neurological phenotypes in mouse models of DS (e.g., trisomy Mmu16) are reports of neurogenesis defects in these models (Haydar et al., 1996; Sweeney et al., 1989).

Detailed characterization and mechanistic studies in animal models of DS, such as the Ts65Dn and Ts1Cje, have confirmed defects in cell proliferation and neurogenesis (Chakrabarti et al., 2007; Contestabile et al., 2009a,b; Moldrich et al., 2009). In agreement with rodent models, a human neuroprogenitor model of DS revealed that despite similar initial production of neurons, progenitors with trisomy HSA21 produced fewer neurons when cultured for over 10 weeks (Bhattacharyya et al., 2009). Examination of granule cell precursors from the Ts65Dn mouse revealed that prolonged G1 and G2 phases of the cell cycle contributed to decreased proliferation (Contestabile et al., 2009a). Examination of cortical and hippocampal neuroprogenitors in the Ts65Dn model also revealed evidence of a longer cell cycle contributing to reduced neurogenesis (Chakrabarti et al., 2007; Contestabile et al., 2007). Furthermore, reductions in neurogenesis in the Ts65Dn mouse model are associated with decreased synaptogenesis in the first postnatal week (Chakrabarti et al., 2007). Multiple neuronal cell types are potentially influenced by alterations in neurogenesis and neurodevelopment, including the serotonergic, noradrenergic, GABAergic, and cholinergic neurons (Bar-Peled et al., 1996; Dierssen et al., 1997; Fiedler et al., 1994; Granholm et al., 2000; Kleschevnikov et al., 2004; Whittle et al., 2007). Finally, the neurogenesis defect may not occur only in development, as the Ts1Cje line exhibits a reduction in adult neurogenesis with a concomitant rise in production of astrocytes (Hewitt et al., 2010).

DYRK1A is a member of the dual-specificity tyrosine-regulated kinase family that maps to HSA21 21q22.2. The *Drosophila* homolog of *DYRK1A, minibrain* (*mnb*), is required for postembryonic neurogenesis. Loss of *mnb* causes reduced optic lobes and central brain likely caused at least in part by abnormal spacing of neuroprogenitors in the larval brain (Tejedor et al., 1995). This gene family shares homology with other kinases involved in regulation of cell division. The DYRK kinase family is so named because of its autophosphorylation of tyrosine residues in its YXY activation loop and serine/threonine phosphorylation of its protein substrates. The subsequent mapping to HSA21, findings of early neural expression in humans and rodents, and overexpression in DS brain and the Ts65Dn mouse model drew attention to this gene as a candidate for contributing to the neurogenesis and neurodevelopment phenotypes in DS patients (Guimerá et al., 1996; Guimera et al., 1999; Shindoh et al., 1996; Song et al., 1996). Decreased expression of the mouse homolog causes developmental delay and alteration in brain morphology (Fotaki et al., 2002). To more specifically examine the influence of this gene on neurogenesis in DS, D'Arcangelo and colleagues overexpressed mouse *Dyrk1A* in the cortex by *in utero* electroporation (Yabut et al., 2010). They report that overexpression promotes neuronal maturation while inhibiting proliferation of neural progenitors (Yabut et al., 2010). Minimal influence of cell fate was observed, suggesting that *Dyrk1A* acted predominantly by influencing production of neurons rather than alterations in the neurodevelopmental program itself. Furthermore, these phenotypes were dependent on kinase

activity and nuclear export and protein degradation of cyclin D1 (Yabut et al., 2010). In further support of a role of this gene in regulation of neurogenesis and brain size, patients with a loss of the *DYRK1A* gene present with microcephaly (Fujita et al., 2010; Moller et al., 2008).

Other genes likely also contribute to defects in neurogenesis and neurodevelopment. For example, the *Olig1* and *Olig2* genes contribute to an imbalance in excitatory and inhibitory neuronal systems (Chakrabarti et al., 2010). While many neuronal populations exhibit decreased numbers, examination of the Ts65Dn model revealed an increase in the parvalbumin and somatostatin subclasses of inhibitory neurons, with no change in the number of calretinin inhibitory neurons (Chakrabarti et al., 2010). Restoration of disomy to the *Olig1* and *Olig2* genes was found to rescue this phenotype. Other genes that may contribute include *TTC3*, which has been shown to inhibit neuronal differentiation in a cell culture model (Berto et al., 2007). *Sim2* plays a critical role in *Drosophila* neurogenesis (Chrast et al., 2000), and the HSA21 gene *Sim2* mouse homolog exhibits CNS-specific expression patterns consistent with a role in mammalian neurogenesis (Rachidi et al., 2005). Finally, altered responses to key neuronal proliferative signaling systems may also underlie alterations in neurogenesis. Cerebellar granule neuron precursors normally exhibit a strong mitogenic response to the morphogen Sonic hedgehog (SHH). Purified granule neuron precursors from the Ts65Dn model were found to have a significantly reduced proliferative response to SHH (Roper et al., 2006a). Interestingly, administration of a small molecule agonist of the SHH signaling pathway (Smoothed Agonist) was able to rescue the decreased proliferative phenotype of these cells (Roper et al., 2006a). In summary, a complex interplay of developmental signaling and altered expression of multiple HSA21 genes likely contributes to the DS neurogenesis phenotype.

30.4.3 Regional Connectivity and Development of Neural Circuits

One plausible explanation for the learning and memory deficits and other psychiatric and cognitive phenotypes associated with DS is a failure to set up the normal neural circuits and appropriate brain regional connectivity in development. Thus, in addition to alterations in the numbers and types of neurons generated during development (discussed earlier in Section 30.4.2), the establishment of abnormal brain circuitry during development is also hypothesized to contribute to the DS phenotype. However, less work has been done in this area relative to studies examining the contribution of alterations in neurogenesis and/or changes in neuronal activity at the cellular level. Indeed,

reported alterations in brain morphology are often attributed to alterations in regional neurogenesis rather than changes in the neural circuits themselves (Contestabile et al., 2010; Rachidi and Lopes, 2007). MRI studies of people with DS indicate the potential of structural changes (e.g., disproportionate loss of volume in the cerebellum, hippocampus, and a subregion of the superior temporal gyrus and increased subcortical gray matter) to underlie DS cognitive and behavioral phenotypes (Frangou et al., 1997; Pinter et al., 2001a,b; Raz et al., 1995). A recent fMRI study of children with DS during a story-listening task revealed reduced activation of receptive language areas (superior and temporal gyri; Losin et al., 2009). Likewise, a magnetoencephalography study has suggested that cortical activation patterns during motor tasks and motor observational tasks are less coherent in the DS brain, showing broader activation patterns and reduced lateralization (Virji-Babul et al., 2010). Finally, changes in amino acid and monoamine neurotransmitters (e.g., serotonin, dopamine, and GABA) in the DS fetal brain also suggest defects in the development of neural circuits (Whittle et al., 2007). Despite evidence that alterations in brain structure and connectivity underlie mental retardation in DS and other developmental disorders, there is growing recognition that ameliorative therapy may still be possible (Dierssen and Ramakers, 2006).

As mentioned previously, a prominent feature of the DS phenotype is reduced brain size. Detailed three-dimensional quantification of brain morphology by high-resolution MRI in the Ts65Dn and Ts1Rhr models has examined the relative contribution of changes in brain volume and brain shape to this phenotype (Aldridge et al., 2007). Such analysis demonstrates severe reductions in cerebellar volume, with minimal volume loss in other brain regions (Aldridge et al., 2007), confirming early observations of reduced cerebellar volume in the Ts65Dn model as well as DS patients (Baxter et al., 2000; Scott et al., 1983). Interestingly, the Ts1Rhr model shows a subtle decrease in overall brain volume, with a relative sparing of the cerebellum (Aldridge et al., 2007). This suggests that genes triplicated only in the large segmental trisomic Ts65Dn model may be responsible for the reduced cerebellar volume phenotype. Furthermore, it is noteworthy that overall brain shape, measured using 29 independent morphological landmarks, is unchanged in the Ts65Dn model (Aldridge et al., 2007). One interpretation of these findings is that alterations in the cell number and perhaps degree of connectivity (see below) may be more important for the DS phenotype than dysmorphic or improper/aberrant neural connections across different brain regions.

Specific HSA21 genes have been implicated in the connectivity and neural circuitry phenotypes in DS. The triplicated *Dscam* gene functions in neuronal morphogenesis and connectivity by contributing to establishment of

diverse neural connectivity patterns in development (Gao, 2007; Schmucker, 2007; Yu et al., 2010). In addition, mosaic spacing, axonal targeting, and appropriate arborization of the neuronal pathways in the mouse and *Drosophila* brain require *Dscam* (Fuerst et al., 2008; Hattori et al., 2007; Hummel et al., 2003). Additional evidence for altered connectivity was acquired indirectly by measures of cellular transport between the hippocampal to forebrain circuit. That the circuit appears to be intact, and indeed more robust than wild type, suggests that this circuit is not functioning properly in Ts65Dn mice (Bearer et al., 2007). Lastly, alterations in the structural features on synapses likely contribute to the DS phenotype. Lucifer yellow injections into neurons of the hippocampus and cortex of the Ts65Dn model revealed enlarged dendritic spines and other changes in synaptic architecture (Belichenko et al., 2004). The *Dyrk1a* gene (trisomic in both Ts65Dn and Ts1Rhr models) has been strongly implicated in defects in both neuronal morphology and connectivity by altering synapse formation and dendritic architecture (Contestabile et al., 2010). Heterozygosity (loss of a single allele) of *Dyrk1a* in the mouse alters cortical circuitry by decreasing dendritic branching and spines (Benavides-Piccione et al., 2005), perhaps via alterations in cAMP-responsive element-binding protein or NFAT activity (Arron et al., 2006; Hammerle et al., 2003). Furthermore, alterations in the Notch signaling pathway due to increased Dyrk1a activity could contribute to alterations in neural developmental pathways in DS (Fernandez-Martinez et al., 2009). Additional evidence for alterations in neural circuitry comes from analysis of electrophysiological alterations in the hippocampus revealing increased connectivity despite reduced excitatory and inhibitory inputs (Hanson et al., 2007). An important question for potential therapeutic intervention is whether these and other changes in neuronal morphology can be altered once established. Evidence in favor of this view is emerging, based in part on improvements in cortical pyramidal cell dendritic and spine phenotypes associated with environmental enrichment in Ts65Dn models (Dierssen et al., 2003). Interestingly, such environmental enrichment-related alterations in brain structure correlate with amelioration of behavioral, cell signal transduction, and neurogenesis phenotypes in the Ts65Dn model (Baamonde et al., 2011; Chakrabarti et al., 2011; Martínez-Cué et al., 2005). These data add to a growing awareness that even neuronal structure-related phenotypes in DS may be amenable to clinical intervention (Dierssen and Ramakers, 2006).

30.4.4 Neuronal Dysfunction in DS

Alterations in neuronal function are diverse, as expected given the DS genotype. Our discussion of a key subset of altered cellular function is split into four broad categories below.

30.4.4.1 Plasticity and Synaptic Function

There is evidence for alterations in both excitatory and inhibitory circuits in DS. Loss of asymmetric synapses (predominantly excitatory), without changes in the number of symmetric synapses (predominantly inhibitory), in the cortex of the Ts65Dn model suggested that the excitatory circuits may be the first to be affected (Kurt et al., 2000). However, detailed examination revealed alterations in the size of symmetric synapses (Belichenko et al., 2009a,b). Furthermore, immunostaining for markers of inhibitory neural circuits revealed increased calretinin GABAergic synapses in the cortex of the Ts65Dn model (Pérez-Cremades et al., 2010). Modulatory circuits may also be affected, as suggested by the loss of striatal interneuron LTP in the Ts65Dn model (Di Filippo et al., 2010). Indeed, changes in synaptic plasticity have been observed throughout the brain including decreased LTP in the hippocampus (Hanson et al., 2007; Kleschevnikov et al., 2004; Siarey et al., 1997). LTP and LTD deficits have also been reported in the Ts1Cje DS mouse model (Siarey et al., 2005). Importantly, the most complete of the segmental trisomic mouse models, the Dp(10, 16, 17) mouse model, validated electrophysiological and corresponding behavioral deficits (Yu et al., 2010). Changes in a pair associative stimulation (PAS) paradigm confirmed these findings of LTP deficits in DS patients (Battaglia et al., 2008). Reduced activation of NMDA receptors, increased $GABA_B$ potassium currents, and elevated rates of mESPCs in the Ts65Dn model likely contribute to the changes in synaptic plasticity (Best et al., 2007, 2008; Kleschevnikov et al., 2004). Depressed hippocampal LTP was found to be suppressed by pharmacological interventions that increase inhibitory tone (Kleschevnikov et al., 2004). The GIRK2 potassium channel, encoded by an HSA21 gene, has also been implicated in changes in the balance of excitatory and inhibitory transmission in DS (Best et al., 2007; Harashima et al., 2006). Another HSA21 gene, *RCAN1*, regulates LTP via phosphatase signaling (Hoeffer et al., 2007). Additionally, LTP and LTD are altered in a *DYRK1A* BAC transgenic model overexpressing this single HSA21 gene (Ahn et al., 2006).

Careful expression analysis of functional components has revealed subtle defects in synaptic functional components in DS. Proteomic analysis of synaptosomal fractions in Ts65Dn mice suggested that the overall composition of synaptic proteins is similar to that in wild-type animals (Fernandez et al., 2009), though careful quantitative assessment of key components (e.g., NR2A, GAD65/67, VGAT, GluR2, Cdk5, neurotrophin-3, and $GABA_A$ receptor) has revealed subtle changes (Altafaj et al., 2008; Belichenko et al., 2009a,b; Pérez-Cremades et al., 2010; Pollonini et al., 2008). One contributing genetic factor is likely to be trisomic expression of *Dyrk1a*, which has been linked to changes in

NR2A expression and calcium transients (Altafaj et al., 2008). The HSA21 gene *SYNJ1* encoding Synaptojanin 1 is a key regulator of the phosphatidylinositol signaling and metabolism that is required for normal neuronal transmission (Voronov et al., 2008).

30.4.4.2 Genetic and Proteomic Dysregulation

The most obvious of the cellular changes expected in DS are gene expression differences due to the extra copy of all HSA21 genes. However, likely due to the complexities of gene regulation, not all HSA21 genes are overexpressed by the expected 1.5-fold (Ait Yahya-Graison et al., 2007; FitzPatrick et al., 2002; Mao et al., 2003, 2005). Indeed, these studies revealed genes on HSA21 whose expression was either unchanged from diploid, overexpressed beyond what is expected from the dose alone, or even downregulated (FitzPatrick, 2005; Rachidi and Lopes, 2008). Furthermore, genes located on other chromosomes also have been found to exhibit profound differences in expression. These results from human tissues have been corroborated across DS mouse models including the Ts1Cje and Ts65Dn (Amano et al., 2004; Hewitt et al., 2010; Kahlem et al., 2004; Moldrich et al., 2009; Wang et al., 2004).

Clearly, the magnitude of expression differences dictates the phenotype, and the temporal and physical pattern of expression contributes as well to the phenotypic consequences of DS. HSA21 gene and HSA21 gene homolog expression maps have been generated to identify tissues and brain regions where and when HSA21 genes are expressed and misexpressed in DS (Gitton et al., 2002; Kahlem et al., 2004; Reymond et al., 2002). The influence of trisomy HSA21 is further complicated by the finding that overexpression of the HSA21 homolog Dyrk1a is sufficient to elicit global changes in cortical gene splicing that are also seen in DS fetal brain samples (Toiber et al., 2010). Thus, even a single gene whose expression is altered by trisomy can influence gene expression throughout the genome. Finally, changes in gene expression do not consistently result in matching changes in protein levels. Thus recent analysis of the DS proteome will also be necessary to achieve an accurate model of the cellular consequences of the DS genotype (Delom et al., 2009; Patterson, 2009; Shin et al., 2006, 2007).

30.4.4.3 Dysregulation of Vital Cellular Processes

The transcriptome and proteome alterations in DS potentially lead to diverse dysregulation of vital cellular processes. For example, several HSA21 genes have been functionally linked to membrane and vesicular trafficking. The HSA21 homologous gene, *Itsn1*, plays a role in endocytic processing and vesicular trafficking (Yu et al., 2010). Misexpression of the HSA21 homolog of β-amyloid precursor protein (β-APP) contributes to

alterations in nerve growth factor (NGF) transport (Salehi et al., 2006), while the *DSCR1/RCAN1* homologue regulates vesicle exocytosis (Keating, 2008). Other changes include alterations in the levels of myo-inositol in the brain, altered proteolytic processing of APP, and increased sensitivity to genotoxic stress (Beacher et al., 2005; Micali et al., 2010; Tansley et al., 2007).

30.4.5 Aging and Neurodegeneration

Neurodegeneration in DS is known to produce significant cognitive deficits and declines in patients afflicted with this illness. The pathogenesis of the disease is thought to be based on several major age-related processes: the formation of amyloid plaques, the degeneration of basal forebrain cholinergic neurons (BFCNs), and increased production of reactive oxygen species (ROS). Neurodegenerative mechanisms contribute to DS cognitive impairment given that early-onset AD occurs with an extremely high prevalence in these individuals (Contestabile et al., 2010). These neurodegenerative processes are known to have a strong genetic component, as several genes promote amyloidosis and respond to oxidative stress in the pathophysiology of DS. As the lifespan of DS individuals has increased significantly in recent years, obtaining greater understanding of pathways critical to the neuropathology of DS has been an active area of research that may yield future therapeutic targets to halt the progression of neurological symptoms.

30.4.5.1 DS and the Formation of Amyloid Plaques and NFTs

Individuals with DS present in the clinic with formations of amyloid plaques and progressive degeneration of BFCN (Casanova et al., 1985; Lockrow et al., 2009; Mufson et al., 2003). The presentations of senile plaques generally occur during middle age and are highly similar to that observed in the pathology of AD. The formation of these AD-type brain lesions occurs by the fourth decade of life, which is 20–30 years earlier in onset than patients suffering from AD (Iqbal and Grundke-Iqbal, 2010; Iqbal et al., 2010). These plaques are causally related to overexpression of β-APP whose gene is triplicated in DS (Contestabile et al., 2010). Full-length β-APP is proteolytically cleaved by β- and γ-secretase generating Aβ peptides, which then form plaques in the DS brain (Contestabile et al., 2010). Aβ lesions in the form of this 'preamyloid' appear by around 12 years of age (though they have been described in the DS neonatal brain as well) and are described as amorphous non-fibrillar aggregates with few dystrophic neurites (Contestabile et al., 2010; Giaccone et al., 1989; Kida et al., 1995; Lemere et al., 1996; Mann and Esiri, 1989; Motte and Williams, 1989; Wisniewski et al., 1994). These

preamyloid plaques progress to mature Aβ plaques that are associated with neuronal damage and generally appear during the third decade of life (Contestabile et al., 2010; Lemere et al., 1996; Wisniewski et al., 1994). Current research suggests that in addition to amyloidosis, overproduction of Aβ can trigger early cognitive impairment in dementia by modulating synaptic activity (Contestabile et al., 2010; Conti and Cattaneo, 2005; Gasparini and Dityatev, 2008). Aβ aggregates block LTP in excitatory synapses and enhance LTD by inhibiting glutamate receptors and downregulating *N*-methyl-D-aspartate receptors (NMDARs; Contestabile et al., 2010; Lambert et al., 1998; Li et al., 2009; Shankar et al., 2008; Townsend et al., 2006; Walsh et al., 2002; Wang et al., 2002).

In addition to Aβ, intraneuronal inclusions of hyperphosphorylated tau, a microtubule-stabilizing protein, develop in the proximal dendrites and cell bodies of neurons and within dystrophic neurites (Contestabile et al., 2010; Gasparini et al., 2007). Abnormal phosphorylation of tau causes the formation of NFTs, neuropil threads, and plaque dystrophic neurites associated with various neocortical tauopathies that cause dementia (Grundke-Iqbal et al., 1986a,b, 1988; Iqbal et al., 1986, 1989, 2009; Lee et al., 1991). In addition, Aβ and tau lesions are known to impact many brain regions in DS such as the prefrontal cortex, hippocampus, basal ganglia, thalamus, hypothalamus, and midbrain (Contestabile et al., 2010; Wisniewski et al., 1985). These lesions are believed to mediate the cognitive decline and dementia associated with DS.

The age-dependent DS phenotypes in the central nervous system are not restricted to cognitive processes but they also impact the visual system. DS patients present with distinctive early-onset cerulean cataracts, 'blue dot' cataracts that emerge at the equatorial periphery of the lens (Moncaster et al., 2010). The lenses of DS individuals have a characteristic pattern of supranuclear opacification accompanied by accumulation of Aβ, amyloid pathology, and fiber cell Aβ aggregates (Moncaster et al., 2010). Laboratory experiments have demonstrated that incubation of human lens protein in synthetic Aβ promoted light scattering, protein aggregation, and amyloid formation suggesting that the DS lens phenotype is a genetic cataract (Moncaster et al., 2010).

30.4.5.2 Degeneration of BFCNs in DS

In addition to amyloid plaque formation, degeneration of BFCNs and decreased activity of choline acetyltransferase with increasing age has been observed in DS. One of the most significant symptoms associated with death of cholinergic neurons in DS patients is memory loss (Ginsberg et al., 2006; Lockrow et al., 2009). In addition, BFCNs are responsible for providing the majority of cholinergic innervations to the hippocampus

and cortex and play a significant role in attention and cognition in both humans and mouse models (Lockrow et al., 2009; Perry et al., 1977; Whitehouse et al., 1982). In particular, DS-related cognitive declines and adult-onset degeneration of BFCNs are observed in Ts65Dn mice (Chen et al., 2008; Cooper et al., 2001; Granholm et al., 2000; Holtzman et al., 1996; Lockrow et al., 2009). These results are not unexpected, as there is a triplication of amyloid precursor protein (*App*) gene in the Ts65Dn mouse (Cataldo et al., 2003; Lockrow et al., 2009). *App* triplication in the Ts65Dn mouse also influences early endosomal processes, NGF trafficking, and loss of BFCNs (Lockrow et al., 2009; Salehi et al., 2006). Interestingly, these declines occur despite absence of amyloid plaques in the Ts65dn mouse model (Seo and Isacson, 2005).

30.4.5.3 ROS, Oxidative Stress, and Neurodegeneration in DS

Based on the close mirroring of the neuropathological findings between DS and AD, the role of mitochondria, specifically oxidative stress, has been highly implicated in the pathogenesis of DS. After development of a prooxidant state early in the progression of the disease, individuals suffering from DS demonstrate elevated levels of DNA damage and lipid peroxidation (Jovanovic et al., 1998; Lockrow et al., 2009; Pallardo et al., 2006). Furthermore, cortical neurons in DS individuals show elevation in ROS, which contributes to neuronal degeneration and induction of apoptosis (Busciglio and Yankner, 1995; Lockrow et al., 2009). Decreased levels of endogenous antioxidants such as α-tocopherol, an inhibitor of lipid peroxidation, have been demonstrated in patients with AD; however, no evidence for a protective effect has been reported for DS individuals (Azzi et al., 2003; Lockrow et al., 2009). ROS elevation does not determine the fate of cortical neurons, as administration of antioxidants such as vitamin E has been shown to be restorative (Behar and Colton, 2003; Lockrow et al., 2009; Schuchmann and Heinemann, 2000). This may provide a therapeutic window into improvement of learning and memory in DS patients.

30.4.5.4 Genetic Component of Neurodegeneration in DS

Genetics also plays a profound role in the development of plaques and NFTs. The protein dual-specificity tyrosine phosphorylation-regulated kinase 1A (DYRK1A) is a serine/threonine kinase that has activity both in neurodevelopment as well as in neurodegeneration (Contestabile et al., 2010). Upregulation of DYRK1A has been demonstrated in DS. This enhancement of expression may result in hyperphosphorylation of tau that further phosphorylates glycogen synthase-3β causing tau self-aggregation into NFTs (Contestabile et al., 2010; Liu et al., 2008). DS

does not solely associate with upregulation of DYRK1A, but its kinase activity is also enhanced, further promoting assembly of tau into filaments (Iqbal et al., 2009; Liu et al., 2008). Similarly, Down syndrome critical region 1 (*DSCR1*), a calcineurin inhibitor, is thought to play a role in DS given its important role regulating mitochondrial function and oxidative stress. *DSCR1* functions as a stress response element as it is upregulated in reaction to elevated hydrogen peroxide (Contestabile et al., 2010; Crawford et al., 1997; Lin et al., 2003). Despite this critical role in reducing oxidative damage to cells, chronic overexpression of *DSCR1* in the context of DS has a number of negative side effects consistent with an AD-type degenerative process (Contestabile et al., 2010). DSCR1 inhibits the Ca2+/calmodulin-dependent protein serine/threonine phosphatase calcineurin and regulates synaptic activity (Contestabile et al., 2010; Ermak et al., 2002; Fuentes et al., 2000; Kingsbury and Cunningham, 2000). DSCR1-mediated inhibition of calcineurin can lead to increased NMDAR mean open time and opening probability, which alters neuronal excitability in the brain (Contestabile et al., 2010; Lieberman and Mody, 1994). In addition to modulating synaptic excitability, calcineurin acts to dephosphorylate tau, and inhibition of this pathway leads to a pathological hyperphosphorylation of tau that correlates with cognitive impairment (Contestabile et al., 2010; Gong et al., 1996; Luo et al., 2008; Yu et al., 2006).

30.5 GENETIC MECHANISMS UNDERLYING DS

The prevailing model of the genetic mechanism underlying the DS phenotype is the 'gene dosage effect' model (Contestabile et al., 2010; Patterson, 2007; Rachidi and Lopes, 2007; Roper and Reeves, 2006; Salehi et al., 2007). This model suggests that individual genes along HSA21 each contribute to specific endophenotypes that culminate in the overall DS phenotype. This is likely an oversimplification, as it does not take into account genetic interactions among HSA21 genes. Thus, the emergent influence of interactions between multiple trisomic genes has also been proposed as a genetic mechanism in DS. However, this model can be viewed as just an elaboration of the 'gene dosage' model that accounts for genetic interaction effects. Indeed, strong evidence exists to support such a role of genetic interactions between HSA21 genes in the DS phenotype. For example, overexpression of homologs for three HSA21 genes (*ITSN1*, *SYNJ1*, and *DSCR1*) alters synaptic function in *Drosophila*, but restoring expression of just one ameliorates this phenotype (Chang and Min, 2009). Likewise, substantial evidence exists supporting a role for functional interactions between the HSA21 genes *DSCR1* and *DYRK1A* (de la Luna and Estivill, 2006). The concept

of the DSCR has been put forward to support the hypothesis that a subset of genes on HSA21 contributes to many of the major DS traits (Contestabile et al., 2010; Patterson, 2009). Extensive phenotyping of mouse models that contain portions of the DSCR has elucidated genetic intervals that contribute to specific brain-related and other phenotypes (Belichenko et al., 2009a,b; Olson et al., 2007). In addition, case reports of patients with microdeletions and/or small segmental duplications have furthered the correlation of gene interval with specific DS endophenotypes; some recent notable examples are cited here (Eggermann et al., 2010; Fujita et al., 2010; Kondo et al., 2006; Lyle et al., 2009; Ronan et al., 2007; Sato et al., 2008). Lastly, nonspecific effects of the genetic imbalance caused by trisomy have the potential to modify global expression patterns to contribute to the DS phenotype (Contestabile et al., 2010; Patterson, 2007; Rachidi and Lopes, 2007; Roper and Reeves, 2006; Salehi et al., 2007). Together, these three genetic mechanisms are thought to underlie the complex genotype–phenotype correlations that exist in DS.

30.6 TRANSLATIONAL AND THERAPEUTIC STRATEGIES IN DS

As detailed above, owing to the strength of evidence that mouse models of DS display clinically relevant phenotypes, researchers have begun to explore pharmacological and other intervention strategies for therapeutic benefit. Therapeutic strategies range from very early phenotypes (e.g., decreased neurogenesis) to behavioral phenotypes (e.g., learning and memory deficits, anxiety) and neurodegenerative phenotypes (e.g., cognitive decline). For example, given the reduced levels of serotonin in the DS fetal brain, the selective serotonin reuptake inhibitor fluoxetine was tested for rescue of the reduced neurogenesis phenotype in the Ts65Dn model (Clark et al., 2006; Whittle et al., 2007). Indeed, 2- to 3-week treatment paradigms increased neurogenesis in the hippocampus, subventricular zone, cortex, and striatum (Bianchi et al., 2010; Clark et al., 2006). Fluoxetine treatment was also found to restore expression levels of the serotonin 1A receptor (5-HT1A) and brain-derived neurotrophic factor (BDNF) as well as to show improvement in a hippocampal-dependent memory task (Bianchi et al., 2010). The NMDA receptor uncompetitive antagonist memantine is FDA-approved for treatment of moderate to severe AD. Memantine was subsequently shown to rescue memory task deficits, reduced neuronal number in the hippocampus, and decreased vesicular glutamate transporter-1 (VGAT1) expression (Costa et al., 2008; Rueda et al., 2010). More recent studies in the Ts65Dn mouse model suggest therapeutic potential for GABA$_A$ receptor inverse agonists or β1-adrenergic

receptor agonists in amelioration of cognitive phenotypes (Braudeau et al., 2011; Faizi et al., 2011). In addition, nutritional manipulation has also shown therapeutic promise, for example, perinatal choline, vitamin E, or green tea extract supplementation (Guedj et al., 2009; Lockrow et al., 2009; Moon et al., 2010). Future studies aimed at counteracting the influence of trisomy HSA21 genes and dysregulated gene networks provide promise of therapeutic intervention.

30.7 SUMMARY

Trisomy of HSA21 perhaps yields a remarkably mild clinical phenotype in the face of the profound genetic insult expected from triplication of over 400 genes. The complexity of the genetics raises an incredible challenge to elucidate genotype–phenotype correlations across the constellation of endophenotypes and incomplete penetrance that contribute to the clinical presentation of this disorder. Experimental models of DS range in complexity, model organism, and genetic completeness. But without doubt, the mainstay of DS basic research has been mouse genetic models with trisomy of mouse chromosomal regions that are syntenic to HSA21 (e.g., Ts65Dn and Dp(10, 16, 17)). However, *Drosophila*, *C. elegans*, yeast, other model organisms and human cell lines also provide important tools in dissecting the function and interactions of HSA21 genes. The recent generation of DS iPSC lines yields the promise of human neuronal models of disease for mechanistic and translational studies. The major neurological phenotypes associated with DS include (1) behavioral, motor, psychiatric, and cognitive alteration; (2) deficient neurogenesis during development and perhaps in adulthood; (3) alterations in neural connectivity and synaptogenesis; (4) neuronal dysfunction including deficits in plasticity; and (5) neurodegenerative features similar to AD. Analysis of the genetic mechanisms underlying DS has revealed a prominent role for a subset of HSA21 genes. This provides hope that therapeutic targeting of specific functional deficits can ameliorate DS endophenotypes and provide clinical and behavioral benefits.

Lissencephalies and Axon Guidance Disorders

E.H. Sherr, L. Fernandez

University of California, San Francisco, CA, USA

OUTLINE

31.1 INTRODUCTION: DISORDERS OF AXON GUIDANCE

During development, neurons extend their axons over long distances to form connections with synaptic targets (Lin et al., 2009; Schmidt et al., 2009). For this process to occur, a choreographed sequence of events must take place (Garbe and Bashaw, 2004; Izzi and Charron, 2011; Lin et al., 2009; O'Donnell et al., 2009). First, neurons and their surrounding target tissues must be specified to express the correct complement of receptors and guidance cues, respectively (Garbe and Bashaw, 2004; Izzi and Charron, 2011; O'Donnell et al., 2009). Second, receptors must be assembled into the appropriate complexes and localized to the axonal or dendritic growth cones, whereas guidance cues must be correctly trafficked to and localized within the extracellular environment (Garbe and Bashaw, 2004; Izzi and Charron, 2011; O'Donnell et al., 2009). Third, signaling mechanisms must be in place to integrate and transmit signals from the surface receptors to changes in the growth cone actin cytoskeleton, resulting in stereotyped steering decisions (Garbe and Bashaw, 2004; Izzi and Charron, 2011; O'Donnell et al., 2009). Each of these steps provides many potential levels for the regulation of axon guidance decisions (Garbe and Bashaw, 2004). These processes of axon guidance are controlled by the so-called axon guidance proteins (Schmidt et al., 2009), and remarkably, only a handful of human disorders resulting from primary errors in these processes have been identified (Engle, 2010).

The physician's ability to detect disorders of axon guidance has been augmented by classic, pathological, radiological, and electrophysiological techniques (Engle, 2010). Diagnostic radiological and postmortem neuropathological studies detect overall changes in white matter volume and major abnormalities of axon tracts demarcated from the background, such as the corpus callosum, anterior and posterior commissures, optic chiasm, and cerebellar peduncles (Engle, 2010). Neuropathological studies can also detect the absence of axons that normally cross the midline at many points in the brain stem and spinal cord, which are more difficult to visualize by standard magnetic resonance imaging (MRI) (Engle, 2010). Electrophysiological studies such as evoked potentials can reveal aberrant central connections of peripheral sensory or motor nerves (Engle, 2010). Exciting advances in neuroimaging and genetics are revolutionizing the ability to define axon guidance disorders (Engle, 2010). Detailed fiber tract anatomy can now be visualized using noninvasive tractography such as diffusion tensor imaging (DTI) and diffusion spectrum imaging (Engle, 2010). These techniques provide tract orientation by determining the anisotropic properties of water diffusion and can be used to reconstruct the trajectories of fiber systems in three-dimensional space (Tovar-Moll et al., 2007; Wahl et al., 2009). Human genetics also is providing unbiased approaches to identify the etiologies of disorders with aberrant axon tracts (Engle, 2010). For some syndromes, animal and *in vitro* studies have confirmed that the encoded protein has a primary role in axon guidance (Engle, 2010). For others, such studies reveal a primary role in neuronal specification and migration rather than, or in addition to, a role in axon guidance (Engle, 2010). Some neurodevelopmental disorders without clinical, pathological, or radiological evidence of aberrant axon tracts have been found to result from mutations in genes that contribute to axon guidance in animal models (Engle, 2010).

The major human genetic disorders that result, or are proposed to result, from defective axon guidance include genetic mutations that alter axon growth cone ligands and receptors, downstream signaling molecules, and axon transport, as well as proteins without currently recognized roles in axon guidance (Engle, 2010). For example, mutations in the β-tubulin isotype III (*TUBB3*) gene have been identified in a series of autosomal dominant disorders of axon guidance, which are known as the *TUBB3* syndromes (Tischfield et al., 2010). Understanding mechanisms of axon growth and axon guidance are critical to elucidating developmental disorders (Yu et al., 2010).

31.2 LIGAND/RECEPTOR SYSTEMS MEDIATING AXON GUIDANCE

During development, neuronal growth cones, the highly motile, specialized structures at the tips of extending axons, follow specific pathways and navigate series of intermediate choice points to find their correct targets (Allen and Chilton, 2009; Bush and Soriano, 2009; Cooper, 2002; Izzi and Charron, 2011; Kaprielian et al., 2001; Nie et al., 2010; O'Donnell et al., 2009; Richards et al., 2004; Schmidt et al., 2009). Pathway selection by axons is oriented by a large variety of short- and long-range guidance cues distributed along the entire pathway, to which different axons respond differently (Barkovich et al., 2009; Bush and Soriano, 2009; Cooper, 2002; Izzi and Charron, 2011; Kaprielian et al., 2001; Richards et al., 2004; Schmidt et al., 2009). Axon guidance proteins can be either secreted or associated with membranes (Kaprielian et al., 2001; Schmidt et al., 2009). In the case of secreted proteins, gradients are formed that enable them to signal over long distances, whereas membrane-bound molecules are responsible for local signaling (Schmidt et al., 2009). Generating precise patterns of connectivity depends on the regulated action of conserved families of guidance cues and their neuronal receptors (Bashaw and Klein, 2010;

Kaprielian et al., 2001; Schmidt et al., 2009). Cell surface receptors residing on growth cones and their associated axons interpret these signals as positive/attractive or negative/repulsive forces (Bush and Soriano, 2009; Izzi and Charron, 2011; Kaprielian et al., 2001; Schmidt et al., 2009). Local regulation of protein synthesis and degradation in the axon also contribute to the rapid changes in growth cone dynamics that occur during axonal navigation (Nie et al., 2010).

Identifying the molecules responsible for guiding growing axons to their target is only the first step; it is crucial to know how they are localized within the neuron itself (Allen and Chilton, 2009). The intracellular signaling cascade initiated on detection of the guidance cue by the axon-bound receptor triggers dynamic rearrangements of the actin cytoskeleton within the growth cone, promoting cycles of extension and retraction of filopodia at the leading edge (Bashaw and Klein, 2010; Cooper, 2002). This allows continual reassessment of the immediate environment by the growth cone (Cooper, 2002). In the case of chemoattraction, movement along the desired trajectory is achieved by elongation of the actin cytoskeleton, leading to the promotion of filopodia extension toward the source of the guidance cue (Cooper, 2002). In contrast, chemorepulsion promotes actin depolymerization and filopodia retraction, resulting in growth cone collapse and ultimately migration away from the ligand source (Cooper, 2002).

Several phylogenetically conserved families of guidance cues and receptors have been discovered (Chiappedi and Bejor, 2010; Koeberle and Bahr, 2004; O'Donnell et al., 2009; Schmidt et al., 2009). The four classic ligand/receptor systems mediating axon guidance are (1) semaphorins (sema) and their plexin (plex) and neuropilin receptors, (2) netrins and their DCC and UNC5 receptors, (3) slits and their roundabout (Robo) receptors, and (4) ephrins and their Eph receptors (Koeberle and Bahr, 2004; Lin et al., 2009; Nie et al., 2010; O'Donnell et al., 2009; Schmidt et al., 2009). It is the type of receptor, or receptor complex, expressed on the growth cone's surface, rather than a given guidance cue, that determines the direction of axon growth (Cooper, 2002; O'Donnell et al., 2009). Additional protein families previously recognized for other developmental functions have been implicated in growth cone guidance, including sonic hedgehog (SHH), bone morphogenetic proteins (BMPs), and wingless-type (WNT) proteins (Chiappedi and Bejor, 2010; Giger et al., 2010; O'Donnell et al., 2009; Schmidt et al., 2009). For example, WNT proteins have been identified as axon guidance proteins that play a role in guiding commissural axons from the spinal cord to the brain (Giger et al., 2010; Schmidt et al., 2009).

The expression of guidance cues and receptors is exquisitely tailored to allow growth cones to make appropriate path-finding decisions at specific times and places throughout development (O'Donnell et al., 2009). A wide variety of mechanisms are in place to ensure the correct presentation and receipt of guidance signals, ranging from spatially and temporally restricted transcriptional regulation of cues and receptors to their specific posttranslational trafficking (Chiappedi and Bejor, 2010; O'Donnell et al., 2009).

Secreted guidance cues, such as netrins and slits, have been shown to act as long-range cues, secreted from intermediate or final targets, and are presumed to form a chemotactic gradient along the pathway of the exploring growth cone (Cooper, 2002). In other instances, these factors can behave as short-range guidance cues, where they act over a distance of only a few cell diameters to affect changes in the direction of growth cone migration at specific choice points (Cooper, 2002). The molecular mechanisms that can influence the spatial distribution of guidance cues are the interaction with heparin sulfate proteoglycans, protein components of the extracellular matrix or axon-bound proteins, and selective proteolytic cleavage of the guidance protein (Cooper, 2002). Guidance receptors transport their ligands along axons to new locations distant from their points of synthesis, thereby determining their spatial distribution (Cooper, 2002).

Regulating the delivery of guidance receptors to the growth cone plasma membrane can have profound influences on axon growth and guidance; the regulation of receptor expression at the cellular level is not only strictly confined to surface expression but also includes regulated removal by endocytosis (Bashaw and Klein, 2010; O'Donnell et al., 2009). Endocytosis may be a necessary aspect of guidance receptor activation and signaling (Bashaw and Klein, 2010). In several cases, receptor endocytosis seems to be an obligate step in receptor activation that is evoked by ligand binding, whereas other examples point to the modulation of guidance responses by receptor endocytosis that is triggered by an independent pathway (O'Donnell et al., 2009). Endocytosis of guidance receptors also is influenced by other membrane receptor systems and can lead to changes in responsiveness to the guidance cue (Bashaw and Klein, 2010). In addition to contributing to receptor signaling, endocytosis can also modulate axon responses by regulating which receptors are expressed at the surface of the growth cone (O'Donnell et al., 2009).

Similar to endocytosis, proteolytic processing contributes to receptor activation and modulates guidance responses (Bashaw and Klein, 2010; O'Donnell et al., 2009). A role for proteolysis in axon guidance was supported by a number of early studies demonstrating that growth cones secrete proteases, and investigators proposed that cleavage of extracellular matrix components is required to advance through the extracellular

environment (O'Donnell et al., 2009). Later, genetic screens for defects in axonal navigation at the midline in Drosophila implicated the Kuzbanian ADAM (a disintegrin and metalloprotease) family transmembrane metalloprotease in the regulation of axon extension and guidance at the midline (O'Donnell et al., 2009). Several additional studies have implicated ADAM metalloproteases and matrix metalloproteases in contributing to axon guidance *in vivo* in both invertebrate and vertebrate nervous systems (O'Donnell et al., 2009).

ADAM10 forms a stable complex with ephrin-A2, and when EphR interacts with ephrin-A2, the resulting ligand–receptor complex is clipped by selective ADAM10-dependent cleavage of ephrin-A2; cleavage events are restricted to only those ephrin ligands that are engaged by receptors (Bashaw and Klein, 2010; O'Donnell et al., 2009). Ligand/receptor binding and formation of an active complex expose a new recognition sequence for ADAM10, resulting in the optimal positioning of the protease domain with respect to the substrate (Bashaw and Klein, 2010; O'Donnell et al., 2009). The ligand dependence of the cleavage event provides an elegant explanation for how an initially adhesive interaction can be converted to repulsion and offers an efficient strategy for axon detachment and attenuation of signaling (Bashaw and Klein, 2010; O'Donnell et al., 2009). The matrix metalloprotease family can play a similar role in converting ephrinB/EphB adhesion into axon retraction by specific cleavage of the EphB2 receptor (Bashaw and Klein, 2010; O'Donnell et al., 2009). Thus, both ephrin ligands and Eph receptors can be substrates for regulated proteolysis, and these proteolytic events seem to be critical in mediating axon retraction (Bashaw and Klein, 2010; O'Donnell et al., 2009). There also seems to be a common regulatory mechanism for the DCC and a number of ephrin ligands in which metalloprotease-mediated ectodomain shedding is followed by intramembranous gamma-secretase cleavage (Bashaw and Klein, 2010; O'Donnell et al., 2009).

31.2.1 Ephrins and Their Eph Receptors

Ephrins are members of a family of guidance molecules that are either anchored to the cell membrane by a glycosylphosphatidylinositol (GPI) linkage or have a transmembrane domain (Bush and Soriano, 2009; Kaprielian et al., 2001; Koeberle and Bahr, 2004). The ephrin/eph family has a variety of important functions, including axonal outgrowth and pruning, neuronal connectivity, synaptic maturation and plasticity, and neuronal apoptosis (Bush and Soriano, 2009; Lin et al., 2009). The Eph receptors represent the largest family of receptor tyrosine kinases in the mammalian genome and regulate various signaling pathways through a number of downstream effectors, including guanine nucleotide

exchange factors (GEFs), guanosine triphosphatase (GTPase)–activating proteins, tyrosine kinases, phosphatases, and adaptor proteins (Nie et al., 2010). Eph/ephrin signaling is important in the formation of retinal connections, other axonal projections, and the corpus callosum (Nie et al., 2010).

The interaction of the Eph receptor tyrosine kinase family with their membrane-bound ligands, the ephrins, drives axon path-finding throughout the developing central and peripheral nervous systems via a chemorepulsive mechanism (Cooper, 2002; Giger et al., 2010). However, it has been shown that chemoattractive functions for ephrins also exist (Koeberle and Bahr, 2004). Eph receptors and their ephrin ligands both are capable of transmitting signals in the cell in which they are expressed: Eph receptor signaling is termed *forward signaling* and ephrin ligand signaling is termed *reversed signaling* (Bashaw and Klein, 2010; O'Donnell et al., 2009). The capacity for bidirectional signaling is a hallmark of the Eph/ephrin signaling system. In addition to their ability to signal through cognate Eph tyrosine kinase receptors, ephrins can also transduce a reverse signal into the cell in which they are expressed (Bush and Soriano, 2009). Binding of ephrin ligands triggers Eph receptor clustering, autophosphorylation, and downstream signaling cascades, which cause cytoskeletal rearrangements and changes in cell adhesion (Nie et al., 2010). Through these mechanisms, Eph receptors control axon turning, retraction, and branching (Nie et al., 2010).

Ephrin ligands and Eph receptors contribute to the guidance of retinal ganglion cell (RGC) axons in the visual system (Koeberle and Bahr, 2004; Nie et al., 2010; O'Donnell et al., 2009). Endocytosis of activated Eph receptors at the growth cone is necessary to allow for proper forward signaling, leading to growth cone retraction (Allen and Chilton, 2009; O'Donnell et al., 2009). In the case of membrane-associated ephrins, endocytosis of the ephrin–Eph complex is required for efficient cell detachment (parallel to proteolytic cleavage; Bashaw and Klein, 2010). Vav family GEFs have been implicated as regulators of Eph receptor endocytosis, signaling, or both (Bashaw and Klein, 2010). Vav proteins may trigger Eph internalization into signaling endosomes from where Eph receptors mediate dynamic changes of the actin cytoskeleton underlying growth cone collapse (Bashaw and Klein, 2010). Alternatively, Vav proteins may act in concert with other regulators of Rho GTPases to regulate Eph repulsive signaling, independent of endocytosis (Bashaw and Klein, 2010). For ephrinB-EphB–induced repulsive guidance, efficient cell detachment requires bidirectional endocytosis (Bashaw and Klein, 2010). Vav proteins may primarily promote cell detachment by mediating local Rac-dependent endocytosis of the ephrin–Eph complex and membrane (Bashaw and Klein, 2010).

Ephrin-A5 has been shown to act as a repulsive cue for somatosensory thalamocortical (TC) axons expressing EphA receptors in the TC system (Torii and Levitt, 2005). It seems to control the topography of TC projections within cortical areas (Torii and Levitt, 2005). Analysis of EphA/ephrin-A mutants suggests that ephrin-A5 signaling may also control the specificity of TC projections into individual cortical areas by regulating the positioning of TC axons within the subcortical telencephalon (ST) (Torii and Levitt, 2005). Gradients of EphA7 and ephrin-A5 exhibit complementary expression patterns from embryonic to postnatal ages, consistent with putative molecular interactions during development (Torii and Levitt, 2005). It has been hypothesized that ephrin-A5 serves as a dominant ligand *in vivo* for EphA7 among combinatorial gradients of ephrin-As (Torii and Levitt, 2005). The gradient of EphA7 receptor levels by neocortical neurons is a critical regulator of the topographic targeting of corticothalamic (CT) axons through local interactions within thalamic nuclei, and this regulation is independent of the relative positioning of CT axons within the ST (Torii and Levitt, 2005). The topography of CT projections can be disrupted while the inter- and intra-areal topography of TC projections develops normally (Torii and Levitt, 2005).

A-type Eph receptors and their ligands, ephrin-As, also have been implicated in controlling cell positioning in a variety of developmental contexts by sorting cell types, restricting their intermingling, or regulating their migration (Torii et al., 2009). EphA and ephrin-A signaling has a proapoptotic effect in the embryonic cortex without affecting the proliferation or cell cycle progression (Torii et al., 2009). EphA and ephrin-A signaling regulates lateral neuronal dispersion and intermingling during the multipolar stage of radial migration, and this mechanism is required to generate cortical columns with appropriate cellular components (Torii et al., 2009).

31.2.2 Semaphorins (Semas) and Their Plexin (Plex) and Neuropilin Receptors

Semaphorins are a large family of secreted and membrane-associated proteins most commonly associated with a role in axon guidance (Parrinello et al., 2008). The most extensively studied biological function of semaphorins is their role in guiding axons to their targets in the developing nervous system by providing repulsive signals (Cooper, 2002; Giger et al., 2010; Koeberle and Bahr, 2004; Parrinello et al., 2008). However, more recently, it has been reported that semaphorins can also act as axonal attractants and mediate adhesive signals in a variety of tissues, both in development and adulthood (Koeberle and Bahr, 2004; Parrinello et al., 2008). For example, semaphorins have also been found to act as

chemoattractive guidance cues for cortical dendrites and olfactory bulb axons (Cooper, 2002).

The first semaphorin receptors to be identified were the neuropilins (Np-1 and -2), which recognize only the secreted semaphorins (Cooper, 2002; Koeberle and Bahr, 2004). Semaphorin 3A–Np-1 interactions are required for the fasciculation of the peripheral fibers of the trigeminal and vagal projections (Cooper, 2002). Np-2 is required for the organization and fasciculation of several cranial and spinal nerves (Cooper, 2002). Receptors for membrane-bound semaphorins are members of the family of plexins (Koeberle and Bahr, 2004). Plexins can interact with Np-1, conferring different semaphoring-binding specificities (Koeberle and Bahr, 2004).

Activation of the semaphorin receptor complex can lead to chemoattractive or chemorepulsive responses depending on the molecular composition of the receptor complex (Cooper, 2002). The growth cone response to semaphorins can be modulated by the direct physical interaction between neuropilins and members of the receptor families, highlighting the importance of receptor cross-talk in determining growth cone responses to guidance cues (Cooper, 2002).

The guidance factor semaphorin 3C, which is expressed by corpus callosum neurons, acts through the Np-1 receptor to orient axons crossing through the corpus callosum; transient neurons work together with their glial partners in guiding callosal axons (Niquille et al., 2009). The transducer that mediates the semaphoring 3C attractive response remains so far undefined (Niquille et al., 2009). Midline glial cells are the principal corpus callosum guidepost cells and secrete guidance factors that channel the callosal axons into the correct path (Niquille et al., 2009). These guidance signaling factors include netrin 1/DCC, Slit2/Robo1, ephrins/Eph, semaphorin/Np-1, and WNT (Niquille et al., 2009). Mutant mice for these guidance cues and their receptors exhibit callosal defects that range from minor, with few axons leaving the callosal track, to severe, with complete agenesis of the corpus callosum (ACC) (Niquille et al., 2009). Transmembrane proteins, including the tyrosine kinase receptors MET, ERBB2, OTK, and VEGFR2, participate in semaphorin responses by regulating diverse intracellular signaling events and functional outcomes (Niquille et al., 2009).

The cell adhesion molecule L1 has also been shown to act as a receptor for semaphorins (Koeberle and Bahr, 2004). A dependency on endocytosis to trigger axon retraction is observed in neurons responding to Sema3A, where the L1 IgCAM (immunoglobulin cell adhesion molecules), a component of the sema receptor complex, mediates endocytosis of the Sema3A holoreceptor in response to ligand binding (Bashaw and Klein, 2010; O'Donnell et al., 2009). The cell adhesion molecules L1

and TAG-1 (transient axonal glycoprotein-1) promote Sema3A activity through interaction and coendocytosis with its receptor neurolipin-1 (Bashaw and Klein, 2010).

Semaphorin 5A (Sema5A) is a membrane-bound protein and interacts with the receptor of plexin 3B (Lin et al., 2009). During development, Sema5A functions as an attractive and repulsive guidance molecule (RGM), and altered expression has been linked with aberrant development of axonal connections in the forebrain (Lin et al., 2009).

Semaphorin 4D (Sema4D) and B-type plexins demonstrate distinct expression patterns over critical time windows during the development of the murine cortex (Hirschberg et al., 2010). Sema4D–plexin-B2 interactions regulate mechanisms underlying cell specification, differentiation, and migration during corticogenesis (Hirschberg et al., 2010).

31.2.3 Netrins and Their DCC and UNC5 Guidance System

The DCC axon guidance receptor and its ligands, the netrins, have been shown to play a pivotal role in the guidance of axonal projections toward the ventral midline throughout the developing nervous system (Cooper, 2002; O'Donnell et al., 2009). The DCC belongs to a family of transmembrane proteins that possess four immunoglobulin domains and six fibronectin type III repeats (Kaprielian et al., 2001). Netrins are diffusible bifunctional molecules that can act as chemoattractants or chemorepellents for developing axons (Koeberle and Bahr, 2004). Secreted netrins and their receptors are one of the well-characterized axon guidance pathway families (Lin et al., 2009). The interaction of netrin-1 with DCC results in a chemoattractive response while interaction with the UNC5 family of netrin receptors results in chemorepulsion (Cooper, 2002; Lin et al., 2009). Netrin-1 functions as a floor plate-derived chemoattractant, which directs the pathfinding of commissural axons (Kaprielian et al., 2001). Netrin-1 binds to DCC that is expressed on commissural axons and their associated growth cones (Kaprielian et al., 2001). Mice lacking DCC or netrin-1 exhibit severe defects in commissural axon extension toward the floor plate and also lack several major commissures within the forebrain, including the corpus callosum and the hippocampal commissure (Cooper, 2002; Kaprielian et al., 2001). Studies have also revealed that DCC is crucial for the migration of some neuronal populations (Cooper, 2002).

In the developing mammalian neural tube, the DCC protein is present on the surface of commissural axons, as they migrate toward the floorplate, the source of the netrin gradient (Cooper, 2002). Once these axons have crossed the floorplate, they no longer respond to netrin despite the fact that they still retain expression of DCC on the axonal membrane (Cooper, 2002). Instead, they become responsive to the chemorepellents Slit2 and class 3 semaphorins, which are produced by the floorplate and the ventral neural tube, respectively (Cooper, 2002). This switch in responsiveness to chemorepulsive cues once having crossed the midline is believed to propel axons away from the midline and explains why axons are never seen to recross the midline after reaching the contralateral side (Schmidt et al., 2009). The key to the silencing of the chemoattractive response of the netrin-1-DCC interaction in this context lies in the absence or presence of the Slit receptor, Robo (Cooper, 2002). Axons projecting toward the midline express DCC but not Robo on their surface (Cooper, 2002). When on the ipsilateral side, netrin engagement by DCC homodimers triggers a chemoattractive response (Cooper, 2002). The direct coupling of the DCC and Robo receptors provides a precise temporal and spatial mechanism that accurately controls growth cone responses at a given choice point comprising conflicting directional information (Cooper, 2002). Slit–Robo chemorepulsion overrides netrin–DCC chemoattraction, thus becoming the driving force for that growth cone (Cooper, 2002).

The DCC is subservient to another chemorepulsive guidance receptor, UNC5 (Cooper, 2002). The chemoattractive response of DCC–netrin interactions is converted to chemorepulsion by the direct interaction between the cytoplasmic domains of DCC and UNC5 in the presence of netrin-1 (Cooper, 2002). In the presence of UNC5, the DCC is forced to change its polarity and act as a chemorepulsive netrin receptor (Cooper, 2002). In the presence of netrin-1, the affinity of the DCC is higher for Robo and UNC5 than it is for another DCC receptor (Cooper, 2002).

Modifying serotonin (5-HT) abundance in the embryonic mouse brain disrupts the precision of sensory maps formed by TC axons (TCAs), suggesting that 5-HT influences TCAs during development (Bonnin et al., 2007). 5-HT 1B and 5-HT 1D receptor expression in the fetal forebrain overlaps with that of the DCC and UNC5c expression. 5-HT coverts the attraction exerted by netrin-1 on posterior TCAs to repulsion (Bonnin et al., 2007).

Protein kinase A (PKA) has a role in regulating translocation of the DCC receptor to the growth cone plasma membrane (O'Donnell et al., 2009). Netrin-dependent inhibition of Rho activity also contributes to the DCC mobilization (O'Donnell et al., 2009). Rho GTPases constitute a major signaling output of guidance receptor activation (O'Donnell et al., 2009). The trafficking and polarized localization of netrin and Slit receptors are critical for proper direction of axon outgrowth (O'Donnell et al., 2009). Specifically, mutations in the UNC-73 Trio-family RacGEF or the VAB-8 kinesin-related protein disrupt the normal localization of the SAX-3 (Robo)

and UNC-40 (DCC) receptors, and in the case of UNC-40, regulation of localization also requires the MIG-2 Rac small GTPase (O'Donnell et al., 2009). These perturbations in normal receptor localization lead to significant defects in Slit and netrin-dependent posterior oriented cell and growth cone migration and further emphasize important regulatory roles for Rho GtPases in the control of axon guidance receptor localization (O'Donnell et al., 2009). In addition to these positive regulatory mechanisms, the trafficking of SAX-3 (Robo) and UNC-5 can also be negatively regulated with important outcomes for axon growth (O'Donnell et al., 2009).

In the regulated endocytosis of the repulsive netrin receptor UNC5 in vertebrate neurons, activation of PKC triggers the formation of a protein complex, including the cytoplasmic domain of UNC5H1, proteins interacting with C-kinase 1 (Pick1), and PKC and leads to specific removal of UNC5H1 from the growth cone surface (Bashaw and Klein, 2010; O'Donnell et al., 2009). Furthermore, the PKC activation leads to colocalization of UNC5A with early endosomal markers (Bashaw and Klein, 2010; O'Donnell et al., 2009). Thus, PKC-mediated removal of surface UNC5 provides a means to switch netrin responses from repulsion, mediated by either UNC5 alone or an UNC5-DCC complex, to attraction mediated by DCC (Bashaw and Klein, 2010; O'Donnell et al., 2009). G-protein-coupled adenosine 2b (A2b) receptor is a likely mediator of PKC activation because activation of A2b leads to the PKC-dependent endocytosis of UNC5 (Bashaw and Klein, 2010; O'Donnell et al., 2009). A2b is a netrin receptor that, together with DCC, appears to be required to mediate axon attraction, although this proposal has been controversial, and other evidence indicates that either A2b plays no role in netrin signaling or its role in netrin signaling is to modulate netrin responses (Bashaw and Klein, 2010; O'Donnell et al., 2009). In the context of UNC5 regulation, A2b acts independently of netrin, and its ability to regulate UNC5 surface levels supports its role as a potent modulator of netrin responses (Bashaw and Klein, 2010; O'Donnell et al., 2009).

31.2.4 Slits and Their Robo Guidance System

Slits are secreted proteins that control midline repulsion during development in vertebrates, signaling through receptors that belong to the Robo family (Allen and Chilton, 2009; Cooper, 2002; Kaprielian et al., 2001; Koeberle and Bahr, 2004). Slit can have dual roles, also promoting axonal growth (Koeberle and Bahr, 2004). Slit is a large extracellular matrix protein that is secreted by midline glia and is associated with the surfaces of axons (Kaprielian et al., 2001).

The Robo receptor is the best demonstration of both the importance of receptor trafficking for mediating axon guidance and the complexities yet to be unraveled (Allen and Chilton, 2009). This system is a striking example of the need for the growth cone to change its response as it grows toward, through, and beyond a guidance cue and the fundamental role played by the surface expression of receptors and their associated signaling components (Allen and Chilton, 2009). In both vertebrates and invertebrates, surface expression of the Robo receptor on axons of longitudinally projecting neurons and on precrossed commissural ones prevents them from approaching the embryonic midline (Allen and Chilton, 2009). Robo is the receptor for the chemorepellent protein Slit, which emanates from the midline (Allen and Chilton, 2009). Downregulation of Robo on commissural axons during midline crossing abrogates the repulsive effect of Slit so that a contralateral projection can be formed (Allen and Chilton, 2009). Following crossing, Robo is then restored to the axonal growth cone, which is not proven to prevent recrossing (Allen and Chilton, 2009).

In *Drosophila*, Slit is expressed by glia at the ventral midline, where it acts as a chemorepulsive guidance cue (Allen and Chilton, 2009; Cooper, 2002). The Slit receptor, Robo, is expressed at high levels on those axons that never cross the midline (Allen and Chilton, 2009; Cooper, 2002). In contrast, axons destined to cross the midline express very low levels of Robo when projecting on the ipsilateral side (Allen and Chilton, 2009; Cooper, 2002). Once on the contralateral side, Robo protein is greatly upregulated on the axonal membrane, and these axons never cross the midline again (Allen and Chilton, 2009; Cooper, 2002). Robo loss-of-function mutations result in both the commissural and noncomissural axons crossing the midline multiple times (Cooper, 2002).

Three Slit and three Robo orthologs have been identified in mammals (Cooper, 2002). The ability of mammalian Slits to act as chemorepulsive guidance cues has been demonstrated for a variety of axon populations, including olfactory bulb, hippocampal, and spinal motor axons (Cooper, 2002). The chemorepulsive activity of Slits has also been implicated in the targeted migration of neuroblasts within the rostral migratory stream toward the olfactory bulb and GABAergic neurons from the ganglionic eminence into the cortex (Cooper, 2002). Slit2 has also been shown to induce axon branching in sensory neurons (Cooper, 2002).

Heparan sulfate proteoglycans are essential for Slit-driven chemorepulsion (Cooper, 2002). These proteoglycans may be responsible for establishing effective local Slit concentrations and/or presenting Slit to the receptor in an appropriate format (Cooper, 2002).

Slit2 binds laminin-1, suggesting that the localization of Slit2 to precise choice points may be due to direct

interactions with the laminin isoforms within the surrounding extracellular matrix (Cooper, 2002). Slit2 also interacts directly with netrin-1 (Cooper, 2002). Both Slit and netrin-1 are coexpressed in many regions of the embryonic brain, including the floorplate of the neural tube (Cooper, 2002). Netrin attracts commissural axons toward the floorplate, while Slit acts to repel axons from the floorplate (Cooper, 2002). Once at the floorplate, the chemoattractive response to netrin-1 is silenced by the direct coupling of the netrin receptor, DCC, with the chemorepulsive Slit receptor, Robo, allowing the growth cones to escape the attractive forces of netrin-1 and move away from the floor plate (Cooper, 2002).

31.3 DOWNSTREAM SIGNALING MECHANISMS AND OTHER PROTEINS INVOLVED IN AXON GUIDANCE

On binding of axon guidance proteins to their growth cone receptors, intracellular signaling cascades are activated, resulting in extensive remodeling of the cytoskeleton and subsequent steering of the growth cone (Izzi and Charron, 2011; O'Donnell et al., 2009; Schmidt et al., 2009). Axon guidance is not a one-way process in which the growth cone passively receives information through its growth cone receptor (Schmidt et al., 2009). Instead, neurons can regulate the expression of receptors on the growth cone surface and modulate their response to axon guidance cues through various mechanisms (Schmidt et al., 2009). Also, different axon guidance cues can influence each other by binding to the same binding partner and/or through interaction of different signaling cascades (Schmidt et al., 2009). Furthermore, axon guidance receptor activity can be regulated by physical interactions between different guidance receptors (Schmidt et al., 2009).

Activation of specific signaling pathways can promote attraction or repulsion, result in growth cone collapse, or affect the rate of axon extension (Izzi and Charron, 2011; O'Donnell et al., 2009). The way a given guidance signal is interpreted also depends on the activities of a number of second-messenger pathways within the cell, and these pathways are potent modulators of axon responses *in vivo* (O'Donnell et al., 2009).

Calcium and cyclic nucleotides (cAMP and cGMP) can act *in vitro* to directly mediate guidance receptor signaling and also can modulate the strength and valence of guidance responses (Bashaw and Klein, 2010; O'Donnell et al., 2009). Disruption of calcium and cyclic nucleotide signaling leads to guidance defects in many systems, and in some cases, direct links have been made to specific guidance receptor signaling pathways (Bashaw and Klein, 2010). These two signaling systems show extensive cross talk in the regulation of growth cone guidance:

Calcium signaling can promote the production of cyclic nucleotides through activation of soluble adenylyl cyclases and nitric oxide synthase, and cyclic nucleotides can regulate cellular calcium concentration by controlling the activity of plasma membrane calcium channels as well as through the regulation of calcium-induced calcium release (CICR) from internal stores (Bashaw and Klein, 2010). This positive feedback could potentially play a role in amplifying responses to shallow gradients of guidance cues (Bashaw and Klein, 2010). High cyclic nucleotide levels favor attraction, whereas low levels favor repulsion (O'Donnell et al., 2009). It is the ratio of cAMP/cGMP that is important in determining the polarity of the guidance response and has implicated calcium channel modulation in the control of guidance responses (O'Donnell et al., 2009). A clear demonstration that cyclic nucleotides and their downstream effectors can convert responses from attraction to repulsion and vice versa during axon guidance *in vivo* is lacking; however, a growing body of evidence supports a potent role for cyclic nucleotide signaling in modulating the strength of receptor responses (O'Donnell et al., 2009).

The signals mediating changes in cyclic nucleotide levels are thought to be independent of the guidance receptors whose responses they modulate; however, a more direct role of guidance receptor signaling in activating cAMP signaling has been suggested in the case of netrin (Ming et al., 1997; O'Donnell et al., 2009). Netrin acting through DCC (or A2b) leads to the elevation of cAMP and activation of PKA, and these events have been proposed to be instrumental in promoting netrin-mediated axon outgrowth and attraction (O'Donnell et al., 2009). There is an important role for cyclic nucleotides in modulating the strength of guidance responses *in vivo* rather than switching the polarity of responses (O'Donnell et al., 2009). The challenge now is to define the signals and receptors that regulate cyclic nucleotide signaling *in vivo* and to define specific contexts where their modulatory effects influence axon guidance (O'Donnell et al., 2009).

Exposure of growth cones to *in vitro* gradients of guidance cues can induce a corresponding gradient of calcium elevation (Bashaw and Klein, 2010). These asymmetric changes in calcium concentrations appear to be instructive signals to direct growth cone turning, because focal elevation of calcium is sufficient to induce turning responses (Bashaw and Klein, 2010). Increases in calcium influx and CICR can be triggered by guidance cues, and the outcome for growth cone behavior (either attraction or repulsion) can be influenced by the magnitude of the calcium elevation, the slope of the calcium gradient, and potentially the specific source of the calcium as well (Bashaw and Klein, 2010). In general, moderate amplitude increases in calcium (often involving CICR) favor attraction, whereas high- or low-amplitude

increases favor repulsion, although differences in neuron type, growth substrate, and resting calcium concentrations can affect growth cone responses (Bashaw and Klein, 2010).

Electrophysiological recordings from growth cones indicate that attractive and repulsive guidance cues trigger rapid and reciprocal changes in membrane potential; attractants such as brain-derived neutrophic factor (BDNF) and netrin lead to membrane depolarization and repellents, such as Slit and semaphorin, lead to hyperpolarization (Bashaw and Klein, 2010). Moreover, the polarity of the change in membrane potential determines attraction versus repulsion (Bashaw and Klein, 2010). For netrin- and BDNF-mediated attraction, transient receptor potential (TRP) calcium channels contribute to membrane depolarization, and calcium influx through these channels is required for chemoattraction (Bashaw and Klein, 2010). BDNF and netrin through engagement of their respective TrkB and DCC receptors lead to calcium release from internal stores and activation of TRP channels: The subsequent TRP channel-dependent membrane depolarization is sufficient to activate voltage-dependent calcium channels (VDCCs), and the resulting calcium influx is essential for attractive turning (Bashaw and Klein, 2010). A role for semaphorins in the activation of cyclic nucleotide gated (CNG) calcium channels strengthens the case for the specific regulation of calcium influx through plasma membrane channels and points to the importance of cross regulation of cyclic nucleotide and calcium signaling (Bashaw and Klein, 2010). Here, Sema signaling through plexin receptors stimulates the production of cGMP, which in turn is required for membrane hyperpolarization, activation of CNG channels, and growth cone repulsion (Bashaw and Klein, 2010).

Similar to calcium signaling, cyclic nucleotides (cAMP or cGMP) can have profound effects on growth cone responses to guidance cues (Bashaw and Klein, 2010). The levels of cyclic nucleotides, specifically the ratio of cAMP to cGMP, can determine whether the response to a guidance cue will be attractive or repulsive, with high cyclic nucleotide levels (or high cAMP/cGMP ratios) favoring attraction and low levels (or low cAMP/cGMP ratios) favoring repulsion; cyclic nucleotide signaling can clearly modulate the strength of receptor responses (Bashaw and Klein, 2010).

Sema–plexin signaling leads to the production of cGMP, and cGMP plays an instructive role in promoting repulsion by regulating membrane hyperpolarization and the influx of calcium through CNG channels (Bashaw and Klein, 2010). Netrin outgrowth and attraction require DCC (or A2b)-mediated elevation of cAMP and activation of PKA (Bashaw and Klein, 2010).

Rho-family GTPases, a subgroup of the Ras superfamily of small GTPases, have been extensively studied for their role in cell motility and regulation of cytoskeletal structures (O'Donnell et al., 2009). Members of the Rho (Rac homology) family include Rac, Cdc42, and RhoA (O'Donnell et al., 2009). Rho-family GTPases catalyze the hydrolysis of bound GTP to GDP, switching from active (GTP-bound) and inactive (GDP-bound) states (O'Donnell et al., 2009). The activity of these GTPases has profound effects on actin cytoskeletal and microtubule dynamics (O'Donnell et al., 2009). Rho-family GTPases are very important in mediating axon guidance receptor signaling output (O'Donnell et al., 2009). Guidance cues including slits, netrins, ephrins, and semaphorins can all influence the activity of Rho-family GTPases (Bashaw and Klein, 2010; O'Donnell et al., 2009). Slits, acting through Robo receptors, lead to decreased levels of active Cdc42 and increased RhoA and Rac activity (Bashaw and Klein, 2010; O'Donnell et al., 2009). Ephrins, through Eph receptors, result in increased RhoA activity as well, but they can also cause transient, decreased Rac activity in RGCs, whereas Eph–ephrin reverse signaling activates Rac and Cdc43 to direct repulsive axon pruning (Bashaw and Klein, 2010; O'Donnell et al., 2009). There is no clear consensus for how Rho GTPases mediate repulsion, because these repulsive guidance pathways each influence RhoA, Rac, and Cdc42 activity in distinct ways (Bashaw and Klein, 2010; O'Donnell et al., 2009).

The primary regulators of Rho GTPase cycling and activity are the Rho-family GEFs and GAPs (GTPase-activating proteins) (O'Donnell et al., 2009). Upstream regulation is likely to provide tissue specific as well as temporal control of Rho GTPase signaling during growth cone guidance (O'Donnell et al., 2009). Guidance receptors can directly regulate Rho GTPases (O'Donnell et al., 2009). Identifying the GEFs and GAPs that function downstream of a given guidance receptor is critical to understanding the mechanism of guidance receptor signal transduction (O'Donnell et al., 2009).

Identification of individual Rho GTPase regulators that are essential mediators of guidance receptor signaling pathways is complicated by at least three major factors: (1) redundancy can obscure important functions, (2) individual GEFs and GAPs can act in multiple signaling pathways, (3) GEFs and GAPs often contribute to only part of any given signaling output (O'Donnell et al., 2009).

Ras-GAP α-chimaerin is an essential mediator of the ephrinB3/EphA4 guidance pathway (Bashaw and Klein, 2010; O'Donnell et al., 2009). The α2-chimaerin isoform contains two interaction domains for EphA4, the N-terminal SH2 domain, which can interact with phosphorylated juxtamembrane tyrosines of EphA4, and a second region in the C-terminus that constitutively interacts with the kinase domain of EphA4 (O'Donnell et al., 2009). The association of α2-chimaerin with Eph

receptors appears to be direct or mediated by the Nck2 (Grb4) adaptor protein (Bashaw and Klein, 2010). EphA4-dependent tyrosine phosphorylation of α2-chimaerin occurs in response to ephrinB3, and this treatment increases the Ras-GAP activity of α-chimaerin (O'Donnell et al., 2009). The interaction with EphA4 activates the intrinsic GAP activity of α2-chimaerin, and this leads to inactivation of Rac1 (Bashaw and Klein, 2010). The cooperative action of α2-chimaerin in reducing Rac1-mediated actin polymerization and ephexin1 in enhancing RhoA-mediated actin depolymerization appears to induce efficient axon retraction (Bashaw and Klein, 2010). In addition, α-chimaerin's diacylglyceron (DAG)-binding C1 domain is very likely to regulate the GAP activity of α2-chimaerin (O'Donnell et al., 2009). The GAP domain in β2-chimaerin is occluded by the N-terminal SH2 motif, mediated by intramolecular interactions with the C1 domain, and ligand binding to the C1 domain is predicted to result in exposure of the Rac-GAP domain (O'Donnell et al., 2009). Increases in DAG production would be expected to increase the Rac-GAP activity of α2-chimaerin (O'Donnell et al., 2009). Similarly, SH2-mediated interactions with receptors may free the GAP domain for Rac inhibition (O'Donnell et al., 2009). Although a reduction in Rac activity is required to mediate ephrin-A-induced collapse, Rac activation also appears to be necessary for responses to ephrins (O'Donnell et al., 2009). Interference with Rac signaling blocks growth cone collapse in response to both semaphorins and ephrins (O'Donnell et al., 2009). Although decreases in Rac activity are observed following ephrin stimulation, reactivation of Rac is temporally correlated with growth cone collapse (O'Donnell et al., 2009).

Rac activity appears to be required for endocytosis; semaphorin 3A or ephrin treatment of retinal growth cones results in Rac-dependent endocytosis, which appears to mediate contact repulsion (O'Donnell et al., 2009). Specifically, for class B Eph/ephrins, bidirectional endocytosis occurs as the ephrin ligand and the Eph receptor are each internalized in trans to neighboring cells in a process that depends on their cytoplasmic domains and Rac activity (O'Donnell et al., 2009). The conserved Vav subfamily of Dbl GEFs plays a central role in this process, which appears to be instrumental for growth cone retraction (O'Donnell et al., 2009). Vav2/3 and α2-chimaerin have opposing effects on Rac1, and yet both are mediators of EphA forward signaling (Bashaw and Klein, 2010). Unlike Vav2/3, α2-chimaerin does not influence Eph receptor endocytosis (Bashaw and Klein, 2010). It is possible that the activated Eph receptor first activates α2-chimaerin to induce axon retraction and then activates Vav2/3 to locally activate Rac1-dependent endocytosis to allow cell detachment (Bashaw and Klein, 2010). Ephrins also function through

Rho activation, and this activation appears to be mediated by the Dbl-family Rho GEF ephexin (O'Donnell et al., 2009). Ephexin activates RhoA, Rac, and Cdc42, but activation of the EphA receptor results in preferential activity toward RhoA (O'Donnell et al., 2009).

Genetic analysis of motor axon guidance in *Drosophila* indicates that plexin-B mediates repulsion in part by binding to active Rac (Bashaw and Klein, 2010). In contrast to plexin-Bs, plexin-A-induced growth cone repulsion requires the activation of Rac (Bashaw and Klein, 2010). The FERM domain-containing GEF protein, FARP2, associates with the plexin-A1/Npn-1 complex (Bashaw and Klein, 2010). Sema3A binding to Npn-1 causes FARP2 to dissociate from plexin-A1, activating FARP2's GEF activity and raising the levels of Rac-GTP in the cell (Bashaw and Klein, 2010). Activation of Rac triggers Rnd1 binding to plexin-A1, thereby activating plexin-A1's intrinsic Ras-GAP activity (Bashaw and Klein, 2010). Activated plexin-A1 downregulates R-Ras activity, which may lead to inhibition of integrin function and growth cone repulsion (Bashaw and Klein, 2010).

In contrast to the mechanism of plexin-B1 activation via Rac sequestration and RhoA activation, growth cone collapse induced by Sema3A requires activation of Rac (O'Donnell et al., 2009). Plexin-A1, together with neuropilin, transduces guidance signals from class 3 semaphorins, leading to Rac activation, Rnd1 recruitment, and reduction in R-Ras activity (O'Donnell et al., 2009).

In the absence of ephrin stimulation, nonphosphorylated ephexin1 is bound to EphA4 and activates RhoA, Rac1, and Cdc42, leading to a balance of GTPase activation that promotes axonal growth (Bashaw and Klein, 2010). Eph tyrosine kinase activity is required, but not sufficient to promote ephexin1 phosphorylation; instead, ephrin-induced clustering of Ephs appears to promote ephexin1 phosphorylation, probably involving Src tyrosine kinase (Bashaw and Klein, 2010). Tyrosine phosphorylation of ephexin1 shifts its exchange activity toward RhoA, thereby causing growth cone collapse *in vitro* (Bashaw and Klein, 2010). When Ephs are activated in a portion of the growth cone, tyrosine phosphorylated ephexin1 may tip the local balance of GTPase activity toward RhoA, thereby causing actin depolymerization and local retraction (Bashaw and Klein, 2010). In other regions of the growth cone that have not made contact with ephrins, ephexin1 promotes growth by activating RhoA, Rac1, and Cdc42 (Bashaw and Klein, 2010).

In motile cells, activation of Rho GTPases results in modulation of cytoskeletal dynamics via effector proteins, and one of the best characterized of these is the dual Cdc42/Rac effector, p21-activated kinase (O'Donnell et al., 2009). A well-established pathway of PAK activation via Cdc42 or Rac results in inhibition of the actin depolymerizing factor cofilin by activating

its inhibitor, LIM kinase (O'Donnell et al., 2009). Other notable targets of PAK include the myosin activator, myosin light chain (MLC) kinase, and the microtubule destabilizing protein, Op18/stathmin, which are each inhibited by PAK phosphorylation (O'Donnell et al., 2009). GTP-bound Rac and Cdc42 regulate Pak activity through binding to its Cdc42/Rac interactive binding domain, relieving autoinhibition of Pak by its N-terminal domain (O'Donnell et al., 2009). Pak likely functions downstream of Rac/Cdc42 in axon guidance (O'Donnell et al., 2009). *Drosophila pak*, *dock*, and *rac* each functions in midline axon repulsion and interacts genetically with the Slit/Robo pathway (O'Donnell et al., 2009). Expression of a constitutively membrane-targeted Pak suppresses defects caused by *rac* loss of function, which suggests that these Rac-dependent defects likely occur through loss of PAK regulation (O'Donnell et al., 2009). Both Cdc42 and Rac likely also function through pathways independently of PAK, particularly in axon growth (O'Donnell et al., 2009). Regulation of outgrowth via Rac can occur through a PAK-independent mechanism; however, guidance mediated through Rac and Cdc42 at least partly involves PAK function (O'Donnell et al., 2009).

Regulation of Pak leads to modulation of actin dynamics in axon growth and guidance by regulating the actin depolymerizing factor, cofilin, by modulating the activity of the serine/threonine kinase, LIMK (lin-11 and Mec-3 kinase) (O'Donnell et al., 2009). Cofilin destabilizes F-actin through pointed-end severing of actin filaments, although this activity may be necessary to maintain the supply of monomeric G-actin, thus promoting actin polymerization (O'Donnell et al., 2009). This activity is inhibited by phosphorylation at the N-terminal Ser3: Phosphorylation at this site is reciprocally regulated by the LIM and TES (testis-derived transcript) kinases and by the Slingshot phosphatase (Shh) (O'Donnell et al., 2009). In some cases, the rate of cycling between phosphorylated and nonphosphorylated states, rather than the absolute level of either species, can determine the influence of cofilin on actin dynamics (O'Donnell et al., 2009). How the LIM kinase and slingshot function in concert to regulate growth cone dynamics by regulating cofilin is of great interest in understanding receptor-mediated guidance (O'Donnell et al., 2009). Cycling of cofilin is required for promoting axon growth (O'Donnell et al., 2009). The LIMK also appears to mediate both axon outgrowth and attraction in certain contexts (O'Donnell et al., 2009). A gradient of phosphorylated cofilin accompanies the attractive response to BMP7, and repulsive responses from the same ligand are mediated by Ssh activity, demonstrating that distinct responses can be generated through activities converging on a single actin regulator (O'Donnell et al., 2009). The LIMK is required for growth cone attraction in certain contexts (O'Donnell et al., 2009).

Reverse signaling by receptorlike ephrinB proteins has been implicated in axon guidance (Bashaw and Klein, 2010). Following interactions with cognate Ephs, ephrinB proteins become clustered, and signaling is initiated either by Src-mediated tyrosine phosphorylation of the ephrinB cytoplasmic tail or by recruitment of PDZ domain-containing effectors (Bashaw and Klein, 2010). The NCK2 (NCK adaptor protein 2) is recruited to the phosphorylated ephrinB protein and is essential for several ephrinB-mediated processes, including spine formation (Bashaw and Klein, 2010). Tyrosine phosphorylation-dependent ephrin-B3 reverse signaling controls the stereotyped pruning of exuberant mossy fiber axons in the hippocampus, and NCK2 has been implicated in this process (Bashaw and Klein, 2010). The NCK2 appears to couple ephrinB3 with DOCK180 and PAK, leading to the activation of RAC1 (ras-related C3 botulinum toxin substrate 1) and CDC42 (cell division cycle 42) and downstream signaling that results in axon retraction/pruning (Bashaw and Klein, 2010).

Although inhibition of RAC can accompany repulsive guidance decisions, activation of RAC may also be involved in mediating responses to repulsive cues exemplified by Eph-dependent growth cone retraction and Ephrin-dependent axon pruning (Bashaw and Klein, 2010; O'Donnell et al., 2009). In the context of Slit–Robo-mediated repulsion, activation of Robo receptors by Slit leads to the activation of RAC, and limiting RAC function reduces the efficiency of Slit–Robo signaling (Bashaw and Klein, 2010; O'Donnell et al., 2009). The conserved RAC GAP, Vilse/CrGAP, contributes to Slit-dependent guidance decisions and antagonizes RAC function (Bashaw and Klein, 2010; O'Donnell et al., 2009). In axons, high levels of Vilse overexpression causes similar defects to Robo loss of function, and low levels of overexpression cause dosage-dependent defects in Slit–Robo repulsion similar to loss of function of Vilse (Bashaw and Klein, 2010; O'Donnell et al., 2009). The consequences of increasing or decreasing Vilse function are similar: Both lead to a compromise in the efficiency of Slit–Robo midline repulsion, suggesting that the precise levels of spatial distribution of Vilse RAC GAP activity may be instructive for Robo repulsion (Bashaw and Klein, 2010; O'Donnell et al., 2009). The interaction of Vilse/crGAP with Robo may be regulated in different subcellular contexts or during distinct stages of Slit–Robo repulsion (O'Donnell et al., 2009). Both the Slit–Robo and the forward Eph pathway use RAC GAP (Vilse for Robo and α-chimaerin for Ephs) and a Rac GEF (Sos for Robo and Vav for Ephs) to mediate repulsion (Bashaw and Klein, 2010; O'Donnell et al., 2009). A complex of proteins, including the adapters Nick, Pak, and Rac, are recruited to the receptors to mediate repulsive signaling (Bashaw and Klein, 2010). Coordinated action of GEFs and GAPs may promote the cycling of Rac

activity, which may be more important than the overall levels of Rac-GTP in a responding growth cone (Bashaw and Klein, 2010; O'Donnell et al., 2009). Alternatively, these GAPs and GEFs may represent distinct steps in the repulsive signal transduction output (Bashaw and Klein, 2010; O'Donnell et al., 2009). Rac activation in the case of Robo receptors may precede internalization as well (Bashaw and Klein, 2010; O'Donnell et al., 2009). Parallel mechanisms of repulsion may exist in these distinct ligand–receptor systems (O'Donnell et al., 2009).

Src family kinases (Src, Fyn, Yes, and others; collectively known as SFKs) are nonreceptor protein tyrosine kinases that have emerged as essential mediators of various guidance receptors (Bashaw and Klein, 2010). SFKs appear to be required in motor (LMC; lateral motor column) axons for limb trajectory selection and are critical for Eph forward signaling (Bashaw and Klein, 2010). Recruitment and activation of SFKs have been documented downstream of reverse signaling via GPI-anchored ephrinA ligands (Bashaw and Klein, 2010). The link between GPI-anchored ephrinAs and SFKs may be provided by transmembrane proteins such as p75 and TrkB (Bashaw and Klein, 2010). SFKs and focal adhesion kinase (FAK) are also essential mediators of netrin signaling (Bashaw and Klein, 2010).

The morphogen SHH mediates cell fate and axon guidance in the developing nervous system by two distinct pathways (Bashaw and Klein, 2010). Cell fate specification by Shh is mediated by the receptor Patched (Ptc) via the canonical pathway requiring the Gli family of transcription factors (Bashaw and Klein, 2010). In contrast, axon guidance by Shh is mediated by SFK in a smoothened-dependent manner via a rapidly acting, noncanonical signaling pathway not requiring transcription (Bashaw and Klein, 2010).

In addition to their critical contributions to downstream signaling, second messengers and Rho GTPases can also influence guidance responses by regulating the surface localization and activation of guidance receptors (Bashaw and Klein, 2010). Netrins induce outgrowth and attractive turning via the DCC family of receptors at least in part by regulating Rho GTPases (O'Donnell et al., 2009). Outgrowth of commissural axons in response to netrin requires Rho GTPase activity (O'Donnell et al., 2009). Netrin induces rapid activation of RAC1, CDC42, and PAK1 (p21 protein-activated kinase 1), which may occur in a complex containing the constitutive components DCC and NCK-1, as well as netrin-induced components, RAC1, CDC42, PAK1, and N-WASP (O'Donnell et al., 2009). Activation of this complex by netrin causes profound changes in growth cone morphology (O'Donnell et al., 2009). Netrin stimulation leads to an increase in the DCC surface levels, and this effect is enhanced by PKA activation (Bashaw and Klein, 2010). Blocking adenylate cyclase, PKA activity, or exocytosis prevents the increase in the DCC surface levels and blunts netrin-induced axon outgrowth (Bashaw and Klein, 2010). In addition to PKA's role in regulating DCC, netrin-dependent inhibition of Rho activity also contributes to DCC membrane localization (Bashaw and Klein, 2010). The trafficking and polarized localization of netrin and Slit receptors are critical for proper direction of axon outgrowth (Bashaw and Klein, 2010). There are important upstream regulatory roles of Rho GTPases in the control of axon guidance receptor localization (Bashaw and Klein, 2010). Trio is an important regulator of axon guidance decisions in several contexts (O'Donnell et al., 2009). Trio contains two Rho GEF domains, one with specificity for Rac and RhoG and the other that activates RhoA (O'Donnell et al., 2009).

Stimulation of RhoA results in activation of Rho kinase (O'Donnell et al., 2009). Rho kinases (ROCK or Rok) are serine/threonine kinases that, similar to PAK, regulate LIMK (O'Donnell et al., 2009). In addition, Rho kinases can regulate myosin activity through the phosphorylation of MLC, which results in activation and increases actin–myosin contractility (O'Donnell et al., 2009). Rho kinase also indirectly regulates myosin activity by phosphorylating and inhibiting MLC phosphatase (O'Donnell et al., 2009). ROCK activity is necessary for RhoA-induced retraction, likely through regulation of myosin II (O'Donnell et al., 2009). Inhibition of ROCK prevents the stability and contraction of actin arcs, which are filamentous actin structures that form in the transition zone of growth cones and affect microtubule bundling and dynamics (O'Donnell et al., 2009). ROCK can phosphorylate LIMK to regulate cofilin activity (O'Donnell et al., 2009). ROCK also phosphorylates the colapsin response mediator protein-2 (CRMP-2) after LPA (lipoprotein, Lp) or ephrin-A5 stimulation inhibits its ability to bind tubulin heterodimers (O'Donnell et al., 2009). CRMP-2 normally promotes axon outgrowth and branching, presumably by nucleating and promoting microtubule assembly (O'Donnell et al., 2009). The same residue in CRMP-2 that is targeted by ROCK downstream of LPA and ephrinA5 is phosphorylated by Cdk5 downstream of Sema3a-induced growth cone collapse, suggesting that independent signaling pathways can converge on the regulation of CRMP-2 phosphorylation (O'Donnell et al., 2009).

The RGM gene family consists of three members, RGMa, RGMb, and RGMc (Severyn et al., 2009). Each gene encodes a protein whose expression is restricted to a small number of tissues and is hypothesized to be involved in distinct biological functions ranging from control of iron metabolism to regulation of axonal guidance and neuronal survival in the developing nervous system (Severyn et al., 2009). RGMa is a cell

membrane-associated GPI-linked two-chain axonal guidance protein found primarily in the developing and adult central nervous system (Severyn et al., 2009). It has been shown that RGMa regulates repulsive guidance of retinal axons via binding to neogenin, a transmembrane protein that is also a receptor for netrins (Severyn et al., 2009).

Nervous system development is highly dependent on the microtubule cytoskeleton (Tischfield et al., 2010). Microtubules are copolymers assembled from tubulin heterodimers, which contain several different α- and β-isotypes (Tischfield et al., 2010). Each isotype may have properties necessary for specific cellular functions (Tischfield et al., 2010). TUBB3, one of at least six β-tubulins found in mammals, is distinct because purified microtubules enriched in TUBB3 are considerably more dynamic than those composed from other β-tubulin isotypes and because its expression is primarily limited to neurons (Tischfield et al., 2010). TUBB3 expression is greatest during periods of axon guidance and maturation; the level decreases in the adult central nervous system but remains high in the peripheral nervous system (Tischfield et al., 2010). The neuronal β-tubulin isotype is required in axon guidance and normal brain development (Tischfield et al., 2010).

During neurite extension, various families of microtubule-associated proteins (MAPs) bind to microtubules to regulate their stability, and hence the rate and direction of process outgrowth (Allen and Chilton, 2009). Some of these proteins appear to be specifically localized in either axons or dendrites (Allen and Chilton, 2009). Understanding how these MAPs become recruited to different compartments could shed light on how this occurs with axon guidance molecules (Allen and Chilton, 2009). The stability of microtubules will directly affect the facility with which motor proteins can convey their cargoes to the growing axon tip (Allen and Chilton, 2009).

Following axogenesis, the proximal section of the axon forms a diffusion impermeable barrier termed the axon initial segment (AIS) (Allen and Chilton, 2009). The AIS, microtubule polarity, and motor protein affinities collectively provide a series of filters to selectively transport necessary proteins to the axonal tip (Allen and Chilton, 2009). The growth cone autonomously executes intrinsic mechanisms to sort and retain from these deliveries those that are required (Allen and Chilton, 2009). The interplay between the cell adhesion molecule L1 and the neuropilin–semaphorin signaling axis provides the best current insight into how the turnover of axon guidance receptors is regulated at the growth cone (Allen and Chilton, 2009). L1 and other members of its family of cell adhesion molecules are important for the overall adhesion of a developing axon to its substrate (Allen and Chilton, 2009). By regulation, the distribution and turnover of semaphorin signaling complexes, L1 and maybe other cell adhesion molecules such as neuronal cell adhesion molecule, required for the signaling of Sema3B and Sema3F through Np-2, may play a key role in determining which receptors reach and stay at the developing axon tip (Allen and Chilton, 2009).

L1 is expressed along the length of the axon, but it is preferentially inserted into the growth cone membrane (Allen and Chilton, 2009). It functions as a critical component of the Sema3A receptor complex by binding Np-1 and determining whether a repulsive or attractive response is generated (Allen and Chilton, 2009). L1 also regulates the turnover of neuropilin receptors by controlling its endocytosis following semaphoring binding (Allen and Chilton, 2009). At the growth cone, L1 interacts with Ezrin–Radixin–Moesin proteins to influence the actin cytoskeleton and axon outgrowth (Allen and Chilton, 2009). L1 is anchored to the axonal membrane via ankyrinB, which is colocalized with L1 along the axonal shaft (Allen and Chilton, 2009). A mechanism is suggested whereby L1 could carry neuropilin to the growth cone and modulate its signaling once there (Allen and Chilton, 2009). Given the large turnover of plasma membrane occurring in developing growth cones, association with L1 in its cycle of surface renewal would be a very efficient means of locally recycling neuropilin, obviating the need to continually transport fresh receptor down the growing axon (Allen and Chilton, 2009). Following a change in its phosphorylation, L1 can subsequently associate with different cytoskeletal components and assume a more passive, adhesive role in the axon (Allen and Chilton, 2009). The interaction between L1 and neuropilin provides a means for both selective targeting of the latter to the developing growth cone and regulation of its endocytic turnover once there (Allen and Chilton, 2009).

There is another mechanism to retain guidance receptors at the axonal tip (Allen and Chilton, 2009). For neuropilin and the receptors for ephrin and netrin guidance molecules, local variations in the composition of the plasma membrane play an important role (Allen and Chilton, 2009). In the axon, glycolipid-enriched complexes, also known as lipid rafts, mediate the sorting of GPI-anchored proteins (Allen and Chilton, 2009). The responses induced by semaphorin and netrin are both dependent on the integrity of lipid rafts within the growth cone (Allen and Chilton, 2009). The GPI-anchored ephrinA and the transmembrane ephrinB families of molecules are also present in lipid rafts (Allen and Chilton, 2009).

Palmitoylation of proteins is a posttranslational modification, which can enhance the association of proteins with lipid rafts, and is a critical component of the nervous system development (Allen and Chilton, 2009). This modification occurs with the netrin receptor, DCC

(Allen and Chilton, 2009). This is required for its proper function in promoting both axonal growth and turning (Allen and Chilton, 2009). Lipid modification and microenvironments could be crucial for getting receptors to the developing growth cone (Allen and Chilton, 2009). Restriction within the growth cone of enzymes, which regulate palmitoylation, could then locally modulate retention of guidance receptors and associated signaling components (Allen and Chilton, 2009).

31.3.1 Agenesis of the Corpus Callosum

The corpus callosum is the largest fiber tract in the central nervous system and the major interhemispheric fiber bundle in the brain (http://www.ncbi.nlm.nih.gov/omim) (Bloom and Hynd, 2005; Donahoo and Richards, 2009; Paul et al., 2007; Richards et al., 2004). It consists of over 190 million axons, connects neurons in the left and right cerebral hemispheres, and is essential for the coordinated transfer of information between them (Bloom and Hynd, 2005; Chiappedi and Bejor, 2010; Donahoo and Richards, 2009; Paul et al., 2007; Richards et al., 2004). The corpus callosum contains homotopic and heterotopic interhemispheric connections (Paul et al., 2007).

Formation of the corpus callosum begins as early as 6 weeks of gestation, with the first fibers crossing the midline at 11–12 weeks of gestation and completion of the basic shape by 18–20 weeks (http://www.ncbi.nlm.nih.gov/omim) (Bloom and Hynd, 2005; Chiappedi and Bejor, 2010). The corpus callosum first enlarges caudally then develops rostrally (Bloom and Hynd, 2005). Myelination occurs slowly over the lifespan, with the process completing in puberty (Bloom and Hynd, 2005). Myelination progresses caudally to rostrally, much as the corpus callosum develops, from the splenium to the genu and rostrum (Bloom and Hynd, 2005; Richards et al., 2004). The most anterior portion of the callosum is the genu, which connects the prefrontal cortices on either hemisphere (Bloom and Hynd, 2005; Richards et al., 2004). The middle portions of the corpus callosum connect the motor and somatosensory regions (Bloom and Hynd, 2005). The caudal part of the body of the corpus callosum connects the cortex from the temporoparietal–occipital junction, as do portions of the splenium, the most posterior section of the corpus callosum (Bloom and Hynd, 2005; Richards et al., 2004). The splenium also connects the dorsal parietal and occipital regions (Bloom and Hynd, 2005).

For the corpus callosum to form, several critical developmental events must occur in sequence (Donahoo and Richards, 2009; Paul et al., 2007). These include correct midline patterning, formation of telencephalic hemispheres, birth and specification of commissural neurons,

and axon guidance across the midline to the final target in the contralateral hemisphere (Donahoo and Richards, 2009; Paul et al., 2007; Richards et al., 2004).

Np-1 has been shown to be involved in corpus callosum formation (Donahoo and Richards, 2009). The first axons to cross the midline arise from neurons in the cingulated cortex (Paul et al., 2007). Cingulate pioneering axons of the corpus callosum express Np-1 at a crucial temporal stage for callosal development (Donahoo and Richards, 2009; Paul et al., 2007). Callosal axons are guided medially to the midline, where they are channeled into the contralateral hemisphere (Donahoo and Richards, 2009). Midline cellular populations that have been shown to assist in the formation of the corpus callosum include the midline zipper glia, the glial wedge, the indusium griseum glia, and the subcallosal sling (Bush and Soriano, 2009; Donahoo and Richards, 2009; Paul et al., 2007; Richards et al., 2004). The glial wedge has been shown to express molecules such as Slit2 required for callosal axons to cross the midline (Richards et al., 2004). The indusium griseum also expresses the guidance molecule Slit2 and resides directly above the corpus callosum (Richards et al., 2004).

After crossing the midline, callosal axons grow into the contralateral hemisphere toward their designated target region, usually homotopic to their region of origin, and then innervate the appropriate cortical layer (Paul et al., 2007). Such processes probably involve both molecular recognition of the appropriate target region and activity-dependent mechanisms that regulate axon targeting to the correct layer and the subsequent refinement of the projection (Paul et al., 2007).

ACC encompasses a broad range of diagnoses and is one of the most frequent malformations in the brain with a reported incidence ranging between 0.5 and 70 in 10 000 births (http://www.ncbi.nlm.nih.gov/omim) (Chiappedi and Bejor, 2010; Richards et al., 2004). Both complete and partial ACC can result from disruption in any one of the multiple steps of callosal development, such as cellular proliferation and migration, axonal growth, or glial patterning at the midline (Bush and Soriano, 2009; Engle, 2010; Paul et al., 2007; Richards et al., 2004). ACC is a clinically and genetically heterogeneous condition, which can be observed as either an isolated condition or a manifestation in the context of a congenital syndrome (http://www.ncbi.nlm.nih.gov/omim. Further heterogeneity in ACC can arise from concomitant abnormalities in the anterior commissure (Paul et al., 2007). Malformation of the corpus callosum can result in either the complete absence of the corpus callosum or partial absence (hypogenesis) or thinning of the corpus callosum (Donahoo and Richards, 2009; Paul et al., 2007; Richards et al., 2004).

The wide range of disorders in which callosal abnormalities are found underscores the importance of

understanding the basic nature of the development and function of the corpus callosum (Bloom and Hynd, 2005).

31.3.1.1 Clinical Characteristics

Corpus callosum dysgenesis accompanies a multitude of inherited disorders and results in a clinical spectrum ranging from normal to severe mental retardation (Engle, 2010; Richards et al., 2004). The most frequent clinical findings in patients with ACC are mental retardation (60%), visual problems (33%), speech delay (29%), seizures (25%), and feeding problems (20%) (http://www.ncbi.nlm.nih.gov/omim).

Isolated ACC, even when not ascertained clinically, still causes behavioral and cognitive impairment (Paul et al., 2007). As more individuals with primary ACC are identified and assessed with sensitive standardized neuropsychological measures, a pattern of deficits in higher order cognition and social skills has become apparent (Chiappedi and Bejor, 2010; Paul et al., 2007). The major anatomical feature of primary ACC is the absence of the corpus callosum, and it is presumed to be the cause of the cognitive and behavioral changes in these individuals (Paul et al., 2007). However, colpocephaly (abnormal enlargement of the occipital horns of the brain) and Probst bundles (large, bilateral, barrel-shaped axonal structures that do not cross the midline) are common in people with primary ACC and together with other subtle anatomical changes probably also affect behavior (Paul et al., 2007).

The functional consequences of structural changes in brain connectivity contribute to cognitive impairment (Paul et al., 2007). Primary ACC has a limited impact on general cognitive ability (Paul et al., 2007). Although the full-scale intelligence quotient (IQ) can be lower than expected based on family history, scores frequently remain within the average range (Paul et al., 2007). In an unexpectedly large number of persons with primary ACC (as many as 60%), performance IQ and verbal IQ are significantly different (Paul et al., 2007). However, there is no consistency with respect to which of the two is more affected (Paul et al., 2007). Impairments in abstract reasoning, problem solving, generalization, and category fluency have all been consistently observed in patients with primary ACC (Chiappedi and Bejor, 2010; Paul et al., 2007). Data from large sample sizes suggest that problem-solving abilities become more impaired as task complexity increases (Paul et al., 2007).

The most comprehensively examined higher cognitive domain in patients with ACC is language (Paul et al., 2007). Overall, individuals with primary ACC have intact general naming, receptive language, and lexical reading skills (Paul et al., 2007). However, impairments have been reported in the comprehension of syntax and linguistic pragmatics, and in phonological processing and rhyming (Paul et al., 2007). With respect to linguistic pragmatics, persons with primary ACC are impaired in the comprehension of idioms, proverbs, vocal prosody, and narrative humor (Paul et al., 2007). Patients with primary ACC also show marked difficulty with expressive language (Paul et al., 2007).

Parents of individuals with primary ACC consistently describe impaired social skills and poor personal insight as the features that interfere most prominently with the daily lives of their children (Chiappedi and Bejor, 2010; Paul et al., 2007). Also, parents frequently report health concerns such as feeding or sleeping issues, elimination problems, and unusual tolerance for pain (Chiappedi and Bejor, 2010). Specific traits include emotional immaturity, lack of introspection, impaired social competence, general deficits in social judgment and planning, and poor communication of emotions (Chiappedi and Bejor, 2010; Paul et al., 2007). Consequently, patients with primary ACC often have impoverished and superficial relationships, suffer social isolation, and have interpersonal conflict both at home and at work because of misinterpretation of social cues (Chiappedi and Bejor, 2010; Paul et al., 2007).

Responses of adults with primary ACC on self-report measures also suggest diminished self-awareness (Paul et al., 2007). The patients' self-reports are often in direct conflict with observations from friends and family (Paul et al., 2007). One potential factor contributing to poor self-awareness may be a more general impairment in comprehension and description of social situations (Paul et al., 2007).

Taken together, the neuropsychological findings in primary ACC highlight a pattern of deficits in problem solving, social pragmatics of language and communication, and processing emotion (Chiappedi and Bejor, 2010; Paul et al., 2007). Behavioral and emotional factors are frequently associated: A tendency for deficient social cognition in individuals with ACC seems to stem from a combination of difficulty integrating information from multiple sources, using paralinguistic cues for emotion, and understanding nonliteral speech (Chiappedi and Bejor, 2010).

The deficits in social communication and social interaction in patients with primary ACC overlap with the diagnostic criteria for autism (Chiappedi and Bejor, 2010; Paul et al., 2007). Furthermore, people with primary ACC may display a variety of other social, attentional, and behavioral symptoms that can resemble those of certain psychiatric disorders (Paul et al., 2007). Examination of symptom overlap between psychiatric disorders and ACC may help to isolate the symptoms that are directly caused by a dysfunction in corticocortical connectivity (Paul et al., 2007).

There are also structural similarities between ACC and some psychiatric disorders (Paul et al., 2007). Structural correlates of abnormal brain connectivity are

evident in essentially every psychiatric disorder that has been examined (Paul et al., 2007). For example, several studies have found altered morphology of the corpus callosum in schizophrenia patients, including changes in size and shape, as well as microstructural changes in callosal regions that are revealed by diffusion MRI (Bloom and Hynd, 2005; Paul et al., 2007). There are also a number of reports of complete ACC in patients with schizophrenia, underscoring a direct connection between ACC and schizophrenia (Paul et al., 2007). Corpus callosum size, especially its anterior sectors, is also decreased in some cases of autism (Bloom and Hynd, 2005; Chiappedi and Bejor, 2010; Paul et al., 2007). Microstructural changes in the corpus callosum have also been found in patients with Tourette's syndrome (a disorder characterized by repetitive, stereotyped, involuntary movements and vocalizations called tics) and attention deficit hyperactivity disorder (Bloom and Hynd, 2005; Paul et al., 2007). Abnormalities in the size of the corpus callosum have also been found in patients diagnosed with mental retardation, Down syndrome, developmental dyslexia, and developmental language disorders (Bloom and Hynd, 2005). Deviant asymmetry of cortical areas, possibly related to callosal abnormalities, has been found in developmental dyslexia and specific language impairment (Bloom and Hynd, 2005).

31.3.1.2 Genetics

The genetics of ACC is variable and reflects the underlying complexity of callosal development (Bush and Soriano, 2009; Chiappedi and Bejor, 2010; Paul et al., 2007). A combination of genetic mechanisms, including single-gene Mendelian mutations, single-gene sporadic mutations, and complex genetics, might have a role in the etiology of ACC (Paul et al., 2007). Retrospective chart reviews and cross-sectional cohort studies report that 30–45% of cases of ACC have identifiable causes (Chiappedi and Bejor, 2010; Paul et al., 2007). Approximately 10% have chromosomal anomalies, and the remaining 20–35% have recognizable genetic syndromes (Paul et al., 2007). However, if only individuals with complete ACC are considered, then the percentage of patients with recognizable syndromes drops to 10–15%, and thus 75% of cases of complete ACC do not have an identified cause (Chiappedi and Bejor, 2010; Paul et al., 2007).

One example of ACC associated with a Mendelian disorder is X-linked lissencephaly with ACC and ambiguous genitalia (XLAG), which results from a mutation in the aristaless-related homeobox gene (ARX) (Chiappedi and Bejor, 2010; Paul et al., 2007).

Another syndrome caused by a single-gene mutation is CRASH syndrome (corpus callosum agenesis, retardation, adducted thumbs, spastic paraplegia, and hydrocephalus), which is accompanied by diminutive corticospinal tracts within the brainstem (Paul et al., 2007). CRASH is caused by mutations in the L1 cell adhesion molecule (L1CAM) gene that codes for a transmembrane cell adhesion protein broadly expressed in the central nervous system (Paul et al., 2007).

Andermann syndrome, an autosomal recessive condition prevalent in the Saguenay-Lac-St-Jean region of Quebec, presents with callosal hypoplasia or ACC, cognitive impairment, episodes of psychosis, and a progressive central and peripheral neuropathy (Chiappedi and Bejor, 2010; Paul et al., 2007). It is caused by mutation of the KCl cotransporter KCC3 (*potassium chloride cotransporters 3*) (Paul et al., 2007).

Mowat–Wilson syndrome (MWS) in addition to ACC causes Hirschsprung disease, congenital heart disease, genitourinary anomalies, microcephaly, epilepsy, and severe cognitive impairment (Chiappedi and Bejor, 2010; Paul et al., 2007). The MWS is caused by heterozygous inactivating mutations in the gene zinc finger homeobox 1b on chromosome 2q22, which codes for SMAD-interacting protein 1 (Paul et al., 2007). ACC is not observed in all MWS cases (Paul et al., 2007).

Aicardi syndrome is another disorder probably caused by sporadic mutations on the X chromosome (Chiappedi and Bejor, 2010; Paul et al., 2007). It is only observed in females and XXY males with Klinefelter syndrome (Paul et al., 2007). It consists of ACC, infantile spasms and chorioretinal lacunae, and additional cerebral and ophthalmological abnormalities (Paul et al., 2007).

ACC is a notable facet of craniofrontonasal syndrome (CFNS) (Bush and Soriano, 2009). Mutations in the EPHRIN-B1 gene result in a wide spectrum of developmental abnormalities that constitute this syndrome (Bush and Soriano, 2009). This syndrome includes cleft palate, craniofrontonasal dysplasia, craniosynostosis, axial skeletal defects such as asymmetry of the thoracic skeleton and limb abnormalities, and neurological defects such as mental retardation (Bush and Soriano, 2009). It is an X-linked condition (Bush and Soriano, 2009).

Some other syndromes associated with ACC are ACC with fatal lactic acidosis, HSAS/MASA syndromes (X-linked hydrocephalus) (L1CAM), acrocallosal syndrome, Chudley–MCCullough syndrome, Donnai–Barrow syndrome, FG syndrome, gentiopatellar syndrome, Temtamy syndrome, Toriello–Carey syndrome, Vici syndrome, ACC with spastic paraparesis (SPG11), CFNS, Fryns syndrome, Marden–Walker syndrome, Meckel–Gruber syndrome, microphthalmia with linear skin defects, Opitz G syndrome, orofaciodigital syndrome, pyruvate decarboxylase deficiency, Rubinstein–Taybi syndrome, septo-optic dysplasia (DeMorsier syndrome), Sotos syndrome, Warburg micro syndrome, and Wolf–Hirschhorn syndrome (Bush and Soriano, 2009; Chiappedi and Bejor, 2010; Paul et al., 2007).

In most individuals with ACC, there is no clearly inherited cause or a recognized genetic syndrome, suggesting that ACC can be caused by sporadic (*de novo*) genetic events (Paul et al., 2007). It is likely that some cases of ACC are caused by haploinsufficiency at other genetic loci (Paul et al., 2007). This is supported by many reports of patients with ACC who have sporadic chromosomal mutations with particular loci identified repeatedly (Paul et al., 2007).

The number of patients with ACC in which chromosomal rearrangements are found has increased following technical improvements, from conventional karyotyping to subtelomeric and array-CGH (comparative genomic hybridization) analysis (Chiappedi and Bejor, 2010). Candidate genes have been located especially on chromosome 1 and also on 3, 7, 8, 13, 15, 18, and 21 (Chiappedi and Bejor, 2010). Data obtained using microarray-based comparative genomic hybridization demonstrate that patients with ACC have chromosomal deletions or duplications that are smaller than those that can be detected using conventional cytogenetics (Paul et al., 2007). The risk of having a child with ACC is nearly threefold higher for mothers aged 40 and above, which is consistent with causal sporadic chromosomal changes (Paul et al., 2007).

Many cases of ACC might be caused by polygenic and other complex interactions (Paul et al., 2007). The abundance of case reports of ACC associated with specific diseases probably also reflects complex underlying mechanisms (Paul et al., 2007).

Environmental factors might contribute to ACC (Chiappedi and Bejor, 2010; Paul et al., 2007). One example of environmental influences on callosal development is provided by fetal alcohol syndrome (FAS) (Chiappedi and Bejor, 2010; Paul et al., 2007). Alcohol exposure *in utero* decreases gliogenesis and glial–neuronal interactions, processes that are vital for corpus callosum development (Paul et al., 2007). Ethanol disrupts the transcription and biochemical function of L1CAM, implicating an interplay of environment and genetics in ACC (Paul et al., 2007). The incidence of ACC in FAS is approximately 6.8% (Paul et al., 2007). In many FAS cases, the corpus callosum is hypoplastic; this may result not only from the disruption of early events in callosal formation but also from later dysregulation of axonal pruning (Paul et al., 2007). Such mechanisms might also cause callosal hypoplasia in other disorders such as schizophrenia and autism (Paul et al., 2007). Other environmental factors may also influence postnatal and prenatal callosal development, including musical training, hypothyroidism, and enrichment or deprivation of experience (Paul et al., 2007).

31.3.1.3 Neuroradiological Findings

Consistent with the broad range of genetic factors involved in ACC, the cognitive, behavioral, and neurological consequences of ACC are wide ranging (Paul et al., 2007; Richards et al., 2004). One approach to defining clinical subsets of the ACC patient population is to categorize individuals according to specific neuroanatomical findings and subsequently relate these to the behavioral symptoms within these groups (Paul et al., 2007). The presence of polymicrogyria (PMG) (an excessive number of gyri on the surface of the brain), pachygyria (too few gyri on the surface of the brain), and heterotopia, detected using MRI, correlate with moderate to severe developmental delay (Chiappedi and Bejor, 2010; Paul et al., 2007).

In ACC, the superomedial aspects of the lateral ventricles are deformed by the fibers of the cerebral hemispheres that were destined to cross in the corpus callosum and that, with agenesis, course instead longitudinally as the bundles of Probst (Chiappedi and Bejor, 2010). Crescentic lateral ventricles result from the impression of medial ventricular wall by these bundles (Chiappedi and Bejor, 2010). The other relevant neuroradiological sign is the eversion of the cingulated gyri which can be seen in coronal scans (Chiappedi and Bejor, 2010).

Ultrasonography can be helpful, even if MRI is thought to be far superior at least for partial agenesis (Chiappedi and Bejor, 2010). Morphologically, two types of ACC can be distinguished: In type 1, axons are present but unable to cross the midline, forming large aberrant fiber bundles (Probst bundles), while in the less frequent type 2, axons fail to form (Chiappedi and Bejor, 2010).

The most relevant sonographic sign in sagittal views is the superior displacement of the third ventricle, while parasagittal views show that the medial cortical sulci radiates superiorly instead of horizontally and the absence of the normally echogenic pericallosal sulcus (Chiappedi and Bejor, 2010). Coronal scans show absence of callosum and Probst longitudinal bundles indenting the dorsomedial aspect of lateral ventricles (Chiappedi and Bejor, 2010).

With partial agenesis, the posterior portion is nearly always affected, with the notable exception of the anterior involvement that occurs when partial agenesis is associated with the holoprosencephalies (Chiappedi and Bejor, 2010).

In MRI, the four components of the corpus callosum are best viewed on sagittal imaging, although its relationship to the cerebral hemispheres is best shown on coronal images (Chiappedi and Bejor, 2010). The corpus callosum is a densely packed white matter structure, with high signal on T_1-weighted and low signal in T_2-weighted images after the age of 24 months (Chiappedi and Bejor, 2010). MRI imaging shows that myelination is more advanced in the posterior parts of the corpus callosum when compared to the anterior regions (Chiappedi and Bejor, 2010).

Prenatal diagnosis of complete callosal agenesis is feasible from the midtrimester onward by expert

sonography (Chiappedi and Bejor, 2010). In the axial view, suspicious findings are absent cavum septi pellucid and teardrop configuration of the lateral ventricles with possible ventriculomegaly; the nonvisualization of the corpus callosum at transfontanellar ultrasound in either the sagittal or coronal plane is diagnostic (Chiappedi and Bejor, 2010). More subtle findings, such as hypoplasia and partial ACC, may also be recognized antenatally (Chiappedi and Bejor, 2010). Fetal MRI is worth doing in order to reinforce a difficult sonographic diagnosis and, at the same time, to exclude possible additional cerebral anomalies, which may be overlooked at ultrasound (Chiappedi and Bejor, 2010).

Malformations of the brainstem and cerebellum have been increasingly recognized in patients with malformations of the cerebrum, including callosal anomalies (Barkovich et al., 2009).

31.3.2 L1 Syndrome

The L1 syndrome is a highly variable X-linked neurological disorder (Bertolin et al., 2010; Engle, 2010; Schafer et al., 2010). It results from mutations in the *L1CAM* gene (Bertolin et al., 2010; Engle, 2010; Schafer et al., 2010; Vos et al., 2010). L1 is a transmembrane neural adhesion molecule that acts as a short-range axon guidance cue and is highly expressed in developing axons and apical dendrites of cortical neurons and within migratory axons of the corpus callosum and corticospinal tract (Bertolin et al., 2010; Engle, 2010; Schrander-Stumpel and Vos, 1993).

The L1CAM is one of a subgroup of structurally related integral membrane glycoproteins belonging to a large class of immunoglobulin superfamily cell adhesion molecules that mediate cell-to-cell adhesion at the cell surface (http://www.ncbi.nlm.nih.gov/omim) (Bertolin et al., 2010; Schrander-Stumpel and Vos, 1993; Vos et al., 2010). The various functions of L1CAM include guidance of neurite outgrowth in development, neuronal cell migration, axon bundling, synaptogenesis, myelination, neuronal cell survival, and hippocampal long-term potentiation (http://www.ncbi.nlm.nih.gov/omim) (Bertolin et al., 2010; Schafer et al., 2010; Schrander-Stumpel and Vos, 1993).

L1 has multiple extracellular binding partners, including β1 integrins, neuronal cell adhesion molecule, TAG-1/axonin-1, contactin, Np-1, and L1 itself, through which it potentiates cell adhesion, provides a mechanical link to the actin cytoskeleton, and serves as a coreceptor to assist in intracellular signal transduction (Engle, 2010). L1 homophilic binding increases cell adhesion and enhances neuronal migration and neurite outgrowth, whereas binding to Np-1 mediates Sema3A-induced growth cone collapse and axon repulsion (Engle, 2010).

L1 has also multiple intracellular binding partners; L1 links to the actin cytoskeleton through interactions with ankyrin or FERM domain-containing proteins, and the interaction of L1 with adaptor protein 2 is required for sorting of L1 to the axonal growth cone (Engle, 2010).

31.3.2.1 Clinical Characteristics

The L1 syndrome was originally recognized as four distinct entities: X-linked hydrocephalus due to stenosis of the aqueduct of Sylvius, MASA syndrome (mental retardation, aphasia, shuffling gait, adducted thumbs), X-linked complicated spastic paraplegia type I, and X-linked corpus callosum agenesis (Bertolin et al., 2010; Engle, 2010; Vos et al., 2010). On the basis of their genetic homogeneity and phenotypic overlap, these disorders are considered a single entity (Engle, 2010; Schafer et al., 2010).

This X-linked syndrome comprises a broad phenotypic spectrum, including hydrocephalus, mental retardation, aphasia, spastic paraplegia, and adducted thumbs (Engle, 2010; Schafer et al., 2010; Schrander-Stumpel and Vos, 1993).

X-linked hydrocephalus with stenosis of the aqueduct of Sylvius is the most common genetic form of congenital hydrocephalus, with a prevalence of approximately 1 in 30 000 (Schrander-Stumpel and Vos, 1993). This accounts for approximately 5–10% of males with nonsyndromic hydrocephalus (Schrander-Stumpel and Vos, 1993). Hydrocephalus may be present prenatally and result in stillbirth or death in early infancy (Schrander-Stumpel and Vos, 1993). Males with hydrocephalus with stenosis of the aqueduct of Sylvius are born with severe hydrocephalus and adducted thumbs (Schrander-Stumpel and Vos, 1993). Seizures may occur (Schrander-Stumpel and Vos, 1993). In less severely affected males, hydrocephalus may be subclinically present and documented only because of developmental delay (Schrander-Stumpel and Vos, 1993). Mild-to-moderate ventricular enlargement is compatible with long survival (Schrander-Stumpel and Vos, 1993).

In hydrocephalus with stenosis of the aqueduct of Sylvius, intellectual disability is usually severe and is independent of shunting procedures in individuals with severe hydrocephalus (Schrander-Stumpel and Vos, 1993). In MASA syndrome, intellectual disability ranges from mild (IQ of 50–70) to moderate (IQ of 30–50) (Schrander-Stumpel and Vos, 1993).

Boys initially exhibit hypotonia of the legs, which evolves into spasticity during the first years of life (Schrander-Stumpel and Vos, 1993). In adult males, the spasticity tends to be somewhat progressive (Schrander-Stumpel and Vos, 1993). Spasticity usually results in atrophy of the muscles of the legs and contractures that together cause the shuffling gait (Schrander-Stumpel and Vos, 1993).

Carrier females may manifest minor features such as adducted thumbs and/or subnormal intelligence (Schrander-Stumpel and Vos, 1993). Rarely do females manifest the complete L1 syndrome phenotype (Schrander-Stumpel and Vos, 1993).

31.3.2.2 Genetics

The *L1CAM* gene is located on the long arm of X-chromosome (Xq28) and is comprised of 29 exons, the first being noncoding, spanning about 16 kb (Bertolin et al., 2010; Schrander-Stumpel and Vos, 1993; Vos et al., 2010). The L1 syndrome results from missense, nonsense, splice site, and frameshift mutations scattered throughout the exons and intron–exon boundaries of the *L1CAM* gene (Bertolin et al., 2010; Engle, 2010; Schrander-Stumpel and Vos, 1993). Since the known *L1CAM* mutations are scattered over the whole coding region, the entire gene has to be sequenced in order to achieve molecular diagnosis (Bertolin et al., 2010). To date, more than 240 different mutations have been reported in the *L1CAM* gene (Bertolin et al., 2010). Most *L1CAM* mutations are unique to each family, that is, they appear to be private mutations (Vos et al., 2010). Only a few families harbor the same recurrent mutation (Vos et al., 2010).

Missense mutations account for over one-third of pathological L1 mutations described, and those affecting extracellular domains result in more severe clinical consequences than those affecting the cytoplasmic part of L1 (Schafer et al., 2010). Some missense mutations affect structurally important amino acid sites in the extracellular domains, which may cause protein misfolding (Schafer et al., 2010). Such missense mutations interfere with homo- and heterophilic ligand binding, intracellular trafficking, neurite growth, and neurite branching (Bertolin et al., 2010; Engle, 2010; Schafer et al., 2010). Children with a truncating mutation are more likely to die before the age of 3 than children with a missense mutation (Vos et al., 2010).

Axon guidance defects occur with both extra- and intracellular mutations (Engle, 2010). The role of L1CAM in neuronal migration and survival, synaptogenesis, and long-term potentiation may also contribute to the phenotype (Engle, 2010).

L1CAM mutation analysis is offered to patients suspected of having L1 syndrome (Vos et al., 2010). Once a mutation has been established, prenatal testing can be performed in subsequent pregnancies, and carrier-ship testing can be carried out to determine the potential presence of an *L1CAM* mutation in female relatives (Vos et al., 2010).

31.3.2.3 Neuroradiological Findings

Neuroimaging reveals hydrocephalus with or without stenosis of the aqueduct of Sylvius in combination with corpus callosum agenesis/hypogenesis and/or cerebellar hypoplasia, small brainstem, and agenesis of the pyramids (corticospinal tracts) (Engle, 2010; Schrander-Stumpel and Vos, 1993). Bilateral absence of the pyramids detected by MRI is an almost pathognomonic inding (Schrander-Stumpel and Vos, 1993). Aqueductal stenosis is not a constant feature of L1 syndrome (Schrander-Stumpel and Vos, 1993).

L1 syndrome cannot be reliably diagnosed on the basis of prenatal ultrasound only (Schrander-Stumpel and Vos, 1993). A diagnosis of hydrocephalus often requires serial ultrasound examination and cannot be guaranteed before 20–24 weeks of gestation or even the third trimester of pregnancy (Schrander-Stumpel and Vos, 1993). Apparently, normal ultrasound findings in a pregnancy with a priori increased risk are not reliable in ruling out L1 syndrome in the fetus (Schrander-Stumpel and Vos, 1993).

31.3.3 Joubert Syndrome and Related Disorders

Joubert syndrome (JS) is an autosomal recessive and genetically heterogeneous trait characterized by combinations of congenital hypotonia, ataxia, abnormal respiratory patterns, mental retardation, social disabilities including autism, and synkinetic mirror movements (Engle, 2010; Parisi, 2009; Valente et al., 2008). The JS can also cosegregate with retinopathy, kidney disease, liver disease, polydactyly, obesity, and/or situs inversus (Engle, 2010; Valente et al., 2008). This spectrum is now called JS and related disorders (JSRD) (Engle, 2010).

The prevalence of JSRD has been estimated as approximately 1:100 000 in the United States, but this is likely an underestimate given by the broad spectrum of features particularly in those with milder manifestations (Parisi, 2009).

JS and JSRD are classified as ciliopathies because the mutated genes encode signal transduction and scaffolding proteins implicated in the function of the primary cilium or its anchoring structure, the basal body (Engle, 2010; Valente et al., 2008). Cilia sense environmental cues and mediate signals through receptor-dependent pathways such as SHH, noncanonical Wnt, and platelet-derived growth factor (PDGF) receptor (Engle, 2010; Parisi, 2009).

The JSRD, similar to many of the disorders considered ciliopathies, shows considerable heterogeneity in clinical features and on a molecular basis (Parisi, 2009; Valente et al., 2008). The clinical features of JSRD are shared by many ciliary disorders and typically involve the renal epithelium, retinal photoreceptor cells, central nervous system, body axis, sensory organs, and others (Parisi, 2009; Valente et al., 2008).

31.3.3.1 Clinical Characteristics

The features necessary for a diagnosis of classic JB include the following: The molar tooth sign on axial views from cranial MRI studies comprised of these three

findings: cerebellar vermis hypoplasia, deepened inter-pendicular fossa, and thick, elongated superior cerebellar peduncles; intellectual impairment/developmental delay of variable degree; hypotonia in infancy; one or both of the following (not required but supportive of the diagnosis): irregular breathing pattern in infancy (episodic apnea and/or tachypnea, sometimes alternating) and abnormal eye movements (nystagmus and/or oculomotor apraxia (OMA)) (Parisi, 2009; Valente et al., 2008).

Many children with JS exhibit dysmorphic facial features that include a broad forehead, arched eyebrows, eyelid ptosis, wide-spaced eyes, open mouth configuration, and facial hypotonia (Parisi, 2009). Some individuals also have polydactyly of the hands and/or feet, which can take many forms (Parisi, 2009).

The JSRD encompasses classic JS as described previously, as well as conditions with other features such as central nervous system anomalies (including occipital encephalocele, corpus callosal agenesis), ocular coloboma, retinal dystrophy, renal disease (including cystic dysplasia or nephronophthisis (NPHP) (cystic kidney disease), and hepatic fibrosis (Parisi, 2009; Valente et al., 2008). When the ocular and renal systems are involved, the syndromes are sometimes described as cerebello-oculo-renal syndromes (Parisi, 2009; Valente et al., 2008). An association between kidney disease and retinal involvement has been observed, with specific findings of NPHP plus retinal dystrophy known as Senior–Loken syndrome (Parisi, 2009; Valente et al., 2008).

One JSRD is the condition known as COACH syndrome (coloboma, oligophrenia/developmental delay, ataxia, cerebellar vermis hypoplasia, hepatic fibrosis) (Parisi, 2009; Valente et al., 2008). Liver involvement, when coupled with renal cystic disease, has prompted the inclusion of JSRD as a congenital hepatorenal fibrocystic disease (Parisi, 2009; Valente et al., 2008).

Cognitive impairment in JSRD is highly variable, with many children exhibiting moderately severe disability (Parisi, 2009). The average age of independent sitting has been reported to be 19 months, and the average of walking is reported to be 4 years for those who developed these skills (Parisi, 2009).

The clinical features related to the complex hindbrain malformation include ataxia, which typically becomes apparent as children develop ambulation, and ocular, oral-motor, and speech dyspraxia (Parisi, 2009). Some children require assistive devices or use sign language to communicate given expressive language impairment (Parisi, 2009).

Seizures have been reported in some children with JSRD (Parisi, 2009). Some children with JSRD and autistic features have been described (Parisi, 2009). Behavioral problems, typically impulsivity, perseveration, and temper tantrums, appear to be relatively common particularly with increasing age (Parisi, 2009).

There is a broad spectrum of ocular findings in JSRD (Parisi, 2009; Valente et al., 2008). Abnormalities of ocular motility are very common, particularly nystagmus, which can be horizontal, vertical, and/or torsional, and typically has a pendular or sometimes see-saw pattern, and OMA, which is characterized by difficulty in smooth visual tracking, dysconjugate eye movements, and head thrusting to compensate for poor saccade initiation (Parisi, 2009; Valente et al., 2008). Nystagmus and OMA are often present at birth and may improve with age (Parisi, 2009; Valente et al., 2008).

Other common ocular anomalies that may require medical or surgical treatment include strabismus, amblyopia, and ptosis (Parisi, 2009). Third nerve palsy, Duane anomaly (unilateral or bilateral restriction in the ability to move the affected eye outward, and when attempting to move the affected eye inward, it retracts into the orbit, resulting in narrowing of the width of the palpebral fissure) and optic disc drusen have also been observed (Parisi, 2009).

Coloboma, a congenital ocular developmental defect, is present in a subset of individuals with JSRD and typically involves the choroids and retina, but rarely the iris (Parisi, 2009). Many children with unilateral or bilateral colobomas also develop liver disease, as in COACH syndrome, but colobomas are not a necessary feature of this disorder (Parisi, 2009). However, retinal dystrophy is not typical in COACH syndrome, in contrast to other JSRDs (Parisi, 2009).

Kidney disease is relatively common on JSRD, with a prevalence of up to 30% of subjects in early surveys; this estimate may be even higher with long-term follow-up given its age-dependent penetrance (Parisi, 2009; Valente et al., 2008). Two different forms of kidney disease have been described: cystic dysplasia and juvenile NPHP (Parisi, 2009).

Cystic dysplasia may be identified prenatally or congenitally by ultrasound findings of multiple cysts of many different sizes in immature kidneys with fetal lobulations (Parisi, 2009; Valente et al., 2008). This finding is the characteristic of Dekaban-Arima syndrome, a JSRD that includes congenital blindness and occasional encephalocele (Parisi, 2009; Valente et al., 2008).

The other, more common renal disorder in JSRD is juvenile NPHP, characterized by tubulointerstitial nephritis and cysts concentrated at the corticomedullary junction (Parisi, 2009; Valente et al., 2008). Most children present with urine-concentrating defects in the first or second decade of life as manifested by polydipsia, polyuria, anemia, and growth failure, with a rise in serum creatinine around 9 years and progression to the end-stage renal disease by approximately 13 years of age (Parisi, 2009; Valente et al., 2008). Mutations in at least nine ciliary genes have been identified in individuals with NPHP, about 20% of whom have extrarenal

manifestations, including cerebellar malformations, OMA, and retinal dystrophy (Vos et al., 2010). It is possible that the renal disease in JSRD is part of a continuum of findings with the common etiology involving abnormal ciliary proteins leading to tubular dysfunction (Parisi, 2009).

In rare cases, the congenital renal disease in JSRD consists of enlarged kidneys, microscopic cysts distributed throughout the cortex and medulla, and infantile hypertension, similar to the renal disease of autosomal recessive polycystic kidney disease (Parisi, 2009; Valente et al., 2008). Several of these patients have *MKS3* (Meckel–Gruber syndrome Gene 3) mutations similar to those with COACH syndrome (Parisi, 2009).

Hepatic involvement in JSRD is likely underreported, as manifestations of liver disease are usually not apparent at birth (Parisi, 2009). However, since current management guidelines recommend routine screening for liver dysfunction in all children with JSRD, hepatic involvement is being identified presymptomatically (Parisi, 2009). The liver disease in COACH syndrome has demonstrated variable progression (Parisi, 2009; Valente et al., 2008). Some JSRD/COACH patients present with evidence of portal hypertension, including hematemesis, esophageal varices or portosystematic shunting, and occasionally life-threatening bleeding events (Parisi, 2009; Valente et al., 2008); others present with elevated or fluctuating levels of serum transaminases (ALT or AST) or gamma-glutamyl transferase (Parisi, 2009). Physical examination findings may include hepatomegaly with or without splenomegaly (Parisi, 2009).

The skeletal findings in JSRD include cone-shaped epiphyses and polydactyly (Parisi, 2009). Cone-shaped epiphyses have been most observed in children with Mainzer–Saldino syndrome (cerebellar ataxia with NPHP and retinal dystrophy) (Parisi, 2009). Polydactyly is often postaxial, although preaxial polydactyly of the hands or great toes has been observed (Parisi, 2009). Mesaxial polydactyly has been described in individuals with the oral-facial-digital type VI syndrome, a JSRD with oral frenulae, lingual tumors or hamartomas, and craniofacial findings that include wide-spaced eyes and a midline lip groove (Parisi, 2009). With age, some children with JSRD develop scoliosis related to abnormal tone (Parisi, 2009).

Endocrine abnormalities are not uncommon in JSRD, and some children exhibit pituitary hormone dysfunction such as isolated growth hormone or thyroid hormone deficiency, or even more extensive panhypopituitarism, with some males demonstrating micropenis (Parisi, 2009).

The vast majority of infants and children diagnosed with JSRD survive the neonatal period and many demonstrate improvement with time in their tone, respiratory function, and feeding behaviors (Parisi, 2009). Because of the risk of later development of retinal, renal, and hepatic complications, ongoing monitoring is essential (Parisi, 2009).

31.3.3.2 Genetics

The JSRD is genetically heterogeneous, and at least nine loci and eight genes *INPP5E* (inositol polyphosphate-5-phosphatase), *AHI1* (Abelson helper integration site 1), *NPHP1*, *CEP290* (centrosomal protein 290 kDa), *TMEM67* (transmembrane protein 67), *RPGRIP1L* (RPGR-interacting protein-1-like protein), *ARL13B* (ADP-ribosylation factorlike 13B), and *CC2D2A* (coiled-coil and C2 domain containing 2A) have been identified (Engle, 2010).

The *INPP5E* gene was identified as causative, and the retinal phenotype is predominant (Parisi, 2009). Also, it is possible that this gene represents another COACH gene (Parisi, 2009). This gene encodes an inositol polyphosphatase-5-phosphatase E necessary for cilia stability and indicates a link between phosphotidylinoditol signaling and ciliary function (Parisi, 2009).

Mutations in the 29-exon gene, *AHI1,* have been identified in JSRD (Valente et al., 2008). This gene encodes a protein of unknown function named jouberin, containing several protein–protein interaction domains (Valente et al., 2008). The most common clinical association in *AHI1*-related JSRD is retinal dystrophy, occurring in ~80% of those with mutations (Parisi, 2009; Valente et al., 2008). Renal disease has been observed in some subjects (Parisi, 2009). However, no subjects with *AHI1* mutations have had features of encephalocele, polydactyly, or liver fibrosis (Parisi, 2009). Other central nervous system anomalies, including PMG, corpus callosum anomalies, and frontal lobe atrophy, have been described in some individuals with *AHI1* mutations (Parisi, 2009). Single heterozygous mutations in the *AHI1* gene have been identified in a number of JSRD patients within the reported screenings (Valente et al., 2008). The vast majority of identified mutations are nonsense (truncating, frameshift, or splice-site mutations) that cluster mainly in the first half of the gene (exons 7–16) and in exons encoding the functional domains (Valente et al., 2008). Missense mutations are rare and are predicted to affect amino acid residues that are crucial for the correct functioning of such domains (Valente et al., 2008). No correlation can be drawn between the type or site of mutations and the associated phenotype (Valente et al., 2008).

The first gene associated with JSRD, the 30-exon *NPHP1* gene, was identified as causing juvenile NPHP (Parisi, 2009). *NPHP* resides within a ~290 kb region of genomic DNA flanked by large inverted repeat elements on chromosome 2q13 that is homozygously deleted in JSRD or NPHP; a few individuals are

compound heterozygotes for a deletion and a point mutation in *NPHP1* (Parisi, 2009; Valente et al., 2008). The *NPHP1* mutation detection rate for the purely renal disorder is ~20–30%, whereas the mutation rate is only about 1–3% in individuals with JSRD (Parisi, 2009). Some individuals with the common deletion have congenital OMA known as Cogan syndrome, and others have Senior–Loken syndrome with retinal impairment, but in general, the neurologic symptoms tend to be milder than in many children with JSRD (Parisi, 2009; Valente et al., 2008).

The large, 54-exon *CEP290* gene, mapping to the long arm of chromosome 12, has been associated with multiple clinical disorders ranging from isolated Leber congenital amaurosis to JSRD, MKS, and BBS (Parisi, 2009; Valente et al., 2008). Most subjects with JSRD due to *CEP290* mutations have retinal dystrophy or congenital blindness, and many also develop renal disease consistent with NPHP or renal cortical cysts (Parisi, 2009; Valente et al., 2008). Findings in some affected individuals have included ocular colobomas, encephaloceles, septal heart defects, hepatic disease, and situs anomalies (Parisi, 2009). The most frequent *CEP290* mutation, and the one that holds the strongest genotype–phenotype correlation, is the intronic mutation c.2991 + 1655>G that creates a splice-donor site and inserts a cryptic exon in the *CEP290* messenger RNA between exons 26 and 27, introducing a stop codon immediately downstream of exon 26 (Valente et al., 2008).

The 28-exon *TMEM67/MKS3* gene, mapping to chromosome 8q22, encodes a 995-amino acid protein called meckelin, which plays a role in primary cilium formation and interacts with other known ciliary proteins (Parisi, 2009; Valente et al., 2008). Originally identified as a causative for MKS, mutations in this gene have been reported in JSRD (Parisi, 2009; Valente et al., 2008). The *MKS3* mutations identified in MKS are typically compound heterozygous missense and truncating mutations or homozygous splice-site mutations that are found across the whole gene length, whereas the disease-associated mutations in JSRD/COACH tend to be missense mutations or the combination of a missense mutation and a splice-site or nonsense mutation, with very few mutations overlapping with those seen in MKS (Parisi, 2009; Valente et al., 2008).

Mutations in the *RPGRIP1L* gene were first identified in patients with the renal form of JSRD (Parisi, 2009). This gene has 26 exons encoding for a 1315 amino acid protein containing several coiled-coil domains, required for protein–protein interactions (Valente et al., 2008). The phenotype spectrum includes renal disease with some affected individuals manifesting occipital encephaloceles and polydactyly, and rarely, retinal disease or colobomas; a few have scoliosis, clubfoot, or pituitary hormone deficiency (Parisi, 2009). Hepatic fibrosis and

COACH syndrome have been described in individuals with JSRD due to *RPGRIP1L* (Parisi, 2009). Overall, estimates of the prevalence of *RPGRIP1L* mutations in the cerebello-renal form of JSDR range from ~9 to 12% (Parisi, 2009).

ARL13B, a 10-exon gene, encodes a protein that is a member of the Ras GTPase family and localizes to the primary cilia of cerebellar neurons, kidney, and retina (Parisi, 2009).

The phenotype in patients with mutations in the 38-exon *CC2D2A* gene has ranged from classic JS to JS with encephalocele to the COACH phenotype with coloboma, liver, and kidney involvement (Parisi, 2009). *CC2D2A* has been shown to interact with *CEP290* (Parisi, 2009). This gene is estimated to cause almost 10% of JSRD (Parisi, 2009).

The genes mentioned previously account for an estimated 50% of causative mutations in JSRD (Parisi, 2009). The same JSRD gene can cause multiple different phenotypes, and several different genes can be associated with the same clinical features (Parisi, 2009; Valente et al., 2008). In addition, clinical features can vary between affected siblings within the same family (Parisi, 2009). This intrafamilial variability supports the existence of genetic modifiers and epistatic effects (Parisi, 2009; Valente et al., 2008). Commercial clinical testing is available for many of the JSRD genes (Parisi, 2009). Additional JSRD genes remain to be identified (Parisi, 2009).

The gene products associated with JSRD are known to localize to the primary cilium and/or basal body and the centrosome apparatus, which has been identified in almost all cell types, and many of these proteins are important for the structure, function, and/or stability of this organelle and its related structures (Parisi, 2009; Valente et al., 2008).

Primary cilia play a role in intraflagellar transport, cell division, tissue differentiation, establishment of body axis, growth, and mechanosensation involved in cellular signaling processes and are essential for signal transduction processes that underlie many aspects of vertebrate development and morphogenesis, including the SHH, Wnt/β-catenin, PDGF receptor alpha signaling pathways, Ras-GTP, and phosphotidylinositol signaling (Parisi, 2009; Valente et al., 2008).

In the developing brain, primary cilia have been involved in regulating some of the most powerful pathways active in the early embryo, such as those of Wnt and Sonic hedgehog (Valente et al., 2008). It appears that cilia can function as a sort of cellular sensor, picking up environmental signals and transducing them to the nucleus, regulating cell cycle and proliferation (Valente et al., 2008).

Also, the proper cell polarity and orientation of tubular structures in tissues require normal ciliary function

(Parisi, 2009). The expanding group of human disorders known as ciliopathies shares overlapping clinical manifestations that reflect the critical role cilia play in the growth and differentiation of various tissues (Parisi, 2009).

31.3.3.3 Neuroradiological Findings

The diagnosis of JSRD is dependent on the presence in MRI of the 'molar tooth' sign, a toothlike shape on axial images at the level of the midbrain–hindbrain junction that reflects cerebellar vermian hypoplasia, a deepened interpeduncular fossa, and horizontally oriented and thickened superior cerebellar peduncle (SCP) (Engle, 2010; Parisi, 2009; Valente et al., 2008). When a diagnosis of JSRD is suspected, a detailed cranial MRI to evaluate the molar tooth sign is essential (Parisi, 2009).

The peculiar neuroradiological malformations seen in JS have their correspondence at the neuropathological level, with various abnormalities of the midbrain and hindbrain being consistently identified in brains from JS patients (Valente et al., 2008). Postmortem studies of individuals with genetically undefined JS have revealed severe cerebellar vermian hypoplasia or absence, with midline clefting, dysplasia of the deep cerebellar and inferior olivary nuclei, elongation of the caudal midbrain tegmentum, reduction in pontine neurons, hypoplasia of the solitary, trigeminal and dorsal column nuclei and tracts, and occasional heterotopia of Purkinje-like neurons (Engle, 2010; Valente et al., 2008).

Approximately 10% of individuals with JSRD demonstrate fluid collections in the posterior fossa resembling the Dandy–Walker malformation (agenesis of the cerebellar vermis, cystic dilation of the fourth ventricle, and enlargement of the posterior fossa (Parisi, 2009). Although hydrocephalus is uncommon in JSRD, rare patients have required a shunt for symptomatic elevations of intracranial pressure (Parisi, 2009).

In addition, occipital encephaloceles or meningoceles have been observed, suggesting overlap with Meckel syndrome, a typical prenatal or perinatal lethal ciliopathy characterized by brain anomalies (especially encephalocele), cystic renal dysplasia, and the hepatic ductal plate malformation (Parisi, 2009). Other brain anomalies in JSRD have included PMG, ACC, and cerebellar heterotopias (Parisi, 2009).

Prenatal imaging via ultrasound and/or fetal MRI is the best and most practical diagnostic option (Parisi, 2009). Extracranial anomalies such as polydactyly or renal cysts and major structural brain malformations such as encephalocele may facilitate prenatal diagnosis of JSRD as early as the first trimester or may suggest the diagnosis (Parisi, 2009). Early diagnosis is more difficult when extracranial findings are not present and because the molar tooth sign has not been reported before 27 weeks of gestation (Parisi, 2009).

31.3.4 Horizontal Gaze Palsy with Progressive Scoliosis

Horizontal gaze palsy with progressive scoliosis (HGPPS) is a rare, clinically and genetically homogeneous disorder in which hindbrain axons fail to cross the midline (Amouri et al., 2009; Avadhani et al., 2010; Bomfim et al., 2009; Engle, 2010). This disorder is characterized by congenital absence of conjugate horizontal eye movements and preservation of vertical gaze and convergence, which is associated with progressive scoliosis developing in childhood and adolescence (Amouri et al., 2009; Avadhani et al., 2010; Bomfim et al., 2009; Otaduy et al., 2009).

31.3.4.1 Clinical Characteristics

Clinical findings characteristic of HGPPS include absence of all horizontal gaze reflexes, conjugate pendular nystagmus, and progressive scoliosis (Bomfim et al., 2009; Engle, 2010; Otaduy et al., 2009). Affected individuals are born with restricted horizontal gaze and develop scoliosis within the first decade of life (Engle, 2010; Otaduy et al., 2009).

The gaze palsy may result from errors in axon connectivity into and out of the abducens nucleus (Bomfim et al., 2009; Engle, 2010). The normal contralateral inputs onto the abducens nucleus from the pontine paramedian reticular formation and vestibular nuclei are predicted to be ipsilateral in HGPPS, and this would likely alter the firing patterns of motor and internuclear neurons (Bomfim et al., 2009; Engle, 2010). Axons of the abducens internuclear neurons would also fail to cross the midline via the medial longitudinal fasciculus to synapse on medial rectus motor neurons in the contralateral oculomotor nucleus, further perturbing horizontal gaze (Bomfim et al., 2009; Engle, 2010).

Although the etiology of scoliosis is also speculative, HGPPS provides the first genetic evidence of a neurogenic cause for this disability (Bomfim et al., 2009; Engle, 2010). It has been suggested that the pathogenesis of progressive idiopathic scoliosis involves a primary neurological dysfunction involving the proprioceptive inputs mediated by the posterior column pathways of the spinal cord and medial lemniscus (Bomfim et al., 2009).

Individuals with HGPPS perform normally on neuropsychological testing and have normal fine motor control without mirror movements, suggesting that the pathologically ipsilateral corticospinal axons find their appropriate target, albeit on the wrong side (Engle, 2010).

The differential diagnosis of HGPPS embraces several genetic disorders of eye movement, such as Duane retraction syndrome (DRS), Möbius syndrome, and others (Bomfim et al., 2009; Otaduy et al., 2009). Clinical and

neuroimaging findings can differentiate these entities from HGPPS (Bomfim et al., 2009).

31.3.4.2 Genetics

HGPPS is an autosomal recessive trait and results from mutations in the *ROBO3* gene (http://www.ncbi.nlm.nih.gov/omim) (Amouri et al., 2009; Avadhani et al., 2010; Bomfim et al., 2009; Engle, 2010; Otaduy et al., 2009). *ROBO3* encodes a transmembrane receptor, and it is a divergent member of the Robo family of axon guidance molecules (Amouri et al., 2009; Engle, 2010; Otaduy et al., 2009). Robo 3 is essential for midline crossing of hindbrain and spinal cord commissural and precerebellar axons (Avadhani et al., 2010; Engle, 2010). Robo 3 is also necessary for midline crossing of precerebellar neurons, and defects in neuronal migration may also contribute to the HGPPS phenotype (Amouri et al., 2009; Avadhani et al., 2010; Engle, 2010).

ROBO3 alternative splicing produces two functionally antagonistic isoforms with distinct carboxy termini (Engle, 2010). *ROBO3.1* inhibits the responsiveness of commissural axons to Slit repellents and is present on commissural axons before and during midline crossing, whereas *ROBO3.3* is Slit responsive and appears on the growth cone postcrossing to block the recrossing (Engle, 2010). HGPPS mutations reported to date alter nucleotides common to both isoforms (Engle, 2010).

Indistinguishable phenotypes result from *ROBO3* nonsense, frameshift, splice-site, or missense mutations spread across the gene, supporting a complete loss of *ROBO3* function (Engle, 2010). Over ten different mutations located in different domains of the encoded protein have been identified and are thought to diminish the function of this receptor (Amouri et al., 2009).

31.3.4.3 Neuroradiological Findings

Electrophysiological and neuroimaging studies in HGPPS support the absence of decussating axons in the pons and medulla (Engle, 2010). MRI reveals ventral flattening and hypoplasia of the hindbrain, absence of facial colliculi, and a butterfly-shaped medulla with a midline pontine cleft (Avadhani et al., 2010; Bomfim et al., 2009; Engle, 2010; Otaduy et al., 2009). The unusual appearance of the medulla and abnormal functional results suggest that sensorimotor projections do not cross the midline in HGPPS (Amouri et al., 2009). Functional MRI reveals ipsilateral rather than the normal contralateral activation in the primary motor cortex following motor tasks (Engle, 2010).

The split pons sign is attributable to abnormal development of the abducens nuclei and medial longitudinal fasciculus occurring between 5 and 8 weeks of gestation (Bomfim et al., 2009). Hypoplasia of the medial lemniscus, which is located posterior to the pyramids, is thought to explain why the inferior olivary nuclei are unusually more prominent than the pyramids (Bomfim et al., 2009). The deep midline cleft along the ventral aspect of the medulla oblongata has been described as the result of uncrossed corticospinal tracts (Bomfim et al., 2009).

DTI, with its ability to demonstrate white matter tracts, is a very suitable technique to further evaluate the abnormalities underlying this disease (Otaduy et al., 2009). Previous DTI studies have described the absences of superior cerebellar and pyramidal decussations, major pontine fibers, and decussation of the superior cerebellar peduncles, with fMRI combined study confirming the ipsilateral sensorimotor findings (Avadhani et al., 2010; Engle, 2010; Otaduy et al., 2009). The cortex, corpus callosum, and exiting cranial nerves appear structurally normal (Engle, 2010).

31.3.5 Kallmann Syndrome

Individuals with Kallman syndrome (KS) have congenital anosmia and hypogonadotropic hypogonadism (HH) (http://www.ncbi.nlm.nih.gov/omim) (Engle, 2010; Fechner et al., 2008; Hardelin and Dode, 2008; Kaplan et al., 2010; Kim et al., 2008). Anosmia is related to the absence or hypoplasia of the olfactory bulb and tracts (Hardelin and Dode, 2008). Hypogonadism is due to gonadotropin-releasing hormone (GnRH) deficiency, which presumably results from a failure of the embryonic migration of neuroendocrine GnRH cells from the olfactory epithelium to the forebrain (Engle, 2010; Fechner et al., 2008; Hardelin and Dode, 2008; Kaplan et al., 2010; Kim et al., 2008). This failure could be a consequence of the early degeneration of olfactory nerve and terminal nerve fibers, because the latter normally act as guiding cues for the migration of GnRH cells (Engle, 2010; Hardelin and Dode, 2008). Defects in GnRH cell fate specification, differentiation, axon elongation, or axon targeting to the hypothalamus median eminence may, however, also contribute to GnRH deficiency, at least in some genetic forms of the disease (Hardelin and Dode, 2008). Both olfactory sensory neurons and GnRH are born in the olfactory placode of the developing nose (Engle, 2010; Fechner et al., 2008). It is proposed that errors in growth and guidance of olfactory axons can result in KS (Engle, 2010).

The prevalence of the disease has been estimated at 1 out of 8000 in boys (Hardelin and Dode, 2008). In girls, the prevalence might be five times lower (Hardelin and Dode, 2008).

31.3.5.1 Clinical Characteristics

Transmitting females have partial or complete anosmia (http://www.ncbi.nlm.nih.gov/omim). Often, the lack of smell goes unnoticed, and individuals with KS

are not diagnosed until they fail to undergo secondary sexual development during the teenage years (Engle, 2010; Fechner et al., 2008; Kaplan et al., 2010; Kim et al., 2008). The KS may also be suspected as early as in infancy in boys, in the presence of cryptorchidism or a micropenis, combined with subnormal LH (luteinizing hormone) and FSH (follicle-stimulating hormone) concentrations (Hardelin and Dode, 2008; Kaplan et al., 2010). Microphallus has been noted in up to 65% of individuals with KS, and cryptorchidism has been reported in up to 73% of males with KS (Kaplan et al., 2010). The postnatal surge in FSH, LH, and testosterone in the male infant, as a consequence of the continued function of the fetal GnRH pulse generator, provides a 6-month window of opportunity to establish the diagnosis of HH (Hardelin and Dode, 2008).

Other frequently occurring features in this syndrome include characteristic face and hand dysmorphia, hypotonia, arhinencephaly, semicircular canal agenesis or hypoplasia, deafness, urinary tract anomalies, orofacial clefting, dysphagia, and tracheo-esophagial anomalies (Fechner et al., 2008; Hardelin and Dode, 2008; Kim et al., 2008).

The renal abnormality most frequently associated with KS is unilateral renal aplasia, but other anomalies such as renal diverticulum, horseshoe kidney, malrotated kidney, multicystic dysplastic kidney, and vesiculoureteral reflux have been reported (Kaplan et al., 2010; Kim et al., 2008). Unilateral renal aplasia is more often right sided in KS patients, while renal agenesis in individuals without KS is more likely to be left sided (Kaplan et al., 2010). All patients with suspected KS should have a renal ultrasound to rule out a renal anomaly (Kaplan et al., 2010; Kim et al., 2008).

Cleft lip $\pm$ palate has been noted in up to 13–14% of individuals with KS (Kaplan et al., 2010; Kim et al., 2008). The incidence of clefting in KS patients is significant, as the incidence of cleft lip $\pm$ palate in the general population is only 0.1–0.2% (Kaplan et al., 2010). In addition to cleft lip $\pm$ palate, cleft palate alone and dental agenesis have been reported in several patients with KS (Kaplan et al., 2010).

The incidence of hearing loss in patients with KS has been reported to be as high as 28% (Kaplan et al., 2010; Kim et al., 2008). Both sensorineural and conductive hearing loss have been described (Kaplan et al., 2010). Hearing loss is commonly unilateral (Kaplan et al., 2010). Individuals in whom KS is suspected should undergo formal auditory evaluation (Kaplan et al., 2010). Abnormalities of the inner ear have been noted on CT scan (Kaplan et al., 2010).

Other less-common findings associated with KS include musculoskeletal anomalies, such as clinodactyly, camptodactyly, and fusion of the fourth and fifth metacarpal bones; oculomotor anomalies, such as ptosis, iris

coloboma, and nystagmus; high-arched palate, unilateral nasal cartilage agenesis; malrotation of the gut; visual attention defects; and cardiac defects (Kaplan et al., 2010; Kim et al., 2008). Cardiac defects reported include atrial septal defect, ventricular septal defect, right-sided aortic arch, double-outlet right ventricle, transposition of the great arteries, and arrhythmias (Kaplan et al., 2010). X-linked ichthyosis, mental retardation, chondrodysplasia punctata, and short stature can also occur, usually as part of a contiguous gene syndrome (Kim et al., 2008).

Studies of X-linked Kallmann syndrome have found instances of renal agenesis and also pointed to mirror movements of the hands (synkinesia), pes cavus, high-arched palate, and cerebellar ataxia (http://www.ncbi.nlm.nih.gov/omim) (Fechner et al., 2008; Kim et al., 2008).

The KS is diagnosed when low-serum gonadotropins and gonadal steroids are coupled with a compromised sense of smell (Fechner et al., 2008; Hardelin and Dode, 2008; Kim et al., 2008). The latter should be ascertained by the means of detailed questioning and olfactory screening tests (Fechner et al., 2008; Hardelin and Dode, 2008; Kim et al., 2008).

The treatment of KS is that of the hypogonadism (Fechner et al., 2008; Hardelin and Dode, 2008; Kim et al., 2008). It aims first to initiate virilization or breast development and second to develop fertility (Fechner et al., 2008; Hardelin and Dode, 2008; Kim et al., 2008). Hormone replacement therapy, with testosterone for males and combined estrogen and progesterone for females, is the treatment to stimulate the development of secondary sexual characteristics (Fechner et al., 2008; Hardelin and Dode, 2008; Kim et al., 2008).

31.3.5.2 Genetics

The KS is genetically heterogeneous (Engle, 2010). Most KS patients present as sporadic cases (two thirds of cases), but many cases are clearly familial and can be inherited as an X-linked, autosomal dominant, and autosomal recessive trait (Engle, 2010; Fechner et al., 2008; Hardelin and Dode, 2008; Kaplan et al., 2010; Kim et al., 2008). In the autosomal dominant form, incomplete penetrance has been emphasized, which makes it difficult to identify affected patients (Fechner et al., 2008; Hardelin and Dode, 2008; Kim et al., 2008). Overall, the autosomal dominant mode of inheritance seems to account for 86% of inherited cases of KS (Fechner et al., 2008).

Six genes have been reported, accounting for approximately 30% of cases: *KAL1* (Kallmann syndrome 1 sequence), *FGFR1* (fibroblast growth factor receptor 1), *PROK2* (prokineticin 2), *PROKR2* (prokineticin receptor 2), *FGF8* (fibroblast growth factor 8), and *CHD7* (chromodomain helicase DNA-binding protein-7) (Engle, 2010;

Kaplan et al., 2010; Kim et al., 2008). These KS genes encode transmembrane receptors and ligands that may be important for growth cone guidance (Engle, 2010). Some KS proteins also interact with one another and with heparan sulfate proteoglycans to amplify downstream signaling pathways (Engle, 2010).

The KS can be oligogenic, resulting from combinations of mutations in more than one KS gene (Engle, 2010; Hardelin and Dode, 2008; Kim et al., 2008). It is possible that oligogenic inheritance accounts in part for the long recognized incomplete penetrance of the disease, at least in some cases (Hardelin and Dode, 2008; Kim et al., 2008).

X-linked KS is caused by loss-of-function mutations in *KAL1*, which is expressed in developing olfactory bulb (http://www.ncbi.nlm.nih.gov/omim) (Engle, 2010; Hardelin and Dode, 2008; Kaplan et al., 2010; Kim et al., 2008). Two-thirds of males harboring *KAL1* mutations also have mirror movements and enlarged, aberrant ipsilateral CSTs, supporting a role of *KAL1* in the guidance of CST and olfactory axons (http://www.ncbi.nlm.nih.gov/omim) (Engle, 2010; Hardelin and Dode, 2008; Kaplan et al., 2010).

The *KAL1* gene is found in the pseudoautosomal region of the X-chromosome and encodes the secreted glycoprotein anosmin-1, which has cell adhesion, neurite outgrowth, and axon guidance and branch-promoting activities (http://www.ncbi.nlm.nih.gov/omim) (Engle, 2010; Fechner et al., 2008; Hardelin and Dode, 2008; Kaplan et al., 2010; Kim et al., 2008). Anosmin-1 requires heparin sulfate for its functions (Kim et al., 2008). Anosmin is required for the normal migration of olfactory and GnRh neurons from the olfactory placode to the hypothalamus (Fechner et al., 2008; Kim et al., 2008).

The vast majority of *KAL1* mutations reported so far are nonsense mutations, frameshift mutations, or large gene deletions, which are expected to inactivate protein synthesis, and are apparently sufficient to produce the abnormal phenotype in males (Fechner et al., 2008; Hardelin and Dode, 2008; Kim et al., 2008). The *KAL1* gene is also expressed in developing Purkinje cells of the cerebellum, meso- and metanephros, oculomotor nucleus, and facial mesenchyme (Fechner et al., 2008).

Mutations in *FGFR1*, also known as *KAL2*, underlie an autosomal dominant form of the disease (Fechner et al., 2008; Hardelin and Dode, 2008; Kaplan et al., 2010; Kim et al., 2008). This gene is localized on chromosome 8p11.2–p12 (Fechner et al., 2008; Kim et al., 2008). *FGFR1* is a member of the receptor tyrosine kinase superfamily (Hardelin and Dode, 2008). FGF signaling controls cell proliferation, migration, differentiation, and survival and thus, plays essential roles in various processes of embryonic development (Hardelin and Dode, 2008; Kim et al., 2008). Mutations in this gene are associated with failed morphogenesis of the olfactory bulbs (Fechner et al., 2008). Mutations of *KAL1* and *KAL2* account for less than 20% of clinical cases (Kim et al., 2008). Anosmin-1 and *FGFR1* are involved in the same cellular signaling pathway (Kim et al., 2008).

Mutations in *PROKR2* and *PROK2* have been found in heterozygous, homozygous, or compound heterozygous states (Hardelin and Dode, 2008; Kaplan et al., 2010; Kim et al., 2008). Most of these mutations are missense mutations, and many are also present in apparently unaffected individuals (Hardelin and Dode, 2008). For most of the mutations, however, deleterious effects on prokineticin signaling have been shown (Hardelin and Dode, 2008). These two genes are likely to be involved in both monogenic recessive and digenic or oligogenic KS transmission modes (Hardelin and Dode, 2008). *PROKR2* belongs to the G-protein-coupled seven trans-membrane domain receptor family (Hardelin and Dode, 2008; Kim et al., 2008).

Other patients carrying heterozygous mutations in *PROKR2*, *PROK2*, or hypomorphic mutations in *KAL1* are expected to carry additional mutations in other, as yet unknown, KS genes (Hardelin and Dode, 2008). For each genetic form of KS identified so far, the clinical heterogeneity of the disease within affected families clearly indicates that the manifestation of KS phenotypes is dependent on factors other than the mutated gene itself, probably factors such as modifier genes and epigenetic factors (Hardelin and Dode, 2008; Kim et al., 2008).

Some of the possible modifier genes and candidate genes that may account for the remaining KS cases are the nasal embryonic LHRH factor (*NELF*), *CHD7*, and early B-cell factor 2 (Kim et al., 2008). *NELF* has been shown to serve as a common guidance molecule for the olfactory axon and GnRH neurons across the nasal region during mouse embryonic development (Kim et al., 2008). *CHD7* is the only known locus associated with CHARGE syndrome (Kim et al., 2008). CHARGE syndrome is a developmental disorder defined by iris coloboma, congenital heart disease, choanal atresia, mental and growth retardation, genital hypoplasia, and ear malformations and/or deafness; it sometimes includes HH associated with a defective sense of smell and abnormal olfactory bulbs development (Kim et al., 2008). *EBF* genes encode a family of transcription factors, and they have been implicated in various neural developmental processes. Their function includes axon navigation and migration (Kim et al., 2008).

A greater variability in the degree of hypogonadism has been observed in patients carrying mutations in *FGFR1*, *FGF8*, *PROKR2*, or *PROK2* than in *KAL1* patients (Hardelin and Dode, 2008). Unilateral renal agenesis occurs in approximately 30% of *KAL1* patients but has not been reported in patients with *FGFR1*, *FGF8*, *PROKR2*, or *PROK2* mutations (Hardelin and Dode, 2008; Kaplan

et al., 2010). If a renal anomaly is present, FISH analysis and/or sequencing of *KAL1* should be the first line genetic test (Kaplan et al., 2010).

Tooth agenesis and hearing impairment are common to several genetic forms of KS, although the mechanism of the hearing impairment could vary between different genetic forms (Hardelin and Dode, 2008; Kaplan et al., 2010). Palate defects should also be considered as one of these shared traits, even though the severity differs between *KAL1* and other genetic forms (Hardelin and Dode, 2008; Kaplan et al., 2010; Kim et al., 2008). Clefting has been associated with mutations in *FGFR1*, *FGF8*, and *CHD7* but not with *KAL1*, *PROK2*, or *PROKR2* (Kaplan et al., 2010). Microphallus and cryptorchidism are more common in patients with *KAL1* mutations versus *FGFR1* mutations (Kaplan et al., 2010). Hearing loss has been reported in patients with *KAL1*, *FGFR1*, *FGF8*, *PKOKR2*, and *CHD7* mutations (Kaplan et al., 2010).

31.3.5.3 Neuroradiological Findings

MRI of the forebrain can be carried out to show hypoplasia or aplasia of the olfactory bulbs and tracts (Fechner et al., 2008; Hardelin and Dode, 2008).

A hypoplastic olfactory bulb seen on cerebral MRI does not always correlate with the degree of olfactory deficit, and normal images can also be found in KS (Kim et al., 2008).

31.3.6 Albinism

Albinism is an autosomal recessive inherited condition present at birth (Renugadevi et al., 2010; Summers, 2009). The phenotype ranges from a complete lack of pigmentation in the skin, hair, and iris, called oculocutaneous albinism (OCA), or a lack of pigmentation in the iris alone, termed ocular albinism (OA) (Gronskov et al., 2007; Renugadevi et al., 2010; Summers, 2009). Several defects can cause albinism, including a complete lack of melanocytes or few pigment cells, interference in the migration of cells to their proper location during embryo development, and failure of the cells to produce melanin because of a lack of tyrosinase or abnormalities within the cells (Renugadevi et al., 2010; Summers, 2009).

The prevalence of albinism in the United States is estimated to be 1 in 18 000 (Summers, 2009). Albinism can affect people of all ethnic backgrounds (Gronskov et al., 2007). Prevalence of the different forms of albinism varies considerably worldwide, partly explained by the different founder mutations in different genes and the fact that it can be difficult clinically to distinguish between the different subtypes of albinism among the large normal spectrum of pigmentation (Gronskov et al., 2007).

31.3.6.1 Clinical Characteristics

OCA is a group of four autosomal recessive disorders caused by either a complete lack or a reduction of melanin biosynthesis in the melanocytes resulting in hypopigmentation of the hair, skin, and eyes (Gronskov et al., 2007; Summers, 2009). Reduction of melanin in the eyes results in reduced visual acuity caused by foveal hypoplasia and misrouting of the optic nerve fibers (Gronskov et al., 2007; Summers, 2009). The clinical spectrum of OCA varies, with OCA1A being the most severe type characterized by a complete lack of melanin production throughout life, while the milder forms OCA1B, OCA2, OCA3, and OCA4 show some pigment accumulation over time (Gronskov et al., 2007). The different types of OCA are caused by mutations in different genes, but the clinical phenotype is not always distinguishable, making molecular diagnosis a useful tool and essential for genetic counseling (Gronskov et al., 2007).

All types of OCA and OA have similar findings, including various degrees of congenital nystagmus, hypopigmentation of the iris leading to iris translucency, reduced pigmentation of the retinal pigment epithelium, foveal hypoplasia, reduced visual acuity and refractive errors, and sometimes a degree of color vision impairment (Gronskov et al., 2007; Renugadevi et al., 2010; Summers, 2009). Photophobia may be prominent (Gronskov et al., 2007; Renugadevi et al., 2010). A characteristic finding is misrouting of the optic nerves, consisting of an excessive crossing of the fibers in the optic chiasma, which can result in strabismus and reduced stereoscopic vision (Gronskov et al., 2007; Summers, 2009). Absence of misrouting excludes the diagnosis of albinism (Gronskov et al., 2007).

A few patients with albinism who have vision 20/50 or better have some rudimentary foveal development, and some thinning of the retina in the foveal area has been demonstrated with optical coherence tomography (Summers, 2009). Careful inspection can show granular melanin pigment in the macula in a few patients with albinism and occasionally finely granular pigment beyond the macula (Summers, 2009). The presence of melanin pigment in the macula correlates with better visual acuity (Summers, 2009). Recognition of visual acuity among persons with albinism varies from 20/20 to 20/400 but is commonly close to 20/80 (Gronskov et al., 2007; Summers, 2009).

Nystagmus typically develops by 6–8 weeks of age (Summers, 2009). Nystagmus is initially slow and has a large amplitude, but the amplitude typically decreases within the first year of life (Summers, 2009). Delayed visual maturation has been reported in albinism (Summers, 2009). Parents with an infant with albinism have noted poor fixation on faces and objects and a delay in visual development (Summers, 2009).

Pattern visual-evoked potentials performed with monocular visual stimulation demonstrate the excessive retinostriate decussation that is characteristic of albinism (Gronskov et al., 2007; Summers, 2009). In individuals with a questionable phenotype for albinism, the visual-evoked potentials can be useful in identifying those with the disorder (Summers, 2009). This abnormal decussation may account for absent stereoacuity that is often found in albinism (Summers, 2009).

Disorders in which albinism is part of a larger syndrome include Hermansky–Pudlak syndrome (HPS), Chediak–Higashi syndrome, Griscelli syndrome, and Waardenburg syndrome type 2 (WS2) (Gronskov et al., 2007; Summers, 2009). All, except WS2, are inherited as autosomal recessive traits and can be distinguished on the basis of clinical and biochemical criteria (Gronskov et al., 2007). Also, an association of hypopigmentation in Prader–Willi syndrome and Angelman disease with a deletion on 15q11 has been found (Gronskov et al., 2007).

Lifespan in patients with OCA is not limited, and medical problems are generally not increased compared to those in the general population (Gronskov et al., 2007). Skin cancers may occur, and regular skin checks should be offered (Gronskov et al., 2007). Development and intelligence are normal (Gronskov et al., 2007).

31.3.6.2 Genetics

The OCA is a group of congenital heterogeneous disorders of melanin biosynthesis in the melanocytes (Gronskov et al., 2007). At least four genes are responsible for different types of OCA (Gronskov et al., 2007; Summers, 2009). The current classification of albinism is determined by the affected gene (Summers, 2009). Most patients are compound heterozygotes (Gronskov et al., 2007). Siblings with albinism can show variable expression in visual function and clinical phenotype, suggesting that other genes modify the classical phenotype (Summers, 2009).

The OCA1 is caused by mutations in the tyrosinase gene (TYR) on chromosome 11q14–21, encoding the enzyme tyrosinase that catalyzes rate-limiting steps in the melanin biosynthetic pathway (Engle, 2010; Gronskov et al., 2007; Renugadevi et al., 2010; Summers, 2009). Mutations completely abolishing tyrosinase activity result in OCA1A, while mutations rending some enzyme activity result in OCA1B, allowing some accumulation of melanin pigment over time (Engle, 2010; Gronskov et al., 2007; Summers, 2009). Almost 200 mutations in TYR are known (Gronskov et al., 2007).

Mutations in the OCA2 gene (formerly known as the P-gene) cause the OCA2 phenotype (Gronskov et al., 2007; Renugadevi et al., 2010; Summers, 2009). This gene maps to chromosome 15q11.2 and encodes an integral melanosomal protein (Engle, 2010; Gronskov et al., 2007; Summers, 2009). OCA2 protein is important for normal biogenesis of melanosomes and for normal processing and transport of melanosomal proteins such as TYR and tyrosinase-related protein1 (TYRP1) (Gronskov et al., 2007; Renugadevi et al., 2010). Seventy-two mutations in OCA2 are listed as causes of OCA (Gronskov et al., 2007).

The OCA3 is caused by mutations in TYRP1 (Gronskov et al., 2007; Renugadevi et al., 2010). It maps to chromosome 9p23 (Renugadevi et al., 2010). TYRP1 is an enzyme in the melanin biosynthesis pathway, catalyzing the oxidation of 5,6-dihydroxyindole-2-carboxylic acid monomers into melanin (Gronskov et al., 2007). Tyrp1 functions to stabilize Tyr (Gronskov et al., 2007).

Mutations in the membrane-associated transporter protein gene (MATP, also known as SCL45A2) cause OCA4 (Gronskov et al., 2007; Renugadevi et al., 2010; Summers, 2009). MATP maps to 5p13.3 and encodes a protein expressed in the melanosomal membrane; it may function as a membrane transporter directing melanosomal traffic and other substances to melanosomes (Gronskov et al., 2007; Renugadevi et al., 2010).

Another type of albinism caused by mutations on OA1 (Xp22.3), OA (OA1), affects males because of X-linked inheritance (Engle, 2010; Gronskov et al., 2007; Renugadevi et al., 2010; Summers, 2009). OA1 encodes a G-protein-coupled receptor on the melanosome membrane (Engle, 2010; Renugadevi et al., 2010).

31.3.6.3 Neuroradiological Findings

Among disorders where albinism is part of a larger syndrome, such as HPS, cerebral atrophy, most marked in the occipital lobes, can be seen (Budisteanu et al., 2010; Gronskov et al., 2007).

31.3.7 Congenital Fibrosis of the Extraocular Muscles Type I

Congenital fibrosis of the extraocular muscles type 1 (CFEOM1) is a complex strabismus syndrome categorized as one of the congenital cranial dysinnervation disorders (Andrews et al., 1993; Engle, 2010; Heidary et al., 2008). It is the most common form of CFEOM (Andrews et al., 1993; Yamada et al., 2005). The minimum prevalence of CFEOM1 has been estimated to be 1/230 000 (Andrews et al., 1993; Heidary et al., 2008).

31.3.7.1 Clinical Characteristics

Affected individuals are born with congenital bilateral nonprogressive blepharoptosis and strabismus as well as congenital bilateral nonprogressive external ophthalmoplegia with the eyes fixed in an infraducted position approximately 20–30° below the horizontal midline (Andrews et al., 1993; Engle, 2010; Heidary

et al., 2008; Kakinuma and Kiyama, 2009; Khan et al., 2010; Yamada et al., 2005). The eyes look down at rest and cannot be elevated, whereas horizontal movement can range from absence to full (Andrews et al., 1993; Engle, 2010). These patients lack binocular vision (Andrews et al., 1993; Yamada et al., 2005). Forced duction testing is positive for marked restriction of extraocular motility (Andrews et al., 1993; Heidary et al., 2008). Patients typically assume a compensatory 'chin up' head posture to fixate on objects (Heidary et al., 2008).

Affected individuals often have ocular synkinesis (aberrant patterns of eye movement), including synergistic convergence, synergistic divergence, Marcus Gunn jaw-winking phenomenon (congenital synkinetic movement due to synkinesis between the upper eyelid and the pterygoids), and no pupillary involvement (Engle, 2010; Heidary et al., 2008; Khan et al., 2010; Yamada et al., 2005). Synkinetic eye movements are thought to result from aberrant axonal routing (Heidary et al., 2008).

The Marcus Gunn jaw-winking phenomenon is categorized clinically as an ocular miswiring syndrome (Yamada et al., 2005). Affected individuals have ptosis accompanied by elevation of the ptotic eyelid on movement of the lower jaw (Andrews et al., 1993; Yamada et al., 2005). It is first noted in young infants when they are being fed (Andrews et al., 1993). This syndrome is proposed to result from misdirection of axons intended to travel within the motor branch of the trigeminal nerve to innervate the ipsilateral pterygoid muscle (Andrews et al., 1993; Yamada et al., 2005). Instead, these axons aberrantly innervate myofibers of the levator palpebrae superioris muscle, which is normally innervated by a branch of the oculomotor nerve (Andrews et al., 1993; Yamada et al., 2005).

There is phenotypic heterogeneity with respect to involvement of the horizontal extraocular muscles (Heidary et al., 2008). Horizontal movements may be severely restricted or absent, and horizontal strabismus may be present with an increased incidence of exotropia versus esotropia (Heidary et al., 2008). As a consequence of the marked limitation of eye movements and the blepharoptosis, many CFEOM patients develop strabismic and deprivation amblyopia (Andrews et al., 1993; Heidary et al., 2008; Yamada et al., 2005). Among families with CFEOM1, the vertical strabismus is quite uniform, but the horizontal strabismus can vary (Andrews et al., 1993). CFEOM1 patients generally show normal cognitive and physical development (Heidary et al., 2008).

31.3.7.2 Genetics

CFEOM1 is inherited as an autosomal dominant trait with complete penetrance and minimal variation in expression (Andrews et al., 1993; Khan et al., 2010; Yamada et al., 2005). It results from heterozygous mutations in *KIF21A* (kinesin family member 21A), which encodes a kinesin motor and maps to 12q12 (http://www.ncbi.nlm.nih.gov/omim) (Andrews et al., 1993; Engle, 2010; Heidary et al., 2008; Kakinuma and Kiyama, 2009; Khan et al., 2010; Yamada et al., 2005). Eighty mutation-positive patients of multiple ethnicities reported to date harbor only 11 unique missense mutations, which are often *de novo*, and 75% harbor 2860C>T (R954W) (Andrews et al., 1993; Engle, 2010). These mutations alter only 7 of the 1675 amino acids in *KIF21A* (Engle, 2010).

The KIF21A is a neuronally expressed protein, which is important in axonal maintenance (Heidary et al., 2008; Yamada et al., 2005). It has been characterized as a member of the Kif4-class superfamily of kinesin motors and acts as a plus-end kinesin motor (Kakinuma and Kiyama, 2009). This gene encodes a developmental motor kinesin responsible for anterograde axonal transport of cargo along neurons such as that of the superior division of cranial nerve III (Engle, 2010; Heidary et al., 2008; Khan et al., 2010).

31.3.7.3 Neuroradiological Findings

Central nervous system maldevelopment, including cortical dysplasia and basal ganglia abnormalities, has been reported (Heidary et al., 2008). Hypoplasia of the superior rectus and levator palpebrae superioris is a common feature of CFEOM1 patients (Heidary et al., 2008). Orbital MRI has demonstrated an absent or severely hypoplastic superior division of the oculomotor nerve (Heidary et al., 2008). Imaging of the skull base has confirmed hypoplasia of the oculomotor nerve as it exited the brain stem (Heidary et al., 2008).

31.3.8 Duane Retraction Syndrome

The DRS is a unilateral or bilateral congenital anomaly of the sixth cranial nerve nuclei with aberrant innervations by supply from the third cranial nerve (Gabay et al., 2010; Yuksel et al., 2010). This syndrome accounts for 1–5% of all cases of strabismus (Zanin et al., 2010). Unilateral Duane syndrome, which accounts for 85% of all cases of DRS, is predominantly sporadic (90%), more prevalent in females (60%), and mainly affects the left eye (Gutowski, 2000; Yuksel et al., 2010; Zanin et al., 2010). It is characterized by marked limitation or absence of abduction, variable limitation of adduction, palpebral fissure narrowing, and globe retraction on attempted adduction (Gabay et al., 2010; Zanin et al., 2010).

Disturbance between the fourth and tenth weeks of embryogenesis seems most obvious and could explain the various nonocular and ocular abnormalities in combination with the Duane's syndrome (Yuksel et al., 2010).

A teratogenic event during the second month of gestation seems to cause most ocular and extraocular abnormalities observed in combination with DRS (Yuksel et al., 2010). Thalidomide has been reported as having a teratogenic effect (Yuksel et al., 2010).

31.3.8.1 Clinical Characteristics

Affected individuals have restricted horizontal gaze greatest with attempted abduction and ocular synkinesis resulting in globe retraction with attempted adduction (Engle, 2010; Gutowski, 2000). When an affected individual attempts to adduct his/her eyes, both the intended medial rectus and the pathologically innervated lateral rectus muscle contract, resulting in retraction of the eyeball into the orbit (Engle, 2010; Gutowski, 2000). Electromyography shows increased electrical activity in a paretic lateral rectus muscle (Engle, 2010; Gutowski, 2000).

Binocular vision is preserved in DRS (Yuksel et al., 2010). The compensation by abnormal head posture allows binocularity in one field of gaze despite the severe eye motility deficit in the other field of gaze (Yuksel et al., 2010). The degree of sensorial binocular status plays an important role in the conjugacy of saccades (Yuksel et al., 2010).

The DRS has been associated with several other conditions where anomalous axonal guidance occurs, such as OCA (Gutowski, 2000; Yuksel et al., 2010). Some other syndromes associated with DRS are Okihiro syndrome (forearm malformation and hearing loss), Wildervanck syndrome (fusion of neck vertebrae and hearing loss), Holt–Oram syndrome (abnormalities of the upper limbs and heart), morning-glory syndrome (abnormalities of the optic disc or blind spot), and Goldenhar syndrome (malformations of the jaw, cheek, and ear, usually on one side of the face) (Yuksel et al., 2010).

Three types of DRS are recognized, depending on the amount of aberrant innervation present (Gutowski, 2000). Palpebral fissure narrowing and retraction of the affected eyeball on adduction tend to be constant findings (Gutowski, 2000). Palpebral fissure narrowing is due to recti contraction and mechanical factors (Gutowski, 2000).

DRS type I consists of defective abduction with normal or minimally defective adduction (Gutowski, 2000; Yuksel et al., 2010). In DRS type II, adduction is defective, and there is exotropia of the affected eye and normal or minimally defective abduction (Gutowski, 2000; Yuksel et al., 2010). Both adduction and abduction are defective in type III (Gutowski, 2000; Yuksel et al., 2010). All three types of DRS frequently produce additional vertical eye movement anomalies, which are characterized by changes in the ocular axes (Gutowski, 2000).

Eye movement recordings are an additional tool for understanding the underlying pathogenesis of DRS (Yuksel et al., 2010). This is a noninvasive technique that has given valuable information about the neural control of movement (Yuksel et al., 2010). Most DRS patients compensate well for the disorder and do not require further management (Yuksel et al., 2010). Standard management of DRS may, in some cases, involve eye muscle surgery (Yuksel et al., 2010).

31.3.8.2 Genetics

The majority of DRS cases are sporadic, with only 2–5% of patients showing a familial pattern (Gutowski, 2000; Yuksel et al., 2010). A high prevalence of DRS has been noted in individuals with thalidomide embryopathy (Gutowski, 2000; Yuksel et al., 2010). Both genetic and environmental factors are likely to play a role in the development of DRS (Yuksel et al., 2010; Zanin et al., 2010).

Studies of sporadic forms of DRS showed 10–20 times greater risk for having other congenital malformations divided in mainly four categories: skeletal, auricular, ocular, and neural (Yuksel et al., 2010). The skeletal abnormalities involved the palate and vertebral column (Yuksel et al., 2010). The auricular malformations included the external ear, the external auditory meatus, and the semicircular canals (Yuksel et al., 2010). Ocular defects concerned the extraocular muscles and the eyelids, including ocular dermoids (Yuksel et al., 2010). Neural defects involved the third, fourth, and sixth cranial nerves (Yuksel et al., 2010).

Most cases of familial DRS are autosomal dominant without associated abnormalities (Gutowski, 2000; Yuksel et al., 2010). There are also several autosomal dominant syndromes in which DRS is a recognized feature (Gutowski, 2000). In some families with dominant DRS, the disease shows reduced penetrance and variable expressivity (Yuksel et al., 2010). An autosomal recessive pattern of inheritance has also been suggested in several reports of DRS (Gutowski, 2000; Yuksel et al., 2010). Autosomal recessive DRS can occur either in isolation or in association with other abnormalities (Gutowski, 2000).

Several chromosomal loci for genes contributing to DRS have been suggested (Gutowski, 2000; Yuksel et al., 2010; Zanin et al., 2010). CHN1 (chimerin 1) is one of the genes responsible for DRS (Engle, 2010; Zanin et al., 2010). Individuals harboring CHN1 mutations have a higher incidence of vertical movement abnormalities and bilateral eye involvement when compared to individuals with nonfamilial DRS (Engle, 2010). CHN1 mutations alter the development of abducens and, to a lesser extent, oculomotor axons (Engle, 2010).

Deletions of chromosomal material on chromosomes 4 and 8 and the presence of an extra marker chromosome, thought to be derived from chromosome 22, has been documented in DRS individuals (Yuksel et al., 2010).

SALL4 (sal-like 4) and *HOXA1* (*homeobox A1*) have been found to be associated also with syndromic forms (Zanin et al., 2010). However, patients with isolated DRS have not been found to carry these mutations (Zanin et al., 2010).

31.3.8.3 Neuroradiological Findings

Motion-encoded MRI has been used for the study of human extraocular muscle function; local physiological contraction and elongation have been quantified (Yuksel et al., 2010). The visualization of the abducens nucleus itself at a neural level remains unfeasible, but the nerve can be explored at the pontomedullar level (Yuksel et al., 2010).

MRI of individuals harboring *CHN1* mutations can reveal hypoplasia of the oculomotor nerve and oculomotor-innervated muscles in addition to the expected abducens nerve hypoplasia and aberrant lateral rectus innervation (Engle, 2010).

MRI has confirmed the maldevelopment of the abducens nerve in DRS and has showed the compensatory innervation by the third nerve at a peripheral level (Yuksel et al., 2010). MRI in cases of DRS type I has demonstrated the absence of the abducens nerve (Yuksel et al., 2010).

31.3.9 Pontine Tegmental Cap Dysplasia

Pontine tegmental cap dysplasia (PTCD) is a cerebellar, brain stem, and cranial nerve malformation syndrome (Engle, 2010). It was first reported in four patients, in 2007 (Barth et al., 2007; Macferran et al., 2010). Pathomechanism of the condition involves a defect in the migration or navigation of axons of rhombencephalic neurons (Szczaluba et al., 2010).

PTCD belongs to a group of related conditions that share in common malformations of the midbrain hindbrain (Macferran et al., 2010). Under this category are those conditions that have in common the molar tooth sign (Macferran et al., 2010).

Conditions described in this group include the following syndromes: Joubert, Senior–Loken, COACH, Dekaban-Arima, oro-facial-digital type VI, and encephalocele with renal cysts (Engle, 2010; Macferran et al., 2010).

It is suggested that many cases of pontocerebellar hypoplasia or Moebius syndrome should be revised for the features of PTCD (Szczaluba et al., 2010). To date, no known etiology for PTCD has been identified (Macferran et al., 2010).

31.3.9.1 Clinical Characteristics

The affected children described to date have mild to severe developmental delay, ataxia, and a combination of restricted horizontal eye movements, ocular apraxia, facial weakness, deafness, and swallowing and feeding impairments (Engle, 2010; Macferran et al., 2010). Also, they have shown bilateral trigeminal nerve dysfunction, seizures, and central ventilation abnormalities (Macferran et al., 2010). Commonly reported somatic abnormalities include vertebral anomalies and craniofacial dysmorphism (Macferran et al., 2010).

31.3.9.2 Genetics

The reported children had neither a positive family history nor consanguineous parents, so it remains to be proved that PTCD is genetic (Engle, 2010). It is plausible that it results from *de novo* dominant mutations or recessive mutations in an unidentified gene (Engle, 2010).

A very small (96 kb) 2q13 deletion has been identified as the first case of a molecular genetic abnormality as the identified cause of the condition (Macferran et al., 2010). The deleted region encompasses the *NPHP1* gene (Macferran et al., 2010). This gene has been reported in association with JS (Macferran et al., 2010).

31.3.9.3 Neuradiological Findings

Neuroimaging reveals pontine hypoplasia with ventral flattening and dorsal protrusion of tissue into the fourth ventricle ('tegmental cap') (Engle, 2010; Macferran et al., 2010). Cerebellar vermian hypoplasia and elongated and laterally misplaced SCP result in a modified molar tooth sign (Engle, 2010; Macferran et al., 2010). The middle and inferior cerebellar peduncles and cranial nerves VII and VIII are small (Engle, 2010; Macferran et al., 2010). DTI reveals failure of the SCP, MCP, and axons of the pontine nuclei to decussate and defines the tegmental cap as an ectopic dorsal transverse fiber bundle (Engle, 2010).

31.4 INTRODUCTION: NEURONAL MIGRATION

Development of central nervous system is a highly complicated process, and it is organized in the following steps (Spalice et al., 2009; Verrotti et al., 2010):

1. Primary neurulation (3–4 weeks of gestation), beginning of neuronal migration (fifth week of gestation)
2. Prosencephalic development (2–3 months of gestation)
3. Neuronal proliferation (3–4 months of gestation)
4. Neuronal migration (1–5 months of gestation)
5. Organization (5 months of gestation to after birth)
6. Myelination (after the birth)

Cell migration has an essential role in the developing cerebral cortex because all neurons that eventually

populate the six-layered cerebral cortex and other brain regions undergo mitosis in distant compartments and then migrate great distances to achieve final positioning (Kerjan and Gleeson, 2007).

Neuronal migration consists of nerve cells moving from their original site in the ventricular and subventricular zones to their final location (Kerjan and Gleeson, 2007; Pang et al., 2008; Spalice et al., 2009; Verrotti et al., 2010). Regulation of timing and direction of these simultaneous migrations are highly ordered (Spalice et al., 2009; Verrotti et al., 2010).

Instructed by extracellular cues, the activation of guidance receptors and their downstream signaling pathways enable newborn neurons to migrate through the developing nervous system until they reach their destination (Valiente and Marin, 2010). On arrival to their final destination, neurons cancel their migratory program and continue their differentiation into mature neurons (Valiente and Marin, 2010). It has been suggested that early patterns of activity generated in the target region may influence this process (Valiente and Marin, 2010).

Neurons originating in the cortical ventricular zone migrate radially to form the cortical plate (CP) and mainly become projecting neurons (Spalice et al., 2009; Verrotti et al., 2010).

Migration of neocortical neurons occurs mostly between the 12th and the 24th weeks of gestation (Spalice et al., 2009; Verrotti et al., 2010). The first postmitotic neurons produced in the periventricular germinative neuroepithelium will migrate to form a subpial preplate or primitive plexiform zone (Spalice et al., 2009). Subsequently, produced neurons, which will form the CP, migrate into the preplate and split it into the superficial molecular layer (or layer I or the marginal zone containing Cajal–Retzius neurons) and the deep subplate (Spalice et al., 2009).

Schematically, the successive waves of migratory neurons will pass the subplate neurons and finish their migratory pathway below layer I, forming successively (but with substantial overlap) cortical layers VI, V, IV, III, and II (Spalice et al., 2009). This means that the neurons that migrate first will stop in the deepest cortical layers, and those that migrate afterward pass through the layers formed previously to form the outer cortical layers according to a migration scheme defined 'inside-out' (Pang et al., 2008; Spalice et al., 2009; Verrotti et al., 2010).

Neocortical migrating neurons can adopt different types of trajectories: A large proportion of neurons migrate radially, along radial glial guides, from the germinative zone to the CP (Spalice et al., 2009; Verrotti et al., 2010). Radial glial cells are specialized glial cells present in the neocortex during neuronal migration (Spalice et al., 2009; Verrotti et al., 2010).

Another important group of neuronal precursors initially adopts a tangential trajectory at the level of the ventricular or subventricular germinative zones before adopting a classic radial migrating pathway along radial glia (Spalice et al., 2009; Verrotti et al., 2010). Tangentially, migrating neurons have also been located at the intermediate zone level (prospective white matter) (Spalice et al., 2009; Verrotti et al., 2010).

The phenotype of radial glial seems to be determined by both migrating neurons and intrinsic factors expressed by glial cells (Spalice et al., 2009; Verrotti et al., 2010). Among the latter, the transcription factor Paired Box Gene (*PAX6*), which is specifically localized in radial glia during cortical development, is critical for the morphology, number, function, and cell cycle of radial glia (Spalice et al., 2009; Verrotti et al., 2010).

There are several molecules involved in the control of neuronal migration and in targeting the exact destination of the neurons (Spalice et al., 2009; Verrotti et al., 2010). These molecules can be divided into four broad categories: molecules of the cytoskeleton, which play an important role in the initiation and ongoing progression of neuronal migration, such as Filamin A, ARF-GEF2, doublecortin, LIS1, TUBA1A; signaling molecules playing a role in lamination, such as reelin and some reelin receptors such as p35, cdk5, and Brn1/Brn2; molecules modulating glycosylation, which seem to provide stop signs for migrating neurons, such as, POMT1, POMGnT1, fukutin, and FAK; and other factors including neurotransmitters such as glutamate and GABA, trophic factors such as brain-derived neurotrophic factor and thyroid hormones, molecules deriving from peroxisomal metabolism, and environmental factors such as ethanol and cocaine (Spalice et al., 2009; Verrotti et al., 2010).

Reelin is crucial for the lamination of cortical structures, but the molecular mechanisms underlying its action remain unclear (Valiente and Marin, 2010). Genetic studies have positioned Reelin, apolipoprotein E receptor 2 (ApoER2), Vldlr, and Dab1 into a common signaling pathway that leads to the phosphorylation of Dab1 in migrating neurons, an event that is required for normal layering of the cortex (Valiente and Marin, 2010). Both structural barriers at the pial surface of the brain and molecular stop signals are involved in mediating neuronal migration arrest (Pang et al., 2008).

Cell migration requires the dynamic regulation of adhesion complexes between migrating cells and the surrounding extracellular matrix proteins (Valiente and Marin, 2010). In many cell types, this process involves integrin-mediated adhesion, but the function of this signaling system in neuronal migration has remained controversial (Valiente and Marin, 2010). The striking morphology of neurons, as they migrate, extends dendrites and axons and connects with other cells, implying

a strictly regulated program of cytoskeletal organization (Kerjan and Gleeson, 2007).

31.5 OVERVIEW OF NEURONAL MIGRATION DISORDERS

Malformations of cortical development are an important cause of epilepsy and development delay (Pang et al., 2008; Spalice et al., 2009; Verrotti et al., 2010). It is estimated that up to 40% of children with refractory epilepsy have a cortical malformation (Pang et al., 2008; Spalice et al., 2009; Verrotti et al., 2010). These malformations have also been associated with mental retardation and cerebral palsy (Mochida, 2009). Malformations of cortical development encompass a large spectrum of disorders related to abnormal cortical development with varied genetic etiologies, anatomic abnormalities, and clinical manifestations (Mochida, 2009; Pang et al., 2008).

Cerebral cortical development requires orchestrated movement of cells arising from different regions within the brain, and born at different times, to achieve specific laminar position, orientation, and connections with other cells (Kerjan and Gleeson, 2007; Pang et al., 2008). Disruptions at these various stages may result in malformations of cortical development (Pang et al., 2008). Although cortical development has been separated into various stages, there is a significant overlap between the stages, and many abnormalities may cause dysfunction at more than one level (Pang et al., 2008).

Malformation syndromes are typically classified based on the earliest disruption of development (Barkovich et al., 2005; Pang et al., 2008). This classification system divides brain malformations into disorders of cell proliferation, neuronal migration, and cortical organization (Barkovich et al., 2005; Mochida, 2009). Neuronal migration disorders include lissencephaly, heterotopia, focal cortical dysgenesis, PMG, and schizencephaly (SCZ) (Verrotti et al., 2010).

The pathogenesis of these malformations is multifactorial: Genetic mutations or environmental insults, whether acquired *in utero* at different stages of brain development, or during the perinatal or postnatal period after corticogenesis, may all contribute to the development of these disorders (Jaglin and Chelly, 2009; Pang et al., 2008). The timing, severity, and type of environmental influences, as well as genetic factors, will ultimately determine the type and extent of the malformation (Pang et al., 2008).

Genetic studies in humans and mice have identified a spectrum of mutations in genes involved in a large array of crucial processes such as cell proliferation, cell adhesion, cell migration, chemoattraction and repulsion, posttranslational modifications, and dynamics of the cytoskeleton that often disrupts the development of the cerebral cortex and can lead to severe cortical malformations (Jaglin and Chelly, 2009).

Following neurogenesis, the disruption of neuronal migration resulting from genetic mutations represents a major cause of cortical dysgenesis and encompasses a large variety of malformations (Jaglin and Chelly, 2009). Many of these genes encode important effectors that modulate cytoskeletal dynamics during the migration of neuronal cells (Jaglin and Chelly, 2009). Mutations in *DCX* (*doublecortin*) and *LIS1* genes, which encode MAPs, have been shown to be associated with a large spectrum of neuronal migration disorders (Jaglin and Chelly, 2009).

Despite the significant progress over the past few years, many cases of cortical dysgenesis are still unexplained (Jaglin and Chelly, 2009). The identification of further genes is important for the transfer to the clinic and genetic counseling, as well as to have a better understanding of the physiopathology of human cortical dysgenesis (Jaglin and Chelly, 2009).

31.5.1 Lissencephaly

Lissencephaly is a group of disorders that is characterized by an abnormally smooth surface of the cerebral cortex (Mochida, 2009; Pang et al., 2008; Vallee and Tsai, 2006; Verrotti et al., 2010). It is a severe brain malformation characterized by agyria (absence of gyri) and pachygyria (reduced number of broadened gyri), thickened cortex, abnormal cortical layering, enlarged ventricles, and neuronal heterotopias (abnormal positioning of neurons) (Ghai et al., 2006; Pang et al., 2008; Reiner et al., 2006; Verrotti et al., 2010). The lifespan of patients with these disorders is short and most of them die within the first year of life, usually because of aspiration pneumonia and sepsis (Reiner et al., 2006).

Lissencephaly is a neuronal migration disorder that results from impaired migration of postmitotic neurons from the ventricular zone to the developing CP (Ghai et al., 2006; Reiner et al., 2006).

On the basis of etiologies and associated malformations, five groups of lissencephaly can be identified: classical lissencephaly, cobblestone lissencephaly, X-linked lissencephaly with ACC, lissencephaly with cerebellar hypoplasia (LCH), and microlissencephaly (Verrotti et al., 2010). The onset of lissencephaly is considered to occur no later than the 12th–16th week of gestation (Verrotti et al., 2010).

Functions of some lissencephaly genes are closely related to microtubules (Mochida, 2009). The network of microtubules and molecular motor, dynein, are critical to this movement of the centrosome and nucleus in migrating neurons (Mochida, 2009). Some lissencephaly

genes are associated with specific neuropathology of the cerebral cortex (Mochida, 2009). Mutations of six genes have been associated with lissencephaly, including *LIS1*, *DCX*, *TUBA1A*, *RELN*, very low-density lipoprotein receptor (*VLDLR*), and *ARX*, whereas codeletion of αWHAE with *LIS1* appears to act as a modifier locus (Spalice et al., 2009).

31.5.1.1 Classical Lissencephaly

Classical lissencephaly, previously known as type 1 lissencephaly, causes a combination of agyria and pachygyria (Kerjan and Gleeson, 2007; Verrotti et al., 2010). This disorder represents one of the most severe disorders of neocortical neuronal migration (Kerjan and Gleeson, 2007). It is distinguished from the other forms of lissencephaly based on the absence of additional characteristic features (Kerjan and Gleeson, 2007). This type of lissencephaly occurs in Miller–Dieker syndrome (MDS) and in isolated lissencephaly sequence (ILS) (Reiner et al., 2006). The incidence of classical lissencephaly has been estimated to be 1.2 in 100 000 births (Verrotti et al., 2010).

Microscopically, the cortex appears poorly structured with only four immature layers of neurons instead of the normal six highly organized layers present in a well-developed brain (Kerjan and Gleeson, 2007; Pang et al., 2008; Verrotti et al., 2010). This disorder is derived from both tangential and radial migration disorders of neurons (Spalice et al., 2009). The pathogenesis of classic lissencephaly is unlikely to be due to defective neuronal migration alone but may include an aspect of abnormal proliferation (Mochida, 2009).

31.5.1.1.1 CLINICAL CHARACTERISTICS

Children with classical lissencephaly are diagnosed in the first few months of life (Kerjan and Gleeson, 2007). ILS is clinically characterized by early hypotonia, which may evolve to limb spasticity, seizures, psychomotor retardation, and often microcephaly (Jaglin and Chelly, 2009; Pang et al., 2008; Spalice et al., 2009; Verrotti et al., 2010). Seizures are present in almost the totality of children with onset in early age, mostly in the first 6–12 months (Spalice et al., 2009; Verrotti et al., 2010). High prevalence (80%) of infantile spasms with or without typical hypsarrhythmia on EEG has been reported (Spalice et al., 2009; Verrotti et al., 2010). Later, most children have a more complex epileptic syndrome, including atypical absences, drop attacks, and myoclonic, partial complex, tonic, and tonic–clonic seizures (Spalice et al., 2009; Verrotti et al., 2010). The EEG demonstrated diffused fast rhythms with high amplitude, considered peculiar of this condition (Spalice et al., 2009).

Children with MDS have a severe form of ILS with facial dysmorphisms, including a prominent forehead, bitemporal hollowing, a short nose with upturned nares, and a long and protuberant upper lip with thin vermillion border and small jaw (Mochida, 2009; Verrotti et al., 2010). Other children with MDS might also present cardiac and renal abnormalities, cryptorchidism, sacral dimple, omphaloceles, and clinodactyly (Verrotti et al., 2010).

31.5.1.1.2 GENETICS

Lissencephaly associated with *RELN*, *VLDLR*, and *ARX* are pathologically and radiologically distinct from lissencephaly because of *LIS1*, *DCX*, and *TUBA1A* (Mochida, 2009). The LIS1 gene is the first gene that was correlated with human lissencephaly (Jaglin and Chelly, 2009; Mochida, 2009; Reiner et al., 2006; Verrotti et al., 2010). LIS1 localizes to chromosome 17p13.3 (Mochida, 2009). LIS1 is a MAP that localizes primarily to the centromere in migrating neurons (Kerjan and Gleeson, 2007; Vallee and Tsai, 2006). LIS1 is highly conserved in evolution both in sequence and in multiple functional aspects (Reiner et al., 2006).

A tight relationship between LIS1, microtubule regulation, and microtubule-based motor proteins has been suggested for many organisms (Reiner et al., 2006). LIS1 controls mitotic spindle orientation in both the neuroepithelial stem cells and the radial glial progenitor cells (Verrotti et al., 2010). It has a role in preserving the normal microtubule network organization (Reiner et al., 2006; Vallee and Tsai, 2006).

In addition to a direct role for LIS1 in regulating tubulin dynamics, LIS1 interacts with a plethora of MAP (Reiner et al., 2006). This includes interactions with DCX, CLIP-170, and MAP1b (Reiner et al., 2006). LIS1 deletion causes dysfunction of the dynein, a microtubular cytoplasmic protein involved in neuronal migration processes (Jaglin and Chelly, 2009; Mochida, 2009; Verrotti et al., 2010). LIS1 interacts with several subunits of the retrograde, microtubule-based motor complex dynein/dynactin (Reiner et al., 2006; Vallee and Tsai, 2006). LIS1 regulates cytoplasmic dynein activity and participates in several dynein-mediated activities such as intracellular transport and mitosis (Reiner et al., 2006; Vallee and Tsai, 2006). In migrating cells, the presence of dynein, dynactin, and LIS1 at the leading cell cortex is essential for directed cell motility (Reiner et al., 2006).

ILS is caused by intragenic mutations or deletions of the LIS1 gene or by small deletions involving 17p13.3 (Ghai et al., 2006; Kerjan and Gleeson, 2007; Mochida, 2009; Verrotti et al., 2010). Complete deletion of both *LIS1* and 14-3-3 αWHAE genes on chromosome 17p13 causes MDS (Ghai et al., 2006; Kerjan and Gleeson, 2007; Mochida, 2009; Pang et al., 2008; Verrotti et al., 2010). MDS has been considered a contiguous gene deletion syndrome (Kerjan and Gleeson, 2007). αWHAE belongs to the 14-3-3 family of proteins that can have

many effects on phosphoproteins, including protection from dephosphorylation (Verrotti et al., 2010). 14-3-3 binds to CDK5/p35-phosphorylated NUDEL, and this binding maintains NUDEL phosphorylation (Verrotti et al., 2010). NUDEL is a LIS1-binding protein that, together with LIS1, regulates the cytoplasmic dynein heavy chain function through phosphorylation by CDK5/p35, a complex known to be essential for neuronal migration (Jaglin and Chelly, 2009; Mochida, 2009; Reiner et al., 2006; Verrotti et al., 2010). A smaller deletion, encompassing the region of LIS1 gene but not the 14-3-3 gene, has been associated with a milder phenotype of isolated LIS (Verrotti et al., 2010). αWHAE is suggested to be a dosage-dependent modifier of the severity of classical lissencephaly (Kerjan and Gleeson, 2007).

Lissencephaly due to mutations or deletions of LIS1 is a dominant trait (Mochida, 2009). Most LIS1 mutations are *de novo*, and therefore the recurrence risk is generally low (Mochida, 2009). However, in some cases, a parent harbors a balanced translocation involving the LIS1 gene, and so their risk of recurrence could be much higher (Mochida, 2009). Most cases of MDS and ILS are sporadic (Ghai et al., 2006). However, approximately 20% of patients with MDS inherited a genetic deletion from a parent (Ghai et al., 2006).

Mutations of the doublecortin (*DCX*) gene on chromosome Xq22.3 are also known to cause classical lissencephaly in males while heterozygous mutations in females are associated with subcortical band heterotopia (SBH) (Jaglin and Chelly, 2009; Mochida, 2009; Reiner et al., 2006; Verrotti et al., 2010). Males with SBH and *DCX* mutations have rarely been reported (Verrotti et al., 2010). SBH is also known as 'double cortex' syndrome as a band of heterotopic neurons is found within the cerebral white matter between a normal-appearing cortex and the ventricular surface higher (Mochida, 2009). About 20% of patients with classical ILS or SBH have mutations of the DCX gene, resulting in X-linked lissencephaly (LISX1) or double cortex syndrome (DC) (Spalice et al., 2009). Mutations in DCX may be inherited from a mother with SBH to her son, causing lissencephaly, or to her daughter, causing SBH (Mochida, 2009). Doublecortin is expressed in postmitotic neurons, but neither in proliferating cells of the ventricular zone during the development period nor in mature neurons of the adult brain (Verrotti et al., 2010). DCX is a cytoplasmic protein that appears to direct neuronal migration by regulating the organization and stability of microtubules (Jaglin and Chelly, 2009; Mochida, 2009; Verrotti et al., 2010). Nearly all mutations identified to date are premature protein truncations or missense mutations that cluster within the repeated tubulin-binding domain of DCX and inactivate its effects on microtubules (Kerjan and Gleeson, 2007).

Mutations in the alpha tubulinic complex (*TUBA1A*) gene located on chromosome 12q12–q14 have been correlated with the agyria–pachygyria-band spectrum of phenotype (Jaglin and Chelly, 2009; Kerjan and Gleeson, 2007; Mochida, 2009; Verrotti et al., 2010). This gene encodes for brain-specific alpha tubulin protein that represents one of the major component of microtubule complex required for cell movement (Mochida, 2009; Verrotti et al., 2010). Mutations in *TUBA1A* are considered to affect the folding of tubulin heterodimers and influence interactions with microtubule-binding proteins (doublecortin and kinesin KIF1A), resulting in disorders of microtubular function and deficits in the motility of neuronal progenitor cells (Verrotti et al., 2010). Congenital microcephaly, spastic diplegia or quadriplegia, and mental retardation are common clinical features seen in patients with the *TUBA1A* mutation phenotype (Mochida, 2009; Verrotti et al., 2010). In addition to microcephaly, rare occurrences of agyria and subcortical heterotopia (SBH) demonstrate that TUBA1A-related lissencephaly could encompass a large spectrum of cortical abnormalities (Jaglin and Chelly, 2009). This abnormal gyral pattern is combined with dysgenesis of the anterior limb of the internal capsule to give a dysmorphic aspect to the basal ganglia (Jaglin and Chelly, 2009). Moreover, other extracortical defects often include complete to partial ACC and mild to severe cerebellar hypoplasia (Jaglin and Chelly, 2009).

Lissencephaly due to *TUBA1A* mutations manifests as a dominant trait, and therefore, the mutations are generally *de novo*, as seen with *LIS1* (Mochida, 2009). Neuronal axonal guidance and/or growth defects, in addition to early neuronal differentiation abnormalities, are likely to be involved in the pathogeny of *TUBA1A*-related cortical dysgenesis (Jaglin and Chelly, 2009).

LIS1 and *DCX* collectively account for about three-quarters of isolated classic lissencephaly, and *TUBA1A* is estimated to account for about 4% of cases (Jaglin and Chelly, 2009; Mochida, 2009). Mutations in these three genes generally cause similar clinical phenotypes, including microcephaly, mental retardation, with or without epilepsy, and motor deficits (Mochida, 2009). Mutations of these three genes lead to this form of lissencephaly in which cortical thickness is increased fourfold and produce a recognizable gradient in which the malformation is more severe anteriorly (*DCX*) or posteriorly (*LIS1* and *TUBA1A*) (Jaglin and Chelly, 2009; Mochida, 2009).

ARX is a homeobox gene that is expressed in the ganglionic eminences and the neocortical ventricular zone (Pang et al., 2008). This gene plays an important role in the proliferation of neuronal precursors and differentiation of the forebrain (Pang et al., 2008). Mutations of ARX are a rare cause of lissencephaly, although less severe mutations result in a more common developmental

disorder, cryptogenic infantile spasms (Spalice et al., 2009). Mutations in this gene cause the X-linked lissencephaly syndrome with ambiguous genitalia (Mochida, 2009; Pang et al., 2008). These patients have neonatal-onset epilepsy, hypothalamic dysfunction causing temperature dysregulation, chronic diarrhea, and ambiguous genitalia (micropenis and cryptorchidism) (Pang et al., 2008). This gene is a transcription factor expressed in the forebrain that regulates nonradial migration of interneurons from ventral regions to the developing cortex (Spalice et al., 2009). Severe seizures are presumably related to a severe deficiency of inhibitory interneurons (Spalice et al., 2009).

Patients with *ARX* mutations have abnormalities of the basal ganglia and absence of the corpus callosum, whereas those with *RELN* and *VLDLR* mutations have less cortical thickening, absence of a cell-sparse zone, and profound cerebellar hypoplasia (Spalice et al., 2009).

Reelin (*RELN*) is a signaling glycoprotein secreted by the early neurons on the surface of the cerebral cortex known as the Cajal–Retzius cells (Pang et al., 2008). This is a large extracellular matrix protein, which, when absent, causes reversal of cortical layers with deeper layers being made up of younger rather than older born neurons (Reiner et al., 2006). Activation of the Reelin signaling pathway is thought to be essential for proper positioning of migratory neurons into the appropriate lamina of the cortex (Pang et al., 2008). Mutations in *RELN* give rise to seizures, developmental delay, and hypotonia (Pang et al., 2008). Also, the loss of cerebellar organization likely contributes to ataxia (Pang et al., 2008). Only a few patients have been described with mutations in this gene, and generalized pachygyria, severe cerebellar hypoplasia, and hippocampal abnormalities seem to be the common features (Mochida, 2009).

VLDLR mutations cause similar abnormalities to *RELN*, with severe cerebellar hypoplasia, but the simplification of gyri may be milder features (Mochida, 2009). The product of the *VLDLR* gene belongs to the same biological pathway as *RELN* (Mochida, 2009). VLDLR, along with APOER2, acts as a receptor for the RELN protein in migrating neurons and transmits the extracellular RELN signal to the intracellular signaling pathway (Mochida, 2009). There is also notable evidence of interaction between RELN signaling and LIS1 (Mochida, 2009).

In some forms of classic lissencephaly, defects in GABAergic inhibitory interneurons have been suggested (Mochida, 2009). GABAergic interneurons of the cerebral cortex are derived in the ganglionic eminence (which develops into basal ganglia) and migrate tangentially into the cerebral cortex (Mochida, 2009). The best known examples of defects in GABAergic interneurons are due to *ARX* mutations (Mochida, 2009). Also, the number of inhibitory neurons is greatly diminished in the brain of patients with a LIS1 (Mochida, 2009).

Lissencephaly is often associated with severe, intractable epilepsy, and defects in interneurons, in addition to abnormal cortical lamination, may be in part responsible for this (Mochida, 2009). Mutations in *TUBA1A* seem to be associated with a lower incidence of epilepsy compared with *LIS1* (Mochida, 2009).

31.5.1.1.3 NEURORADIOLOGICAL FINDINGS

MRI of the brain in classic lissencephaly demonstrates an hour-glass configuration with areas of pachygyria and agyria, poorly developed sylvian and rolandic fissures, and failure of opercularization of the insular areas (Pang et al., 2008). It shows some degree of abnormality in the spacing of the gyri and sulci (Kerjan and Gleeson, 2007). The cortex is moderately thickened (5–10 mm) with white matter signal abnormalities (Kerjan and Gleeson, 2007; Verrotti et al., 2010). Associated findings may include dilatation of lateral ventricles, mild hypoplasia of the corpus callosum, and persistent cavum septum pellucidum (Verrotti et al., 2010).

Mutations in *LIS1* are often associated with abnormalities prevalent in the parietal and occipital cortex, whereas DCX lissencephaly is more pronounced in the frontal and temporal cortex (Pang et al., 2008; Verrotti et al., 2010). Mutations in *TUBA1A* have led to gyral malformations that are more severe in posterior than in anterior regions of the brain, often combined with dysgenesis of the corpus callosum, cerebellar and brainstem hypoplasia, and variable cortical malformation, including subtle SBH, ventricular dilatation, and absence or hypoplasia of the anterior limb of the internal capsule (Pang et al., 2008; Verrotti et al., 2010).

In individuals harboring *ARX* mutations, the lissencephaly is worse posteriorly than anteriorly, and there is absence of the corpus callosum (Pang et al., 2008). The cortex is moderately thickened (5–10 mm) with white matter signal abnormalities as well as cystic or fragmented basal ganglia (Pang et al., 2008). In *RELN* mutations, the lissencephaly is associated with cerebellar hypoplasia and hippocampal and brainstem abnormalities (Pang et al., 2008).

31.5.1.2 Cobblestone Lissencephaly

Cobblestone lissencephaly, previously type II, is a complex brain malformation characterized by global disorganization of cerebral organogenesis (Verrotti et al., 2010). It is characterized by a defective basement membrane in which breaches are formed (Jaglin and Chelly, 2009). It refers to the nodular appearance of the cerebral cortex caused by disorganization of the cortical layers and overmigration of neurons through the pial surface of the brain into the leptomeninges (Jaglin and Chelly, 2009). The cortex displays irregular grooves

imparting a cobblestone pattern and consists of cluster and circular arrays of neurons, with no recognizable layers, separated by glial and vascular septa (Verrotti et al., 2010). The brain phenotype includes multiple anomalies such as hydrocephalus and neuronal overmigration, causing a cobblestone cortex, lissencephaly, and ACC (Reiner et al., 2006). Brainstem abnormalities also may be present (Ghai et al., 2006).

All patients with cobblestone lissencephaly show defects in the O-linked glycosylation of the glycoprotein α-dystroglycan, a protein that bridges the actin cytoskeleton of cells and the extracellular matrix component, laminin callosum (Reiner et al., 2006).

31.5.1.2.1 CLINICAL CHARACTERISTICS

It is associated with various eye abnormalities and congenital muscular dystrophies (Reiner et al., 2006). Cobblestone lissencephaly has been described in three syndromes: the Walker–Warburg syndrome (WWS), muscle–eye–brain disease (MEB), and Fukuyama-type congenital muscular dystrophy (FCMD) (Ghai et al., 2006). WWS is the most severe of these small groups of syndromes (Verrotti et al., 2010). It has a worldwide distribution, while FCMD has been found in Japan and MEB primarily in Finland (Verrotti et al., 2010).

The major clinical features of WWS are macrocephaly, cerebellar malformation, ventricular dilation/hydrocephalus, retinal malformation, anterior chamber abnormality, and congenital muscular dystrophy (Verrotti et al., 2010).

MEB disease results in a severe form of congenital muscular dystrophy with mental retardation and myoclonic jerks (Verrotti et al., 2010). Ocular disorders include progressive myopia, retinal dystrophy, glaucoma, and optic atrophy (Verrotti et al., 2010).

FCMD is the mild form of cobblestone lissencephaly, and it is characterized by severe hypotonia, progressive weakness, and developmental delay (Pang et al., 2008; Verrotti et al., 2010). The majority of patients are unable to walk unsupported (Pang et al., 2008). Mental retardation is a universal finding (Pang et al., 2008). The association of epilepsy and seizure-related disorders in FCMD is widely accepted: Febrile seizures and epilepsy with generalized tonic convulsions appear in about 50% of children, but they are usually not severe (Pang et al., 2008).

31.5.1.2.2 GENETICS

Cobblestone lissencephaly follows an autosomal recessive inheritance pattern (Pang et al., 2008). Several genes have been implicated in the etiology of WWS (Verrotti et al., 2010). Different mutations have been found in the proteins O-mannosyltransferase 1 and 2 (POMT1 at 9q34 and POMT2 genes) and also in each of the fukutin (FKTN at 9q31–33) and fukutin-related 9

protein (FKRP at 19q13–32) genes (Pang et al., 2008; Verrotti et al., 2010).

The MEB gene has been localized on the chromosome 1p32–34 (POMGnT1 gene for protein O mannose β-1,2-N-acetylglucosaminyltransferase) (Pang et al., 2008; Verrotti et al., 2010). FCMD is associated with mutations of the gene FKTN on chromosome 9q31, which encodes a novel 461-amino acid protein termed 'fukutin' (Pang et al., 2008; Verrotti et al., 2010).

All these genes are involved in the glycoylation of α-dystroglycan, an extracellular protein capable of binding to components of extracellular matrix such as laminin, agrin, neurexin, and perlecan (Pang et al., 2008; Verrotti et al., 2010). Mutations in these genes compromise the integrity of the superficial marginal zone of the cortex, so that neurons overmigrate beyond this structure into the pial surface, forming the cobblestone (Pang et al., 2008; Verrotti et al., 2010).

31.5.1.2.3 NEURORADIOLOGICAL FINDINGS

Brain MRI demonstrates the typical cobblestone lissencephaly with varying degrees of severity (Pang et al., 2008; Verrotti et al., 2010). MRI in WWS and MEB reveals pontine hypogenesis with a distinct dorsal 'kink' at the mesencephalic-pontine junction; a 'Z-shaped' hypoplastic brainstem is considered a key feature (Pang et al., 2008; Verrotti et al., 2010).

31.5.1.3 Lissencephaly X-linked with ACC

Lissencephaly X-linked with ACC (XLAG) includes a thickened cortex and three-layered cortex with gyral malformations that are more severe in posterior than anterior brain regions, atrophic striatal and thalamic nuclei, poorly myelinated white matter, ACC, and ambiguous genitalia (Jagla et al., 2008; Miyata et al., 2009; Okazaki et al., 2008).

31.5.1.3.1 CLINICAL CHARACTERISTICS

XLGA is associated with intractable neonatal onset epilepsy, temperature instability, probably due to a hypothalamic dysfunction, severe diarrhea, postnatal microcephaly, abnormal genitalia with micropenis and cryptorchidism, and early death (Jagla et al., 2008; Miyata et al., 2009; Okazaki et al., 2008).

31.5.1.3.2 GENETICS

XLAG results from defects in the ARX (aristaless-related homeobox) gene located at Xp22.13 (Okazaki et al., 2008). The ARX gene product has two functional domains, prd-like homeodomain, and aristaless domain (Okazaki et al., 2008). Disruption of the prd-like homeodomain leads to XLAG (Okazaki et al., 2008). The functional domain, prd-like homeodomain, has very important functions in the formation of the normal brain in early development (Okazaki et al., 2008).

The major function of ARX protein is thought to be not only the regulation of proliferation and tangential migration of GABAergic interneurons but also the radial migration of pyramidal neurons death (Okazaki et al., 2008).

31.5.1.3.3 NEURORADIOLOGICAL FINDINGS

Imaging studies show a thick cerebral cortex (5–6 mm) with anterior pachygyria and posterior agyria (Okazaki et al., 2008). Other findings include abnormal signal of white matter, absence of corpus callosum, and cystic or fragmental basal ganglia (Okazaki et al., 2008).

31.5.1.4 Lissencephaly with Cerebellar Hypoplasia

LCH has been recently defined as a different group of lissencephaly, which is neither classical nor cobblestone type (Verrotti et al., 2010). It is associated with severe abnormalities of the cerebellum, ranging from vermian hypoplasia to total aplasia with either classical or cobblestone lissencephaly, and abnormalities in the hippocampus and brainstem (Hong et al., 2000; Verrotti et al., 2010).

31.5.1.4.1 CLINICAL CHARACTERISTICS

Affected children show a motor, language, and cognitive delay; they neither sit and stand unsupported nor develop linguistic skills (Verrotti et al., 2010). Hypotonia and severe ataxia are frequent; in addition, generalized epilepsy begins at an early age (Verrotti et al., 2010).

31.5.1.4.2 GENETICS

It is an autosomal recessive disorder (Hong et al., 2000) that maps to chromosome 7q22 and is associated with mutations in the gene encoding reelin (RELN) (Hong et al., 2000; Verrotti et al., 2010). The mutations disrupt splicing of RELN cDNA, resulting in low or undetectable amounts of reelin protein (Hong et al., 2000). RELN encodes a large secreted protein that acts on migrating cortical neurons by binding to the VLDLR, the APOER2, α3β1 integrin, and protocadherins (Hong et al., 2000). LCH is also correlated with mutations of the gene, which encodes for VLDLR (Verrotti et al., 2010).

31.5.1.4.3 NEURORADIOLOGICAL FINDINGS

MRI demonstrates diffuse pachygyria, hippocampal dysplasia, and hypoplastic brainstem (Verrotti et al., 2010). Cerebellar manifestations range from midline hypoplasia to diffuse volume reduction and disturbed foliation (Verrotti et al., 2010).

31.5.1.5 Microlissencephaly

Microlissencephaly differs from other variants of LIS1 by the presence of a severe microcephaly (Verrotti et al., 2010). It is caused by an abnormal neuronal proliferation or survival combined with neuronal migration disorders (Verrotti et al., 2010). Two main types of microlissencephaly are recognizable: type A (Norman-Roberts syndrome) with no infratentorial anomalies and type B (or Barth syndrome), which is associated with a severe hypoplasia of the cerebellum and corpus callosum (Verrotti et al., 2010). A recent form has been reported in which primordial osteodysplastic dwarfism is associated with severe microcephaly (Verrotti et al., 2010).

31.5.1.5.1 CLINICAL CHARACTERISTICS

Norman-Roberts syndrome presents with a wide phenotypic heterogeneity (Natacci et al., 2007). Clinical characteristics include microcephaly, bitemporal hollowing, a low sloping forehead, slightly prominent occiput, widely set eyes, a broad and prominent nasal bridge, and severe postnatal growth deficiency (Verrotti et al., 2010). Neurological features include hypertonia, hyperreflexia, seizures, and severe mental retardation (Verrotti et al., 2010).

31.5.1.5.2 GENETICS

Norman-Roberts syndrome is an autosomal recessive disorder (Natacci et al., 2007).

31.5.1.5.3 NEURORADIOLOGICAL FINDINGS

The brain MRI has shown changes consistent with lissencephaly type I (Verrotti et al., 2010).

31.5.2 Heterotopia

Heterotopia is a neuronal migration disorder characterized by a cluster of disorganized neurons in abnormal locations, and it includes three main groups: periventricular nodular heterotopia (PNH), SBH, and marginal glioneural heterotopia (Spalice et al., 2009; Verrotti et al., 2010).

PNH is a rare malformation in which primary neuronal cells never begin migration and remain adjacent to the lateral ventricles (Pang et al., 2008; Spalice et al., 2009; Verrotti et al., 2010). PNH may involve both sides of the brain or, less frequently, be restricted to a single hemisphere (Spalice et al., 2009; Verrotti et al., 2010). Apparently, the cerebral cortex is normal (Pang et al., 2008).

SBH or 'double cortex' syndrome is characterized by a diffuse laminar band of gray matter located below the cerebral cortex and separated from it by a thin band of white matter (Pang et al., 2008; Spalice et al., 2009; Verrotti et al., 2010).

Marginal zone heterotopias or leptomeningeal glioneuronal heterotopias are one form of dysplasia in which ectopic nests of glial and neuronal cells are observed in the cortical MZ or overlying leptomeninges, respectively (Verrotti et al., 2010).

31.5.2.1 Clinical Characteristics

The spectrum of clinical presentation of PNH is wide (Spalice et al., 2009). Epilepsy is the main aspect (Pang et al., 2008; Spalice et al., 2009). About 90% of patients with PNH have epilepsy that can begin at any age, and it is usually intractable (Pang et al., 2008; Spalice et al., 2009; Verrotti et al., 2010). There is no clear relationship between the epilepsy severity and extent of nodular heterotopia (Pang et al., 2008). Surgical removal of the heterotopia cortex is generally successful (Spalice et al., 2009; Verrotti et al., 2010).

Other symptoms of PNH include severe developmental delay, microcephaly, and infantile spasms (Verrotti et al., 2010). However, in general, these patients have normal intelligence. Some patients may have learning problems such as impaired reading fluency (Pang et al., 2008). Some patients with PNH have also been described with Chiari I and amniotic band syndrome (Spalice et al., 2009; Verrotti et al., 2010).

The main clinical manifestation of SBH is epilepsy (Spalice et al., 2009). Individuals with SBH have variable degrees of mental retardation and intractable epilepsy, which seem to correlate with the thickness of the band and the overlying cortex (Spalice et al., 2009; Verrotti et al., 2010).

The cortex may be normal or associated with pachygyria (Verrotti et al., 2010). Lennox–Gastaut syndrome is another potential presentation (Spalice et al., 2009). Epilepsy surgery for focal seizures yields poor results, while callosotomy has been associated with improvement in drop attacks (Spalice et al., 2009). The clinical spectrum of SBH in male subjects overlaps with that in females in terms of seizure type representation, epilepsy syndromes, and response to antiepileptic therapy (Verrotti et al., 2010). However, there is increased heterogeneity with respect to cognitive function, neuroimaging, and molecular genetic data in males compared with females (Verrotti et al., 2010).

31.5.2.2 Genetics

PNH can be caused by genetic mutations or extrinsic factors, such as infections or prenatal injuries (Pang et al., 2008; Verrotti et al., 2010). Mutations of the *FLNA* gene (Xq28) cause bilateral PNH in the majority of patients; this form is often fatal for males, therefore explaining the female preponderance (Pang et al., 2008; Spalice et al., 2009; Verrotti et al., 2010). This gene encodes for Filamin A, an actin-binding protein that stabilizes the cytoskeleton to generate the forces necessary for cell mobility and mediates focal adhesions along the ventricular epithelium (Pang et al., 2008; Spalice et al., 2009; Verrotti et al., 2010). There is enrichment of FLNa (filamin A, alpha) in postmitotic migrating neurons, an expression pattern that might be maintained in part by FILIP (filamin-A-interacting protein), a potent degrader of FLNa (Spalice et al., 2009). FLNa mutations resulting in PH often involve truncation or disruption of the actin-binding domain, indicating that FLNa's ability to cross-link actin may be necessary for migration (Spalice et al., 2009).

The autosomal recessive form of PNH is caused by mutations in the *ARFGEF2* (ADP-ribosylation factor guanine exchange factor 2) gene localized at 20q13.13, which encodes for the protein brefeldin-inhibited GEF2 (Pang et al., 2008; Spalice et al., 2009; Verrotti et al., 2010). Mutations in ARF-GEF may impair the targeted transport of FLNA to the cell surface within neural progenitors along the neuroependyma (Pang et al., 2008; Verrotti et al., 2010). The disruption of these cells could contribute to PNH formation with microcephaly (Verrotti et al., 2010).

PNH has also been associated with copy number variations, including duplication 5p15.1 or 5p15.33 and deletion 6q26–q27 or 7q11.33 (Spalice et al., 2009; Verrotti et al., 2010). At least 15 distinct PNH syndromes have been described (Spalice et al., 2009).

SBH is caused by alterations in two genes: *LIS1* at 17p13.32 and *DCX* at Xq22.3–q23.3 (Pang et al., 2008; Verrotti et al., 2010). Mutations of the *DCX* gene have been found in all familial cases and in 53–84% of patients with sporadic, diffuse, or anteriorly predominant band heterotopia, which represent the most common forms of SBH (Verrotti et al., 2010). Other genetic causes of SBH remain unexplained (Verrotti et al., 2010). The DCX protein is thought to direct neuronal migration by regulating the organization and stability of microtubules necessary for neuronal motility (Pang et al., 2008).

31.5.2.3 Neuroradiological Findings

MRI patients with X-linked dominant mutation show bilateral symmetric nodules lying adjacent to the lateral ventricular walls; additional findings include hypoplasia of the corpus callosum and posterior fossa abnormalities such as cerebellar hypoplasia and enlarged cisterna magna (Pang et al., 2008; Verrotti et al., 2010). Unilateral PNH is commonly located in the posterior paratrigonal zone of the lateral ventricles and may involve the adjacent white matter (Verrotti et al., 2010).

Patients with autosomal recessive mutations of the *ARFGEF2* gene present with microcephaly, slightly enlarged ventricles, and delayed myelination (Pang et al., 2008; Verrotti et al., 2010). Symmetrical nodular heterotopia lining the ventricles is also seen, and the overlying cortex may be thinned with abnormal gyri (Pang et al., 2008).

MRI of the brain in SBH demonstrates two parallel layers of gray matter, a thin outer ribbon and a thick inner band, separated by a very thin layer of white matter (Pang et al., 2008; Verrotti et al., 2010).

31.5.3 Polymicrogyria

PMG is a cortical malformation characterized by an irregular brain surface with an excessive number of small and partly fused gyri separated by shallow sulci, giving the surface of the cortex its characteristic lumpy appearance (Pang et al., 2008; Spalice et al., 2009; Verrotti et al., 2010).

PMG can be focal or diffused, unilateral or bilateral (Pang et al., 2008; Verrotti et al., 2010). It is a very common cortical malformation and can be an isolated lesion associated with other brain malformations such as heterotopia, white matter lesions, or a part of several multiple congenital anomaly/mental retardation syndromes (Spalice et al., 2009; Verrotti et al., 2010). Bilateral involvement of the cortex is frequently seen, with a symmetric or asymmetric distribution, affecting the frontal, frontoparietal, parieto-occipital, perisylvian, and mesial occipital regions (Pang et al., 2008; Spalice et al., 2009).

PMG pathogenesis is not understood; brain pathology demonstrates abnormal development or loss of neurons in middle and deep cortical layers, variably associated with an unlayered cortical structure (Spalice et al., 2009). Two types of PMG can be identified histopathologically: a simplified four-layered form (in which there is a layer of intracortical laminar necrosis with subsequent alterations of late migration and postmigratory disruption of cortical organization) and an unlayered form (in which the molecular layers are continuous and do not follow the borders of convolutions and the neurons below have radial distribution while laminar organization is absent) (Verrotti et al., 2010). The incidence of PMG is unknown because of its clinical and etiological heterogeneity (Verrotti et al., 2010).

31.5.3.1 Clinical Characteristics

The wide spectrum of clinical manifestations is related to the extension of PMG, which varies greatly (Spalice et al., 2009). Almost all children with PMG have a high risk of developing epilepsy (Verrotti et al., 2010). Seizures usually begin between 4 and 12 years of age, and they are drug resistant in approximately 65% of patients (Spalice et al., 2009; Verrotti et al., 2010). A small number of children present with focal epilepsy, while the most frequent seizure types are atypical absences, tonic or atonic drop attacks, or tonic–clonic convulsions (Spalice et al., 2009; Verrotti et al., 2010).

In the bilateral frontal type, the most common symptoms include delayed motor and language milestones, spastic hemiparesis or quadriparesis, and mild to moderate mental retardation (Spalice et al., 2009; Verrotti et al., 2010). In the bilateral frontoparietal form, the clinical presentation is characterized by global developmental delay, esotropia, and pyramidal and cerebellar signs

and seizures, which occur in 94% of patients and are mostly generalized (Verrotti et al., 2010).

Bilateral perisylvian PMG-affected patients can present pseudobulbar palsy with diplegia of the facial, pharyngeal, and masticatory muscles and pyramidal signs and seizures (Verrotti et al., 2010). Infantile spasms may be the presenting seizure type even if seizures develop only before the end or after the first decade (Verrotti et al., 2010). Most patients develop multiple seizure types, and seizure control is poor in more than half of the cases (Verrotti et al., 2010).

Other forms of PMG, such as bilateral parasagittal parietooccipital, bilateral generalized, and unilateral ones, can produce various kinds of seizures and EEG abnormalities (including status epilepticus during sleep), cognitive slowing, motor delay, and cerebral palsy (Verrotti et al., 2010).

31.5.3.2 Genetics

PMG has been associated with mutations of a few genes, including *SRPX2* (sushi-repeat-containing protein, X-linked 2), *PAX6* (paired box 6), *TBR2* (T-box-brain2), *GPR56* (G-protein-coupled receptor 56), *KIAA1279*, *RAB3GAP1* (RAB3 GTPase-activating protein subunit 1), and *COL18A1* (collagen, type XVIII, alpha 1), with all but *SRPX2* found in rare syndromes (Spalice et al., 2009).

The genetic role in the etiopathogenesis of PMG is also supported by its association with Aicardi syndrome, Zellweger syndrome, and WWS or with chromosomal abnormalities such as 22q11 deletion, 1p36 monosomy, and trisomy of chromosome 13 (Pang et al., 2008; Verrotti et al., 2010).

The familial transmission of PMG has been identified in bilateral frontoparietal, bilateral perysylvian, and bilateral generalized forms (Pang et al., 2008; Verrotti et al., 2010). Bilateral frontoparietal PMG seems to be related to the mutation of the gene *GPR56* on chromosome 16q12.2–21 with an autosomic recessive inheritance (Pang et al., 2008; Verrotti et al., 2010). This gene encodes for a G-protein-coupled receptor, a regulator of cell cycle signaling in neuronal progenitor cells at all ages, and plays an essential role in the regional patterning of the human cerebral cortex (Spalice et al., 2009; Verrotti et al., 2010).

Bilateral perysylvian PMG is mainly attributed to different patterns of inheritance, including X-linked dominant, X-linked recessive, autosomal recessive, autosomal dominant with reduced penetrance, autosomal recessive with pseudodominance, and autosomal dominant (Verrotti et al., 2010). A locus for X-linked bilateral perisylvian PMG maps on the distal long arm of the X chromosome (Xq28), but the linkage has not been confirmed and no gene has been identified (Verrotti et al., 2010).

TBR2 is a gene involved in the genesis of PMG, associated with microcephaly and corpus callosum agenesis (Verrotti et al., 2010). It maps to chromosome 3p (Verrotti et al., 2010). This gene encodes a transcription factor, a member of the T-box family, critical in invertebrate embryonic development of the central nervous system and mesoderm (Verrotti et al., 2010). It may also be involved in neuronal division and migration (Verrotti et al., 2010).

31.5.3.3 Neuroradiological findings

MRI in PMG demonstrates small irregular gyri and an indistinct gray and white matter junction (Verrotti et al., 2010). The polymicrogyric cortex often appears mildly thickened (6–10 mm) because of cortical overfolding (Verrotti et al., 2010). T2 signals within the cortex are usually normal, although there may be delayed myelination (Verrotti et al., 2010).

31.5.4 Schizencephaly

SCZ is a structural abnormality of the brain, characterized by congenital clefts spanning the cerebral hemisphere from the pial surface to the lateral ventricle and lined by cortical gray matter with communication between the ventricles and extra-axial subarachnoid space (Pang et al., 2008; Spalice et al., 2009; Verrotti et al., 2010). Cleft localization varies widely, but the perisylvian region is more frequently involved (Spalice et al., 2009; Verrotti et al., 2010). The cortex overlying the cleft is often polymicrogyric (Verrotti et al., 2010). Actually, SCZ is classified within the same group as PMG (Pang et al., 2008; Verrotti et al., 2010).

This malformation can be unilateral or bilateral, symmetric or asymmetric, and can be divided into two subtypes: 'closed or fused lips' or type I (if the cleft walls are in apposition) and 'open lips' or type II (if the cleft walls are separated) (Pang et al., 2008; Spalice et al., 2009; Verrotti et al., 2010). Type II SCZ is more common than type I (Barth et al., 2007). SCZ tends to involve the insular, precentral, and postcentral regions (Pang et al., 2008). In addition, SCZ is often associated with septo-optic dysplasia (Spalice et al., 2009). The etiology of this disorder has not been clearly established, and several causes, including genetic, vascular, toxic, metabolic, and infectious factors, may be involved (Spalice et al., 2009; Verrotti et al., 2010).

31.5.4.1 Clinical characteristics

Patients with unilateral closed-lipped SCZ generally have mild hemiparesis and seizures but no impairment of normal developmental milestones (Pang et al., 2008; Spalice et al., 2009; Verrotti et al., 2010). When the cleft is open, patients have mild to moderate developmental delay, microcephaly, seizures, spasticity, and hemiparesis (Pang et al., 2008; Verrotti et al., 2010). Patients with bilateral clefts show severe mental deficits and severe motor abnormalities, including spastic quadriparesis (Pang et al., 2008; Spalice et al., 2009; Verrotti et al., 2010). Blindness due to optic nerve hypoplasia can be common (Verrotti et al., 2010). Language development is more likely to be normal in patients with unilateral SCZ compared to patients with bilateral clefts (Spalice et al., 2009; Verrotti et al., 2010). Noncentral nervous system manifestations have also been reported, such as gastroschisis and bowel atresias (Pang et al., 2008).

Several types of seizure have been reported, including generalized tonic–clonic, partial motor, and sensorial (Spalice et al., 2009; Verrotti et al., 2010). Infantile spasms have been described in a few children (Verrotti et al., 2010). Seizures are usually resistant to medical therapy, and stabilization may be achieved through surgery (Verrotti et al., 2010).

31.5.4.2 Genetics

EMX2 (empty spiracles homeobox 2) gene mutations may be correlated with type II SCZ (Pang et al., 2008; Spalice et al., 2009; Verrotti et al., 2010). *EMX2* is a homeotic gene expressed in proliferating neuroblasts and is probably involved in controlling cortical migration and structural patterning of the developing rostral brain (Pang et al., 2008; Spalice et al., 2009; Verrotti et al., 2010). However, recent studies criticize the true role of *EMX2* in SCZ (Pang et al., 2008; Spalice et al., 2009; Verrotti et al., 2010).

31.5.4.3 Neuroradiological findings

In addition to PMG, MRI may demonstrate agenesis of the septum pellucidum and agenesis or thinning of the corpus callosum, hippocampal malformations, posterior fossa abnormalities, ventricular diverticula and arachnoid cysts, and multiple calcifications (Pang et al., 2008; Verrotti et al., 2010). Periventricular heterotopic nodules have also been found in a minority of cases (Verrotti et al., 2010). The malformations associated with SCZ may also involve extracerebral structures (Verrotti et al., 2010).

Nomenclature

ARHGAP11B Rho GTPase activating protein 11B
ATP10A ATPase, class V, type 10A
C15orf2 Chromosome 15 open reading frame 2
CHRNA7 Cholinergic receptor, nicotinic, alpha 7
CTCF CCCTC-binding factor
CYFIP1 Cytoplasmic FMR1 interacting protein 1
Dube3a *Drosophila* ube3a
ECT2 Epithelial cell transforming sequence 2 oncogene
GABRA5 Gamma-aminobutyric acid (GABA) A receptor, alpha 5

Gabrb3 Mice GABA A receptor, subunit beta 3 gene
GABRB3 Gamma-aminobutyric acid (GABA) A receptor, beta 3 gene
GABRG3 Gamma-aminobutyric acid (GABA) A receptor, gamma 3
HBII52 Small nucleolar RNA, C/D box 115 cluster
Idic (15) Isodicentric chromosome 15
Int dup (15) Interstitial duplication chromosome 15
KLF13 Kruppel-like factor 13
MAGEL2 MAGE-like 2
MECP2 Methyl CpG binding protein 2
MKRN3 Makorin ring finger protein 3
MTMR10 Myotubularin-related protein 10

MTMR15 Myotubularin-related protein 15
NDN Necdin homolog
NIPA1 Nonimprinted gene in Prader–Willi syndrome/Angelman syndrome chromosome region 1
NIPA2 Nonimprinted gene in Prader–Willi syndrome/Angelman syndrome chromosome region 2
OTUD7A OTU domain-containing 7A
PWRN1 Prader–Willi region non-protein-coding RNA 1
SmN Survival of motor neuron 1
snoRNAs Small nucleolar RNAs
SNRPN Small nuclear ribonucleoprotein polypeptide N
SNURF SNRPN upstream reading frame
TCF4 Transcription factor 4
TRPM1 Transient receptor potential cation channel, subfamily M, member 1
TUBGCP5 Tubulin, gamma complex associated protein 5
UBE3A Ubiquitin protein ligase E3A
Ube3a Mice Ube3a

32.1 COMPLEX GENOMIC CHARACTERISTICS AND GENE REGULATION AT THE HUMAN 15q LOCUS

The chromosome 15q locus is an enormously complex region of the human genome responsible for several devastating neuropsychological syndromes as well as a major causative locus in autism spectrum disorder (ASD) (see Chapter 34). Gene regulation in this region is extremely complex and is governed by a variety of molecular changes, including DNA methylation, antisense transcripts, microRNAs, and genomic rearrangements. The purpose of this chapter is to provide a broad introduction to some of the neurological disorders and causative genes in the 15q11–q13 locus.

Chromosome 15 is acrocentric; thus, it essentially has one long coding arm (q) and a short arm (p) containing mostly heterochromatin arrays of ribosomal RNA genes, satellite sequences, and other repetitive DNA sequences. The long q arm contains 2.9% of the coding genes in the human genome (Zody et al., 2006). A key structural feature of chromosome 15 is the high number of low-copy segmental duplications, with 8.8% of its euchromatin being inundated with low-copy repeats (LCRs) (Zody et al., 2006). These LCRs predispose genes in the region to dosage changes due to both deletion and duplication events mediated by nonallelic homologous recombination (NAHR) events and result in a spectrum of neurodevelopmental disorders (mechanism reviewed in Shaw and Lupski, 2004). This locus is complicated even further by a 2-Mb cluster domain of genes preferentially expressed from one parental allele or imprinted genes.

Imprinted genes are epigenetically marked in gametes to drive expression of that gene from a single parental allele in the offspring. An epigenetic mark (or imprint) is set depending on the gene and on the germ cell. In fertilization, somatic cells of the developing embryo contain both maternally and paternally inherited alleles; this epigenetic mark ensures that just one allele is expressed (Weaver et al., 2009). In the embryonic germ cells, the original imprint is erased and a new one is added depending on the sex and the gene. This parent-specific expression is directly due to these epigenetic modifications of the DNA (DNA methylation, histone modifications, and noncoding RNAs) and not due to changes in the primary sequence, thus altering the conformation of chromatin fibers and therefore the regulation of the expression of the nearby genes. Although these modifications can have dramatic effects on the phenotype, they do not alter the primary DNA sequence. The monoallelic expression of an imprinted gene may occur only in one of possibly several isoforms, or in particular tissues, or at particular stages of development. The untranslated mRNA H19 was the first gene shown to be imprinted in humans (Zhang and Tycko, 1992); as many as 40 such genes have now been identified, and another 156 new genes have been predicted by both computational and experimental approaches to be regulated in a parent-specific manner through epigenetic modification (Luedi et al., 2007).

The 15q11–q13 region contains several genes that show parent-of-origin-specific expression and others that show biallelic expression in the brain. Genes expressed exclusively from the paternal chromosome in the brain are *MKRN3*, *MAGEL2*, *NDN*, *SNRPN*, and a cluster of *snoRNAs*. *C15orf2* and *PWRN1* are genes that have shown monoallelic expression in human fetal brain (Buiting et al., 2007). Two genes show maternal-specific expression in the brain: *UBE3A*, an E3 ubiquitin ligase responsible for Angelman syndrome (AS) phenotypes that shows biallelic expression in most tissues except for a preferential expression of the maternal allele in human brains, and *ATP10A*, which also is preferentially expressed in the maternal chromosome in human brain as well as in fibroblasts (Herzing et al., 2001; Meguro et al., 2001). Recently it has been suggested that the *ATP10A* may be monoallelic in expression, dependent on sex and common genetic variation and not regulated by an imprinting mechanism (Hogart et al., 2008).

Recently, a large region between *Snrpn* and *Ndn* was found to be imprinted in the mouse brain, with several paternally expressed ncRNAs and a paternally expressed gene called *DOKist4* (Gregg et al., 2010). Although the phenotypic outcome of these additional paternally expressed genes and ncRNAs is still unknown, it clearly speaks to the complexity of this locus in terms of genotype to phenotype correlations.

This region is one of the most unstable regions in the human genome (Knoll et al., 1993) because of a number of complex LCRs that predispose the region to misalignment during meiosis I, which leads to unequal NAHR events involving both sister chromatid and interchromosomal exchanges (Lupski, 1998; Robinson et al., 1998).

In addition, there is a high rate of recombination in women in this locus (Robinson and Lalande, 1995). 15q11–q13 homologous pairing is an epigenetic regulatory mechanism disrupted by genomic rearrangements such as duplications and deletions. CCCTC-binding factor (*CTCF*) controls the process of X chromosome pairing as well as pairing at the 15q11–q13 locus (Meguro-Horike et al., 2011). At least five recurrent breakpoints (BPs) have been identified containing LCRs involved in microdeletions, microduplications, inversions, as well as isodicentric chromosomes (see Figure 32.1).

Severe phenotypic consequences at the 15q locus can be caused by deletions, duplications, mutations, or defects on a single active allele, be it maternal or paternal. In rare instances, two copies of chromosome 15 can be inherited from a single parent (uniparental disomy), causing the same severe phenotypic consequences as loss of function for one 15q allele. The two primary genomic disorders that cause neuropathology in this region are the Prader–Willi syndrome (PWS) and Angelman syndrome (AS), whose phenotypes result from loss of the paternal or maternal contribution of the 15q11–q13 genomic region, respectively. The first nine individuals with PWS were described in 1956 by the endocrinologists Prader, Labhart, and Willi (Clarke and Boer, 1995). By 1976, it

was apparent that a recurrent microdeletion could be visualized by high-resolution chromosome analysis in patients with PWS and AS (Ledbetter et al., 1981). In 1989, it was established that AS is a direct result of maternal deletion, whereas PWS results from a paternal deletion of the same region on chromosome 15 (Knoll et al., 1989). This 2-Mb domain is often referred to as the PWS/AS critical region. In 95% of PWS/AS patients, there are two main types of deletions: class I deletions, with breakpoints at BP1 (proximal) to BP3 (distal), and class II deletions, with breakpoints from BP2 (proximal) to BP3 (distal) (see Figure 32.1). The remaining 5% of PWS/AS patients have the distal breakpoint at BP4. Patients with smaller deletions from BP1 to BP2 have been identified, but these individuals do not present with classic PWS or AS and may represent a distinct neurological syndrome unrelated to the primary causative genes for PWS and AS (Doornbos et al., 2009). As with most genomic disorders, these LCRs mediate not only deletion events, but also reciprocal duplication events. The same LCRs and therefore the same breakpoints in addition to BP5 can mediate inverted dup(15) marker chromosomes and some cases of interstitial duplications and triplications of chromosome 15q11–q13 (Roberts et al., 2002). The clinical presentation associated with deletions tends
FIGURE 32.1 15q11.1–q13.3 region. Maternal and paternal alleles are shown separately. Maternally expressed genes are in pink, paternally expressed in *blue*, biallelically expressed genes in green, and the genes silenced on a particular allele are in *black*. *ATP10A* varies among populations, so its pink/blue. Dots pink and blue refer to AC-IC and PW-IC, respectively. The five different common breakpoints for both duplications and deletions in this region appear as dotted lines.

to be more uniform, and commonly includes dysmorphology, which facilitates diagnosis, while duplications present with a more subtle phenotype that often includes autism when maternally inherited, but may also include anxiety and other neurological effects in paternally inherited duplications (Hogart et al., 2010). The widespread use of array comparative genomic hybridization (array CGH) has increased the frequency of detection of submicroscopic interstitial 15q duplications, as well as smaller, possibly pathogenic deletions in this region. Smaller deletions and duplications found in neurodevelopmental disorders such as schizophrenia and autism will be described later in this chapter.

32.2 EPIGENETIC CONTROL OF GENE EXPRESSION ACROSS 15q11–q13

Imprinted gene expression on 15q is coordinately controlled in *cis* by an imprinting center (IC), a genetic element functional in germline and/or early postzygotic development that regulates the establishment of parental specific allelic differences in replication timing, DNA methylation, and chromatin structure. In other words, the IC's function is to reset the maternal and paternal imprints. A mutation at the IC sets the imprint permanently, and the parental imprint will be fixed on the chromosome on which the mutation arose, resulting in a heritable form of the imprinting disorder (Saitoh et al., 1996). The IC regulates imprinting in the whole region and is located in the 5′ untranslated region of the small nuclear ribonucleoprotein polypeptide N (*SNRPN*) gene. The PWS/AS IC has two functional components: a 4.3-kb DNA segment at the promoter of *SNRPN* involved in PWS (PWS-IC) and a 0.9-kb element ~35 kb upstream of *SNRPN* which regulates the gene responsible for AS (AS-IC) (Buiting et al., 1995). AS-IC acquires a primary imprint during gametogenesis, thus establishing the maternal epigenotype. The inactive maternal IC is marked by CpG methylation and by histone H3 Lys 9 di-methylation, while the active paternal IC is marked by histone H3 Lys4 methylation (Soejima and Wagstaff, 2005). The unmethylated maternal allele of the AS-IC most likely binds a *trans*-acting factor that confers methylation on the PWS-IC maternal allele after fertilization. It is assumed that, once established, the PWS-IC paternal epigenotype spreads across the entire PWS/AS domain in the soma.

32.2.1 Epigenetic Control Across the 15q Region

Histone acetylation and chromatin structure are influenced by DNA methylation, resulting in the production of compacted chromatin that is refractory to transcription. In the PWS/AS region, *MKRN3*, *NDN*, and *SNRPN* are silenced by maternal-specific CpG methylation of the promoter/exon I region (Driscoll et al., 1992; Glenn et al., 1996; Jay et al., 1997).

The *SNRPN* gene is a bicistronic-imprinted gene that encodes two polypeptides, the SNURF (SNRPN upstream reading frame) and the SmN (splicing factor involved in RNA processing) (Gray et al., 1999). This gene has 10 exons: exons 1–3 encode the SNURF protein, and exons 4–10 encode the SmN. This SNRP–SmN transcript unit also hosts the genes to encode multiple noncoding RNAs (snoRNAs), and it serves as the start site for the *UBE3A* antisense transcript (Runte et al., 2001). Because the CpG island of the promoter is hypermethylated on the maternal chromosome and hypomethylated on the paternal chromosome, the gene is transcribed exclusively from the parentally inherited chromosome and shows a high level of expression in the brain and the heart. Different methods have taken advantage of the differentially methylated *SNRPN* promoter for the diagnosis of PWS and AS. Our group recently utilized this differentially methylated region to develop a high-resolution melting curve assay to determine the parent of origin of the duplicated chromosome in individuals with 15q duplication (Urraca et al., 2010).

32.3 GENES KNOWN TO CAUSE DISEASE IN THE REGION

32.3.1 The E3 Ubiquitin Ligase Gene (*UBE3A*)

The *UBE3A* gene product is the canonical HECT domain E3 ubiquitin ligase enzyme known as E6-associated protein (E6-AP). Although originally identified as a host protein that interacts with viral E6 protein during papillomavirus infection (Huibregtse et al., 1993), the primary role of this enzyme is thought to be the monoubiquitination of protein substrates that are destined for recycling by the ubiquitin proteasome system or are tagged for trafficking to various cellular compartments. In addition to this enzymatic function, E6-AP can also function as a transcriptional co-activator of steroid hormone receptor genes (Nawaz et al., 1999). Maternal deficiency for *UBE3A* results in the neurodevelopmental disorder Angelman syndrome (Kishino et al., 1997). This gene exhibits maternal allele-specific expression in most regions of the brain in mice and humans, with the strongest expression restricted to hippocampal and cerebellar neurons (Albrecht et al., 1997; Dindot et al., 2008). The discovery of maternally inherited loss-of-function mutations in *UBE3A* has clearly established *UBE3A* as the causative gene in AS (Kishino et al., 1997; Matsuura et al., 1997). Although a handful of putative UBE3A substrates have now been identified, most notably the Arc protein which regulates synaptic AMPA receptors (Greer et al., 2010) and ECT2

protein which is a key regulator of the actin cytoskeleton (Reiter et al., 2006), it is still unclear if the key proteins responsible for the AS phenotype are regulated by UBE3A at the protein or transcriptional level, or both.

Cytogenetic abnormalities in the PWS/AS region have been described in 1–3% of autistic individuals. Consistent with a role for *UBE3A* in autism are studies that have demonstrated copy number variants not only at the *UBE3A* locus, but also at other loci regulating the ubiquitin–proteasome pathway in autistic individuals (Glessner et al., 2009). The *UBE3A* gene itself has been proposed as a candidate gene for autism susceptibility, although linkage and association studies have been somewhat inconsistent (Cook et al., 1998; Guffanti et al., 2010; Nurmi et al., 2001).

32.3.2 SnoRNA Cluster

Small nucleolar RNAs (snoRNAs) are noncoding RNAs located in the nucleolus which are involved in rRNA modifications. Pre-rRNA maturation includes endonucleolytic and exonucleolytic cleavages plus modifications such as methylation or pseudouridylation. There are two main classes of snoRNA: the C/D box snoRNAs, which are associated with methylation, and the H/ACA box snoRNAs, which are associated with pseudouridylation (Bachellerie et al., 2002). There is a cluster of C/D box snoRNA genes encoded in the 15q11–q13 region that are processed from introns of the paternally expressed *SNURF-SNRPN* sense *UBE3A* antisense transcript (see Figure 32.1). *HBII52* has 47 copies, *HBII85* has 24 and the others genes (*HBII-36, HBII-13, HBII-437, HBII-238A*, and *HBII-438B*) one copy each. These snoRNAS are highly expressed in the brain (Cavaille et al., 2000). Recent studies demonstrate that chromatin de-condensation of MBII/HBII snoRNAs plays a significant role in the regulation of nucleolar size during neuronal maturation (Leung et al., 2009). Reports on balanced translocations affecting the paternal copy of 15q11–q13 and three microdeletions in the snoRNA region (15q11.2) have now implicated the *HBII-85* snoRNA as the key paternally expressed causative gene(s) for the PWS phenotype (De Smith et al., 2009; Duker et al., 2010; Gallagher et al., 2002; Sahoo et al., 2008).

32.3.3 Gamma-Aminobutyric Acid Genes

The 15q11–q13 region contains a cluster of GABA$_A$ receptor subunits genes: *GABRB3*, *GABRA5*, and *GABRG3*, which encode for the gamma-aminobutyric acid (GABA) receptor subunits β3, α5, and γ3, respectively. During development, GABA$_A$ receptors play a role in proliferation, migration, and differentiation of precursor cells that direct the development of the embryonic brain (Owens and Kriegstein, 2002). GABAergic dysfunction in the brains

of autistic individuals has been reported and particular attention has been devoted to the GABRB3 subunit (Pizzarelli and Cherubini, 2011). It has been observed that this gene is normally biallelically expressed in the brain, but in autistic individuals monoallelic expression has been found in combination with a reduction in GABA receptor protein (Hogart et al., 2007). Additional studies indicate that *GABRB3* expression is reduced in the parietal cortex cerebellum of subjects with autism (Fatemi et al., 2009). It has been shown that a rare coding variant of the GABRB3 gene is associated with autism when transmitted maternally (Delahanty et al., 2011). This same variant was identified in two independent families segregating with childhood absence epilepsy (Tanaka et al., 2008).

32.3.4 CYFIP1 and Other Autism-Related Genes

More severe behavioral problems (autism, ADHD, and obsessive–compulsive disorder) appear in patients with type I deletions (BP1–BP3) than in patients with type II deletions (BP2–BP3); this could be influenced by the genes between BP1 and BP2: *TUBGCP5*, *NIPA1*, *NIPA2*, and *CYFIP1*. The latter three of these are widely expressed in the central nervous system, while TUBGCP5 is expressed in the subthalamic nuclei. Patients with a microdeletion at 15q11.2 between BP1 and BP2, which includes the four genes, present delayed motor and speech development, dysmorphisms, and behavioral problems (Doornbos et al., 2009). It seems that the haploinsufficiency of *NIPA1* does not cause any disease, as PWS/AS patients do not exhibit progressive spastic paraplegia compared to autosomal dominant hereditary spastic paraplegia. In terms of autism, more attention has been focused on *CYFIP1* since Prader–Willi phenotypes have been observed in fragile X syndrome (FXS) patients (see Chapter 33), and it was found that the fragile X associated protein (FMRP) acts in concert with CYFIP1 protein to regulate mRNA translation in neurons (Napoli et al., 2008). In patients with this FXS sub-phenotype that show PWS overlap, *CYFIP1* mRNA levels are generally reduced by two- to fourfold as compared to normal controls or individuals with FXS without PWS features (Nowicki et al., 2007).

32.4 CONTIGUOUS GENE DELETION/ DUPLICATION SYNDROMES ON 15q

32.4.1 Deletion Syndromes

32.4.1.1 PWS (OMIM #176270)

PWS is a contiguous gene syndrome caused by the loss of function in those genes situated within the 15q11–q13 region. The syndrome is the direct result of loss of a paternally expressed gene or genes in the 15q

region. The molecular events resulting in PWS include interstitial deletions (70%), uniparental disomy (UPD) (25%), imprinting center defects (<5%), and, on rare occasions, chromosomal translocations (<1%).

The syndrome has a prevalence of 1/15,000–1/30,000, and the main clinical features include an initial failure to thrive, followed later in life by an obsession with food and other behavioral problems, including intellectual disability (for a detailed review of phenotypic features and management, see Cassidy and Driscoll, 2009; Goldstone et al., 2008, respectively). There are also significant phenotypic differences between patients with 15q deletions as opposed to maternal UPD. In UPD patients, the facial features and the hypopigmentation are less frequent than in patients with the deletion; in contrast, sleep disorders and behavioral abnormalities such as psychosis and autism are more common (Cassidy, 1997). Seizures are present in half of the individuals with a deletion and in less than 10% in UPD cases (Varela et al., 2005). Individuals with class I deletions have a more severe phenotype than those with class II deletions, including self-injurious behavior, deficits in adaptive behavior, obsessive–compulsive behavior, and difficulties in visual-motor integration (Butler et al., 2004). Cardiovascular and respiratory disorders related to the obesity that results from obsessive food compulsion are the most frequent causes of death in these patients. In 1993, a group of clinicians established the clinical diagnostic criteria for PWS (Holm et al., 1993). With the availability now of molecular laboratory testing, when there are clinical findings pointing to the disorder the revised criteria recommends to test for PWS at different ages depending on the phenotypes observed (Gunay-Aygun et al., 2001). The most widely used laboratory test is based on the paternal differences in DNA methylation from the 5′ end of the *SNRPN* gene. PWS deletion patients have only a maternal methylated allele. Since the phenotypic outcomes can be somewhat variable depending on the size and character of a genomic defect, it is important to determine the molecular class of the loss of function for genetic counseling purposes. Chromosomal analysis can identify large deletions and translocations, *SNRPN* fluorescence *in situ* hybridization (FISH) probes detect deletions, and DNA polymorphisms from the patient and parents are useful in the diagnosis of UPD cases. MS-HRM has also been shown to be an efficient and cost-effective method for the identification of PWS or AS deletions (Hung et al., 2011; White et al., 2007).

32.4.1.2 Angelman syndrome (OMIM 105830)

Angelman syndrome (AS) was first recognized in 1965 by physician Harry Angelman (pronounced as if a "male angel"), who described three unrelated subjects all presenting with a similar curious phenotype, including inappropriate laughter, happy demeanor, and a "puppet-like" dangling of the arms (Angelman, 1965). The estimated prevalence of AS is between 1:1000 and 1:20,000 (Williams, 2005). AS is a neurogenetic disorder characterized by severe intellectual disability, ataxia, seizures, EEG abnormalities, bouts of inappropriate laughter, absent speech, autistic-like behavior, sleep disorder and postnatal microcephaly, macrostomia, maxillary hypoplasia, and prognathia (Williams et al., 2006). AS is difficult to detect in infancy, as hypotonia and developmental delay are fairly nonspecific features that can occur in infancy for a number of reasons. The characteristic phenotypes become clearer after age one. Seizure onset is often between 1 and 3 years. Many seizure types have been reported, but atypical absence and myoclonic seizures are most frequent. The most common EEG finding is the presence of triphasic delta activity with a maximum over the formal regions (Conant et al., 2009). The Angelman phenotype becomes less striking in adulthood, the sleep problems improve, but most patients continue to have seizures (for further review and diagnostic approaches, see Van Buggenhout and Fryns, 2009). It has been proposed that, to rule out AS, *SNRPN* methylation assay tests should be performed on any patient with developmental delay, severe intellectual disability, speech impairment, and happy disposition (Varela et al., 2004).

The molecular causes of AS include interstitial deletions of the maternal chromosome (70%), paternal UPD in 3–5% of the cases, imprinting center mutations in 10%, and maternally inherited *UBE3A* mutations in 5–10%, leading to the absence of the gene product. Of the ∼10% of AS patients who do not have chromosome 15q defects, it appears that at least some of these individuals may have mutations in potential UBE3A pathway genes such as *MECP2* and the transcription factor *TCF4* (Takano et al., 2010; Watson et al., 2001). Maternally derived deletions and *UBE3A* mutations result in a more severe phenotype than uniparental disomy or imprinting defects, both of which still retain two intact copies of *UBE3A*. These maternal loss-of-function individuals often have severe microcephaly, greater delay in developmental milestones, more severely impaired communication skills, and more severe seizures, in addition to hypopigmentation in the deletion cases (Lossie et al., 2001). The nonimprinted gene responsible for this pigmentation loss is the *OCA* gene, which also causes type II oculocutaneous albinism and is located in the distal portion of 15q11–q13 within the common class I and class II deletion boundaries (Fridman et al., 2003). Comparing the main deletion classes, there are no major phenotypic differences, except for the absence of speech in class I patients (Varela et al., 2004) and perhaps an increased risk for ASD in class I individuals (Peters et al., 2004).

32.4.2 Duplications Syndromes

As many as 3–5% of individuals with broad ASD have copy number changes at the 15q locus (Hogart et al., 2010). Two types of 15q duplications have been identified that result in an ASD phenotype. These duplications can occur as either simple interstitial duplications containing fewer than 18 genes or more complex extra-chromosomal isodicentric duplications containing >60 genes.

32.4.3 Isodicentric Chromosome 15q Duplications

A marker chromosome is a structurally abnormal, unidentified extra piece of chromosomal material. Marker chromosomes usually occur in addition to the normal chromosome complement and are thus also referred to as supernumerary chromosomes. When a marker chromosome occurs in the PWS/AS region, the isodicentric chromosome 15 [idic(15)], it is formed by the inverted duplication of proximal 15q resulting in an additional small di-centromeric chromosome detectable by cytogenetic and FISH analysis (Battaglia, 2005). This [idic(15)] is one of the most common supernumerary marker chromosomes in humans (Webb, 1994). Idic (15) marker chromosomes that do not include the PWS/AS critical region have no obvious clinical effect (Huang et al., 1997), whereas most of those including this region are maternally derived, arise *de novo*, and lead to a neurobehavioral phenotype (Battaglia, 2008). Most idic (15) chromosomes arise through BP3:BP3 or BP4:BP5 recombination events (see Figure 32.1). The clinical features of idic (15) syndrome include moderate to profound developmental delay/intellectual disability, autism or autistic-like behavior, central hypotonia, minor dysmorphisms, and seizures (Battaglia, 2008). Tetrasomy of this region is associated with a more severe phenotype than trisomy, suggesting that there is a dosage effect for a gene or genes duplicated in this region. In particular, there is an apparent correlation between the frequency and severity of seizures in these individuals and the increase in copy number, clearly implicating the duplicated GABA receptor gene cluster as a contributor to the increased seizure risk and the difficult seizure management.

32.4.4 Interstitial 15q11–q13 Duplication

This submicroscopic duplication is almost impossible to detect by traditional karyotype analysis; however, with the widespread use of array CGH in the clinic, it is now becoming a frequent cause of ASD where chromosomal rearrangements are involved. Most int dup (15) patients with an interstitial duplication 15q11–q13 share the common deletion breakpoints

of PWS/AS and are the result of the reciprocal NAHR event that forms the common PWS/AS deletions. In most cases, the duplication is *de novo*, but there are a few familial cases, which have been critical to understanding the difference in phenotype associated with maternal versus paternal inheritance of the duplication. There is only one report of an interstitial duplication that expanded during meiosis when transmitted from a carrier mother to her son; otherwise, the duplication is stable (Gurrieri et al., 1999). There is a wide range of severity in the developmental disabilities; however, most individuals with this smaller duplication present with a mild, somewhat sociable form of autism combined with moderate-to-severe anxiety disorder. The severity of the phenotype does not show an obvious correlation between the duplicated region sizes. There has been one report of an adult with a maternally derived int dup (15) who had a severe phenotype characterized by intractable epilepsy (Orrico et al., 2009). However, in the authors' own cohort of 15 interstitial duplication 15q subjects, just two individuals present with severe seizures (manuscript in review).

Like the deletions, there is also a parent-of-origin effect for the duplications containing the PWS/AS critical region. Maternally transmitted 15q duplication is most frequently detected, because it is consistently associated with autistic features with variable degrees of developmental delay. Unfortunately, genotype–phenotype correlations have not consistently demonstrated that these duplications are the sole cause of ASD in these cases. Boyar et al. reviewed the literature and described the phenotype in 31 confirmed maternal cases, with intellectual disability, developmental delay, learning disabilities, language impairment, and autism/autistic-like behavior as the most common finding, followed by hypotonia, repetitive behavior, hyperactivity, poor attention, and clumsiness. Less frequent are seizures, echolalia, aggression, and hypopigmentation (Boyar et al., 2001).

On the other hand, very few cases of paternally transmitted 15q duplication have been reported, and most of these individuals appear neurotypical, as one can see from familial cases in which unaffected mothers have transmitted paternally derived duplication chromosomes to their affected children (Cook et al., 1997; Roberts et al., 2002). However, there are a few paternal cases reported with speech delay and behavior problems. Mohandas et al. reported a patient with nonspecific developmental delay and partial agenesis of rostral corpus callosum; Mao et al. described a patient with global developmental delay, depression, obesity, food-seeking behavior, and self-injurious tendencies; and Roberts et al. presented a series of 16 cases in which only one patient had paternal duplication, and his phenotype included developmental delay and behavioral disorder (Mao et al., 2000; Mohandas et al., 1999; Roberts et al., 2002).

The maternal bias of duplication-associated risk in autism suggests the requirement of a maternally expressed transcript for greatest ASD risk, clearly implicating the maternally expressed *UBE3A* gene in the ASD phenotype in 15q duplication individuals.

32.5 COMPLEX DISEASES

32.5.1 Microdeletion 15q13.3

The use of array CGH in patients with developmental delay, intellectual disability, and/or dysmorphic features has resulted in the recognition of a recurrent 15q13.3 microdeletion (Ben-Shachar et al., 2009; Sharp et al., 2008). The critical deletion spans 1.5 Mb and arises through NAHR between LCR sequences on BP4 and BP5, telomeric to PWS/AS region.

The first description of recurrent 15q13.3 microdeletion was by Sharp et al., who screened for idiopathic intellectual disability using whole-genome array CGH or quantitative polymerase reaction (PCR) and found the microdeletion with a frequency of 1/350. Interestingly, in their series 7 out of 9 had epilepsy and/or abnormal EEG findings (Sharp et al., 2008). Incomplete penetrance (65–70%) has been reported and some relatives of 15q13.3 microdeletion individuals were reported as neurotypical, while others had intellectual disability, epilepsy, and/or neuropsychiatric disorders (Ben-Shachar et al., 2009; Shinawi et al., 2009).

Based on the findings of Sharp et al., a case-control study was conducted in patients with idiopathic generalized epilepsy, and there were 12 cases with the 15q13.3 microdeletion (12/1223) and none in the controls (0/3699). However, in these 12 cases, 9 cases did not have dysmorphic features or intellectual disability. Dibbens et al. proposed the segregation of the microdeletion as a susceptibility variant, because they analyzed families and they found that the microdeletion did not account for all the epilepsy risk in their families (i.e., there were multiple affected individuals without the microdeletion as well as unaffected individuals with the deletion (Dibbens et al., 2009)). Finally, there is a report of a patient carrying a homozygous microdeletion, inherited from both parents, with severe epileptic encephalopathy, retinopathy, autistic features, and choreoathetosis (Masurel-Paulet et al., 2010).

The chromosomal region for the 15q13.3 microdeletion encompasses seven genes: *ARHGAP11B, MTMR15, MTMR10, TRPM1, KLF13, OTUD7A,* and *CHRNA7* (see Figure 32.1). The PWS-IC seems to regulate *CHRNA7* levels with MECP2 as the link between epigenetic mark and transcriptional regulation (Yasui et al., 2011). The *CHRNA7* gene is highly expressed in the brain and is considered a good candidate gene, at least for the epilepsy phenotypes in 15q13.3 deletion individuals. *CHRNA7* encodes a synaptic ion channel protein that mediates neuronal signal transmission, and mutations in other members of the nicotine receptor subunit gene family cause the autosomal dominant nocturnal frontal lobe epilepsy.

A smaller deletion ($\sim$680 kb) that includes the *CHRNA7* gene has been identified with a frequency of 1 in 2960, but the phenotype is quite similar to the larger deletion of 1.5 Mb (Shinawi et al., 2009). In some ethnicities, the BP4–BP5 region can be inverted (Sharp et al., 2008), which predisposes this region to the smaller deletion by NAHR between CHRNA7-LCR copies on the normal and inverted chromosomes (Shinawi et al., 2009).

32.5.2 Schizophrenia and Behavioral Abnormalities

Schizophrenia is a severe mental disorder characterized by hallucinations, delusions, cognitive deficits, and apathy. Like other common diseases, it is a complex genetic disorder with high heritability (Lichtenstein et al., 2009). There is no doubt that genetic factors play a role in the pathogenesis of the disorder, but there is no single major gene that confers the risk for the whole phenotype. It is likely that common alleles of small effect and some rare alleles with relatively large effects are combining to increase susceptibility to the development of schizophrenia (Wang et al., 2005). Nowadays, it is known that there are copy number variations (microdeletions/microduplications) that contribute to the etiology of schizophrenia. Genome-wide scans for structural variants have identified deletions on chromosomes 1q21.1, 3q29, 15q11.2, 15q13.3, and 22q11.2 and duplications on chromosomes 16p11.2 and 16p13.1 that increase the risk of schizophrenia (Consortium, 2008; Ingason et al., 2011; Mccarthy et al., 2009; Mulle et al., 2010; Stefansson et al., 2008). Maternal 15q11–q13 duplication has also been found to be a risk factor for schizophrenia, with an odds ratio of 7.3 (Ingason et al., 2011).

Interestingly, a genome-wide linkage analysis showed that an endophenotype found in schizophrenia, P50 auditory gating deficit, is linked (LOD score = 5.3) to chromosome 15q13–q14, the locus for the *CHRNA7* gene (Freedman et al., 1997). This gene is considered a candidate gene for schizophrenia based on positive association studies (Freedman et al., 2001; Stephens et al., 2009).

32.5.3 Microduplication 15q13.3

Recently, a few individuals with the reciprocal duplication between BP4 and BP5 have been reported. This duplication originates by NAHR between BP4 and BP5 LCRs and presents with no recognizable phenotype as

in the microdeletion cases with developmental delay/intellectual disability and psychiatric disease, but not epilepsy. There is also inter- and intrafamilial variability suggesting incomplete penetrance, since other family members with the duplication appear clinically neurotypical (Van Bon et al., 2009). Interestingly, a smaller duplication (358–680 kb) that includes the *CHRNA7* gene has been reported with the same clinical outcomes as the larger BP4–BP5 duplication. These cases are all inherited and some family members also present with a psychiatric disease that can be due to a very low penetrance or could be explained as a risk factor for alcoholism and psychiatric or behavioral disorders (Szafranski et al., 2010). Thus, the only reports of this smaller duplication differ in the duplication size, but all include the *CHRNA7* gene (Szafranski et al., 2010). Therefore, studies to date show a remarkably variable expressivity for this 1.5-Mb deletion/duplication on chromosome 15q13.3, which includes neurotypical phenotype, intellectual disability, autism, seizures, bipolar disorder, and schizophrenia.

32.6 ANIMAL MODELS OF 15q REGION DISORDERS

Perhaps no other single region of the human genome has been the inspiration for such a variety of transgenic mouse models as the 15q region. One clear advantage of studying the 15q region in mice is that the entire 15q11.2–q13 locus from BP1–BP5 is syntenic to the mouse chromosome 7qC region, making it feasible to study not only single-gene disorders, but also the effects of multiple-gene deletions and duplications in the genomic disorders that occur at 15q in humans.

Several mouse models have now been produced for the single-gene imprinting disorder AS through both knock-out and knock-in strategies (Jiang et al., 1998; Miura et al., 2002). As in the human conditions, these mice only exhibit phenotypes when the *Ube3a* deficiency is passed though the maternal germline. These models have provided a system for the study of ataxia, motor control, and long-term potentiation (LTP) defects observed in AS patients. They have also been used to identify novel phenotypes due to loss of *Ube3a* related to cerebellar controlled lick rhythm (Heck et al., 2008) and experience dependent maturation of cortical neurons of the visual cortex (Kashiro et al., 2009; Yashiro et al., 2009). In addition, the recent construction of a YFP–*Ube3a* fusion mouse has revealed not only that *Ube3a* is maternally expressed in most regions of the brain, but also that the paternally inherited allele is not completely silent, as previously thought (Dindot et al., 2008). In addition, GFAP-positive neuronal precursors in the vermus are not subject to imprinted regulation

and show bi-allelic expression of *Ube3a* (Dindot et al., 2008). Mice with a maternal deletion from *Ube3a* to *Gabrb3* had increased seizure activity, altered ultrasonic vocalization, and impairment in learning and memory tasks (Jiang et al., 2010).

Two recently developed mouse models have revealed details about the function of the PWS/AS imprinting center as well as the molecular mechanism of PWS phenotypes. HBII-85 snoRNAs sequences are highly conserved between humans and mice. Mice lacking the MBII-85 snoRNA ortholog show postnatal growth retardation, delayed sexual maturation, motor learning deficit, and hyperphagia, as well as other features seen in PWS patients (Ding et al., 2008). The snoRNAs at this locus and a neuron-specific long antisense UBE3A transcript (Rougeulle et al., 1998) that initiates at the *SNRPN* promoter (see Figure 32.1) are both involved in the complex orchestration of allele-specific repression that results in the *UBE3A* gene being expressed from the maternal allele and the MBII-85 snoRNA from the paternal allele. The development of a mouse with a 35-kb targeted deletion of the PWS-IC has greatly accelerated the understanding of the epigenetic and transcriptional changes that must take place to cause allele-specific expression (Yang et al., 1998). This mouse model of PWS accurately recapitulates neonatal phenotypes including feeding difficulties, failure to thrive, and small size. However, it has proven difficult to utilize this model for behavioral studies in adult mice due to its early lethality in a C57BL/6 genetic background. Chamberlain et al. were able to solve this dilemma by moving the PWS-IC[del] mutation to a variety of genetic backgrounds until they were able to rescue this lethality, which appears to be unrelated to the mutation at the PWS-IC (Chamberlain et al., 2004). This adult viable PWS-IC[del] mouse was used to identify cognitive abnormalities as well as to assay imprinted expression for genes in the 15q/7C region, with particular emphasis on *Ube3a*, which is known to be maternally expressed in neurons, as well as for two genes that have been the subject of some debate in the literature, *ATP10A* and the *Gabrb3* cluster, which were both shown to be biallelically expressed in neurons in this mouse model of PWS (Relkovic et al., 2010). In an effort to understand how the snoRNA cluster, and specifically the PWS-associated *HBII-85* gene, is regulated in neurons, Leung et al. looked for changes in chromatin decondensation and nucleolar size in the brains of PWS-IC[del] animals and compared them to brain tissue from both AS and PWS *SNRPN>UBE3A* deletion individuals (Leung et al., 2009). In both the animal model and the human brain samples, they identified a large region (~888 kb) from the *Snrpn* gene to the *Ube3a* gene (see Figure 32.1) that undergoes dramatic chromatin decondensation in neurons on the paternal allele only, thus providing an open chromatin conformation and presumably

transcriptionally active zone around the paternal *Snrpn* promoter, which transcribes the *HBII-85* snoRNA gene as well as the antisense-*Ube3a* transcript (Leung et al., 2009). Most individuals with PWS are also deleted for additional 15q genes or have maternal uniparental disomy for this region, resulting in overexpression of the maternal *UBE3A* gene. Although loss of paternal *HBII-85* transcription alone may not account for all aspects of the Prader–Willi phenotype, the use of this imprinting center mouse model to reveal the complex mechanisms of imprinted expression and regional epigenetic regulation on 15q is just now becoming evident.

32.6.1 Additional Mouse Models for Genes Deleted or Duplicated in the 15q11–q13 Region

One complication in the phenotypic analysis of AS, PWS, and duplication 15q autism is that most of these individuals are deleted or duplicated for a region encompassing some 18 genes, including several genes that, when deleted in mouse models, cause phenotypes on their own. The *Gabrb3* null mice, for example, display epilepsy, learning and memory deficits, as well as defects in social behavior (Delorey et al., 1998). There is also an interesting relationship between the *p* gene and the *GABRA5* and *GABRB3* subunits genes. Deletion of both *p* alleles causes rearrangements of Gabaα5 and Gabaβ3 receptors, producing a peculiar phenotype characterized by ataxia, jerky gait, and seizures (Nakatsu et al., 1993). Obviously, the duplication of this cluster in humans contributes to the difference in severity of phenotypes observed between interstitial duplication 15q individuals and the more severely affected isodicentric 15q duplication cases, where as many as 6 copies of the *GABRB3* cluster may be present (Hogart et al., 2007).

A mouse model of paternal uniparental disomy showed high incidence of failure to thrive with spontaneous death in the first month, similar to both the *HBII-85*-deficient and PWS-IC^{del} models of PWS. Survivors developed obesity, hyperactive behavior, ataxic gait, and electroencephalograph with high-amplitude delta rhythmic activity (Cattanach et al., 1997).

In an effort to reflect the interstitial duplication 15q syndrome in mice more accurately, Nakatani et al. used chromosomal engineering techniques to duplicate the entire 7qC region syntenic to typical human class II duplication breakpoints in interstitial duplication 15q cases (Nakatani et al., 2009). It was somewhat surprising that the animals with paternally but not maternally inherited duplications of 7qC showed poor social interaction, behavioral inflexibility, abnormal ultrasonic vocalizations, and anxiety. However, the animals with maternal duplication did trend toward significance on several tests, and, more importantly, an accurate test for autism

assessment in mice has not yet been developed; so, in the future, these animals may exhibit subtle autistic features, like their human counterparts. That being said, as more interstitial duplication 15q cases are identified using array-CGH methods, there has been an increase in the number of paternal 15q duplication cases, who typically present with both anxiety and sleep problems but generally do not have cognitive defects (L. Reiter and N.C. Schanen, unpublished observations). In the end, this mouse model of int dup(15) may be a better reflection of the actual phenotypes observed in a large cohort of int dup(15) from both maternal and paternal origins.

32.6.2 *Drosophila* Models of 15q Syndromes

A recent avenue of research has been the construction of human disease models in the well-studied and easily manipulated genetic model organism *Drosophila melanogaster* (Doronkin and Reiter, 2008; Pfleger and Reiter, 2008). A model for Angelman syndrome revealed motor defects, LTP deficits, and circadian rhythm abnormalities in flies lacking the *UBE3A* ortholog *Dube3a* (Wu et al., 2008). Flies lacking Dube3a or even overexpressing Dube3a in the nervous system did not show any gross morphological changes in brain structure of neuronal connections as predicted by phenotype-observed mouse models of AS. Additional studies revealed that both overexpression and loss of Dube3a can affect the number and complexity of dendritic arbors in the fly peripheral nervous system (Lu et al., 2009), suggesting that Dube3a may control more subtle aspects of synaptic connectivity and is perhaps not involved in nervous system development, *per se*.

Our group has capitalized on the mis-expression methodologies available in the *Drosophila* system, primarily the GAL4/UAS system, which allows for overexpression of a given construct in a variety of specific tissue types or under the control of temporal regulators such as heatshock induction (Duffy, 2002). Using a proteomics approach, the authors of this study have identified over 80 unique protein or transcription targets of Dube3a (manuscript in revision). The first is a Rho-GEF involved in actin cytoskeletal remodeling, which the authors identified as a protein that decreased in intensity when they overexpressed human UBE3A in fly heads (Reiter et al., 2006). This protein, known as Pebble in flies and ECT2 in mammals, physically interacts with both fly and human UBE3A proteins in 293T cells. In addition, in a mouse *Ube3a* loss-of-function model of AS changes in Ect2 expression is observed in both the hippocampus and cerebellar regions of the brain (Reiter et al., 2006). More recently, the authors identified a protein called Punch in flies and GTP cyclohydrolase I in mammals using

overexpression of fly Dube3a in heads. The regulation of Punch, however, appears to be through the transcription co-activation function of Dube3a, as the ubiquitin ligase function is not required for increased Punch transcript levels, increased dopamine levels, or hyperactivity observed in these flies (Ferdousy et al., 2011).

32.7 CONCLUSIONS

Human chromosome 15q11–q13 is a complex genomic region subject to regulation by parental imprinting. Several LCRs in this region predispose 15q to genomic rearrangements, causing parent-specific dosage changes that lead to a variety of neurodevelopmental disorders, including autism. The widespread use of array-CGH technology to detect CNVs in the 15q region has made it a focal point for the study of PWS/AS autism and even certain forms of schizophrenia. In addition, animal models of 15q disorders run the gamut from flies to mice and include not only single gene knock-outs, but also chromosomally engineered models duplicating or deleting the entire region of the mouse genome syntenic to 15q11.2–q13. With such a wide array of resources available in both human and model organism genetics, it is only a matter of time before someone unlocks the mechanisms of gene regulation, methylation, imprinting, and genomic recombination that cause these neurological disorders with the hope of eventually designing therapeutics for the treatment of these syndromes.

Glossary

Array-CGH: A microarray method commonly used to identify deleted and duplicated segments of the genome.

C57BL/6 C57 black 6: A common inbred strain of laboratory mouse.

Endophenotype: Psychiatric concept that refers to a biomarker (neurophysiologic, biochemical, endocrinological, neuroanatomical, cognitive, or neuropsychological) that is associated with the phenotype in the populations, is heritable, is illness independent (manifests in individuals whether or not illness is active), co-segregates with illness, and is found in non affected family members at a higher rate than in the general population (Gottesman and Gould, 2003).

Epigenetic: Refers to DNA and chromatin modifications that can affect gene function without change in the genotype.

Epigenotype: DNA-exclusive states of gene expression and epigenetic modification; the maternal state and the paternal state.

HBII: Nomenclature used for human genes of the snoRNA cluster; there are different genes (as HBII-13, HB-36, HBII-85, etc.).

HRM: High-resolution melting curve analysis; a method that can quickly distinguish short DNA fragments which differ by as little as a single nucleotide without the need for DNA sequencing.

GAL4/UAS: Bipartite expression system used in *Drosophila* that was derived from the yeast GAL4 gene promoter.

Imprinting: A difference in gene expression that depends on the parent of origin of the allele.

Imprinting center (IC): A region of the DNA usually marked by differential methylation that regulates the imprinted expression of a gene or genes in the region.

Knock-in mouse: Insertion of a protein-coding cDNA sequence at a particular locus in the mouse within the gene of interest.

Knock-out mouse: One or more genes turned off through a targeted mutation in the mouse.

Ortholog: Genes in different species that are similar in DNA sequence and also encode proteins with the same function.

Penetrance: The proportion of individuals with a genotype known to cause disease and present clinical symptoms.

Segmental duplication: Regions bigger than 1 kb that are not high-copy repeats and have more than 90% identity to another region in the genome.

Syntenic: Gene loci that are in sequence on a chromosome between two species.

Uniparental disomy: Two copies of a specific chromosome, both inherited from one parent.

33.1 INTRODUCTION

33.1.1 Fragile X Syndrome and Fragile X-Associated Disorders

Fragile X syndrome (FXS) and the fragile X family of disorders may affect generations of a family in a variety of ways. It is essential for readers to understand the spectrum of involvement from FXS and premutation disorders, as significant advances in the knowledge of these disorders have occurred in recent years. As one enters into a new stage of targeted treatments, identification and understanding of the fragile X-associated disorders are even more important. The study of fragile X-associated disorders serves as a pathway for gaining insight into the molecular pathogenesis of other neurodevelopmental disorders.

FXS is the most common inherited cause of intellectual disability (ID) and the most common single genetic cause of autism. It is also known as Martin–Bell syndrome and, in South America, as Escalante syndrome. The syndrome was first described in 1943 by Martin and Bell, two British physicians who reported a sex-linked ID syndrome in a large family without definitive physical characteristics (Martin, 1943). Sex-linked ID in the sons of otherwise unaffected daughters of a Saskatchewan family was described by Renpenning in 1962 (Renpenning et al., 1962). In 1969, Lubs noted an unusual secondary constriction of the long arm of the X chromosome in a family with four intellectually disabled males and three carrier females (Lubs, 1969). Further investigations were aided by studies showing that observation of these fragile sites on the X chromosome depended on what type of tissue culture medium was used, allowing increased frequency of observation (Sutherland, 1977). The fragile X chromosome and ID were further linked to macroorchidism by Turner

(Turner et al., 1978) and Sutherland (Sutherland and Ashforth, 1979). In 1981, Richards et al. reexamined the pedigree described by Martin and Bell in 1943, which did not appear to have physical anomalies. Seven members of the original family reported by Martin and Bell were evaluated, and five were found to carry the fragile X chromosome. Unusual physical features were also noted upon further examination, including large ears, prognathism, and macroorchidism (Richards et al., 1981). Of note, the family described by Renpenning in 1962 was reevaluated by Fox and colleagues, and members of the family were found to have microcephaly and no macroorchidism, both of which are atypical of FXS. It has since been suggested that Renpenning syndrome refers to the condition of mental retardation, microcephaly, and sex-linked inheritance, but without an associated fragile X chromosome (Fox et al., 1980).

The molecular etiology of the FXS, an unstable cytosine–guanine–guanine (CGG) repetitive sequence region of DNA on the X chromosome, was discovered in 1991 (Verkerk et al., 1991; Yu et al., 1991). A mutation in the *fragile X mental retardation-1* (*FMR1*) gene leads to expanded CGG repeats on the 5′ end of the *FMR1* gene in successive generations (Fu et al., 1991). The number of CGG repeats determines whether an individual is categorized as having a full mutation, or a premutation, or is in the gray or intermediate zone (Figure 33.1).

33.1.1.1 Full Mutation

In the general population, the number of CGG repeats ranges from 5 to 44 repeats. Greater than 200 CGG repeats confers the full mutation (Maddalena et al., 2001). In the full mutation, the *FMR1* gene is usually completely methylated and transcription of *FMR1* mRNA is silenced, so that very little fragile X mental

FIGURE 33.1   A family affected by fragile X. *Left*, a young man with fragile X syndrome; *middle*, his mother who is a premutation carrier; *right*: his maternal grandmother who is a premutation carrier with FXTAS. Notice the young man's gaze away from the camera.

retardation protein (FMRP) is produced (Bell et al., 1991; Pieretti et al., 1991). It is a lack of this protein that leads to the syndrome (Loesch et al., 2004). FXS is characterized by features including developmental delay, deficits in short-term memory, and speech delays. Affected individuals may have hyperactivity, attention difficulties, and an autism spectrum disorder (ASD). A sometimes subtle physical phenotype can be associated with the full mutation, including macroorchidism (from puberty onward) and prominent ears. These are discussed in detail later in the chapter.

Studies of the prevalence of FXS have focused on individuals with significant cognitive impairment. These studies resulted in a prevalence of 1 in 3,600 to 1 in 4,000 (Crawford et al., 2002; Turner et al., 1996). The allele frequency in the general population is 1 in 2,500 for both males and females identified in newborn screening (Fernandez-Carvajal et al., 2009b; Hagerman, 2008). Most affected people have the full mutation with >200 CGG repeats; however, in rare cases, the disorder can be caused by a deletion or point mutation in the *FMR1* gene or by an FMRP deficit in the upper range of the premutation.

33.1.1.2 Premutation Carriers

Carriers of fragile X, also known as premutation carriers, are defined as having 55–200 CGG repeats (Maddalena et al., 2001). The prevalence of the premutation ranges from 1 in 250 to 810 in males and 1 in 130 to 260 in females (Dombrowski et al., 2002; Fernandez-Carvajal et al., 2009b; Hagerman, 2008). The premutation was previously thought to have no implications for disease. Most individuals with the premutation are cognitively unaffected. However, research has shown effects of the premutation, first in reproduction with the discovery of fragile X-associated primary ovarian insufficiency (FXPOI). Primary ovarian insufficiency (POI) refers to menopause before the age of 40. Neurological symptoms including tremor and ataxia were reported in 2001 in an older male subgroup of fragile X premutation carriers (Hagerman et al., 2001). In children with the premutation, most are unaffected, but a subgroup demonstrates evidence of difficulties including attention deficits and social deficits (Farzin et al., 2006). A pattern of psychiatric problems in a subgroup of premutation carriers is also emerging, which is discussed later in the chapter.

33.1.1.3 Gray or Intermediate Zone

Among the general population, noncarriers have 5–54 CGG repeats. However, those with 45–54 repeats have been discovered to have unique features as well. These individuals are known as being in the gray or intermediate zone (Maddalena et al., 2001). They are usually phenotypically unaffected, although there can be elevated *FMR1* mRNA and twice the rate of POI in the general

population (Bodega et al., 2006; Bretherick et al., 2005; Loesch et al., 2007). On occasion, alleles in the gray zone can be unstable, and, therefore, this category requires further study for both phenotypic involvement and allelic stability. There have been rare reports of males with gray zone alleles who have had some fragile X features, but whether the features are due to the gray zone allele is not certain (Aziz et al., 2003).

33.2 CLINICAL DESCRIPTION

33.2.1 Clinical Description of FXS

The phenotype of FXS can be quite broad, with a mix of physical, cognitive, and behavioral features. Typically, children with FXS are not diagnosed until 3 years of age, when their behaviors bring them to the attention of their physician (Bailey et al., 2003). ID is a key feature in FXS, as it is the most common inherited cause of ID. Eighty-five percent of males and 25–30% of females are found to have an IQ <70 (de Vries et al., 1996; Hagerman et al., 1992, 2008b; Loesch et al., 2004). Lower FMRP levels are associated with more severe cognitive deficits. Females with FXS usually present with learning disorders and a normal or borderline IQ (Chonchaiya et al., 2009a).

33.2.1.1 Clinical Phenotype

The classical physical phenotype associated with males with FXS is of a person with macroorchidism, large and prominent ears, and a long, narrow face. This physical picture is typical for adult males with FXS. The physical features are often not present in the prepubertal child with FXS (Chudley and Hagerman, 1987).

Macroorchidism was the first physical feature identified in FXS. It is present in more than 90% of adult males (Merenstein et al., 1996). The macroorchidism does not appear to affect fertility as males with FXS are fertile (Willems et al., 1992). The sperm of full-mutation males alone contains the premutation (Reyniers et al., 1993). Due to this, fathers with FXS pass on the premutation to all of their daughters, and as they pass on their Y chromosome to their sons, the latter are not affected. Using an orchidometer, Butler et al. compiled growth charts for 185 males with FXS including height, weight, and testicular volume measurements. In the study, the average testicular volume in an adult male with FXS was 45 ml with a 95% confidence interval of 25–70 ml (Butler et al., 1992). The normal testicular volume is around 25–30 ml (Prader, 1966), and a volume greater than 30 ml is considered to be macroorchidism.

Prominent ears were described in 78% of 97 prepubertal boys with the full mutation (Merenstein et al., 1996). The ears can be long and wide and may demonstrate loss

FIGURE 33.2   Image of a young boy with fragile X syndrome. Note the broad forehead, epicanthal folds, and mildly prominent ears with cupping of the pinnae bilaterally.

FIGURE 33.3   Hyperextensibility of MP joints with extension to 90°.

FIGURE 33.4   Single palmar crease in a boy with FXS.

FIGURE 33.5   Double-jointed thumb in a boy with FXS.

of the antihelical fold, leading to 'cupping' of the upper pinna (Hagerman, 2002b). If the prominent ears are undesired, a surgical pinning procedure can be done (Figure 33.2).

Facial features were characterized in a retrospective study of children with FXS by Hockey and Crowhurst. Common characteristics in prepubertal children included puffiness around the eyes, strabismus, and hypotonia (Hockey and Crowhurst, 1988). Epicanthal folds were described by Simko et al. (1989). A high palate is a common finding, and often the palate is narrow as well (Simko et al., 1989). Jaw length increases disproportionately to body height in patients with FXS (Loesch and Sampson, 1993), and jaw prominence can be seen in adults, in addition to a long face after puberty. Dental maturity may be advanced in FXS, more so in younger children. Dental maturity was advanced in girls with the premutation as well (Kotilainen and Pirinen, 1999).

Connective tissue abnormalities are seen in FXS, including pes plenus, joint laxity, scoliosis, and hyperextensibility of the finger joints (Hagerman et al., 1984). Davids et al. examined 150 males with FXS and found pes planus in 50% of them. Hyperextensibility of the metacarpal–phalangeal (MP) joints was observed in 73% of patients younger than 11 years of age, in 56% of those 11–19 years old, and in 30% of those older than 20 years of age. Hyperextensibility is defined as an MP joint angle greater than or equal to 90° (Davids et al., 1990). Double-jointed thumbs may also be a physical finding. The skin is soft and 'velvety' in texture in FXS. A single or bridged palmar crease and calluses from hand-biting behaviors may be present. Hypotonia is described in young patients (Hagerman et al., 1983), and it appears to be due to a general effect of CNS dysfunction. Clonus may be present in adult FXS individuals more frequently than in children with FXS. It should be noted that approximately 30% of individuals with FXS do not have the typical physical features (Figures 33.3, 33.4, and 33.5).

In female individuals with FXS, the spectrum of physical involvement is tempered by the unaffected X chromosome. Phenotypic involvement is closely associated

with the activation ratio (Abrams et al., 1994; Sobesky et al., 1996). The activation ratio refers to the fraction of normal *FMR1* alleles on the active X chromosome. Females with FXS were described in 1971 by Escalante, who noted flat feet and a high palate (Escalante, 1971). Cronister et al. looked at 105 full-mutation females and found an increased incidence of voluntary thumb dislocation and hyperextensible MP joints compared to 90 unaffected controls (Cronister et al., 1991). Mildly prominent ears are a common finding in prepubertal girls. Female individuals with FXS may have the full spectrum of involvement including ID and physical features or, on the other side of the spectrum, have no ID. Angkustsiri et al. reported a girl with the full mutation who had not only gifted intellectual abilities but also mild auditory processing problems and significant anxiety (Angkustsiri et al., 2008).

33.2.1.2 Behavioral Phenotype

Young children with FXS may present with language delays and are diagnosed with developmental delays at an average age of 21 months (Bailey et al., 2003). Hyperactivity is commonly reported, as are irritability, tantrums, perseveration, self-injurious behavior, mood instability, hand flapping, and hand biting (Hagerman, 2002b).

Patients with FXS often seem to have hyperarousability to auditory, visual, or tactile stimuli. This may be due to autonomic dysregulation with both sympathetic hyperarousal to sensory stimuli (Miller et al., 1999) and decreased parasympathetic activity compared to controls (Boccia and Roberts, 2000). Hyperactivity was noted in 47% of boys with FXS by Finelli et al. (1985). Bregman et al. found attention problems in all of 14 boys studied, but only 71% met the criteria for attention deficit hyperactivity disorder (ADHD; Bregman et al., 1988). ADHD may be the initially noted complaint in higher-functioning boys with FXS (Hagerman et al., 1985). Impulsivity is evident in boys with FXS when compared to boys with Down syndrome and unaffected control boys (Munir et al., 2000). Sullivan and colleagues have documented attention deficits in the majority of boys with FXS studied (Sullivan et al., 2006).

Shyness and social anxiety are commonly seen in both males and females with FXS and may improve with age. It may be more of a problem in females with FXS because ADHD symptoms are often more severe in boys, and ADHD may serve to temper the shyness (Merenstein et al., 1996). Psychiatric problems may also occur in individuals with FXS. Franke et al. evaluated psychiatric problems in mothers with the full mutation and in siblings with both the premutation and without the premutation. Fifty-four percent of full-mutation mothers had a psychiatric problem. Anxiety disorders were seen in 46% of those mothers with the full mutation, and social

phobia was seen in 31%. Bipolar disorder was present in 15% and major depressive disorder (MDD) in 15%. Schizotypal and schizoid personality disorder was seen in 23% and avoidant personality disorder in 23% (Franke et al., 1998).

Executive function defects and difficulties with math are commonly reported in females with FXS. Attention problems are less frequent in females in comparison to males, with around 33% having ADHD (Hagerman et al., 1992). Females tend to have less hyperactivity but impulsivity is usually evident. Selective mutism may be seen in females as well (Hagerman et al., 1999).

33.2.1.3 Autism

Autism is a disorder characterized by deficits in social communication, language, and repetitive movements. It is closely related to FXS, as approximately 2–7% of individuals with autism will be positive for the fragile X mutation (Brown et al., 1986; Reddy, 2005; Wassink et al., 2001). Once a child receives the diagnosis of autism or ASD, fragile X DNA testing is recommended. Around 25% of males with FXS were diagnosed with autism in the 1990s using the Childhood Autism Rating Scale (Bailey et al., 1998). When evaluated with current gold standard diagnostic tools such as the Autism Diagnostic Observation Schedule and the Autism Diagnostic Interview, 30–35% of males meet the diagnostic criteria for autism (Harris et al., 2008; Rogers et al., 2001). Autistic-like features such as hand biting, hand flapping, perseveration, shyness, and poor eye contact have been noted in FXS, but it is the core social and communication deficits that lead to a diagnosis of autism (Baumgardner et al., 1995; Hagerman et al., 1986; Hatton et al., 2006; Kaufmann et al., 2004; Kerby and Dawson, 1994; Lewis et al., 2006). Social communication is not typically a weak point in the majority of patients, except in those with autism. Individuals with FXS are typically sensitive to social cues (Simon and Finucane, 1996).

In females with FXS as well, autism has been diagnosed, but on a less frequent basis than in males. Several studies have been conducted that evaluated the number of females with FXS and autism, and the rate is approximately 4–10% (Dissanayake et al., 2009; Hagerman, 2002a; Leigh et al., 2010).

33.2.1.4 Associated Medical Conditions

Seizures are the most important medical problem associated with FXS. They occur in approximately 20% of individuals and are more common in early childhood (Berry-Kravis, 2002; Hagerman and Stafstrom, 2009; Musumeci et al., 1999). The seizures are usually well controlled by anticonvulsants if treated early, but, in some cases, multiple anticonvulsants are necessary (Berry-Kravis, 2002). All types of seizures can occur, but partial complex seizures are perhaps the most common.

Strabismus has been noted in 8–40% of patients with FXS (Hatton et al., 1998; King et al., 1995; Maino et al., 1991; Storm et al., 1987). The type of strabismus reported has included exotropia, esotropia, and hyperdeviations. Surgery or patching may be necessary for correction, and, if found on physical examination, a referral to an ophthalmologist is recommended.

Otitis media has been reported by Hagerman and colleagues in 63% of 30 boys with FXS in comparison to 15% of their typical siblings and 38% of developmentally disabled children without FXS. Forty-three percent were treated with polyethylene (PE) tubes or prophylactic antibiotics for persistent middle ear effusions (Hagerman et al., 1987). Monitoring for otitis media should be done, as the resulting effects such as hearing loss may worsen language and cognitive defects. The facial structure in FXS is thought to contribute to the propensity for otitis media. Sinusitis was noted in 23% of 43 fragile X full-mutation males (Hagerman, 2002b).

Mitral valve prolapse (MVP) has been observed in FXS and is likely due to connective tissue abnormalities. Loehr et al. found MVP by echocardiogram in 55% of 40 male and female full-mutation individuals, and the prolapse was associated with a click or murmur on physical examination (Loehr et al., 1986). A study of 13 males and females using standard ECG, Holter ECG, and echocardiography found MVP in 77%, tricuspid prolapse in 15%, and mild pulmonary artery dilation in 23%. Other defects were noted including posterior aortic leaflet prolapse, mild aortic regurgitation, and mild pulmonary artery dilation (Puzzo et al., 1990). Any signs or physical examination symptoms suggestive of a cardiac problem warrant a referral to a cardiologist for further evaluation.

In FXS, abnormal growth patterns have been noted, including macrocephaly (Meryash et al., 1984). Short stature is common in both males and females (Loesch et al., 1987). There is evidence of hypothalamic–pituitary dysfunction with enhanced cortisol levels after stress and a blunted thyroid stimulation hormone response to thyrotropin-releasing hormone (Hessl et al., 2004; Wilson et al., 1988; Wisbeck et al., 2000).

The Prader–Willi phenotype (PWP) of FXS is characterized by extreme obesity with a full, round face; small, broad hands and feet; a small penis; and hyperphagia (de Vries et al., 1993; Nowicki et al., 2007). This PWP is phenotypically similar to Prader–Willi syndrome, but occurs without cytogenetic or methylation abnormalities at 15q11–13. It is estimated to occur in <10% of males with FXS, and occasionally occurs in females. CYFIP1 mRNA levels are generally reduced by two- to fourfold in the patients with the PWP compared to individuals with FXS alone and controls (Nowicki et al., 2007).

Children with FXS typically have disordered sleep early in childhood, and this usually improves with time (Kronk et al., 2009). Treatment with melatonin can improve this wakefulness in the middle of the night (Wirojanan et al., 2009).

33.2.2 Premutation Involvement

The authors' understanding regarding involvement in the premutation has evolved over the years: from considering those with the premutation as completely unaffected or 'nonpenetrant' in the 1980s to identification of premature ovarian failure (POF) in approximately 20% of women with the premutation in 1991 (Cronister et al., 1991) and now to the presence of a large spectrum of psychiatric, medical, and neurological problems in a limited number of carriers (Chonchaiya et al., 2009a). Over the last decade, the understanding of the molecular mechanism leading to premutation involvement through RNA toxicity related to elevated levels of *FMR1* mRNA first identified by Tassone et al. (2000a) has grown. Below each type of premutation, the involvement is described in detail.

33.2.2.1 Developmental Involvement in Children with the Premutation

Involvement in children with the premutation was first identified in 1995 with a report of ADHD and social difficulties in high-end premutation carriers (Hagerman et al., 1996). Further reports of developmental problems followed (Aziz et al., 2003; Goodlin-Jones et al., 2004; Tassone et al., 2000b), and it was the problems seen in some young carriers that led to the discovery of elevated mRNA in carriers (Tassone et al., 2000a). Although the original cases were biased by clinic referral, Farzin et al. carried out a controlled study comparing the developmental problems of boys with the premutation who presented clinically as the proband to those who were identified through cascade testing once the proband had been diagnosed and to brothers who did not have the premutation. High rates of ASD (73%) and ADHD (90%) were found in those that were the probands compared to a rate of 8% of ASD and 38% of ADHD in the non-probands, and no ASD and 13% of ADHD in the typical brothers without the premutation (Farzin et al., 2006). Although the rate of ASD was not significantly different in the nonproband boys with the premutation compared to the non-carrier brothers, social deficits as measured by the Social Communication Questionnaire were significantly higher than in the unaffected brothers. Therefore, a subgroup of boys with the premutation is at a higher risk for ASD, social anxiety, and social interactional difficulties, in addition to ADHD.

Similar findings of premutation involvement were seen in the family comorbidity study of Bailey et al. where 1276 families completed an online survey about the children affected by fragile X in the family. Although

most of the patients evaluated by this survey had the full mutation, the survey also included 57 boys and 199 girls with the premutation. Developmental delay was found in 32% of males and 6% of females with the premutation, attention problems in 45% of males and 14% of females, hyperactivity in 30% of males and 3% of females, autism in 19% of males and 1% of females, and anxiety in 36% of males and 31% of females (Bailey et al., 2008). However, this survey may also be biased toward clinical involvement in those with the premutation. Determining the predictors of those at risk with the premutation and the percentage who will be affected by developmental problems will require larger studies of unselected populations, such as those who are identified by newborn screening. Such studies are currently underway with longitudinal follow-up of those in whom the premutation was identified at birth.

Recent studies by Chen and colleagues of premutation neuronal cell cultures from the *FMR1* knock-in (KI) mouse have demonstrated a deficit of neuronal cell branching and larger synaptic connections compared to neurons without the premutation. In addition, enhanced neuronal cell death in culture was seen by 21 days of division compared to neurons without the premutation (Chen et al., 2010). These findings suggest that premutation neurons may be more vulnerable to early cell death, which could lead to developmental problems of connectivity, such as ASD in early development, or perhaps neurodegeneration in later life. Additionally, neurons with the premutation may be a population genetically vulnerable to environmental toxins that could increase neuronal cell death. The authors have recently published four cases of carriers who were exposed to environmental neurotoxins from chemical plants in close proximity to their home and whose neurological symptoms began early in life (Paul et al., 2010). These neurological problems included multiple sclerosis (MS) symptoms in early adulthood in two women and fragile X-associated tremor/ataxia syndrome (FXTAS) symptoms beginning in their 40s to early 50s. This is earlier than the mean age of onset of FXTAS symptoms at age 60 as reported by Leehey et al. (2007) and described below.

33.2.2.2 Fragile X-Associated Tremor/Ataxia Syndrome

The FXTAS was first reported in five cases of older males with the premutation described in 2001 (Hagerman et al., 2001). All these patients had an intention or action tremor combined with ataxia leading to frequent falls. They progressed to needing a cane and eventually a wheelchair as weakness, autonomic dysfunction, and fatigue developed. The brain imaging demonstrated brain atrophy and white matter disease, usually in the periventricular region and in the middle cerebellar peduncles (MCP) sign of the cerebellum (Brunberg et al., 2002). Subsequently, criteria for the diagnosis of FXTAS were outlined in 2003 (Jacquemont et al., 2003) and then modified in 2004 (Hagerman and Hagerman, 2004). The modifications included the presence of eosinophilic intranuclear inclusions in neurons and astrocytes reported by Greco et al. (2002, 2006) that are unique to FXTAS. These inclusions occur throughout the central and the peripheral nervous system with the highest rate in the hippocampus and limbic system (Greco et al., 2006; Hunsaker et al., 2011). Molecular studies of the inclusions have demonstrated the presence of elevated *FMR1* mRNA in addition to other proteins (Iwahashi et al., 2006). The inclusions may help to arrest the cellular dysregulation that occurs in the presence of elevated mRNA, and they are also seen in the KI premutation mouse (Brouwer et al., 2008; Wenzel et al., 2010).

Recently, inclusions have been seen in peripheral tissue including the myenteric plexi of the gastrointestinal system, in the thyroid gland, in the adrenal gland, and in the testicles, particularly in the Leydig cells that make testosterone (Gokden et al., 2009; Greco et al., 2007; Louis et al., 2006). Impotence and testosterone deficiency are common and often occur even before the onset of FXTAS (Hagerman et al., 2008a). A report by Jacquemont et al. (2004) surveyed all the positive families in California, and a study was carried out on all the premutation carriers. It was found that in male carriers, 17% in their 50s were affected by tremor and ataxia, 38% in their 60s, 42% in their 70s, and 75% in their 80s. These rates were significantly different compared to age-matched male relatives who did not have the premutation. The female carriers were not significantly different from controls in this study.

Subsequently, the authors and others have reported on older female carriers who have developed FXTAS (Berry-Kravis et al., 2007; Coffey et al., 2008; Hagerman and Hagerman, 2004; O'dwyer et al., 2005; Rodriguez-Revenga et al., 2009). Typically, fewer females with the premutation develop FXTAS (8–16%) compared to males (Coffey et al., 2008; Rodriguez-Revenga et al., 2009), and when they do develop FXTAS, they have less brain atrophy, less white matter disease, and only 13% have the MCP sign (Adams et al., 2007). Seritan and colleagues reported the presence of dementia in approximately 50% of male carriers with FXTAS, but it is rare in female carriers with FXTAS (Seritan et al., 2008).

Cognitive problems usually begin with memory deficits and then progress to executive function deficits by the time the patients present with tremor and ataxia problems (Brega et al., 2008; Grigsby et al., 2006, 2007, 2008; Koldewyn et al., 2008; Loesch et al., 2003). Many patients may have a disinhibited sense of humor, leading to problems in public, which can be a burden to families. The dementia that develops is a frontal subcortical

dementia initially, and, on occasion, the initial symptom of FXTAS can be cognitive disorientation (Bourgeois et al., 2009). Treatment of the cognitive loss includes the use of medications important for Alzheimer disease such as memantine, since glutamate toxicity may be a factor in the pathophysiology of this disease. Treatment of early depression or anxiety as described below is also important.

33.2.2.3 Primary Ovarian Insufficiency

Approximately 16–20% of carriers can experience POI, and in carriers this is called FXPOI. As the CGG repeat number increases, the prevalence of POI is increased until about 120 repeats, and then the prevalence will drop to less than 16% (Sullivan et al., 2005). There is evidence that RNA toxicity affects the viability of the granulosa cells that support the ovum, although RNA toxicity may also decrease the viability of the ovum directly. Women with the premutation may also demonstrate mild elevations of follicle stimulation hormone (FSH) compared to controls even before they go into FXPOI (Welt et al., 2004). Of note, POI was previously referred to as premature ovarian failure (POF), but was renamed POI because a limited number of patients may become pregnant after experiencing the lack of menses (Welt, 2008). The American College of Obstetrics and Gynecology has recommended that all women who present with POI should be screened by fragile X DNA testing to see if they have the premutation (ACOG Committee Opinion, 2006). Approximately 1–7.5% of those with spontaneous POI have the premutation, and 13% of those who have a familial history of POI turn out to have the premutation (Welt, 2008). Once FXPOI is diagnosed, there are treatments including hormonal support and treatment of the emotional problems that often accompany this diagnosis (Nelson, 2009; Wittenberger et al., 2007).

33.2.2.4 Psychiatric Manifestations of Premutation Carriers

Emotional problems are common in carriers of the premutation both with and without FXTAS. A study carried out by Rodriquez-Ravenga et al. evaluated 34 women with the premutation and a child with FXS compared to 39 women without the premutation but with a child with developmental disabilities (DD) compared to age-matched control women without the premutation and without a child with DD. They used psychiatric questionnaires including the Symptom Checklist-90 (SCL-90) and the Beck Inventory to assess psychiatric problems. They found higher rates of psychiatric problems in women with the premutation and in women with a child with DD compared to controls, and this likely reflects the increased emotional stress that occurs in raising a child with FXS or DD. However, the women with the premutation had higher scores on the depression subtest than the other two groups of women (Rodriguez-Revenga et al., 2008). Similar results were seen utilizing the SCL-90 in 144 women and 68 men with the premutation (Hessl et al., 2005). Compared to published normative data, there was a higher rate of obsessive–compulsive symptoms in carriers of both sexes compared to controls. In addition, elevations in the *FMR1* mRNA levels correlated with increased symptoms on the obsessive–compulsive scale and on the psychoticism scale in males both with and without FXTAS (Hessl et al., 2005).

Roberts et al. utilized the Structured Clinical Interview for DSM IV (SCID) for mood and anxiety disorders in 93 women with the premutation. They found a significant increase in the rate of lifetime major depressive disorder (MDD) in premutation women (43%) that was significantly different from the rate of MDD in the National Comorbidity Survey Replication (NCS-R) data set. Forty-eight percent of these women had their first episode before the birth of their child with FXS, and the mean age of the first episode was 27 years. In the overall group, 31% had sought help from a professional, and 35% were on psychiatric medication. The premutation group also had four times the rate of lifetime panic disorder without agoraphobia and current agoraphobia without depressive disorder compared to the NCS-R. There was an inverse correlation between the CGG repeat number and the prevalence of depression, suggesting that the lowered FMRP levels at the upper end of the premutation range was protective for MDD (Roberts et al., 2009). Sobesky and colleagues in their studies of women with the full mutation found a protective benefit of lowered FMRP in that executive function deficits in the full mutation interfered with their understanding of psychiatric problems (Sobesky et al., 1996). The same issue may occur at the upper end of the premutation range.

Bourgeois et al. carried out an SCID on 85 individuals with the fragile X premutation, 47 with the FXTAS (33 males, 14 females, mean age 66) and 38 without FXTAS (16 males, 22 females, mean age 52). They found that in FXTAS, 30 cases (65%) met the lifetime Diagnostic and Statistical Manual, fourth edition, text revision (DSM-IV-TR) criteria for mood disorder, and 24 cases (52%) met the lifetime DSM-IV-TR criteria for anxiety disorder. Among the non-FXTAS subjects, there were 15 cases (42%) of lifetime mood disorder and 18 cases (47%) of lifetime anxiety disorder. When compared to age-specific NCS-R data, the lifetime prevalence of any mood disorder, MDD, any anxiety disorder, panic disorder, specific phobia, and post-traumatic stress disorder (PTSD) was significantly higher in subjects with FXTAS. The lifetime rates of social phobia in individuals with the premutation without FXTAS were significantly higher than NCS-R data (Bourgeois et al., 2011). Therefore, individuals with the premutation may manifest psychiatric

problems well before the onset of neurological problems. The psychiatric problems are likely related to the RNA toxicity that is apparent in the limbic system before the onset of FXTAS. Hormonal difficulties may also exacerbate the psychiatric problems that are common in carriers, as noted earlier.

33.2.2.5 Associated Medical Conditions in Carriers

A recent study of 146 women with the premutation demonstrated that approximately 8% who were not initially referred for this problem suffered from FXTAS (Coffey et al., 2008). In addition, in those with FXTAS, about 61% had hypertension, 50% had thyroid problems, usually hypothyroidism, 22% had seizures, and 43% had fibromyalgia; all these problems were higher than that found in age-matched controls without the premutation. Neuropathy problems were diagnosed in 53% in those with FXTAS, which is expected, but many women without FXTAS but with the premutation had neurological symptoms. These problems include symptoms of numbness and tingling in 34%, muscle pain in 20%, and intermittent tremor in 9% of women without FXTAS. These problems were more frequent than in age-matched controls without the premutation. MS occurs in 2–3% of carriers, which is a higher prevalence than what is seen in the general population of women (Zhang et al., 2009). One carrier who experienced a rapid decline over 15 years of MS demonstrated both active MS lesions in the CNS with inflammation and inclusions of FXTAS (Greco et al., 2008). There appears to be more autoimmune disease in carriers, and this is currently being investigated.

33.3 GENETICS AND NEUROBIOLOGY

33.3.1 Genetics – FMR1 Gene

The genetic cause of FXS, the *FMR1* gene mutation, was elucidated in 1991 (Verkerk et al., 1991). The gene is 38 kB in length (Penagarikano et al., 2007). It has an unstable CGG region at the 5′ promoter region, and the fragile site is located at band Xq27.3 (Harrison et al., 1983). The fragile site was named FRAXA and was the first fragile site described on the X chromosome.

33.3.1.1 Trinucleotide Repeat Disorder

FXS was one of the first disorders associated with a trinucleotide repeat expansion. These trinucleotide repeat expansions may occur in coding regions in syndromes such as in Kennedy disease (spinal–bulbar muscular atrophy). The expansion can also occur in noncoding regions, as is the case in FXS. The reason for the trinucleotide repeat expansion is unclear. One theory is that it occurs during an unequal exchange of genetic material during meiosis or mitosis (Penagarikano et al., 2007).

Premutation alleles are unmethylated. The premutation alleles are unstable and may undergo expansions during oogenesis (Fu et al., 1991; Oberle et al., 1991). This leads to the phenomenon of premutation carrier progeny having either the premutation or the full mutation. It is known that all mothers of children with the full mutation either are premutation carriers or have the full mutation themselves. In general, premutation sizes of 90–100 CGG repeats usually expand to the full mutation (Nolin et al., 2003). There has been no documentation of a normal-sized allele expanding to a full mutation in one generation. However, there has been one instance reported of a gray zone allele expanding to a full mutation in two generations. The maternal grandfather had 52 CGG repeats (gray zone), his daughter had 56 CGG repeats (premutation), and his grandson had the full mutation with 538 CGG repeats (Fernandez-Carvajal et al., 2009a).

As stated previously, having greater than 200 CGG repeats is considered a full mutation. It is sometimes reported as a single number or may be reported as a range of repeat sizes. The *FMR1* gene, its upstream CpG island, and surrounding sequence are hypermethylated, which inactivates the gene (Sutcliffe et al., 1992). With complete methylation, there is little or no *FMR1* mRNA produced. Methylation of the gene works to inactivate transcription directly by inhibiting the binding of transcription factors and also works indirectly by inducing condensation of the chromosome, which then prevents transcription factors from binding (Penagarikano et al., 2007). This leads to the halting of production of *FMR1* mRNA and the gene's product, FMRP. It is the loss of this protein that leads to the phenotype in FXS (Pieretti et al., 1991).

Mosaicism may refer to the size of the allele or the pattern of methylation. Approximately 12% of individuals with the full mutation are considered to be size mosaics, with a combination of premutation or full-size alleles. Six percent of full-mutation individuals are methylation mosaics, with both methylated and unmethylated alleles present on Southern blot (Rousseau et al., 1994). The percentage of methylation can have significant effects on the phenotype. Merenstein and colleagues examined methylation in 218 full-mutation male patients, and those with complete methylation had the lowest IQ scores and greatest physical involvement (Merenstein et al., 1996).

There are additional ways to cause the fragile X phenotype besides the trinucleotide expansion. More than 15 different deletions affecting the *FMR1* gene and point mutations that can lead to the phenotype have been reported (De Boulle et al., 1993; Gedeon et al., 1992; Hammond et al., 1997). The phenotype of FXS can also occur in an individual with the premutation who has significantly low levels of FMRP.

Contraction of the allele occurs when an individual transmits a smaller-sized allele to offspring. This has been documented in mother-to-daughter transmission of the *FMR1* gene (Brown et al., 1996) and also in approximately one-third of father-to-daughter transmissions (Fisch et al., 1995; Nolin et al., 1996).

33.3.1.2 FMRP and Upregulation of Other Proteins

The FMRP has a maximum length of 632 amino acids and a molecular mass of 80 kDa (Ashley et al., 1993). It is involved in a variety of cellular processes and is expressed in different types of tissues but primarily in neurons and in the testes (Devys et al., 1993; Khandjian et al., 1995). FMRP has been shown to interact as a selective RNA-binding protein (Bassell and Warren, 2008). FMRP shuttles between the nucleus and cytoplasm and is localized to dendrites (Feng et al., 1997). It is involved in regulating the translation of a subset of mRNAs at synapses. It has been hypothesized that FMRP is involved in chromatin remodeling in the nucleus as well (Krueger and Bear, 2011). Usually, FMRP inhibits translation, but this inhibition is released with activation of metabotropic glutamate receptors (mGluRs). Activation of the mGluR5 pathway leads to long-term depression and weak synaptic connections (Bear et al., 2004). In the absence of FMRP, there is upregulation of the mGluR5 pathway leading to a reduction of alpha-amino-3-hydroxy-5-methyl-4-isoxazole-propionic acid (AMPA) receptors in the dendrite. Without FMRP, there is dysregulated translation of other mRNAs, which leads to altered synaptic plasticity (Brown et al., 2001).

Individuals with FXS have more dendritic spines, which are thinner and longer compared to those in unaffected individuals. Bagni and Greenough presented a description of how FMRP may lead to the synaptic alterations, including regulation of translation and protein interactions including Cytoplasmic FMR1-interacting protein 1 (CYFIP1), Cytoplasmic FMR1-interacting protein 2 (CYFIP2), myosin VA, and nucleolin (Bagni and Greenough, 2005). The effect of the FMRP defect on synapses has been demonstrated in a *Drosophila* model of FXS, where the loss-of-function models show defects in synaptic structure and disturbed neurotransmission. The *dfxr* (*Drosophila* fragile X-related) gene was shown to inversely regulate expression of a microtubule-associated protein, Futsch. Therefore, dFXR was proposed to function as a translational repressor of Futsch (Zhang et al., 2001). Subsequent work has led to the understanding of FMRP as a master protein that regulates hundreds of mRNAs usually through inhibition of translation (Darnell et al., 2011). The synaptic structural defect can be seen in the fragile X mouse model as well. Cruz-Martin and colleagues observed a delayed downregulation in dendritic spine turnover from immature filopodia to mature spines during the early postnatal period compared to wild-type mice. This suggests a developmental delay in the maturation of dendritic spines in FXS (Cruz-Martin et al., 2010).

The decrease in FMRP may explain the increased prevalence of developmental delays and autism. FMRP regulates the translation of proteins associated with autism including neuroligins, neurorexins, the SHANK family of proteins, PTEN, and CYFIP (Bassell and Warren, 2008; Darnell et al., 2005, 2011).

The extracellular signal-related kinase (ERK) pathway seems to be affected in the fragile X mouse model, and the ERK1/2 pathway activation is delayed in individuals with FXS (Weng et al., 2008). Osterweil and colleagues found that basal protein synthesis in the hippocampus of the knockout (KO) mouse was reduced to wild-type levels when treated with an mGluR5 inhibitor as well as an ERK 1/2 inhibitor (Osterweil et al., 2010). The ERK pathway may also be a target for therapies in FXS.

Besides upregulation of the mGluR5 pathway, the lack of FMRP is associated with upregulation of the mammalian target of rapamycin (mTOR) pathway and downregulation of the PTEN pathway, the GABA receptors, and the dopamine pathway (Bassell and Warren, 2008; D'hulst and Kooy, 2007; Wang et al., 2008). These pathways may be the targets of treatment for FXS, which is discussed later. The review by Krueger and Bear can be referred to for further details regarding milestones in the pathophysiology of FXS and implications for treatment approaches as well (Krueger and Bear, 2011).

33.3.1.3 Inheritance

The inheritance pattern of FXS is X-linked with variable penetrance. Since it is an X chromosome-linked disorder, it affects more males than females.

33.4 TESTING

33.4.1 DNA Testing

The first method for testing for FXS was cytogenetic testing. The newest standard method of screening for FXS is through DNA testing, which includes a polymerase chain reaction (PCR), and Southern blot. The advantage of PCR is that it uses smaller amounts of DNA, is less expensive, and has a faster result time in comparison to the Southern blot. Its drawback is that it cannot detect longer DNA sequences, which is why both PCR and Southern blots are typically used. The number of CGG repeats is typically reported, as is methylation status in the full mutation. Using both methods, testing is 99% sensitive (McConkie-Rosell et al., 2005). Testing methods do not typically look for conventional mutations.

Guidelines for testing have been issued by the American College of Medical Genetics (Sherman et al., 2005; Table 33.1).

Individuals with mental retardation, developmental delay, or autism, especially if they have any physical or behavioral characteristics of fragile X syndrome, a family history of fragile X syndrome, or male or female relatives with undiagnosed mental retardation

Individuals seeking reproductive counseling who have a family history of fragile X syndrome or a family history of undiagnosed mental retardation

Fetuses of known carrier mothers

Affected individuals or their relatives in the context of a positive cytogenetic fragile X test result who are seeking further counseling related to the risk of carrier status among themselves or their relatives

Source: Sherman S, Pletcher BA, and Driscoll DA (2005) Fragile X syndrome: Diagnostic and carrier testing. Genetics in Medicine 7: 584–587.

Other conditions that may be related to the fragile X family of disorders should also be evaluated with fragile X testing. For women experiencing ovarian dysfunction, the American College of Medical Genetics recommends testing with elevated FSH levels, especially if they have a family history of POF, or FXS, or relatives with undiagnosed mental retardation. Testing for the fragile X premutation and FXTAS is recommended for those individuals who are experiencing late-onset intention tremor and cerebellar ataxia of unknown origin, especially if they have a family history of movement disorders or FXS, or relatives with undiagnosed mental retardation (Sherman et al., 2005).

A new method for quantifying FMRP has been discovered, which uses an ELISA assay (Iwahashi et al., 2009). It is now possible to look more quantitatively at exactly how much protein a particular individual with FXS is able to make.

33.4.2 Newborn Screening/Blood Spot

Population-based screening was examined by Palomaki (1994), and subsequent studies showed the efficacy of screening programs in identifying carriers and affected fetuses (Pesso et al., 2000; Toledano-Alhadef et al., 2001). Fetal testing through amniotic cells or chorionic villi is also possible when one of the parents is known to be a carrier.

Different methods for screening large populations for FXS have been developed using newborn blood spots and PCR. Coffee et al. described screening 36 124 de-identified newborn males with an assay. The assay had 100% specificity and sensitivity for detecting *FMR1* methylation in males and detected excess *FMR1* methylation in 82% of females with full mutations. They identified 64 males with *FMR1* methylation and found 7 to have the full mutation (Coffee et al., 2009). Another method utilizing nested PCR was developed by Tassone et al., and this can identify both males and females with the full mutation or the premutation (Tassone et al., 2008). This methodology was implemented in Spain where a total of 10 000 newborn blood spots were screened. So far, this study has reported on 5267 male blood spots where 199 gray zone alleles, 21 premutation alleles, and two full-mutation alleles (1 in 2633) have been identified (Fernandez-Carvajal et al., 2009b). Modifications to the Tassone technique have been carried out and recently reported (Filipovic-Sadic et al., 2010). Newborn screening is currently occurring in numerous centers around the United States.

33.4.3 Cascade Testing

Identifying affected members of a family is important, as changes in the fragile X gene can affect multiple family members through its unstable trinucleotide expansion. Usually, a proband is identified, which is often an affected child with FXS. Other members of the family should be identified and counseled about being tested.

33.4.4 Genetic Counseling

Genetic counselors are important members of the treatment team, particularly in helping patients and their families understand the diagnosis. Counseling sessions provide key educational opportunities. Important issues to be discussed should include discussion of the clinical presentation and inheritance patterns, treatments, therapies, follow-up recommendations, referrals for medical, educational, and mental health treatments, and contact information for support groups (McConkie-Rosell et al., 2005). Degree of involvement in both the premutation and the full mutation should be reviewed by the genetic counselor for the whole family tree. There are typically multiple family members involved whenever a proband is identified (Chonchaiya et al., 2009b; McConkie-Rosell et al., 2007).

33.5 TARGETED TREATMENTS

With better understanding of the molecular pathways affected by the lack of FMRP, targeted treatments are currently being studied as described below.

33.5.1 mGluR5 Antagonists

FMRP normally modulates dendritic maturation involving inhibition of the mGluR system 1- and 5-mediated translation in neurons (Aschrafi et al., 2005; Weiler et al., 2004). The mGluR5 system has been found to be upregulated in the fragile X KO mouse, with a

resulting enhanced long-term depression in the hippocampus (Huber et al., 2002). Long-term depression is the phenomenon of a decrease in synaptic effectiveness, thus leading to weakened synaptic connections (Bear and Abraham, 1996).

Lack of inhibition of the mGluR5 system also results in increased internalization of AMPA receptors (Snyder et al., 2001). AMPA receptors in the synapse have been correlated to synaptic protrusion. The mGluR systems are excitatory systems involved in many different areas, and the resulting upregulation may explain some of the physical and neurological aspects of FXS including seizures, electroencephalographic abnormalities including spike wave discharges, anxiety, tactile defensiveness, and difficulty with coordination (Bear et al., 2004).

Features of the fragile X KO mouse have been thought to be due to the increased activity of the mGluR5 system. The effects of decreasing mGluR5 receptors have been evaluated in the KO mouse model of fragile X. In 2007, Dolen et al. created a fragile X KO mouse that also had a 50% decrease in the number of mGluR5 receptors. The mouse demonstrated rescue of phenotypic features such as dendritic spines and a normalization in audiogenic seizures. Macroorchidism was the one feature studied that was not rescued by decreasing mGlur5 receptors (Dolen et al., 2007). mGluR5 antagonists have also been shown to rescue the *Drosophila* model of fragile X (McBride et al., 2005).

mGluR5 antagonists are being studied as a targeted treatment for FXS. In the *FMR1* KO mouse, treatment with MPEP (2-methyl-6-(phenylethynyl)-pyridine hydrochloride), an mGluR5 antagonist, was shown to decrease the startle response and rescue the protrusion phenotype of hippocampal neurons (de Vrij et al., 2008). Trials of mGluR5 antagonists in patients with FXS have also begun. One example is fenobam, a highly potent and selective mGluR5 antagonist. In 2009, Berry-Kravis and colleagues completed a pilot single-dose trial of fenobam and observed calm behavior in 9 out of 12 patients studied with no significant adverse effects. There was an improvement in 6 out of 12 patients in prepulse inhibition testing, which is a measure of impulse control and sensorimotor gating (Berry-Kravis et al., 2009). The use of the mGluR5 antagonists is likely to be beneficial in treating seizures because seizures are ameliorated in the KO animal model with mGluR5 antagonists (Hagerman and Stafstrom, 2009; Yan et al., 2005). AFQ056, an mGluR5 antagonist, was studied in 30 male individuals with FXS aged 18–35 in a double-blind, crossover study. Improvements were seen in seven patients who had fully methylated *FMR1* promoter regions and no response in patients with partial promoter methylation. The most common adverse event was mild to moderately severe fatigue or headache (Jacquemont et al., 2011).

33.5.2 GABA Agonists

GABA dysregulation has been observed in the fragile X KO mouse, and amygdala hyperexcitability has been normalized in the knockout mouse with treatment using the GABA agonist, gaboxadol (Olmos-Serrano et al., 2010). Studies of the GABA B agonist arbaclofen, which is the R isomer of baclofen, are currently being carried out, including a double-blind crossover study in children and adults with FXS from 5 years of age and older. Arbaclofen works at a presynaptic receptor and lowers the level of glutamate at the synapse. It also lowers the level of excess protein produced at the synapse in FXS. A trial of arbaclofen in 63 patients with FXS has shown efficacy in those with autism or significant social deficits (Berry-Kravis et al., 2010).

33.5.3 Minocycline

Minocycline is a second-generation semisynthetic tetracycline derivative (Shetty, 2002). It was first introduced in 1967 and is generally well tolerated (Smith and Leyden, 2005). Minocycline is commonly used as an antibiotic in the treatment of acne vulgaris, and its class of medications, tetracyclines, are the treatment of choice for certain bacterial infections such as Rocky Mountain spotted fever and brucellosis. It has been investigated as a neuroprotective agent in neurological diseases including Huntington's disease, amyotrophic lateral sclerosis, and MS (Kim and Suh, 2009). The mechanism of action by which minocycline exerts its neuroprotective effects is not precisely known, but likely has to do with its anti-inflammatory and anti-apoptotic effects. Minocycline's effects are reported to be through inhibition of cytochrome *C*, caspases 1 and 3, cytokines, and the suppression of metalloproteinase activity (Chen et al., 2000; Stirling et al., 2005). The latter effect is the key to minocycline's efficacy in the treatment of FXS.

As stated before, the lack of FMRP in FXS leads to upregulation of other proteins, one of these being matrix metalloproteinase 9 (MMP9). Matrix metalloproteinases are involved in extracellular degradation of proteins and are important for synaptic structure and plasticity (Sternlicht and Werb, 2001). Elevated MMP9 activity has been proposed as one mechanism for impaired dendritic spine maturation in FXS. Bilousova et al. demonstrated that minocycline treatment lowers MMP9 levels and matures synaptic connections in cultured hippocampal cells and that minocycline treatment for 1 month rescued synaptic abnormalities in the *FMR1* KO mouse. The treated mice showed improvements in anxiety on elevated plus maze and exploratory behavior on Y maze (Bilousova et al., 2009).

Minocycline treatment trials for FXS are currently underway. Utari and colleagues described 50 males and

females with FXS who were treated clinically with minocycline for 2 weeks or more. Using parent impressions, behavioral and cognitive changes were noted including improvements in language (54%), attention (50%), social communication (44%), and anxiety (30%). The side effects described included pigmentation of the nails (in one patient), loss of appetite, gastrointestinal upset, loose stools, and headache (Utari et al., 2010). An open-label study by Paribello and colleagues showed significant improvement in the Aberrant Behavior Checklist irritability subscale scores, Clinical Global Impression Scale – Improvement scores, and visual analog for behavior scores after 8 weeks of treatment with minocycline (Paribello et al., 2010). Currently, trials of minocycline are underway including a double-blind controlled trial in children and adolescents with FXS.

Side effects of minocycline include graying of teeth and gums, particularly in those younger than 8 years of age, gastrointestinal upset, sun sensitivity, and, in rare cases, pseudotumor cerebri and a lupus-like syndrome. These side effects should be monitored in any child or adult undergoing minocycline treatment. For children treated for longer than 3–6 months, an antinuclear antibody blood test should be done and, if positive, consideration should be given as to whether to continue with the medication in the long term.

33.5.4 Riluzole

Riluzole is a medication that is considered to have inhibitory effects on the glutamatergic system and is thought to potentiate the GABA system. It is approved for use in amyotrophic lateral sclerosis in adults. It has been associated with improvements in treatment-resistant depression (Zarate et al., 2004) and, in combination with other medications, was helpful in treatment-resistant obsessive–compulsive disorder (OCD) (Grant et al., 2007). In a 6-week, open-label study in six adults with FXS, riluzole was well tolerated; although it was associated with corrected peripheral ERK activation, riluzole was associated with a clinical response in only one of the six participants (Erickson et al., 2011).

33.5.5 Symptomatic Treatments

A number of currently available medications are useful in the treatment for individuals with FXS and are discussed in detail below.

33.5.5.1 *For Mood Stability*

Mood instability is seen in the majority of boys with FXS, and perhaps the best medication for this problem is a low dose of aripiprazole (Chonchaiya et al., 2009a; Hagerman et al., 2009). Aripiprazole is an atypical antipsychotic that has fewer problems with weight gain than risperidone, although most children do gain weight on this medication. In the authors' experience, aripiprazole is helpful for anxiety and for ADHD symptoms in addition to tantrums. Usually, just 0.5–2 mg works best when given at bedtime to younger children. Rarely does the dose need to go over 5 mg, and sometimes a higher dose leads to an increase in irritability or activation.

Additional mood stabilizers include anticonvulsants such as valproate or lamotrigine, and these medications can be helpful for aggression. Lithium may also be considered a targeted treatment for FXS because it works by lowering the mGluR5 system. An open trial of lithium was helpful in a small cohort of children and adults with FXS who had a poor response to other medications (Berry-Kravis et al., 2008).

33.5.5.2 *For ADHD Symptoms*

ADHD symptoms respond well to stimulants with approximately 66% demonstrating a positive response if the medications are given after 5 years of age (Hagerman et al., 2009). The alpha agonists including clonidine and guanfacine can also be helpful for calming the hyperarousal and tantrum behavior (Hagerman et al., 1998, 2009). These medications are often more helpful than stimulants for the child under 5 years of age. Clonidine can also be helpful for sleep disturbance, although melatonin should be tried first for sleep problems (Wirojanan et al., 2009).

33.5.5.3 *For Anxiety*

Anxiety is almost a universal problem for individuals with FXS and for many carriers as described above. The use of selective serotonin reuptake inhibitors (SSRIs) is very helpful for these problems. Fluoxetine is the most activating of the SSRIs, but that activation may be helpful to boost language in those with selective mutism. Sertraline has had the most common use in young children, and it deserves further study regarding its ability to enhance language in toddlers and to decrease the rate of autism (Hagerman et al., 2009). Many patients may benefit from a combination of a stimulant for ADHD and an SSRI for anxiety.

33.6 BEHAVIORAL INTERVENTIONS

33.6.1 Educational

Effective treatment for FXS consists of a combination of medication therapies as discussed previously and behavioral interventions. With the variable phenotype of FXS and premutation involvement, individualized therapy recommendations are essential. There have been very few studies examining educational and behavioral

therapies in FXS (Hall, 2009). Formal testing for language abilities and cognitive measures may be helpful in formulating an educational and therapy plan. Children with FXS will qualify for specialized educational methods including an individualized education plan.

Work in related disorders such as autism has shown that behavioral interventions can help, especially when started at a young age (Dawson et al., 2010). For those with FXS plus autism, well-established treatment models such as the Denver model (Dawson et al., 2010) and discrete trial training (Applied Behavior Analysis) (Smith et al., 2007) are recommended. Early identification of children with FXS is important, as therapies may be implemented sooner. Additionally, for patients with social deficits such as ASD or social anxiety, social skills groups may be helpful.

Behavior problems have been one of the greatest concerns in parent surveys (Bailey et al., 2000). Different types of therapies have been initiated, including sensory integration therapy and psychological counseling for behavioral interventions. Heightened sensitivity to sensory stimuli is related to hyperarousal and the autonomic dysfunction previously described. Occupational therapists trained in sensory integration therapy as well as fine motor therapy can be a valuable resource for the patients and their families for behavioral problems (Scharfenaker et al., 2002). Eye contact may be improved through behavioral intervention and was shown to be enhanced using a method of percentile scheduling with reinforcement in three out of six fragile X males studied (Hall et al., 2009). However, therapy to improve eye contact is controversial because it may worsen anxiety. A parent-initiated sleep therapy was evaluated in a population of five autistic children and seven children with FXS. The program reduced settling down to sleep and night awakenings (Weiskop et al., 2005).

Speech and language therapy can be essential to the development of a child with FXS as most can have speech delays. An audiology evaluation may be helpful, especially if hearing loss is suspected or recurrent otitis media is a problem. A conductive hearing loss due to fluid accumulating behind the ear is common in FXS. If this occurs as a child during the particularly crucial formative years of speech, it can further delay language development, so aggressive treatment with ear, nose and throat (ENT, also known as otolaryngology) evaluation and PE tubes is recommended (Hagerman, 2002a). Physical therapy can be used to help with the coordination difficulties in FXS and in premutation carriers with FXTAS.

For all of the above therapies, it must be emphasized that while the hours spent working with a therapist are fundamental, a home therapy program that families can continue to implement is needed to achieve the most benefit from the therapies.

33.6.2 Computer Work

Technological advances have been very helpful in providing a way for those with FXS to improve deficiencies. Assistive technology refers to technology that can help enhance functional abilities. For example, computerized learning systems have been created such as Writing with Symbols, which is a word prediction program. Assistive technology may also refer to picture cards, such as those used in the Picture Exchange Communication System. These can enhance communication, particularly for those who have speech delays (Hess et al., 2009). These devices can be obtained through the school or through private purchase. Children with FXS are often adept at computer use, making these interventions enjoyable as well as educational. There are also assistive technology specialists who can provide support with these interventions. There are current trials to assess the utility of assistive technology alone and in combination with medications.

For patients with FXTAS, using computer-assisted devices such as video games or the Nintendo Wii system with a balance board may be helpful to improve balance. Studies examining this are beginning, and the Wii system was found to be useful in improving balance and lower limb muscle strength in a pilot study of unaffected women (Nitz et al., 2010).

33.7 SUMMARY AND FUTURE PERSPECTIVES

33.7.1 Summary

In summary, FXS and its associated disorders have a rich history as a group of disorders caused by a CGG trinucleotide repeat sequence in a single gene, *FMR1*. Although the fragile X family of disorders has an identified single gene mutation cause, the resulting clinical phenotype can be quite diverse. Individuals with FXS may display ID, attention problems, autistic features or autism, as well as physical features including macroorchidism and prominent ears. Females with FXS may have learning disabilities, social anxiety, or impulsivity, in addition to variable physical features. Premutation carriers may develop FXTAS, with cognitive problems, tremor, and difficulties with balance. FXPOI may also occur in female premutation carriers in addition to psychiatric problems, hypertension, autoimmune dysfunction, and mild neurological problems such as neuropathy. Testing is widely available using PCR and Southern blotting in blood and also in amniotic cells or other tissue. Newborn screening is being studied around the world to increase early identification and treatment. Genetic counseling is important, given the possible implications of a diagnosis for both patients and their extended families.

A greater understanding of how the lack or deficiency of FMRP brings about the phenotype of FXS is developing, including the involvement of pathways such as the mGluR5 pathway, GABA pathways, AMPA receptors, PTEN pathway, and mTOR pathway. Treatments have been developed that use the understanding of these pathways to provide reversal of the neurobiological deficits in FXS. mGluR5 antagonists, GABA agonists, and minocycline as well as medications to help anxiety, aggression, and mood stabilization are currently being employed. Educational and behavioral interventions are also important components of a treatment regimen.

33.7.2 Future Perspectives

Treatment for FXS will likely combine both targeted treatments to reverse the neurobiological abnormalities and educational and learning paradigms to strengthen the synaptic connections that are facilitated by the targeted treatments. New treatments are being assessed now in cultured neurons for both premutation and full-mutation disorders. The use of mGluR5 antagonists has been shown to be helpful in a model of autism in the mouse (Silverman et al., 2010), and this suggests that these targeted treatments for FXS will also be helpful for autism. Currently, studies of arbaclofen are being conducted in autism, and trials of mGluR5 antagonists will be initiated in autism in the near future. Fragile X is leading the way for new targeted treatments in autism and perhaps for other neurodevelopmental disorders that have similar molecular dysfunctions. The future is bright for reversing the intellectual disabilities and the autism in FXS.

O U T L I N E

34.1 INTRODUCTION

34.1.1 The History of Autism

The term *autism* was coined in 1911 by Swiss psychiatrist Eugen Bleuler to designate one of the hallmarks of schizophrenia, namely the social withdrawal resulting in enclosure in one's self (self = α′υτός autòs, in ancient Greek) (Bleuler, 1911). During the following three decades, this term reached an ever broader audience in psychiatry, mainly through the work of Eugène Minkowski (1927), who addressed schizophrenic autism in great detail in his famous text 'La Schizophrénie'. However, schizophrenic autism must not be confused with autism spectrum disorder (ASD), which defines an independent nosological entity and not a mere symptom. This disorder was first described in 1943 by Leo Kanner in a cohort of 11 children, who essentially shared an 'enclosure in one's self' as their distinctive trait (Kanner, 1943). Only 1 year later, in 1944, the Austrian pediatrician Hans Asperger described four boys displaying some, but not all, of the behavioral symptoms present in Kanner's patients (Asperger, 1944a). Asperger's work, written in German, reached a wider audience after it was publicized in 1981 by Lorna Wing, who described 34 individuals, ranging from 5 to 35 years of age, whose clinical picture was closer to Asperger's cases than to Kanner's (Wing, 1981). Thereafter, it was translated into English by Uta Frith in 1991 (Asperger, 1944b). Hence, the existence of clinical heterogeneity in autism is by no means a recent acquisition; it was recognized from the beginning that autistic patients do indeed share some common features, primarily an enclosure in one's self, and display an impressive variability in symptom patterns, developmental trajectories, disease course, and severity of impairment, spread along a dimensional continuum that was later designated as the 'autism spectrum' (Piven et al., 1997). This impressive clinical variability is underscored by an equally impressive degree of etiological heterogeneity, which has led the term *autisms* to designate a set of neurodevelopmental disorders with early onset in life that share autism as a common feature but that are produced through distinct processes. This chapter will summarize the current state of knowledge regarding these 'autisms'; readers interested in 'schizophrenic autism' are referred to the excellent review by Parnas et al. (2002).

34.1.2 Definition and Epidemiology of Autism Spectrum Disorder

ASD is characterized by deficits in social interaction and communication, as well as by stereotyped behaviors and insistence on sameness (i.e., restricted patterns of interest and activities) (American Psychiatric Association, 1994). Its onset occurs in early childhood, before 3 years of age (American Psychiatric Association, 1994). ASD essentially encompasses three different pervasive developmental disorders listed in the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) (American Psychiatric Association, 1994), namely autistic disorder, Asperger disorder, and pervasive developmental disorder not otherwise specified (PDD-NOS). These separate diagnostic categories likely will merge into a single comprehensive ASD category in the upcoming DSM-V (American Psychiatric Association, 2012) following the ever-swinging logic behind categorical diagnosis in psychiatry, which historically alternates between analysis and synthesis.

The incidence of ASD has risen dramatically during the last two decades, from 2–5 in 10 000 to approximately 1–2 in 1000 children; broader diagnostic criteria and increased awareness in the medical community certainly have contributed to this trend, but a real increase in incidence, possibly due to gene–environment interactions, is also likely (Fombonne, 2005; Persico and Bourgeron, 2006; Rutter, 2005). Males are particularly susceptible, with male-to-female ratios ranging from approximately 4:1 to 8:1, depending on disease severity and recruiting context (Fombonne, 2005; Rutter, 2005). An additional layer of complexity stems from comorbidity with seizures and mental retardation (MR) present in up to 30% and 65% of cases, respectively (Fombonne, 2005; Tuchman and Rapin, 2002).

34.1.3 Neuropathological and Systemic Abnormalities in Autism Spectrum Disorder

Altered neurodevelopment occurring during the first and second trimesters of prenatal life is now widely recognized as the underlying neuropathological cause of ASD (DiCicco-Bloom et al., 2006). Postmortem studies of autistic brains have uncovered important neuroanatomical abnormalities in the central nervous system (CNS) of ASD patients, generally resulting from reduced programmed cell death and/or increased cell proliferation, altered cell migration, and abnormal cell differentiation with reduced neuronal size and abnormal wiring (Bauman and Kemper, 2005). These neuropathological anomalies, especially the patchy cytoarchitectonic abnormalities present in the cerebral and cerebellar cortex, would seemingly explain the imbalance in local vs long-distance connectivity on the one hand and excitatory vs inhibitory connectivity on the other currently believed to underlie disrupted sensory integration, altered social information processing, and frequent comorbidity with epilepsy (Courchesne and Pierce, 2005; Geschwind and Levitt, 2007; Rubenstein and Merzenich, 2003). All these neurodevelopmental processes physiologically occur

during the first and second trimesters of pregnancy (Rice and Barone, 2000). Hence, despite some methodological limitations and predictable brain-to-brain variability, neuropathological studies collectively have been instrumental in indicating a prenatal origin for autism. Further support comes from behavioral analyses demonstrating a delayed appearance or inhibition of specific motor reflexes already on the day of birth or early on in neonates later diagnosed with an ASD (Teitelbaum et al., 2004). An additional confirmation of the existence of a prenatal time window for autism vulnerability comes from studies of teratogenic drugs and congenital infections known to cause autism in some cases (see Section 34.4). This temporal framework ought to be considered when attempting to incorporate potential environmental factors into realistic pathogenetic models, which should not necessarily exclude modulatory roles for early postnatal exposures but *must* incorporate this crucial prenatal component.

Viewing autism exclusively as a brain disease would be an oversimplification; ASD patients also display variable degrees of systemic involvement, with signs and symptoms frequently including macrosomy (Sacco et al., 2007a), gastrointestinal disorders (Buie et al., 2010), and immune dysreactivity (Ashwood et al., 2006; Jyonouchi et al., 2005). In summary, autism should be viewed as a multiorgan systemic disorder, primarily involving but not restricted to the nervous system, with prenatal onset and postnatal clinical expression.

34.1.4 Toward a Classification of the Autisms

To address the great heterogeneity present in ASD, investigators have aimed at identifying subgroups of patients who at least partly share common pathophysiological underpinnings. These attempts essentially have followed two complementary strategies, namely the study of endophenotypes and the use of genetic approaches:

1. An endophenotype can be best described as a familial and heritable quantitative trait associated with a complex disease (Gottesman and Gould, 2003). The most important endophenotypes reported to date in autism research are summarized in Table 34.1. A detailed discussion of endophenotypes will be provided elsewhere (Persico and Sacco, 2013). The study of endophenotypes in complex disorders, such as autism, provides several advantages: (a) the lesser complexity of an endophenotype and its greater proximity to the genetic level, as compared with clinical affection status and behavioral symptoms, facilitates the interpretation of the results; (b) a continuous measure reflects more faithfully the existence of a continuum of signs and symptoms in the autism spectrum compared with a categorical

'case versus control' distinction; and (c) standardized and automated procedures are used to measure biological parameters (Sacco et al., 2010).

2. For more than two decades, autism has been identified as 'the most genetic' neuropsychiatric disorder because of the monozygotic twin concordance rate as high as 73–95%, impressive heritability (>90%, as estimated by twin studies), and

TABLE 34.1 Endophenotypes in the Autism Spectrum

Behavioral/neurodevelopmental

- Delayed expressive speech (Alarcón et al., 2008; Spence et al., 2006)
- ADI-R domains: social interaction domain; restricted and repetitive behaviors (Liu et al., 2008; Sakurai et al., 2006)
- Savant skills: absolute pitch, calendar calculations, etc. (Wallace et al., 2009)
- Social Responsiveness Scale scores (Duvall et al., 2007)

Neuropsychological

- Pattern of face processing (Adolphs et al., 2008; Hernandez et al., 2009; Klin et al., 2002)
- Executive functions (Delorme et al., 2007)

Neurophysiological

- Reduced cingulate self-response in a visual imagery task, when playing with a human partner (Chiu et al., 2008)
- Abnormal patterns of cortical auditory activation (Boddaert et al., 2003; Bonnel et al., 2010; Bruneau et al., 2003; Gomot et al., 2008)
- Dysfunctional mirror neuron systems (Cattaneo et al., 2007; Dapretto et al., 2006; Martineau et al., 2010)
- Centroparietal and temporal EEG related to autistic behaviors and intellectual impairment (Roux et al., 1997)
- Blunted or delayed frontal activation during visual attention tasks (Belmonte et al., 2010)

Morphological

- Macrocephaly (Fombonne et al., 1999; Lainhart et al., 1997; Miles et al., 2000; Sacco et al., 2007a; Stevenson et al., 1997; Woodhouse et al., 1996)
- Macrosomy (Bigler et al., 2010; Dissanayake et al., 2006; Lainhart et al., 2006; Sacco et al., 2007a; van Daalen et al., 2007)
- Minor physical anomalies (Hammond et al., 2008; Miles et al., 2008; Tripi et al., 2008)

Biochemical

- Hyperserotoninemia (Hérault et al., 1996; McBride et al., 1998; Mulder et al., 2004; Piven et al., 1991)
- Oligopeptiduria (Reichelt et al., 1981; Sacco et al., 2010)
- Urinary dopamine and HVA levels (Hameury et al., 1995)
- Decreased plasma fatty acids (Vancassel et al., 2001)

Endocrine

- Decreased melatonin plasma levels (Melke et al., 2008)
- Decreased oxytocin plasma levels (Modahl et al., 1998)

Immunological

- Increased proinflammatory and IL-10-producing immune cells, decreased CD4+ T lymphocytes, increased naive and effector memory CD8+ T lymphocytes (Saresella et al., 2009)

a noticeable sibling recurrence risk (5–6% for full-blown autistic disorder, approximately 15% for broad ASD) (for reviews of autism genetics, see Abrahams and Geschwind, 2008; Freitag, 2007; Geschwind, 2011; Muhle et al., 2004; Persico and Bourgeron, 2006). These heritability estimates, obtained primarily in the UK and in Northern Europe in the early 1990s, were not replicated by a more recent California-based twin study that supported a larger proportion of variance explained by shared environmental factors as opposed to genetic heritability (55% vs. 37% for strict autism, respectively) (Hallmayer et al., 2011). Conceivably, the relative weight of genetic and environmental factors may be region-specific and change over time. Nonetheless, the parallel increase in sibling recurrence risk, estimated by recent baby sibling studies at 18.7% (26.2% for males and 9.1% for females) (Ozonoff et al., 2011), and the presence of mild autistic traits in many first-degree relatives of autistic patients (Piven et al., 1997) still point toward a strong genetic component in ASD playing a sizable permissive role at a minimum. Linkage and association studies have identified numerous susceptibility genes located on various chromosomes, especially 2q, 7q, 15q, and on the X chromosome. The clinical heterogeneity of ASD is believed at least partly to reflect the complexity of its genetic underpinnings, the general underlying mechanisms of which are summarized in Table 34.2.

34.2 'CLASSIC' SYNDROMIC AUTISMS

34.2.1 General Description

In approximately 10% of ASD cases, autistic symptoms are part of a broader syndrome due to a known medical cause. These syndromes can stem from (a) genomic DNA mutations, triplet repeat expansions, or cytogenetic abnormalities visible by classical G band karyotyping, conditions summarized in Table 34.3; (b) mitochondrial DNA (mtDNA) mutations or gene dosage abnormalities, which are listed in Table 34.4; or (c) copy number variants (CNVs), genomic DNA microdeletions/microduplications detectable only using microarray technologies. Genetic and genomic forms have been reviewed by Gillberg (1998), Cohen et al. (2005), Feinstein and Singh (2007), Zafeiriou et al. (2007), and Benvenuto et al. (2009); autism linked to mitochondrial disease and mtDNA abnormalities has been reviewed recently by Palmieri and Persico (2010) and by Rossignol and Frye (2011); CNVs have been reviewed by Merikangas et al. (2009), Guilmatre et al. (2009), Weiss (2009), and Carvalho et al. (2010).

In general, malformations and/or facial dysmorphisms, moderate-to-profound mental retardation, severe epilepsy, neurological signs, and symptoms are largely more frequent in syndromic autism than in idiopathic forms. Overall, the M:F gender ratio is close to 1, although males are particularly prone to suffer from specific syndromes. Abnormal growth in the form

TABLE 34.2   Mechanisms Underlying the Complexity of Autism Genetics

1. Genetic heterogeneity	Different contributing genes cause the disease in distinct patients, who may display similar clinical phenotypes
2. Different modes of inheritance	
(a) Polygenic or oligogenic	Several functional polymorphisms located in different genes and widely distributed in the general population ('common variants'), each conferring a small risk, are collectively required for an individual to develop the disease
(b) Monogenic	Genetic mutations or genomic rearrangements affecting a single gene cause the disease, typically in a single or in very few patients ('private' or 'rare variants,' respectively)
(c) Combined genetic and genomic quasi-recessive mode	Convergence onto the same individual of one allele carrying a null mutation inherited from one parent and the other allele carrying a genomic rearrangement (typically a microdeletion) inherited from the other parent. Both mutation and microdeletion are recessive, and neither by itself is pathogenic in either parent; they may even be present at low frequency in the general population
Phenocopies	Cases exclusively due to environmental factors and clinically indistinguishable from genetic cases
Variable penetrance and expressivity	Variable degrees of phenotypic expression of genetic variants: generally high level of pathology caused by rare variants, lower degree of expression for common variants
Epistasis	Gene–gene interactions, with permissive and blunting effects exerted by common variants ('modifier genes'). Phenotypic expression is complex, and not a mere summation of single-gene effects. By this mechanism, an identical mutation can produce different phenotypes in different individuals or mouse inbred strains
Gene–environment interactions	Genes may confer vulnerability to or protection from the disease by lowering or raising the threshold of sensitivity to pathogenic environmental factors

TABLE 34.3 Syndromic Autisms Due to Known Mutations, Triplet Repeat Expansions, or Cytogenenetic Abnormalities Visible by G Band Karyotyping

	Gene/ch. region	Prevalence	Percentage of autistic patients with the syndrome	Percentage of patients with the syndrome who are autistic	Signs and symptoms
Fragile X syndrome	FMR1	1/3500–1/9000	2.1	25–33	Facial dysmorphisms, macroorchidism, poor eye contact, social anxiety, language impairment, stereotypies, hyperactivity, sensory hyper-reactivity
Tuberous sclerosis	TSC1 TSC2	1–1.7/10000	1–4% (8–14% if seizures present)	16–65	Hamartomas in skin, CNS, kidney, heart, lungs, retina; autism, mental retardation, learning disability, epilepsy (infantile spasms)
Neurofibromatosis type 1	NF1	1/3000–1/4000	≤1.4	?	Café-au-lait macules, neurofibromas, axillary or groin frecklings, optic pathway tumors, bone dysplasias
Untreated phenylketonuria	PAH	1/10000–1/15000	–	5.7	Microcephaly, hypertonia, mental retardation, language impairment, psychomotor agitation, autism, seizures
Adenylosuccinate lyase deficiency	ADSL	?	≤1	80–100	Mental retardation and severe autism, seizures, psychomotor regression
Smith–Lemli–Opitz syndrome	DHCR7	1/10000–1/60000	≤1	46–53	Microcephaly, facial dysmorphism, malformations (sometimes lethal, usually cleft palate, cardiac m., hypospadia), short stature, variable mental retardation, sensory hyper-reactivity, language impairment, self-injurious behavior, sleep disturbance, opisthokinesis and other stereotypies
Cohen syndrome	COH-1 ?	1/105000	≤1	48	Microcephaly, facial dysmorphism, truncal obesity, hematologic and eye abnormalities, mental retardation, motor clumsiness, hypotonia, language impairment, autism
Cornelia de Lange syndrome	NIPBL SMC1A SMC3 ?	1/10000	≤1	35–50	Facial dysmorphism, growth deficiency with short stature, major malformations (especially cardiac, gastrointestinal, musculoskeletal), developmental delay, mental retardation, feeding difficulties, extreme shyness, self-injurious behavior, hyperactivity with attention deficit, aggression, obsessive-compulsive behavior, depression
Sotos syndrome	NSD1	1/10000–1/50000 (?)	≤1	?	Macrocephaly, pre- and postnatal overgrowth, facial dysmorphism, developmental delay
Cole–Hughes macrocephaly	?	?	≤1	?	Macrocephaly, mental retardation, attention deficit and hyperactivity, developmental delay, autism, language impairment, obesity, delayed bone age, facial dysmorphism
Lujan–Fryns syndrome	UPF3B MED12	?	≤1	80	X-linked mental retardation with marfanoid habitus (tall stature, facial dysmorphism), hypotonia, mild-to-moderate mental retardation, ascending aortic aneurysm, autism, aggression, hyperactivity, emotional instability
San Filippo syndromes: A	SGSH	0.3–1.6/100000	≤1	?	Prominent regression or developmental delay, autism, motor and verbal stereotypies, hyperactivity, aggression, sleep disturbance,

TABLE 34.4 Syndromic Autisms Due to mtDNA Mutations or Rearrangements

References	Mutation	mtDNA gene	Number of patients	Signs and symptoms
Graf et al. (2000)	8363G>A	tRNA^{Lys}	Two siblings	Brother: autism, behavioral regression, extreme hyperactivity, lack of attention, mild fine and gross motor dyspraxia
				Sister: partial complex seizures, unsteady gait, myoclonus, swallowing dysfunction, moderate mental retardation
Fillano et al. (2002)	Large mtDNA deletions		Five ASD patients	Autism, ataxia, cardiomyopathy
Pons et al. (2004)	3243A>G	tRNA$^{Leu(UUR)}$	Two ASD and their two mothers	Highly heterogeneous: typically mitochondrial encephalopathy with lactic acidosis and stroke-like episodes (MELAS), or maternally inherited progressive external ophthalmoplegia. In these two patients, autism with developmental delay, clumsiness, attention deficit, neurologic deterioration in the presence of fever, microcephaly or macrocephaly
	?	mtDNA? genomic DNA?	One ASD with mtDNA depletion	Autism, muscle hypotonia, seizures, myoclonus, and developmental delay
Weissman et al. (2008)	3397A>G	ND1 subunit of complex I	25 ASD patients with primary mit. disorder (3/25 mtDNA mutation carriers)	Autism, excessive fatigability and/or exercise intolerance, gastrointestinal dysfunction, cardiovascular abnormalities, facial dysmorphisms, microcephaly or macrocephaly, developmental gross motor delays, growth retardation
	4295A>G	tRNA^{Ileu}		
	11984T>C	ND4 subunit of complex I		

of microsomy, or less frequently macrosomy, is not unusual. In many syndromes, clinical manifestations of autism can be highly heterogeneous, even in the presence of the same well-characterized mutation or genomic rearrangement.

34.2.2 Mitochondrial Autisms

Biochemical parameters linked to mitochondrial function are frequently abnormal in ASD (Giulivi et al., 2010; Palmieri and Persico, 2010; Rossignol and Frye, 2011).

As many as 5% of autistic children even satisfy diagnostic criteria for a full-blown mitochondrial disease (Rossignol and Frye, 2011). Yet, mutations or chromosomal rearrangements in mtDNA or nuclear DNA (nDNA) are detected only in approximately 20% of children with ASD and mitochondrial disease (i.e., ≤1% of all ASD children), and each mtDNA mutation or chromosomal rearrangement listed in Table 34.4 is detected in ≤0.1% of all cases. Hence, mitochondrial dysfunction appears to be secondary in the vast majority of patients, that is, downstream of other pathophysiological abnormalities such as excessive oxidative stress (Palmieri and Persico, 2010). Importantly, since mitochondrial function requires approximately 1500 nuclear genes and oxidative phosphorylation involves at least 80 proteins, only 13 encoded by mtDNA, mutations, and chromosomal rearrangements should be sought both in nDNA and in mtDNA (Shadel, 2008; Zeviani and Di Donato, 2004). Indeed, chromosomal rearrangements, which could affect mitochondrial functions, include deletions in 15q11–q13 (cytochrome C oxidase subunit 5A, COX5A), 13q13–q14.1 (mitochondrial ribosomal protein 31, MRPS31), 4q32–q34.68 (electron-transferring-flavoprotein dehydrogenase, ETFDH), and 2q37.3 (NADH dehydrogenase ubiquinone 1 alpha subcomplex 10, NDUFA10), as recently reviewed by Smith et al. (2009).

Mitochondrial autism, despite an even more prominent clinical heterogeneity, often displays some peculiarities which should prompt clinicians to request molecular investigations (Palmieri and Persico, 2010; Rossignol and Frye, 2011). Its neurological signs and symptoms, such as oculomotor abnormalities, dysarthria, ptosis, hearing deficits, hypertonia, and movement disorders, are generally atypical for autism. Behavioral regression, especially in concomitance with fever, is frequently reported by parents (Shoffner et al., 2010; Weissman et al., 2008). Except in the case of mitochondrial depletion, family history is generally positive for mitochondrial diseases in the maternal lineage. At least one biochemical parameter among several typically assessed to screen for mitochondrial disorders is usually abnormal in children. The incidence of microcephaly and microsomy is unusually high, reaching approximately 20% of all cases. Neuroanatomical abnormalities are relatively frequent, although highly variable in nature (Nissenkorn et al., 2000; Shoffner et al., 2010; Weissman et al., 2008). 'Ragged red fibers,' characterized by a segmental proliferation and accumulation of abnormal mitochondria under the sarcolemmal membrane, are usually visible in muscle biopsies of adults, but in most affected children muscle tissue histology will be negative.

34.2.3 Copy Number Variants

The recent advent of microarray-based high-resolution genome analysis has dramatically increased our ability to detect genomic deletions and duplications. CNVs are deletions and duplications of at least 1 kb in size, undetectable by standard chromosomal banding and karyotyping techniques. They are, however, discernible using microarray-based approaches, such as array-comparative genome hybridization (CGH) techniques employing either bacterial artificial chromosome (BAC) or single nucleotide polymorphism (SNP) arrays, whereby signal intensity is used to estimate the number of alleles. Initial genome-wide studies reported enhanced frequencies of CNVs in autistic patients compared to controls (on average 6–10% vs. 1–3%, respectively). In particular, Jacquemont et al. (2006) found 8 of 29 (27.5%) autistic patients carrying deletions or duplications between 1.4 and 16.0 Mb in size, including six *de novo* chromosomal rearrangements. Sebat et al. (2007) found *de novo* CNVs in 12/118 (10%) autistic children from simplex families (i.e., families with only one autistic child) and in 2/196 (2%) normal trios. Marshall et al. (2008) found 27/427 (6.3%) autistic patients carrying *de novo* CNVs, which were more common in simplex (4/56=7.1%) than in multiplex (1/49=2.0%) families. Christian et al. (2008) reported the presence of seven *de novo* and 44 inherited CNVs in 397 ASD patients. Collectively, these results were compatible with the existence of genomic instability in a sizable subgroup of autistic patients. However, later studies have not replicated genome-wide differences in CNV frequency between ASD patients and controls using genomic DNA extracted from leukocytes or lymphoblastoid cell lines (Bucan et al., 2009; Glessner et al., 2009; Pinto et al., 2010). We have recently performed a small-scale study using genomic DNA extracted from neocortical post-mortem specimens, finding increased genomic instability in only one out of ten autistic brains compared to ten matched controls (Roberto Sacco, Antonio M., Persico, Shawn Levy, and colleagues, unpublished observation). Therefore, excessive genomic instability may characterize some families with autistic patients, but it does not represent a widespread hallmark of autism either in the CNS or in peripheral tissues. CNV location may instead play a more relevant role compared to CNV frequency and mean size. Rare or even private CNVs seemingly affect the coding region of functionally important genes more often among ASD patients than in controls: disrupted loci belong to gene families involved in synaptogenesis, cell proliferation and migration, ubiquitination, and GTPase/Ras signaling (Bucan et al., 2009; Glessner et al., 2009; Pinto et al., 2010). This conclusion has been further strengthened by two large data sets that have recently uncovered highly heterogeneous *de novo* copy-number variants which collectively affect several hundred loci and presumably account for 5–8% of cases of simplex forms of ASD (Levy et al., 2011; Sanders et al., 2011; for comment see Schaaf and Zoghbi, 2011). Network-based functional analysis of these rare CNVs confirms the involvement of these loci in synapse development, axon targeting, and neuron

motility (Gilman et al., 2011). We shall encounter again many of these genes in surveying monogenic forms of autism (Section 34.3).

Most CNVs are unique to any given patient, both in size and genomic distribution. However, recurrent micro-deletion syndromes have also been identified: their chromosomal location and associated clinical features are listed in Table 34.5 (Fernandez et al., 2010; Kumar et al., 2008; Liang et al., 2009; Rajcan-Separovic et al., 2007; Weiss et al., 2008). In general, CNVs can be associated with a variety of clinical features, including major or minor malformations, facial dysmorphisms, severe neurological symptoms, full-blown autism, milder autism-spectrum traits, or even behavioral disorders outside of the autism spectrum (frequently seen in siblings carrying the same CNV as their autistic sib). Variable penetrance and great phenotypic heterogeneity thus characterize CNV expressivity to the same extent as we have seen occur in many 'classical' syndromic forms listed in Table 34.3. This is true to the point that it is often difficult to determine whether in a given patient a CNV is the sole cause of autism, confers vulnerability to the disease, or represents a chance finding. Indeed, the majority of CNVs are inherited from either one of the parents, who may show some autism spectrum traits, but certainly do not satisfy criteria for autistic disorder. Also, a sizable percentage of population controls carries CNVs, available in public databases (Iafrate et al., 2004). Finally, many CNVs found in ASD patients are not autism specific, but are found also in patients with mental retardation, schizophrenia, or other psychopathologies.

34.3 NOVEL SYNDROMIC FORMS OF MONOGENIC AUTISMS

34.3.1 General Description

In recent years, several monogenic forms of autism have been uncovered (see review by Lintas and Persico, 2009). Each is present in a small number of patients (i.e., <1%) and can result from mutations or cytogenetic anomalies proved to be absent from large pools of control chromosomes. These findings have led to the proposal that most autisms may represent a collection of syndromes due to rare, if not even, private mutations or CNVs (Buxbaum, 2009). However, causal mutations and chromosomal rearrangements should ideally appear *de novo*, but they are more often segregating in the family, which again underscores their variable degree of penetrance and heterogeneous expressivity. We shall now review the characteristics and neurobiological bases of the most important monogenic forms recently discovered, which are listed in Table 34.6.

34.3.2 Synaptic Genes

Several genes involved in monogenic autisms are known to play a role in synapse formation, maturation, and stabilization. This functional role in the establishment and fine-tuning of neuronal connections is pathophysiologically appealing, when considering autism as a 'dysconnection syndrome' (Courchesne and Pierce, 2005; Geschwind and Levitt, 2007; Rubenstein

---

TABLE 34.5 Syndromic Autisms Due to Recurrent CNVs

Ch region	Del/Dup	Neurodevelopmental signs and symptoms	Other signs and symptoms
1q21	Del	Autism, attention deficit, hyperactivity, antisocial behavior, anxiety, epilepsy, mental retardation, developmental delay, depression, hallucinations, schizophrenia	Minor dysmorphisms, cardiac defects, cataracts, multiple congenital malformations
	Dup	Autism, attention deficit, hyperactivity, epilepsy, mental retardation, developmental delay, impaired language, learning disability	Minor dysmorphisms, multiple congenital malformations
2p15–2p16.1	Del	Autism, developmental delay	Microsomy, microcephaly, dysmorphic features
15q13	Del	Autism, attention deficit, hyperactivity, aggression, anxiety, epilepsy, mental retardation, developmental delay, impaired language, schizophrenia	Minor dysmorphisms, cardiac defects
	Dup	Autism, anxiety, bipolar disorder, mental retardation, developmental delay, obsessive-compulsive disorder, language delay	Minor dysmorphisms, hypotonia, obesity, recurrent ear infections
16p11.2	Del	Autism, Asperger syndrome, attention deficit, hyperactivity, dyslexia, bipolar disorder, anxiety, epilepsy, mental retardation, developmental delay, language impairment, schizophrenia	Minor dysmorphisms, hypotonia, multiple congenital malformations
	Dup	Autism, attention deficit, hyperactivity, anxiety, epilepsy, mental retardation, developmental delay, obsessive-compulsive disorder	

and Merzenich, 2003). However, there are also issues raising caution in interpreting autistic signs and symptoms as merely due to reduced synaptogenesis, as briefly addressed in Section 34.6.

34.3.2.1 The Neuroligin Genes (NLGN3, NLGN4, and NLGN4Y)

The *NLGN3*, *NLGN4*, and possibly *NLGN4Y* genes, located in human ch Xq13, Xq22.33, and Yq11.2, respectively, have been found to host mutations seemingly responsible for behavioral phenotypes, including autism

(Table 34.6). Neuroligin genes encode for cell adhesion molecules located postsynaptically in glutamatergic (*NLGN1*, *NLGN3*, *NLGN4*, *NLGN4Y*) and GABAergic (NLGN2) synapses (for reviews, see Betancur et al., 2009; Craig and Kang, 2007; Südhof, 2008). At the extracellular level, postsynaptic neuroligins interact with presynaptic α- or β-neurexins (see Section 34.3.2.3); at the intracellular level, neuroligins associate with postsynaptic scaffolding proteins, such as SHANK3 (see Section 34.3.2.2). This network of synaptic proteins appears to play a critical role in synapse generation,

MR, mental retardation; PDD-NOS, pervasive developmental disorder not otherwise specified; (?), clinical phenotype not described.

maturation, stabilization, and maintenance (Betancur et al., 2009; Craig and Kang, 2007; Südhof, 2008). *In vitro* assays initially suggested that the interaction between neuroligins and neurexins may trigger the formation of functional presynaptic boutons in contacting neurites, both in neuronal and even in non-neuronal cells (Dean et al., 2003; Scheiffele et al., 2000). Later studies of triple knockout mice lacking neuroligins 1, 2, and 3 showed that their absolute numbers of synapses are unchanged, whereas synaptic transmission is severely hampered, leading to respiratory failure and death on the day of birth (Varoqueaux et al., 2006). These results underscore the role of neuroligins as critical to synaptic function, more than to synaptogenesis *per se*.

Jamain et al. (2003) reported one frameshift (D396X in *NLGN4*) and one missense (R451C in *NLGN3*) mutation in two unrelated Swedish families, both inherited from apparently unaffected mothers. Mouse mutants carrying the human R451C mutation show a mild behavioral phenotype, described by Tabuchi et al. (2007) and by Chadman et al. (2008). Reduced ultrasonic vocalizations in males represent the most consistent behavioral abnormality, followed by impaired social novelty preference (Tabuchi et al., 2007, but see Chadman et al., 2008). Surprisingly, enhanced spatial learning abilities and increased inhibitory synaptic transmission were also recorded (Tabuchi et al., 2007). Functional *in vitro* studies of the R451C mutation show defective vesicle trafficking with partial retention of NLGN3 in the endoplasmic reticulum. Reduced synapse induction properties are due to blunted NLGN3 delivery to the cell membrane, as mutated NLGN3 retains synaptogenetic properties in the minority of cells where delivery to the membrane does occur (Chih et al., 2004; Chubykin et al., 2005; Comoletti et al., 2004). These abnormalities lead to reduced glutamate-driven excitation in the neocortex, while AMPA-driven excitation, NR2B subunit delivery, and long-term potentiation are all enhanced in the hippocampus (Etherton et al., 2011a). Instead, the R704C mutation initially reported by Yan et al. (2005) causes a

major and selective decrease in AMPA receptor-mediated synaptic transmission, leaving the number of synapses unchanged (Etherton et al., 2011b).

Multiple studies collectively confirm the low frequency of *NLGN* gene mutations among idiopathic ASD patients (Table 34.6) (Lintas and Persico, 2009). The clinical phenotype of patients carrying *NLGN* mutations is highly heterogeneous, ranging from severe autistic disorder to Asperger's syndrome (the 'speech-preserved' variant of autism), PDD-NOS (the autism variant satisfying only some, but not all diagnostic criteria), nonspecific X-linked mental retardation, specific language impairment, and Tourette syndrome (Table 34.6). Disease onset may be slow and insidious or sudden and regressive (see Section 34.6). Mutation carriers typically display no dysmorphic feature and are phenotypically indistinguishable (Lintas and Persico, 2009).

34.3.2.2 The SH3 and Multiple Ankyrin Repeat Domains 3 Gene (SHANK3)

The *SHANK3* gene, located in chromosome 22q13.3, encodes for a scaffolding protein found in the postsynaptic density complex of excitatory synapses, where it binds to neuroligins and to actin, affecting actin polymerization, growth cone motility, dendritic spine morphology, and synaptic transmission (Durand et al., 2011). Several recent studies have described rare mutations or small cytogenetic rearrangements affecting *SHANK3* in patients with an autistic phenotype mainly characterized by severe expressive language impairment (Table 34.6). Similarly, 13 patients carrying deletions of the terminal 22q13 region encompassing or breaking the *SHANK3* locus all share mental retardation and severe delay in or absence of expressive speech (Dhar et al., 2010). As for neuroligins, also *SHANK3* mutations or deletions/duplications represent rare events, affecting only 9/1054 (0.85%) ASD individuals (see Table 34.6). No evidence of association was found in large samples (Qin et al., 2009; Sykes et al., 2009), demonstrating that the *SHANK3* gene hosts rare variants, but not common variants. With the possible exception of language impairment, mutations and cytogenetic abnormalities affecting *SHANK3* display highly variable phenotypic expression: (a) they are most often inherited from parents described as either healthy or epileptic; (b) in some families, they are present also in unaffected siblings of the autistic proband; (c) two *de novo* mutations, R536W and R1117X, different from those found in ASD patients, were detected in patients with borderline or moderate mental retardation and either schizoaffective disorder, attention-deficit/hyperactivity disorder (ADHD), or schizophrenia/atypical chronic psychosis (Gauthier et al., 2010). Importantly, autistic individuals carrying inherited 22q13 deletions involving *SHANK3* (800 kb in Durand et al. (2007) and 3.2 Mb at 22q13

in Moessner et al. (2007)) due to a paternal balanced translocation have siblings with partial 22q13 trisomy diagnosed with Asperger syndrome, showing early language development and ADHD. Hence, a physiological window for *SHANK3* may be functionally crucial to cognitive development in humans.

34.3.2.3 The Neurexin 1 Gene (NRXN1)

Presynaptic neurexins are able to induce postsynaptic differentiation by interacting with postsynaptic neuroligins (Betancur et al., 2009; Craig and Kang, 2007; Südhof, 2008). In addition, α neurexins are involved in neurotransmitter release, as they link calcium (Ca^{2+}) channels to synaptic vesicle exocytosis (Missler et al., 2003; Zhang et al., 2005). The three neurexin genes (*NRXN1*, *NRXN2*, and *NRXN3*, located on human ch 2p16.3, 11q13, and 14q24.3–q31.1, respectively) have two independent promoters, yielding long and short mRNAs which encode for α and β neurexins, respectively (Ichtchenko et al., 1995). Several studies have reported rare sequence variants or CNVs affecting the *NRXN1* locus, as summarized in Table 34.6. However, an exact definition of *NRXN1* roles in autism is complicated by an extreme interindividual variability in genotype–phenotype correlations. An initial *NRXN1*β screening conducted by Feng et al. (2006) identified two heterozygous missense mutations (S14L and T40S) present in 4/264 (1.5%) ASD patients and not in 729 controls (Table 34.6). These 'mutations' are actually rare segregating polymorphisms found also in first-degree relatives, who clinically range from apparently normal behavior to hyperactivity, depression, and/or learning problems. Similarly, one of two chromosomal rearrangements affecting the *NRXN1* gene was also shown to be paternally inherited in one patient (Kim et al., 2008). In another study, a *de novo* heterozygous 300 kb deletion in the coding exons of the *NRXN1* gene was found in two autistic sisters (Autism Genome Project Consortium, 2007); interestingly, one girl was reported to be nonverbal, whereas the other only had mild language regression. CNVs disrupting the *NRXN1* coding sequence can result in schizophrenia and not in ASD (Kirov et al., 2009; Rujescu et al., 2009). This phenotypic variability is further underscored by a large retrospective study involving 3540 individuals, identifying in 12 of them exonic *NRXN1* microdeletions causing very heterogeneous clinical phenotypes including ASD, mental retardation, language delay, and muscle hypotonia to a variable degree (Ching et al., 2010). Finally, a recent study by Zweier et al. (2009) concerning a girl with severe mental retardation and autism demonstrated the inheritance in compound heterozygosity of a 180 kb deletion from her unaffected mother and a stop mutation in exon 15 from her healthy father. These genetic abnormalities are predicted to deprive this patient of the longer alpha *NRXN1* isoform, whose lack cannot be functionally complemented

by the shorter beta isoform, leading to significantly decreased numbers of synapses both in alpha *NRXN1* knockout mice and in *Drosophila* (Etherton et al., 2009; Li et al., 2007a; Zeng et al., 2007). In Section 34.6, we shall return to compound heterozygosity as a viable mechanism able to explain the complexities of rare variant contributions to autism pathogenesis in some families.

34.3.3 Chromatin Architecture Genes

Rett syndrome is a peculiar PDD initially described by the Austrian pediatrician Andreas Rett in 1966. This severe neurodevelopmental disorder is characterized by regression, autism, microcephaly, stereotyped behaviors, epilepsy, and breathing problems (Chahrour and Zoghbi, 2007; Rett, 1966). The discovery that approximately 80% of females with Rett syndrome carry *de novo* mutations in the methyl-CpG-binding protein 2 (MeCP2) gene, which plays a critical role in determining chromatin structure by modulating DNA methylation (Amir et al., 1999), spurred great interest in the role of this gene in other PDDs and more broadly in the role of epigenetic mechanisms in autism.

34.3.3.1 The Methyl-CpG-Binding Protein 2 Gene

The methyl-CpG-binding protein 2 (MeCP2) binds to methylated CpG dinucleotides, recruiting histone deacetylase 1 (HDAC1) and other proteins involved in chromatin repression at specific gene promoters. It thus acts as a transcriptional repressor (Chahrour and Zoghbi, 2007), not only during development but throughout adult life (McGraw et al., 2011). *De novo* mutations of the *MECP2* gene located on chromosome Xq28, in addition to classical Rett syndrome, can also result in asymptomatic phenotypes, mild mental retardation, and verbal Rett variants, depending upon the specific mutation, the genetic background of the patient, and the X-inactivation pattern, which is highly skewed in the presence of mutations affecting X-linked genes, such as *NLGN3* and *MECP2*, albeit not being skewed in ASD families altogether (Gong et al., 2008). Instead, *MECP2* mutations are generally lethal in males (Amir et al., 1999; Chahrour and Zoghbi, 2007).

Several groups have screened the *MECP2* gene for mutations in nonsyndromic ASD patients, finding positives in 5 of the 397 females (1.3%) and none of the 741 males assessed to date (Lintas and Persico, 2009) (Table 34.6). Three *de novo MECP2* mutations have been found in two out of eleven studies assessing female ASD patients: the IVS2+2delTAAG splice variant in intron 2, the frameshift mutation 1157del41, and the nonsense mutation R294X (Carney et al., 2003; Lam et al., 2000). Two additional *de novo* mutations, R133C and R453X, were identified in two autism-spectrum girls fulfilling

criteria for the 'preserved speech' variant of Rett syndrome (Zappella et al., 2003). A few other missense, intronic, or 3′-UTR variants listed in Table 34.6 either are inherited from one of the parents, or it is not specified whether they are inherited or occurring *de novo*. Importantly, young girls carrying *MECP2* mutations appear autistic and mentally retarded, but display none of the symptoms typical of Rett syndrome (epilepsy, microcephaly, stereotypies, and breathing problems). Also, regression is not consistently reported by parents (Carney et al., 2003). Signs and symptoms more typical of Rett syndrome may appear when they grow older (Young et al., 2008). There is thus a rationale for *MECP2* gene screenings in female autistic patients and for follow-up programs to monitor these patients clinically over time (Lintas and Persico, 2009).

34.3.4 Morphogenetic and Growth-Regulating Genes

Many syndromic patients display facial dysmorphisms, minor or major malformations, microcephaly or macrocephaly either in isolation or as part of a broader microsomy or macrosomy, respectively (Tables 34.3 and 34.5). Also, idiopathic autistic children sometimes display minor facial dysmorphisms, which are beginning to be characterized using standardized or even automated methods for consistency (Hammond et al., 2004, 2008; Miles et al., 2008; Tripi et al., 2008). In addition, head and body growth rates are often abnormal. Macrocephaly has been consistently found in approximately 20% of autistic patients (Fombonne et al., 1999; Lainhart et al., 1997; Miles et al., 2000; Sacco et al., 2007a; Stevenson et al., 1997; Woodhouse et al., 1996). Head circumference in these ASD patients is typically normal at birth, and an overgrowth seemingly develops over the first few years of life (Courchesne et al., 2007). This macrocephaly is part of a broader macrosomy in most, though not all, patients (Bigler et al., 2010; Dissanayake et al., 2006; Lainhart et al., 2006; Sacco et al., 2007a). On the contrary, a small subset of idiopathic autistic patients is instead microcephalic and usually also microsomic (see Figures 1 and 2 in Sacco et al., 2007a).

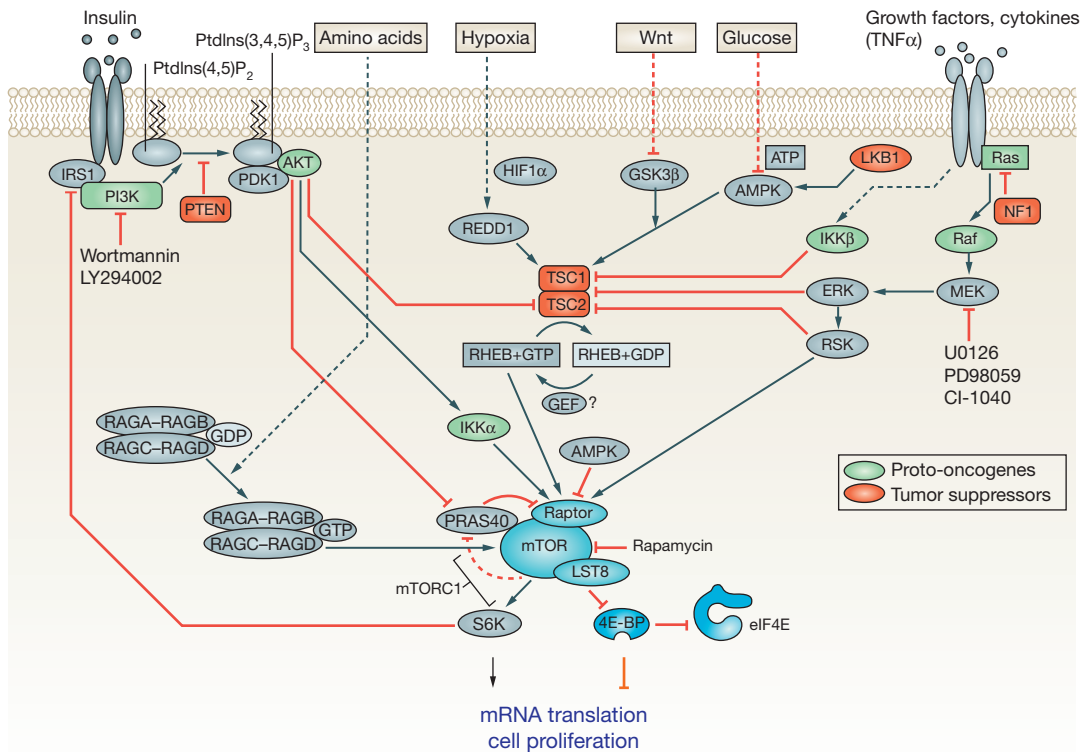
34.3.4.1 The Homeobox A1 Gene (HOXA1)

HOXA1 is a homeobox gene located on chromosome 7p15.3. It is critically involved in the development of head and neck structures directly or indirectly derived from the distal part of rhombomere 4 and from rhombomere 5 during embryogenesis (Chisaka et al., 1992; Mark et al., 1993; Rossell and Capecchi, 1999): these include brainstem, cerebellum, several cranial nerves, medium and internal ear, and occipital and hyoid bones. Both common and rare *HOXA1* gene variants have been

sought. The common A218G polymorphism exerts a sizable effect on head growth rates both in autistic and in typically developing children, with the G allele yielding faster head growth and smaller cerebellar volumes (Canu et al., 2009; Conciatori et al., 2004; Muscarella et al., 2007, 2010). This measurable effect on the growth of regions known to be involved in autism, such as the cerebellum (Courchesne, 1997), is intriguing, despite the nonreplication of an initial report suggesting that this common *HOXA1* variant could possibly contribute to autism (Ingram et al., 2000b; but see Gallagher et al., 2004; Li et al., 2002; Romano et al., 2003; Sen et al., 2007; Talebizadeh et al., 2002). The G allele leads to the substitution of the second of ten contiguous histidines by an arginine (His73Arg). This stretch of ten histidines underlies protein–protein interactions, which could be modulated by this gene variant, although direct experimental evidence is still lacking.

In reference to rare *HOXA1* gene variants possibly causing autism, the study of five consaguineous families from Saudi Arabia and of one from Turkey disclosed homozygous stop codon mutations in ten affected individuals (Bosley et al., 2007; Tischfield et al., 2005). Two different mutations were identified: a c.84 C>G mutation, which results in the introduction of a stop codon (Y28X) in the Turkish patient, and a 175–176insG, which causes a reading frame shift and a premature protein truncation in nine Saudi Arabian patients (Bosley et al., 2007; Tischfield et al., 2005). Mutation carriers show some phenotypic similarities, including horizontal gaze abnormalities, deafness, focal weakness, hypoventilation, vascular malformations of the internal carotid arteries and cardiac outflow tract, mental retardation, and autism: this set of clinical symptoms and malformations was named Bosley–Salih–Alorainy syndrome (BSAS) (Bosley et al., 2007). Importantly, all signs and symptoms (even vascular malformations) display a significant degree of interindividual variability in both presence and severity, with developmental delay and autism reported only in a subset of patients (see Section 34.6). Many signs and symptoms of BSAS overlap with those present in the Athabascan brainstem dysgenesis syndrome found in Native American children carrying a distinct *HOXA1* R26X mutation (Bosley et al., 2008). Since these causal mutations are recessive, similar phenotypes should be sought only in areas where inbreeding is substantial. In other geographical areas, oligogenic heterozygosity also involving rare *HOXA1* variants may play a role in idiopathic autism (Schaaf et al., 2011).

34.3.4.2 The Phosphatease and Tensin Homolog Gene (PTEN)

PTEN is a tumor suppressor gene located on human chromosome 10q23, which favors cell-cycle arrest in G1 and apoptosis. In conjunction with other tumor-suppressor genes, such as *TSC1*, *TSC2*, and *NF1*, it balances the stimulation physiologically exerted on cell proliferation and body growth by nutrient availability (sugars and proteins), insulin release, and pro-inflammatory cytokines, through the ERK/PI3K/mTOR pathway (Figure 34.1) (Ma and Blenis, 2009). Mutations inactivating these tumor-suppressor genes cause diseases often associated with syndromic autisms (see Table 34.3). *PTEN* knockout mice indeed display macrosomy, macrocephaly, CNS overgrowth with thickening of the neocortex and cytoarchitectonic abnormalities in the hippocampus, excessive dendritic and axonal growth, and increased numbers of synapses (Kwon et al., 2006). Furthermore, in humans, germline mutations resulting in *PTEN* haploinsufficiency facilitate cell-cycle progression and oncogenesis, leading to macrocephaly/macrosomy and to cancer development, respectively (Eng, 2003). Germline *PTEN* mutations have been documented in the vast majority of patients diagnosed with Cowden syndrome, which carries enhanced risk for breast, endometrial, and thyroid cancers (Eng, 2003). Also, individuals suffering from other related hamartoma disorders, such as Bannayan–Riley–Ruvalcaba syndrome, Proteus syndrome, and Proteus-like syndromes, display germline *PTEN* mutations in 60%, 20%, and 50% of cases, respectively (Eng, 2003). Interestingly, genetic syndromes due to *PTEN* germline haploinsufficiency are also frequently associated with autism or mental retardation, as initially reported by Goffin et al. (2001) (e.g., see Boccone et al., 2006). Instead, several missense mutations affecting evolutionarily conserved amino acid residues have been detected in macrocephalic individuals affected by idiopathic autism (Table 34.6). ASD patients carrying *PTEN* mutations are invariably characterized by severe to extreme macrocephaly (i.e., cranial circumference >97th percentile or +2 SD, but most *PTEN* mutation carriers typically display ≥+3 SD). In some cases, the overgrowth starts prenatally, whereas other *PTEN* mutation carriers display a normal head circumference at birth and macrocephaly develops only postnatally, as generally occurs in macrocephalic autistic children (Courchesne et al., 2007). In addition, the majority of macrocephalic autistic patients are actually macrosomic, underscoring a systemic disruption of body growth control mechanisms (Sacco et al., 2007a). Although all mutation carriers share macrocephaly as a unifying feature, behavioral phenotypes can again differ significantly between patients, and some mutations are inherited from apparently normal fathers (Varga et al., 2009). The incidence of *PTEN* de novo mutations can be estimated at 4.7% (6/126) among macrocephalic/macrosomic ASD patients, who in turn are approximately 20% of all ASD patients (Lintas and Persico, 2009). The percentage of PTEN mutation carriers may be even higher in selected clinical populations (Butler et al.,


2005; Varga et al., 2009). This high genetic yield and the predisposition toward malignancies underscore the importance of screening for *PTEN* mutations in macrocephalic/macrosomic autistic children (Herman et al., 2007a,b; Lintas and Persico, 2009; McBride et al., 2010; Schaefer and Mendelson, 2008; Varga et al., 2009).

34.3.4.3 The Eukaryotic Translation Initiation Factor 4E Gene (EIF4E)

The *EIF4E* gene, located on human chromosome 4q21–q25, encodes the rate-limiting component of eukaryotic translation initiation and the downstream effector in the mTOR pathway (Figure 34.1). Recently, a balanced translocation disrupting the *EIF4E* locus was found in an autistic boy with loss of initial language and social interactions at 2 years of age (Neves-Pereira et al., 2009) (Table 34.6). In the same study, both affected children of 2/120 multiplex families were found to inherit a C insertion from an apparently unaffected father, extending to eight a stretch of seven cytosines located in the basal promoter element of the *EIF4E* gene (4-EBE) (Neves-Pereira et al., 2009). The C_8-4EBE allele seemingly binds with much higher affinity an abundant nuclear protein (probably hnRNPK), resulting in a twofold increase in gene expression compared to the C_7-4EBE allele (Neves-Pereira et al., 2009). Interestingly, despite carrying the same paternally inherited C_8-4EBE allele, only one of these four autistic children underwent

behavioral regression, as had occurred to the proband carrying the *de novo* translocation (Neves-Pereira et al., 2009).

34.3.5 Calcium-Related Genes

Many lines of evidence indicate that excessive Ca^{2+} signaling is pivotal in the pathophysiological processes leading to autism, as reviewed by Krey and Dolmetsch (2007). Excessive intracellular Ca^{2+} spikes can modulate the aspartate/glutamate mitochondrial carrier AGC1, leading to abnormal energy metabolism and enhanced oxidative stress (for review, see Palmieri and Persico, 2010). Rare gain-of-function mutations causing autism or multisystem disorders encompassing autistic behaviors have been detected in genes encoding ion channels either directly conducting Ca^{2+} or indirectly prolonging the opening time of voltage-gated Ca^{2+} channels.

34.3.5.1 The Ion Channel-encoding Genes CACNA1C, CACNA1F, CACNA1H, BKCa, and SCN2A

Gain-of-function mutations in the gene encoding for the L-type voltage-gated Ca^{2+} channel $Ca_v1.2$ (*CACNA1C*) cause Timothy syndrome, a multisystem disorder characterized by lethal arrhythmias, webbing of fingers and toes, congenital heart disease, immune deficiency, intermittent hypoglycemia, autism, and mental retardation (Splawski et al., 2004). Similarly, mutations

in the L-type voltage-gated Ca^{2+} channel Ca$_v$1.4 (*CACNA1F*) cause an incomplete form of X-linked congenital stationary night blindness (CSNB2), frequently accompanied by cognitive impairment and autism or epilepsy, but only with gain-of-function and never with loss-of-function *CACNA1F* mutations (Hemara-Wahanui et al., 2005; Hope et al., 2005). Surprisingly, *CACNA1F* is not expressed in the CNS, except for the pineal gland (Hemara-Wahanui et al., 2005). In general, these gain-of-function mutations reduce or block voltage-dependent channel inactivation, resulting in excessive Ca^{2+} influx (Hemara-Wahanui et al., 2005; Splawski et al., 2004). Also, mutations and chromosomal abnormalities indirectly boosting cytosolic Ca^{2+} levels or amplifying intracellular Ca^{2+} signaling by hampering Ca^{2+}-activated negative feedback mechanisms have been found associated with autism. An autistic boy was found to carry a balanced translocation disrupting one copy of the *KCNMA1* gene, which encodes the α subunit of the large conductance Ca^{2+}-activated K$^+$ (BK$_{Ca}$) channel: the inactivation of one copy of this gene results in a more depolarized resting membrane potential and in a relatively less efficient control of neuronal excitability (Laumonnier et al., 2006). The R1902C variant located in the *SCN2A* gene decreases the affinity of this voltage-gated sodium channel for Ca^{2+}-bound calmodulin, which would stabilize the inactivation gate and minimize sustained channel activity during depolarization (Kim et al., 2004; Weiss et al., 2003). The situation is less clear with mutations affecting the *CACNA1H* gene, which encodes for the T-type voltage-gated Ca^{2+} channel Ca$_v$3.2 (Splawski et al., 2006). These mutations are found in ASD families and not in controls, but do not fully segregate with an autistic phenotype; furthermore, mutant channels require greater depolarizations to activate conductance and overall conduct substantially less than wild-type channels (Splawski et al., 2006). However, in the case of these autism-predisposing mutations, more depolarized potentials are also necessary to produce channel inactivation, indicating that longer-lasting calcium influx will be generated by small perturbations from the resting membrane potential (Splawski et al., 2006). Therefore, studies of patients carrying mutations in calcium-related genes collectively support excessive Ca^{2+} signaling as a critical player in the pathophysiological processes leading to autism.

34.4 NONSYNDROMIC AUTISMS: THE ROLE OF COMMON VARIANTS

34.4.1 General Description

Functional polymorphisms widely distributed in the general population can indeed confer vulnerability or protection in complex disorders, such as autism. Conceivably,

a host of unfavorable common variants could even cause a disease phenotype, either directly or by lowering the sensitivity threshold to widespread environmental agents. Common genetic variants are typically sought by applying a candidate gene or, more recently, a genome-wide association approach. Although several common variants have been found associated with autism, as reviewed in detail elsewhere (Abrahams and Geschwind, 2008; Freitag, 2007; Muhle et al., 2004; Persico and Bourgeron, 2006), the evidence from independent replications and from functional studies is not equally strong for all of them (see Tables 2 and 4 in Abrahams and Geschwind, 2008). We shall now briefly summarize the results and pathophysiological bases concerning some of the most consistently replicated genes.

34.4.2 Reelin (RELN)

The *RELN* gene encodes for reelin, a critical stop signal for migrating neurons in several CNS districts, including the neocortex, the cerebellum, and the hindbrain (Herz and Chen, 2006; Rice and Curran, 2001). *RELN* maps to human chromosome 7q22, in a region linked with autism in several studies (Muhle et al., 2004; Persico and Bourgeron, 2006). Reelin acts by binding to a variety of receptors, including the VLDL receptors, APOE-R2, and α3β1 integrins, and by exerting a proteolytic activity on extracellular matrix proteins (D'Arcangelo et al., 1999; Hiesberger et al., 1999; Quattrocchi et al., 2002). *Reeler* mice lack reelin protein due to spontaneous deletions of the *RELN* gene (D'Arcangelo et al., 1995). Their brains display major cytoarchitectonic abnormalities (Goffinet, 1984), the distribution of which largely overlaps with regions of altered neuronal migration in autistic brains, as reviewed by Persico and Bourgeron (2006). Importantly, post-mortem studies have documented reductions in *RELN* and *DAB1* gene expression, as well as elevations in *VLDLR* mRNA, in the cerebral and cerebellar cortex of autistic individuals compared to controls (Fatemi et al., 2005; Lintas and Persico, 2010). Similar reductions have been found *in vivo* when measuring reelin plasma levels in ASD patients compared to controls (Fatemi et al., 2002; Lugli et al., 2003).

RELN gene mutations resulting in a lack of reelin protein yield the Norman–Roberts syndrome, a severe autosomal recessive disease characterized by lissencephaly and cerebellar hypoplasia, with severe mental retardation, abnormal neuromuscular connectivity, and congenital lymphoedema (Hong et al., 2000). *RELN* gene variants with a less dramatic functional impact have been found to confer liability to neuropsychiatric disorders, such as autism and schizophrenia (for review, see Lintas and Persico, 2008). Genetic association studies on *RELN* gene variants and autism are listed

[a]*Only the two SNPs found associated with autism are listed here, out of 34 SNPs assessed.*
[b]*Only one SNP found associated with autism is listed here, out of 12 SNPs assessed.*

in Table 34.7. A polymorphic GGC repeat located immediately 5′ of the AUG translation initiation codon and ranging from 4 to 23 repeats in our sample (Persico et al., 2001, 2006) has been found associated with autism in several, though not all, studies. In particular, 'long' GGC alleles (i.e., >10 GGC repeats) were shown to decrease *RELN* gene expression in neuronal (SN56 and N2A) and non-neuronal (CHO) cell lines (Persico et al., 2006). These alleles are present in approximately 20% of autistic individuals, compared with 10% of population controls. Other studies have pointed toward more 3′ regions of this large gene as possibly hosting functional variants. Some studies reporting no association with the GGC triplet repeat have nonetheless found rare variants of potential interest (Bonora et al., 2003). *RELN* variants different from those involved in autism may possibly contribute to schizophrenia: the GGC variant does not seem to confer

vulnerability to schizophrenia, which has instead been found to be associated with SNP rs7341475 located in intron 4 (Shifman et al., 2008). However, this SNP does not appear to influence brain structure, working memory, or *RELN* gene expression, so the functional correlates of this association remain unclear (Tost et al., 2010). Gene–gene interactions with other schizophrenia liability genes (Hall et al., 2007) and epigenetic control of *RELN* gene expression (Grayson et al., 2006; Lintas and Persico, 2010) may perhaps play more prominent roles than single functional variants in conferring vulnerability to schizophrenia, especially after puberty.

Possible gene–gene and gene–environment interactions involving *RELN* have been previously presented, especially in reference to PON1 gene polymorphisms and prenatal exposure to organophosphate pesticides (see Section 34.4 and Persico and Bourgeron, 2006). Briefly, reelin's proteolytic activity, crucial for

neuronal migration, is inhibited by organophosphates (Quattrocchi et al., 2002). Furthermore, the *PON1* gene, encoding for the organophosphate-detoxifying enzyme present in human serum, is also associated with autism and provides evidence of gene–gene interactions with *RELN* alleles (D'Amelio et al., 2005). We thus proposed a gene–gene–environment interaction model, whereby individuals carrying genetic or epigenetic variants resulting in reduced *RELN* gene expression and in less active paraoxonase isoforms, if exposed prenatally to organophosphates during critical periods in neurodevelopment, will more likely suffer from altered neuronal migration resulting in autistic disorder (Persico and Bourgeron, 2006). We have recently measured two different *PON1* enzymatic activities in the serum of 174 ASD patients, 144 controls, and 175 first-degree relatives finding significant reductions in arylesterase, but not in diazoxonase activity, primarily due to a functional inhibition of this enzymatic activity and not due to quantitative decreases in PON1 protein levels (Gaita et al., 2010). These results were unexpected, because diazoxon is one of the most widespread organophosphates in the United States, whereas decreases in arylesterase activity have so far been recorded in the presence of enhanced oxidative stress and/or immune activation, as during viral hepatitis C (Ferré et al., 2005; Kilic et al., 2005), influenza (van Lenten et al., 2001), and HIV infections (Parra et al., 2007). Recent neuroanatomical, gene expression, and brain imaging studies strongly support an abnormal activation of the immune system in autism (see Sections 34.4.5.3 and 34.6). Within this framework, *RELN*–*PON1* interactions may be better explained by a joint modulation of inflammatory processes, especially monocyte recruitment and migration into the CNS (Ahmed et al., 2003; Cameron and Landreth, 2010; Gaita et al., 2010; van Lenten et al., 2002).

34.4.3 The MET Protooncogene

The MET receptor tyrosine kinase, encoded by the *MET* protooncogene located in human ch 7q31, plays an important role in modulating cell proliferation and migration, as reviewed by Levitt et al. (2004) and by Levitt and Campbell (2009). Briefly, the MET receptor binds hepatocyte growth factor (HGF), which is translated as an inactive precursor and activated by proteolytic cleavage to yield the MET receptor ligand: this cleavage is achieved by the protease plasminogen activator, urokinase-type (uPA), when uPA binds to its receptor, the urokinase plasminogen activator receptor (uPAR) (see Figure 3 in Levitt et al., 2004). The cleavage-mediated activation of HGF can instead be suppressed by the plasminogen activator inhibitor-1 (PAI-1). *MET* gene variants have been found to be associated with autism in four

independent studies involving at least seven distinct family samples (Campbell et al., 2006, 2008; Jackson et al., 2009; Sousa et al., 2009). The *MET* gene variant conferring autism vulnerability in the initial study was the C allele at rs1858830, located in the *MET* gene promoter (Campbell et al., 2006). This allele dramatically reduces the binding of transcription factors SP1 and PC4, thereby decreasing *MET* transcription assessed in neuronal (SN56 and N2A) and non-neuronal (HEK) cell lines using luciferase-expressing reporter constructs (Campbell et al., 2006). The association between autism and the C allele at rs1858830 was replicated by the same group in an independent sample (Campbell et al., 2008), whereas a study from the IMGSAC Consortium found autism associated with SNP rs38845, located in intron 1 of the *MET* gene (Sousa et al., 2009). A fourth study, employing only case–control contrasts, confirmed an association with the C allele at rs1858830 in a South Carolina, and not in an Italian cohort (but the latter was deeply underpowered: South Carolina sample = 174 ASD patients vs. 369 controls; Italian sample = 65 ASD patients vs. 126 controls) (Jackson et al., 2009).

Analyses of postmortem tissue from the superior temporal gyrus (Brodmann area 41/42) confirmed an approximate twofold decrease in *MET* transcript and protein expression in ASD patients compared to matched controls (Campbell et al., 2007). Moreover, significantly lower MET protein levels were found among controls carrying the C/C, as compared to the G/G genotype at rs1858830 (Campbell et al., 2007). The same tissues unveiled increased expression of the *HGF*, *PLAUR*, and *SERPINE1* genes, which encode for HGF, uPAR, and PAI-1, respectively (Campbell et al., 2007). Conceivably, decreased *MET* gene expression at the neocortical level triggers compensatory increases in the expression of other molecules belonging to the same pathway, such as *HGF*, *PLAUR*, and *SERPINE1*. The latter two genes apparently also host common genetic variants independently contributing to autism vulnerability: a *SERPINE1* haplotype and the *PLAUR* promoter T allele at rs344781 are both associated with autism (Campbell et al., 2008). Significant gene–gene interactions have also been shown for *MET* and *PLAUR* (Campbell et al., 2008).

The functional correlates of this genetic predisposition are perhaps more interesting than its behavioral correlates, which appear rather nonspecific (Campbell et al., 2010). The MET/HGF pathway is known to play an important role in the developing CNS, in the immune system, and in gastrointestinal repair, all strongly linked to the pathophysiology of autism. Blunted MET/HGF signaling negatively affects interneuron migration from the ganglionic eminence into the cerebral cortex and granule cell proliferation in the cerebellum (Ieraci et al., 2002; Levitt et al., 2004): reduced numbers of neocortical GABAergic interneurons and a reduction in

cerebellar size, especially in the vermis, may be particularly relevant to the elevated comorbidity between autism and epilepsy, as well as to brain imaging findings of reduced cerebellar vermis size in ASD patients (Courchesne, 1997). The same also occurs in zebrafish, where *MET* is critically involved in cerebellar development and, interestingly, in the migration of cells forming the facial motor nucleus (Elsen et al., 2009; also see Section 34.4.2, Rodier et al. (1996), and Rodier (2002)). In the mouse, *MET* expression is especially pronounced in cortical projection neurons between P7 and P14, when long-range cortical connections are wired through neuronal sprouting and active synaptogenesis (Judson et al., 2009). Emx1-Cre-driven deletion of *MET* in dorsal pallially derived forebrain neurons affects dendritic development both in pyramidal cells (decreased apical and increased basal dendritic harbor length) and in medium spiny neurons (increased dendritic harbor length), the latter postsynaptic to *MET*-expressing corticostriatal afferents during development. The number of dendritic spines is unchanged, but spine head volume is significantly enlarged (Judson et al., 2010). These same animals show a twofold stronger connectivity between cortical layers 2/3 and corticostriatal, but not corticopontine, layer 5 pyramidal neurons (Qiu et al., 2011). Although human genetic variants modulate *MET* gene expression to a moderate extent, compared to these experimental manipulations, these studies clearly implicate excessive local and decreased long-range connectivity at the neocortical level as the most likely mechanism underlying the ASD risk conferred by *MET* gene alleles.

Additional evidence converging on the MET/HGF pathway also comes from *Plaur*-deficient mice, which show disrupted forebrain interneuron development, increased susceptibility to seizures, anxiety, and abnormal social behavior (Levitt et al., 2004). These same *Plaur* knockout mice also display severely impaired granulocyte and monocyte migration toward inflammatory foci (Allgayer, 2006). The MET/HGF pathway is indeed known to play both 'pro-inflammatory' roles (stimulating leukocyte adhesion and migration, migration of dendritic cells, antagonizing the effects of TGF-β) and anti-inflammatory roles (suppression of the antigen-presenting function of dendritic cells; blunting of eosinophila and airway hyperresponsiveness in animal models of asthma) (Beilman et al., 2000; Okunishi et al., 2005). Finally, the C allele at rs1858830 has been found to be associated primarily with autistic syndromes encompassing gastrointestinal symptoms (Campbell et al., 2009), which are frequently encountered in autistic patients (Buie et al., 2010). Autistic children with gastrointestinal symptoms may also display decreased serum levels of HGF (Russo et al., 2009; Sugihara et al., 2007), again pointing toward the translation of impaired MET/HGF signaling into inefficient gastrointestinal repair mechanisms.

Collectively, current evidence points toward multiple common gene variants promoting a dysregulation of the MET/HGF pathway, which represents a significant contributor to neurodevelopmental, immune, and gastrointestinal abnormalities in autism.

34.4.4 The Oxytocin Receptor Gene

The oxytocin receptor gene (OXTR) is a high-affinity G-protein-coupled receptor encoded by the *OXTR* gene located on human ch 3p26.2. It binds oxytocin (OXT), a nine-amino-acid neurohypophyseal hormone encoded by the *OXT* gene, which also encodes for neurophysin I and is located on human ch 20p13. This hormone and neuromodulator, largely distributed in limbic areas such as the nucleus accumbens and the amygdala, in addition to well-established roles in parturition and breast feeding, physiologically influences social cognition in a relatively species- and sex-specific manner (for review, see Carter, 2007; Carter et al., 2008). OXT or OXTR knockout mice display impaired social memory, while parturition is largely unaffected (Ferguson et al., 2000; Takayanagi et al., 2005). Interestingly, only male mice with a targeted forebrain OXTR knockout fail to recognize individuals of their own species, suggesting the existence of compensatory mechanisms in females (Sun et al., 2008). Heterozygous *reeler* mice display reduced neocortical *OXTR* gene expression, suggesting an intriguing crosstalk between the RELN and OXT pathways (Liu et al., 2005). Several human studies employing an intranasal administration paradigm demonstrate that OXT stimulates affiliative behaviors, subjective feelings of trustworthiness, facial recognition, and in general all social cognitive functions evolutionarily involved in the establishment of a strong emotional bond between parents and neonate (Ebstein et al., 2009).

Genetic studies of the OXT and arginine vasopressin (AVP) systems were undertaken under the assumption that a disruption of these hormonal/neurochemical systems could underlie the deficits in social cognition which characterize ASD patients (for review, see Ebstein et al., 2009). Indeed, at least six out of eight genetic studies performed to date have reported a positive association between ASD and the *OXTR* gene (Table 34.8). This consistency is surprising, especially when considering that many studies were severely underpowered. Single marker and haplotype association analyses primarily point toward a haplotype block encompassing exon 3 and the beginning of intron 3 as possibly hosting a functional variant conferring autism liability, although some evidence also points toward the 3'UTR of the gene encoded by exon 4 (Table 34.8). Findings on the *OXT* gene have been less consistent, if not entirely negative. Some studies have reported positive findings for the AVP receptor gene *AVP1a* (Kim et al.,

2002; Wassink et al., 2004; Yirmiya et al., 2006) and for the gene encoding CD38, a transmembrane glycoprotein mainly expressed in immune cells (NK, T, B cells and macrophages) and responsible for triggering the release of OXT in neurons (Jin et al., 2007; Munesue et al., 2010). Interestingly, another study (Gregory et al., 2009) described a genomic deletion encompassing the *OXTR* gene in an autistic proband belonging to a multiplex family and in his mother, who displayed relevant obsessive–compulsive traits. The other affected sibling did not carry the deletion, but instead his *OXTR* promoter was hypermethylated at CpG islands located at −934, −924, and −901 bp from the translation start site. Hypermethylation of the *OXTR* promoter at several CpG islands located between −860 and −959 was also demonstrated in genomic DNA extracted from leukocytes and from post-mortem brain tissue of autistic patients, compared to matched controls (Gregory et al., 2009). As predicted, enhanced methylation was correlated with decreased *OXTR* transcript levels in temporocortical post-mortem brain tissue (Gregory et al., 2009). Hence, predisposition to autism can be apparently conferred by the *OXTR* locus through distinct genomic, genetic, and epigenetic mechanisms, all resulting in hampered OXT signaling (Gurrieri and Neri, 2009). Abnormal neuropeptide processing in autistic children, yielding reduced OXT blood levels despite enhanced concentrations of OXT precursor (Green et al., 2001; Modahl et al., 1998), may further exacerbate this deficit, bringing OXT signaling below a critical threshold necessary for the physiological development of social behavior. Based on the influence of *OXTR* gene variants on amygdalar volume, which is bilaterally smaller in healthy adults carrying the G allele at rs2254298 (Furman et al., 2011; Inoue et al., 2010), blunted OXT signaling can be predicted to have a negative impact on the development and function of specific cortical and limbic regions critical to social cognition.

34.4.5 The Contacting-Associated Protein-Like 2 Gene (CNTNAP2)

The *CNTNAP2* gene, located on human ch 7q35–q36, encodes for the contacting-associated protein (CASPR2), a member of the Neurexin family which also includes Neurexin1 (see Section 34.3.2.3). This locus was originally identified by two groups applying linkage analysis both on affection status and on language delay, used as a quantitative trait locus (QTL) (Alarcón et al., 2008; Arking et al., 2008). Follow-up association analyses carried out on potential candidate genes supported *CNTNAP2* as being solely responsible for the linkage peak (Alarcón et al., 2008; Arking et al., 2008), although negative association findings were also published (Li et al., 2010). The *CNTNAP2* allele appears to confer autism vulnerability primarily in males (Alarcón et al., 2008), and possibly if

inherited from the maternal side (Arking et al., 2008). *CNTNAP2* was shown to be highly expressed in frontal and temporal regions of the human fetus, as well as striatum, amygdala, and thalamus, all areas strongly involved in linguistic functions and emotional information processing (Abrahams et al., 2007; Alarcón et al., 2008). T1-weighted anatomical MRI scans performed in 314 healthy volunteers revealed that the autism-associated allele seemingly yields reduced gray and white matter volumes and fractional anisotropy, following sex-specific distributions involving several autism-related brain regions, such as frontal cortex, fusiform gyrus, and cerebellum (Tan et al., 2010). Further analyses by fMRI revealed that carriers of the *CNTNAP2* risk allele have widespread and bilateral connectivity distributed throughout the frontal cortex and anterior temporal poles, whereas the protective allele is associated with a left-lateralized network composed of left inferior frontal gyrus, insula, anterior temporal pole, superior temporal gyrus, and angular gyrus (Scott-Van Zeeland et al., 2010). The latter results point toward *CNTNAP2* alleles as conferring autism vulnerability by affecting the lateralization and possibly the extent of long-range connectivity. At the cellular level, the *Drosophila* orthologs of *CASPR2* and *NRXN1* have been shown to colocalize partly at synaptic active sites, and overexpression of either gene increases the density of active zones and modulates the shape of synapses (Zweier et al., 2009). These 'synaptic' roles for *CNTNAP2*, especially if applied to long-range neural pathways connecting language-related cortical regions, would indeed fit with the converging evidence on synaptic roles summarized here for several other genes (see Section 34.3.2).

Multiple lines of evidence point toward the relative nonspecificity of many 'autism' genes, which may play cognitive roles that, if deranged, can translate into different human disorders: this seems to apply even more to *CNTNAP2*. Several rare genetic variants and *de novo* cytogenetic abnormalities in *CNTNAP2* have been described in autistic probands, which oftentimes present also with seizures and regression (Bakkaloglu et al., 2008; Jackman et al., 2009; Poot et al., 2010; Rossi et al., 2008). However, *CNTNAP2* was also identified by genome-wide CNV analysis as relevant to the development of idiopathic generalized and focal epilepsies (Mefford et al., 2010). Further evidence linking *CNTNAP2* perhaps more directly with language development than with autism *per se* comes from the functional connection between *CNTNAP2* and *FOXP2*, a transcription factor critically involved in the development of expressive language (Lai et al., 2001): *FOXP2* binds to the promoter of *CNTNAP2* and dramatically downregulates its expression (Vernes et al., 2008). *CNTNAP2* gene variants have also been found to be associated with specific language impairment (Vernes et al., 2008). Moreover, common *CNTNAP2* variants

have been found to confer vulnerability to schizophrenia and bipolar disorder (O'Dushlaine et al., 2010), whereas rare variants have been described in ADHD patients (Elia et al., 2010). Meanwhile, although several rare variants present in autistic probands were not found in large numbers of control chromosomes, the vast majority are inherited from an unaffected parent and many of them are transmitted to some, but not all, affected siblings in multiplex families, suggesting that they may enhance autism risk, but are not sufficient to cause the disease (Bakkaloglu et al., 2008). Hence, *CNTNAP2* may play a broader role in shaping the autistic phenotype toward language deficit and possibly epilepsy, rather than strictly conferring autism vulnerability.

34.4.6 The Engrailed 2 Gene

The Engrailed genes play an important role in the patterning of the midbrain/hindbrain region, the only CNS area where they are actively expressed during development (Davis et al., 1998). In particular, engrailed 2 (*EN2*) is expressed in cerebellum, pons, periaqueductal gray, and colliculi. *EN2* knockout mice display decreased seizure threshold to kainic acid (Tripathi et al., 2009) and a relatively subtle behavioral phenotype, with abnormalities in developmental motor, social, and memory tasks (Cheh et al., 2006). Their cerebellar size is reduced and their compartmentalization is interestingly disrupted both in the vermis and in cerebellar hemispheres (Kuemerle et al., 1997; Millen et al., 1994, 1995). In addition, 5-HT and 5-hydroxy-indolacetic acid (5-HIAA) levels are doubled in the cerebellum only (Cheh et al., 2006). The role of *EN2* in cerebellar development and the frequency of cerebellar abnormalities reported in neuroanatomical and brain imaging studies of ASD patients (Courchesne, 1997) spurred interest in genetic studies of *EN2* as early as 1995, when a significant association with autism was first reported by Petit et al. Nine studies followed this initial report, and at least seven of them replicated the initial association in various racial and ethnic groups (Table 34.9). The *EN2* gene, located in human chromosome 7q36.3, encompasses two exons and one intron. The most replicated association was found with the A–C haplotype at SNPs rs1861972 and rs1861973, embedded into intron 1. Following transfection with constructs encompassing the luciferase reporter gene, this haplotype consistently yields approximately 20% higher expression levels in neuronal PC12 cells, non-neuronal HEK293T cells, and in primary cultures of mouse cerebellar granule cells harvested on postnatal day 6 (P6) (Benayed et al., 2009). This difference in gene expression is not due to cryptic splicing, but rather to allele-specific transcription factor binding. Increased expression of *EN2* can be predicted to result in faster differentiation of the midbrain/hindbrain

region and of cerebellar circuits (Benayed et al., 2009). This should occur at the expense of the proliferating and migrating pools, thus yielding decreased Purkinje cell numbers and cytoarchitectonic abnormalities in the cerebellar cortex.

34.4.7 Gamma-Aminobutyric Acid Receptor β3 (GABRB3)

Several lines of investigation indicate the existence of abnormalities in the brain gamma-aminobutyric acid (GABA) system of autistic children. The frequent co-morbidity with epilepsy and the morphogenetic roles of GABA, an inhibitory neurotransmitter in adult brain but an excitatory neurotransmitter during prenatal neuro-development due to high intracellular chloride concentrations in immature neurons (see review by Jentsch et al., 2002), have spurred interest into GABA receptor (GABAR) subunit genes as potential candidates for autism (Blatt et al., 2001; Hussman, 2001). In addition,

the 15q11–q13 region deleted/duplicated in 1–4% of autistic patients (see Tables 34.3 and 34.5) (McCauley et al., 2004; Schroer et al., 1998) encompasses the GABAA receptor gene cluster, which consists of three GABAR genes, namely *GABRB3*, *GABRA5*, and *GABRG3*. Investigations of these genes have provided some support especially to *GABRB3*. A significant association between autism and markers located within or nearby *GABRB3* has been found in most studies (Buxbaum et al., 2002; Cook et al., 1998; Curran et al., 2005; Kim et al., 2006; Martin et al., 2000; McCauley et al., 2004; Yoo et al., 2009), although negative reports have also appeared (Ma et al., 2005; Maestrini et al., 1999; Menold et al., 2001; Salmon et al., 1999; Tochigi et al., 2007). Some have proposed that behavioral traits, such as savant skills and insistence on sameness, may be especially linked to genes located in the 15q11–q13 region (Nurmi et al., 2003; Shao et al., 2003). Maternal transmission of a *GABRB3* signal peptide variant (P11S), previously implicated in childhood absence epilepsy, is associated with autism (Delahanty et al., 2011). This rare variant, present in 17 (1.47%) of

1152 simplex and multiplex families, yields reduced whole-cell current and decreased β3 subunit protein on the cell surface due to impaired intracellular β3 subunit processing (Delahanty et al., 2011). *GABRB3* gene variants must also be viewed within the framework of the entire set of GABAR-encoding genes, as several gene–gene interactions between them have been detected (Ashley-Koch et al., 2006; Ma et al., 2005).

In addition to genetic variants, epigenetic dysregulation of the *GABRB3* locus may also contribute to autism. *GABRB3* expression is reduced on average by as much as 50% in several neocortical and cerebellar regions (Fatemi et al., 2009). Interestingly, a sizable subset of ASD brains displays either monoallelic or abnormally downregulated *GABRB3* expression instead of the normal levels of biallelic expression present in controls (Hogart et al., 2007, 2009). Interestingly, GABRB3-deficient mice exhibit impaired social and exploratory behaviors, deficits in nonselective attention, and hypoplasia of the cerebellar vermis, all features relevant to autism (DeLorey et al., 2008). In addition, mice deficient in MeCP2 display reductions in GABRB3 protein, as MeCP2 acts as a positive regulator of *GABRB3* gene expression (Samaco et al., 2005). Collectively, these results suggest the existence of genetic and epigenetic influences leading to a behaviorally relevant downregulation of *GABRB3* in autistic brains.

34.4.8 The Serotonin Transporter (SLC6A4) and Integrin β3 Subunit Genes

Elevated whole-blood serotonin (5-HT), present in about one-third of ASD patients, represents one of the most consistent biological endophenotypes in autism research (Table 34.1). Hyperserotoninemia appears to be a genetically determined familial trait, as first-degree relatives display mean 5-HT blood levels intermediate between those of their autistic family members and of population controls (Abramson et al., 1989; Cook et al., 1990; Leventhal et al., 1990; Piven et al., 1991). In most patients, elevated 5-HT blood levels in autism seemingly stem from accumulation of 5-HT in platelets due to increased densities of functionally active serotonin transporter (5-HTT) molecules on platelet membranes, with no change in 5-HTT affinity for 5-HT and no elevation in free 5-HT plasma level (Cook et al., 1988; Katsui et al., 1986; Marazziti et al., 2000). Autism-associated hyperserotonemia has been the object of intense investigation, because either it could play a role in the etiological processes leading to the disease, or it could at least mark a relatively homogeneous subgroup of ASD patients. Genes encoding proteins involved in 5-HT metabolism and neurotransmission include, among others, the 5-HT transporter gene (*SLC6A4*) and the integrin β3 subunit gene (*ITGB3*). The serotonin transporter (5-HTT) responsible for platelet 5-HT uptake is identical in its primary sequence to the 5-HTT expressed in serotoninergic neurons: both are indeed produced by a single *SLC6A4* gene, located on chromosome 17q12 (Lesch et al., 1993). In reference to functional common variants, this gene contains two variable number tandem repeats (VNTRs) affecting expression levels: (a) the 5-HTT gene-linked polymorphic region (5-HTTLPR), located in the promoter, encompasses a 'long' 16-repeat allele, yielding approximately 50% higher 5-HTT gene expression and tritiated 5-HT uptake compared with homozygosity for the 'short' 14-repeat allele or with heterozygosity (Lesch et al., 1996); (b) the serotonin transporter intron 2 (STin2) VNTR includes 9, 10, and 12 repeat alleles, with the latter acting as a transcriptional enhancer (MacKenzie and Quinn, 1999). Overall, meta-analyses of association studies between autism and these two VNTRs have been negative, although there may be some association with the 5-HTTLPR 'short' allele in North-American families only (see review Huang and Santangelo, 2008). Furthermore, contributions of these VNTRs to enhanced 5-HT blood levels appear marginal at best (Anderson et al., 2002; Betancur et al., 2002; Coutinho et al., 2004, 2007a,b; Cross et al., 2008; Persico et al., 2002). Hence, immune factors, such as TNFα and other proinflammatory cytokines, which are known to activate 5-HTT transport activity (Zhu et al., 2006), as well as common variants in other genes, such as *ITGB3* (see below), may influence 5-HT blood levels to a larger extent.

In addition to these two common VNTRs, several rare *SLC6A4* variants have been identified as significantly enhancing autism risk. In particular, four coding substitutions located at highly conserved positions and 15 other variants located in 5′ noncoding and other intronic regions are transmitted to autistic probands exhibiting rigid-compulsive behaviors (Sutcliffe et al., 2005). Two of these variants, Phe465Leu and Leu550Val, confer elevated 5-HTT surface density (V_{max}), while retaining a capacity for acute protein kinase G (PKG) and p38 mitogen-activated protein kinase (MAPK) regulation; five other variants (Thr4Ala, Gly56Ala, Glu215Lys, Lys605Asn, and Pro612Ser) demonstrate no change in V_{max}, but show a complete loss of 5-HT uptake stimulation after acute PKG and p38 MAPK activation (Prasad et al., 2005). Finally, two other variants, Gly56Ala and Ile425Leu, show markedly reduced 5-HTT association with protein phosphatase 2A (PP2A), leading to profound and long-lasting 5-HTT internalization following phosphorylation by PKC (Prasad et al., 2005, 2009). When expressed stably in CHO cells, both Gly56Ala and Ile425Leu display a striking loss of 5-HTT protein following catalytic activation (Prasad et al., 2009). Since the Gly56Ala variant is less rare than the other variants, it will be interesting to see the results of studies contrasting wild-type Gly56 versus mutated Ala56 mice (Veenstra-Vanderweele et al., 2009). Collectively, despite

showing a complex array of effects, rare *SLC6A4* variants conferring autism vulnerability (a) display enhanced 5-HT transport activity, presumably leading to decreased extracellular 5-HT levels and/or shorter exposure of 5-HT receptors to their ligand, or (b) lose the plastic regulation normally mediated by intracellular kinases and able to adapt 5-HTT activity to the functional needs of local circuits (Prasad et al., 2009).

The *ITGB3* gene was first identified as a QTL for 5-HT blood levels, initially in the Hutterites (Weiss et al., 2004, 2005a) and then in the general population (Weiss et al., 2005b). *ITGB3* maps in ch 17q21.32, under a replicated linkage peak for autism (Cantor et al., 2005; Stone et al., 2004), and *ITGB3* alleles, either alone or in interaction with *SLC6A4*, have been found at least nominally associated with autism in all five studies performed to date (Coutinho et al., 2007a,b; Ma et al., 2010; Mei et al., 2007; Weiss et al., 2006a,b). Several lines of evidence support functional interactions between *ITGB3* and *SLC6A4*: (a) the integrin receptor composed of an αIIb subunit and of the *ITGB3*-encoded β3 subunit was recently identified as a novel component of the *SLC6A4* regulatory protein complex (Carneiro et al., 2008; Weiss et al., 2006a); (b) the *ITGB3* SNP rs5918 (Leu33Pro) modulates *SLC6A4* trafficking and transport activity (Carneiro et al., 2008); (c) *ITGB3* and *SLC6A4* gene expression levels are correlated in human and mouse tissues (Weiss et al., 2006a); and finally, (d) several published studies have described significant *SLC6A4* and *ITGB3* interactions for both autism risk and 5-HT blood levels, with a male-specific effect (Coutinho et al., 2007a,b; Ma et al., 2010; Mei et al., 2007; Weiss et al., 2004, 2005b, 2006a,b). Recent results from our laboratory point toward the existence of at least two distinct functional genetic *ITGB3* variants, located at opposite ends of the *ITGB3* gene: the 5′ variants significantly influence 5-HT blood levels in ours and in other studies (Weiss et al., 2006b), whereas autism-associated SNPs cluster toward the 3′ end of the gene (Napolioni et al., 2011). Interestingly, these results closely resemble the association patterns previously reported for asthma and wheezing versus allergies and IgE levels, also associated with 5′ and 3′ markers, respectively (Thompson et al., 2007; Weiss et al., 2005c).

Finally, mice carrying a combined haploinsufficiency at *PTEN* and *SLC6A4* (PTEN+/−;SLC6A4+/−) develop larger head sizes and greater sex-specific behavioral abnormalities, compared to PTEN+/−;SLC6A4+/+ or PTEN+/+;SLC6A4+/− mice (Page et al., 2009). This influence of 5-HT on the penetrance of other morphogenetic and neurodevelopmental genes is not entirely surprising in view of the many neurotrophic roles exerted by 5-HT during development (for review, see Di Pino et al., 2004; Persico, 2009). Yet, this study underscores the urgent need to move from assessments of 5-HTT and ITGB3 contributions to the 'presence/absence' of autism, toward less reductionist and more biologically meaningful approaches, addressing 5-HT modulation of the disease phenotype in the context of gene–gene interactions.

34.5 NONSYNDROMIC AUTISMS: ENVIRONMENTAL FORMS

34.5.1 General Description

Certain environmental factors have been shown to enhance the risk of developing autism significantly, to the point that at least in some patients they can be regarded as 'the primary cause' of the disease (for review, see Landrigan, 2010). These environmental agents include teratogenic drugs, namely valproic acid, misoprostol, and thalidomide, as well as prenatal rubella and cytomegalovirus (CMV) infections. Cases conclusively shown to derive from exposure to these environmental agents are relatively rare, and the role of genetic vulnerability conferred by common variants at the individual level cannot be overlooked. Nonetheless, these cases possess high heuristic potential, as the time window of exposure is usually known and often narrow, typically occurring during early prenatal neurodevelopment.

34.5.2 The Fetal Anticonvulsant Syndrome

Prenatal exposure to phenytoin, sodium valproate, and carbamazepine, either alone or in combination, causes the 'fetal anticonvulsant syndrome.' In the largest population-based study reported to date (Rasalam et al., 2005), strict diagnostic criteria for autistic disorder were met by 5/56 (8.9%) and 2/80 (2.5%) children exposed to valproate and carbamazepine alone, respectively; including also patients treated with drug combinations, cumulative percentages rise to 9/77 (11.7%) and 5/110 (4.5%) for valproate and carbamazepine, respectively. Differently from idiopathic autism, the M:F ratio here is close to 1 (Moore et al., 2000; Rasalam et al., 2005). Clinical descriptions of these children are provided both in larger cohort studies (Moore et al., 2000; Rasalam et al., 2005) and in a number of case reports (Christianson et al., 1994; Williams and Hersh, 1997; Williams et al., 2001): patients almost invariantly display speech delay, whereas motor delay is much less prevalent; cognitive impairment is typically mild or absent, and there is no history of regression or loss of skills; major malformations are sometimes present, but minor facial dysmorphology is certainly more prevalent (notice the hypertelorism, frontal bossing, and other dysmorphic features in Figures 1 and 2 of Moore et al., 2000).

Sodium valproate is believed to exert its teratogenic effects mainly by inhibiting histone deacetylase (Phiel et al., 2001): the persistent acetylation of histones and demethylation of cytosine at the promoters of neurodevelopmentally relevant genes would then lead to a dysregulation in excess of their gene expression. This pharmacological effect impinges on epigenetic mechanisms partly overlapping with those involved in *MECP2* hemizygosity, as summarized above, yielding a broad range of neurodevelopmental and behavioral abnormalities. As predicted by its pharmacological action, valproic acid increases the expression of several neurally relevant genes, such as *HoxA1* (Stodgell et al., 2006), GATA-3 (Rout and Clausen, 2009), WNT (Wiltse, 2005), and RELN and GAD67 (Dong et al., 2007). Curiously, reduced expression has been reported for *NLGN3* (Kolozsi et al., 2009) and for genes involved in the differentiation of serotoninergic neurons, including Sonic hedgehog, its receptor Patched, and the transcription factors Gli1 and Pet-1 (Miyazaki et al., 2005). The latter effect delays differentiation, resulting in enhanced growth and abnormal distribution of serotoninergic pathways (Miyazaki et al., 2005; Tsujino et al., 2007). Neuroanatomical anomalies primarily include abnormal cerebellar cytoarchitectonics and brainstem nuclei formation (Ingram et al., 2000a; Rodier, 2002; Rodier et al., 1996). Particularly reminiscent of human autism are the local hyperconnectivity present in the neocortex and the abnormal morphology of motor cortical neurons, accompanied by delayed motor development (Rinaldi et al., 2008; Schneider and Przewłocki, 2005; Snow et al., 2008). Other neurochemical and behavioral abnormalities include increased monoamine concentrations due to enhanced expression of tyrosine hydroxylase (D'Souza et al., 2009; Narita et al., 2002), altered circadian rhythms (Tsujino et al., 2007), elevated nociceptive threshold and enkephalinergic tone (Schneider et al., 2001, 2007), abnormal fear conditioning and amygdala processing (Markram et al., 2008), increased LTP due to enhanced expression of NMDA receptors (Rinaldi et al., 2007), and a hyperactive mesocortical dopaminergic pathway (Nakasato et al., 2008). These human and animal data, in conjunction with data from Rett patients and MECP2 inactivation, strongly underscore the importance of epigenetic control over gene expression as an important player in autism pathogenesis (LaSalle, 2007; Schanen, 2006).

34.5.3 Other Teratogenic Agents: Thalidomide and Misoprostol

Thalidomide and misoprostol are two teratogenic drugs, known to induce a variety of systemic malformations. Thalidomide was commercialized as a sedative drug in the late 1950s before being withdrawn from the market in 1961. Teratogenicity is due to its angiogenesis inhibiting activity, which causes multiple systemic malformations, as well as abnormal cortical development and neuronal hyperexcitability (Hallene et al., 2006). Misoprostol is a methyl ester derivative of prostaglandin E1, used especially in Central and South America to treat gastric ulcers, but also a popular abortion inducer due to its powerful stimulatory effect on uterine contractions: the teratogenic effects of misoprostol have been studied in children born after unsuccessful abortion attempts (Bandim et al., 2003). These two drugs display several interesting parallels: both hamper fetal blood perfusion either directly (thalidomide) or indirectly (misoprostol); both produce systemic and especially ophthalmologic malformations, primarily coloboma and microphtalmos (Miller et al., 2004, 2005); both frequently cause prenatally exposed children to develop signs of Moebius sequence, including horizontal strabismus (Duane syndrome) and facial nerve palsy due to the involvement of the VI and VII cranial nerves (Bandim et al., 2003; Miller et al., 2005); both are associated with enhanced risk of autism and/or mental retardation, provided exposure occurs early in development (Miller et al., 2005; Strömland et al., 1994). The critical period for teratogenetic induction of autism has been defined in great detail for thalidomide, where it appears to be restricted to as early as 4–6 weeks into gestation (i.e., 6–8 weeks since the last menstrual cycle) (Miller et al., 2005; Strömland et al., 1994). The critical period for misoprostol has not been defined with the same precision, but it is known that maximum fetal vulnerability occurs during the first 2 months of pregnancy, and possible 5–6 weeks after fertilization (i.e., 7–8 weeks since the last menstrual cycle) (Bandim et al., 2003). Patients with idiopathic Moebius sequence and with no history of prenatal exposure to thalidomide or misoprostol have been found at enhanced risk of autism by some (Gillberg and Steffenburg, 1989), but not by others (Briegel et al., 2009). It will be important to determine conclusively whether there is a significant association between Moebius sequence and autism, because this would demonstrate that autism specificity is conferred more by a sensitive time window during development, rather than by the specific nature of prenatal insults or teratogenic mechanisms involved.

34.5.4 Environmental Pollutants as Potential Teratogens

The number of potentially teratogenic chemicals to which pregnant women may be exposed is theoretically elevated. In practice, prolonged and/or intensive exposure at critical times would be necessary to negatively influence development in any meaningful way (Rice and Barone, 2000). Such an exposure may occur in some geographical areas, primarily for ambient and

indoor air pollutants (exterminators, can sprays, and pest bombs), and for pesticides routinely used in agriculture (Landrigan, 2010; Zhang and Smith, 2003). Compounds for which preliminary evidence supports possible roles in enhancing autism risk include organochlorine pesticides, organophosphates (most clearly chlorpyrifos), heavy metals, and chlorinated solvents (Engel et al., 2007; Roberts et al., 2007; Whyatt and Barr, 2001; Whyatt et al., 2003; Windham et al., 2006). Prenatal exposure to organophosphates, such as chlorpyrifos, has been found to be associated with lower IQ, developmental delay, ADHD, and autism-spectrum traits defined as PDD-NOS (Eskenazi et al., 2008; Rauh et al., 2006). Some individuals may be genetically vulnerable to suffer from the consequences of prenatal organophosphate exposure, depending on functional genetic variants at loci such as *PON1*, the gene encoding for paraoxonase, and the HDL-associated serum enzyme responsible for organophosphate detoxification in humans (D'Amelio et al., 2005; Gaita et al., 2010). More definitive evidence linking autism, genetic vulnerability, and prenatal exposure to toxic agents is being sought through various efforts, including large epidemiological studies, such as the 'Childhood Autism Risks from Genetics and the Environment' (CHARGE) study (Hertz-Picciotto et al., 2006).

34.5.5 Congenital Viral Infections

Rubella and CMV represent the two infectious agents best known to enhance autism risk following a congenital infection (for review, see Libbey et al., 2005; van den Pol, 2006). Autistic children prenatally infected with these viruses generally present severe mental retardation and physical anomalies, such as ophthalmologic malformations, deafness, and cardiac malformations. Brain imaging findings are highly variable, ranging from cortical malformations (polymicrogyria, pachygyria, heterotopias) indicative of migration defects to abnormal intensity of the periventricular white matter suggestive of abnormal myelination in the absence of any cortical malformation. Epilepsy and cerebral palsy are also frequent.

34.5.5.1 Congenital Rubella

The largest longitudinal study involving several hundred children prenatally exposed to rubella virus estimates at 7.4% the rate of autism in this group; risk appears especially high if the infection occurs during the first 8 weeks postconception (Chess, 1971, 1977; Chess et al., 1978). Congenital rubella symptoms often change over time: some neurodevelopmental symptoms undergo remission, others are permanent, others may progressively worsen or even appear in late childhood or adolescence (Banatvala and Brown, 2004).

Interestingly, mental retardation and autism do not co-vary over time in these children, but seemingly follow independent trajectories (Chess, 1977). The occurrence of 'late-onset' autism (i.e., onset later than 3 years of age) following congenital rubella has also been reported (Chess et al., 1978).

These data should be viewed with some caution, because: (a) the incidence of ASD among 'rubella children' was estimated well before the establishment of current standards for a clinical diagnosis of ASD and (b) these variable clinical courses should be confirmed by applying current diagnostic criteria and modern tools for clinical follow-up. However, the former limitation can be predicted to lead to an underestimation of ASD incidence following congenital rubella, since ASD diagnostic criteria have now become overinclusive, as compared to Kanner's classical criteria which would have been applied in the seventies (Berger et al., 2010). Secondly, not only psychiatric, but also physical signs and symptoms of congenital rubella change significantly over time (the 'late manifestations' can even appear during adolescence or adulthood). Furthermore, even in idiopathic ASD, a spontaneous remission by age 3 of autistic behaviors diagnosed at a younger age is not an entirely unusual event (Turner and Stone, 2007; van Daalen et al., 2009). Finally, the partial spontaneous improvement of severe autistic behaviors rapidly developed by some children following postsurgical cerebellar vermal lesions without any specific rehabilitation (Riva and Giorgi, 2000) suggests that environmental etiologies can produce clinical courses more unstable than those seen in the majority of idiopathic ASD children.

34.5.5.2 Congenital Cytomegalovirus Infection

Evidence linking prenatal CMV infection to autism is more circumstantial. Several case reports have been published (Ivarsson et al., 1990; Kawatani et al., 2010; López-Pisón et al., 2005; Markowitz, 1983; Stubbs, 1978; Stubbs et al., 1984; Sweeten et al., 2004; Yamashita et al., 2003), but risk estimates are essentially based on a small cohort of seven prenatally CMV-infected children, two of whom displayed autistic features ($2/7 = 28.6\%$) (Yamashita et al., 2003). The presence of normal cortical gyri, indicating a substantial sparing of neuronal migration even in the presence of periventricular white matter abnormalities, led the authors to point toward the third trimester of pregnancy as the critical time window for autism-causing CMV infections (Yamashita et al., 2003). It remains to be determined to what extent autism ensues from direct viral damage, from the strong immune response driven by herpes viruses, such as CMV, or from the nature and location of cerebral malformations which are particularly frequent in congenital CMV infection (Engman et al., 2010).

34.5.5.3 *Future Perspectives: Possible Novel Roles for Congenital Viral Infections*

In addition to congenital rubella and CMV infections, our group is currently exploring vertical viral transmission as a novel mechanism potentially able to explain high 'heritability' (i.e., parent-to-offspring transmission) in the presence of relatively low rates of disease-specific genetic abnormalities (Maher, 2008). Viral genomes present in parental gametes (egg and/or sperm cells) could be passed onto the offspring already at the time of fertilization, and start being actively transcribed in permissive cells of the fetus only at a later stage during development (Lintas et al., 2010; Persico, 2010). Gamete-mediated vertical viral transmission has been well documented for several viruses, including human immunodeficiency virus, hepatitis B virus, and hepatitis C virus (Englert et al., 2004). Alternatively, seminal fluids could act as vehicles for viral transfer from father to offspring, passing horizontally through the mother. In either case, damage would be due to direct viral interference with cellular functions in permissive fetal cells, to maternal immune response prenatally, and to the patient's immune response in the late prenatal and postnatal periods.

We have recently found the genomes of polyomaviruses (BKV, JCV, and SV40) in *post-mortem* temporo-cortical tissue (Brodmann areas 41/42) belonging to 10/15 autistic patients and 3/13 controls ($P < 0.05$) (Lintas et al., 2010). Also, a trend toward poly-viral infections, including multiple polyoma and/or other neurotropic viruses, was recorded (40% vs. 7.7%, respectively; $P = 0.08$). Congenital polyomavirus infections, either alone or in synergy with other viruses, could conceivably explain several puzzling features of autistic disorder, as discussed in Lintas et al. (2010). Briefly, (a) converging experimental approaches have demonstrated an inappropriate and persistent activation of the innate immune system, compatible with an unresolved, early-onset viral infection accompanied by autoimmune phenomena (Garbett et al., 2008; Lintas et al., 2009; Vargas et al., 2005); (b) polyomaviruses can cause autoimmune disorders (Rekvig et al., 2006), which are also frequently encountered in first-degree relatives of autistic patients (Comi et al., 1999); (c) polyomaviruses can produce genomic instability through the activity of their early gene product large-T antigen (LTAg) (Frisque et al., 2006); (d) polyomavirus replication is more active in males, as witnessed by viruria consistently higher in males compared to females (Knowles, 2006); (e) JCV can indeed infect cultured neural progenitor cells, oligodendrocytes and astrocytes, whereas neurons are nonsusceptible to JCV infection (Hou et al., 2006); (f) following transformation of canine MDCK cells and human mesothelial cells, the LTAg of SV40 polyomaviruses has been shown to induce the production and secretion of HGF, which in turn activates by phosphorylating its receptor encoded by the *MET* gene (Cacciotti et al., 2001), which hosts some of the most consistently replicated common variants conferring vulnerability to autism (see Section 34.5.3); and (g) a recent MRI study documented for the first time the presence of temporal lobe and/or white matter abnormalities similar to those produced by viral infections, in as many as 36% of autistic children (Boddaert et al., 2009).

These preliminary results should be viewed with caution, because polyomavirus infections in autistic brains could be the consequence of immunosuppression or tissue susceptibility rather than the cause of autism (Persico, 2010). Furthermore, viral infections may have been active only prenatally and during early infancy, making it difficult to assess viral roles using biomaterials collected later in life. We are currently undertaking a thorough search of polyomaviruses in male gametes of fathers of autistic children and controls, which has already confirmed that a sizable percentage of mobile sperm samples from ASD fathers host polyomavirus genomes (Lintas and Persico, unpublished results), as previously shown by others for control samples (Martini et al., 1996). It will be very interesting to assess whether polyomavirus genomes extracted from mobile sperm cells are able to develop a cytopathic effect in permissive cells following transfection.

34.6 CONCLUSIONS: WHERE AND HOW DO COMMON VARIANTS MEET WITH RARE VARIANTS AND/OR WITH THE ENVIRONMENT?

A single pathophysiological scenario is clearly not compatible with the diversity of nonsyndromic autisms. Yet, the data summarized in this survey allow one to reach some firm conclusions and foster evidence-based speculation.

(1) Specific rare genetic variants have been convincingly shown to cause autism, at least in some cases; however, genotype–phenotype correlations are extremely labile. Not only can mutations located in the same gene result in very different clinical phenotypes, as repeatedly described in Tables 34.5–34.9 for multiple genes: the very same mutation can cause behavioral and morphological phenotypes displaying a surprising degree of variability in different patients, even in affected members of the same extended family. A clear example, introduced in Section 34.3.4.1, is provided by interindividual differences in cerebrovascular malformations seen in individuals from consanguineous families homozygous for

truncating *HOXA1* mutations, each resulting in HoxA1 protein isoforms lacking all functional domains (Bosley et al., 2007; Tischfield et al., 2005). This phenotypic variation is not at all novel in human genetics (Wolf, 1997): a similar degree of interindividual phenotypic variability occurs in syndromic forms due to well-characterized mutations, triplet repeat expansions, or genomic rearrangements, such as fragile-X syndrome or tuberous sclerosis (Table 34.3). This phenotypic variability closely mimics the impressive phenotypic variability seen when a gene inactivated by homologous recombination is backcrossed onto the genetic backgrounds of different mouse inbred strains (Doetschman, 2009). These phenotypic differences clearly emphasize the importance of common genetic variants ('genetic background,' 'modifier genes') in determining the penetrance and expressivity of rare variants.

(2) CNV studies performed to date provide several indications. Briefly: (a) estimates of the percentage of ASD patients and population controls carrying CNVs are likely to increase with the improvement of available technologies; (b) if there truly is a subgroup of ASD patients with excessive genomic instability, its size is relatively small (≤10%) and thus subject to high stochastic variability in independent samples; (c) CNVs *per se* may be more immediately related to evolution than to health and disease: their presence in population controls is physiological, subject to high stochastic variability in independent human samples and may be related to increasing paternal age according to rodent models (Flatscher-Bader et al., 2011); (d) when pathogenic, CNVs seemingly act as rare variants with variable penetrance and expressivity: some *de novo* CNVs may act dominantly and even display complete penetrance, while other CNVs may follow a 'quasi-recessive' mechanism, as described by Zweier et al. (2009) for *NRXN1* (see Section 34.3.2.3) and in a recent report by Vorstman et al. (2010), who identified an autistic individual carrying a maternally inherited deletion and a paternally inherited nonsynonymous amino acid substitution, both affecting the *DIAPH3* locus in human ch. 13q21.2; (e) the genomic location of a CNV is more critical to its pathogenic potential than the total number or mean size of CNVs present in a given individual. CNVs most frequently encountered in ASD patients often encompass genes which, when mutated, are responsible for monogenic forms of autism, such as *NLGN4*, *SHANK3*, and *NRXN1*; (f) the progressive transfer of array-based approaches from the laboratory into clinical

practice will indeed enhance the ability of clinicians to detect an increasing number of submicroscopic *de novo* chromosomal abnormalities; (g) deletions and duplications spanning entire genes affect expression only in a minority of 'gene dosage-sensitive loci,' as only approximately 29% of genes duplicated in trisomy 21 are actually overexpressed at or above RNA levels predicted on the basis of allele copy number (Aït Yahya-Graison et al., 2007; Lockstone et al., 2007). Homeostatic mechanisms regulating gene expression through *trans*-acting elements and noncoding RNAs can exert negative feedbacks able to establish close-to-normal gene expression levels. Hence, the conclusive definition of a given CNV as the primary cause of ASD in a given patient cannot be exclusively based on genomic data, as currently proposed (Kaminsky et al., 2011; Miller et al., 2010), but requires functional demonstration of abnormal gene expression in patient-derived cells or cell lines. Genomic evidence of *de novo* status or the absence of a patient's CNV in a very large sample of control chromosomes should be regarded as highly suggestive, but not as conclusive evidence of pathogenicity until gene expression correlates are demonstrated.

(3) Environmental factors can represent the primary cause of autism in some cases. Toxic and viral agents generally also produce major/minor malformations and neurological signs, essentially due to brainstem damage. However, no environmental teratogen or congenital infection causes autism in every single exposed subject, as summarized in Section 34.5. This again underscores the permissive role of common genetic variants, which determine the sensitivity threshold to environmental teratogens and infectious agents. Given the prenatal timing of autism-inducing teratology, more attention should be paid to common genetic variants characterizing the 'feto-maternal' unit, rather than merely the offspring.

(4) Stochastic events typically represent an overlooked nuisance to scientists, but they have been shown to provide significant contributions to deranged developmental processes (Kurnit et al., 1987). Part of the variance in affection status, symptom pattern, and disease severity currently attributed to common genetic variants may actually depend on stochastic events, possibly 'personalizing' genotype–phenotype correlations on top of differences in genetic background.

(5) A history of clinical regression, even when documented by home videos, does not necessarily imply the existence of environmental factors striking at the time when behavioral abnormalities

become manifest. Several children carrying pathogenic mutations in *NLGN* genes or in *EIF4E* ever since conception undergo apparently normal development until a severe regression occurs at approximately 2 years of age, with loss of initially acquired social and verbal milestones (see Sections 34.3.2.1 and 34.3.4.3. Regression may, thus, simply stem from a functional collapse of neural networks, occurring at the time when either they should come 'online' to support the harmonious expansion of social cognition or they are overwhelmed by pathological levels of oxidative stress or other dysfunctional processes (see below).

(6) Environmental forms indicate that pathogenic processes responsible for autism must act early on in neurodevelopment, possible as early as weeks 4–8 post-conception. An exclusively postnatal exposure of a non-genetically-vulnerable individual to prolonged psychological traumas, toxic chemicals, infectious microorganisms, and pathological reactions to vaccines, may in some cases produce psychopathology, but this is clearly distinguishable from autism (the closest example being the 'quasi-autism' of Romanian adoptees institutionalized until adoption and grown in a state of early deprivation of interpersonal contacts, which has a distinctive set of symptoms and a generally more favorable prognostic outcome, as described by Rutter et al. (2007)). In addition, autism induction may be more related to the prenatal timing of the pathogenic insult than to the nature of the insulting agent *per se*.

(7) *SHANK3*, *NRXN1*, *NLGN3*, and *NLGN4* are commonly addressed as 'synaptic genes' and their role in synaptogenesis is often depicted as critical in determining the functional disconnection of distant cortical and subcortical regions, which seemingly characterizes the CNS of autistic patients (Belmonte et al., 2010; Courchesne and Pierce, 2005; Geschwind and Levitt, 2007; Rubenstein and Merzenich, 2003). The major limit of this interpretation is that the peak of synaptogenesis in association cortices occurs late in human neurodevelopment, namely around 2 years of age. This timing is incompatible with abnormalities in cell proliferation and migration clearly documented by neuroanatomical studies of post-mortem brains and with the early prenatal timing of environmental insult in teratological forms. Furthermore, *NLGN* knockout mice and mice carrying human mutations, such as R451C, display relatively modest behavioral phenotypes overall in comparison to the severity of human autism (Chadman et al., 2008; Radyushkin et al., 2009). Finally, *NLGN* gene inactivation in *C. elegans*

surprisingly yields increased sensitivity to oxidative stress as one of its main biochemical features (Hunter et al., 2010). Hence, the critical pathogenetic step may not consist in reduced synapse formation, which has never been convincingly described in ASD brains; it may also not consist in structural abnormalities of long-range neural pathways, which have been assumed to exist on the basis of neurophysiological data more than being demonstrated neuroanatomically; instead, it could consist in the excessive energy requirements imposed on brain cells by malformed and malfunctioning synapses, leading to excessive oxidative stress and consequent functional disconnections (Chauhan and Chauhan, 2006; Palmieri and Persico, 2010; Palmieri et al., 2010).

(8) Abnormal growth rates, either of the head alone or more often of the whole body, represent a frequent feature in autistic children, especially during early infancy (Courchesne et al., 2007). Converging evidence from several syndromic forms strongly points toward the ERK/PI3K/mTOR pathway as playing a pivotal role in autism (Figure 34.1) (Levitt and Campbell, 2009; Ma and Blenis, 2009). A thorough understanding of intracellular pathways involved in autism pathogenesis will be critical, as novel treatments are beginning to show promise of reversing genetically determined abnormalities even in adult mouse models of PTEN haploinsufficiency, fragile-X, and Rett syndrome (Dölen et al., 2007; Tropea et al., 2009; Zhou et al., 2009). Different autisms converging downstream on an hyperactivation of the ERK/PI3K/mTOR pathway may clinically improve using pharmacological inhibitors of this pathway, regardless of the upstream genetic background responsible for generating this biochemical imbalance.

(9) Common genetic variants are typically considered as conferring autism vulnerability. However, genetic variants conferring protection from autism could be equally important. As a concrete example, subjects VII16, 17, 47, and 48 in Hope et al. (2005), despite carrying the very same I745T mutation in the *CACNA1F* gene yielding congenital stationary night blindness type-2 in 16 members of this extended family (see Section 34.3.5.1), do not suffer from autism or profound mental retardation, presumably through the action of protective gene variants. In families with an autistic proband, protective gene variants are preferentially transmitted from parents to unaffected siblings. Electrophysiological data indicate that 'unaffected' family members suffer from disconnections between distant cortical regions

similar to those affecting their autistic siblings, but can implement compensatory circuits which are apparently not available to affected family members (Belmonte et al., 2010). Protective genetic variants may consist in the 'non-predisposing' allele at some loci, but conceivably there should be instances where one allele can be pathogenically neutral and the other can be exquisitely protective, as occurs with the sickle cell anemia allele conferring protection from malaria (Allison, 2009). *SLC25A12* and *GLO1* are two examples of genes possibly hosting common protective variants (Palmieri et al., 2010; Sacco et al., 2007b).

(10) Neuroanatomical, genome-wide expression, and brain imaging studies provide converging evidence of an abnormal activation of the immune system in autism, and particularly of its innate components (Garbett et al., 2008; Laurence and Fatemi, 2005; Petropoulos et al., 2006; Vargas et al., 2005; for review of genome-wide expression studies, see Sacco et al., 2011). This could be due to abnormal synaptic function and/or molecular processing leading to proinflammatory cytokine production, as occurs in Alzheimer disease (Meda et al., 1999). However, temporal lobe abnormalities reminiscent of virally generated lesions have been detected in 48% of autistic children in a recent brain imaging study (Boddaert et al., 2009). These results are compatible with the presence of a persistent, virally triggered immune reaction in a subgroup of genetically predisposed autistic children. Studies of vertically transmitted viruses are thus justified, as they may thus contribute to solve the mystery of the 'missing heritability' (Maher, 2008) in autism research.

(11) In a translational perspective, it may be initially easier to estimate autism risk using a limited set of the most influential common variants, than to search for rare or private variants by sequencing a large enough panel of candidate genes, if not the entire genome. A first example of a test providing combinatorial autism risk estimates from four loci, each hosting one common biallelic SNP, has recently been published (Carayol et al., 2010). As the number of common variants will increase, current 18% sensitivity will hopefully rise to match an already satisfactory 92% specificity (Carayol et al., 2010). In general, this diagnostic approach will be most useful in estimating the risk of autism in (a) newborn siblings of autistic children and (b) sporadic cases displaying initial behavioral abnormalities at 1–2 years of age and potentially evolving by age 3 toward normal behavior, or into full-blown autism, softer ASD traits, specific language impairment, ADHD, or other behavioral syndromes. However, the latter use will require testing the specificity of common variants conferring autism vulnerability, which may not reliably separate behavioral syndromes given the labile genotype–phenotype correlations presented throughout this survey. Tests of this sort will be increasingly sought, as early behavioral intervention programs, targeted to address ASD signs and symptoms much earlier than age 3, have begun showing significant efficacy in controlled trials (Dawson et al., 2010; for review, see Rogers and Vismara, 2008; Howlin et al., 2009) and are being actively pursued in many clinical centers. Interestingly, treatment response is also not a uniform dimension, as post-treatment measures always display larger dispersion compared to pretreatment, indicating the presence of treatment 'responders' and 'nonresponders' (Dawson et al., 2010). Therefore, genetic and biochemical markers may also be sought to predict treatment response. Finally, the short-term efficacy of early intervention programs is comforting, though not entirely unexpected when considering that environmental enrichment largely reverses behavioral abnormalities in an animal model as 'organic' as rats prenatally exposed to valproic acid (Schneider et al., 2006), and in *MECP2* knockout mice (Lonetti et al., 2010). Early interventions most likely yield better outcomes because they act during critical periods of greater plasticity in postnatal brain development. It will be important to see whether behavioral improvements are permanent, or whether periodic/continuous maintenance treatment will be required, most likely through parent training strategies.

Neurodevelopmental Genomics of Autism, Schizophrenia, and Related Disorders

J.F. Cubells, D. Moreno-De-Luca

Emory University School of Medicine, Atlanta, GA, USA

35.1 INTRODUCTION AND HISTORICAL OVERVIEW

In 1943, Leo Kanner first described 'infantile autism' as "... children's *inability to relate themselves* in the ordinary way to people and situations from the beginning of life" (page 242, emphasis in original; Kanner, 1943). The modern Diagnostic and Statistical Manual of Mental Disorders, 4th edition text revision (DSM-IV TR; American Psychiatric Association, 2000), categorizes that classical syndrome as autistic disorder, which is thought of as a part of a heterogeneous spectrum of behaviorally defined disorders, the autism spectrum disorders (ASDs). By definition, the ASDs manifest clinically within the first 3 years of life; impair language, communication, and social interaction; and are typified by idiosyncratic interests and repetitive behaviors. In the DSM-IV TR, ASDs also include Asperger disorder, defined as the presence of autism symptoms in the absence of language

delay and intellectual disability (ID), and pervasive developmental disorder not otherwise specified, in which autistic features are present but do not meet full criteria for a diagnosis of autistic disorder (see Chapter 34).

Kanner explicitly borrowed his diagnostic term from Eugen Bleuler (1950), who used 'autism' to describe the process of withdrawal into one's own world, which he identified as a hallmark of a heterogeneous set of adult behavioral disorders in his classic book, *Dementia Praecox or the Group of Schizophrenias.* Today, 'schizophrenia' refers to a set of behaviorally defined syndromes, the diagnostic features of which include 'positive symptoms' such as hallucinations, delusions (firmly fixed false beliefs not explained by cultural context), thought disorder, and disorganized or bizarre behavior and 'negative symptoms' such as apathy, anhedonia (inability to feel pleasure), and social withdrawal. Schizophrenia is one of several 'schizophrenia spectrum disorders' (SSDs) that include schizoaffective disorder, in which

cycles of depression and/or mania occur together with chronic psychosis, and psychotic disorder not otherwise specified, which includes individuals with psychosis who do not meet full criteria for schizophrenia. Family studies also suggest that a nonpsychotic syndrome, called schizotypal personality disorder, is part of the schizophrenia spectrum (Kety et al., 1971, 1994; Tienari et al., 2003). To avoid the misconception that either autism or schizophrenia is a unitary disorder, we will use the terms ASD and SSD throughout this chapter.

35.2 PHENOTYPIC SIMILARITIES AND DIFFERENCES BETWEEN ASD AND SSD

ASD and SSD both produce lifelong disability and, as we have seen from the history of their nosology, share as hallmark manifestations, impaired abilities to function in human social groups. ASD and SSD share many other phenotypic characteristics, but there are also some important differences. ASD and SSD patients share higher rates of ID (Bhaumik et al., 2008; Hemmings, 2006; Matson and Shoemaker, 2009; Morgan et al., 2008), epilepsy (Ep; Gaitatzis et al., 2004), and motor disturbances (Welham et al., 2009) compared with the general population. To make a diagnosis of an ASD according to the criteria of the DSM-IV-TR, behavioral signs of the disorder must be evident by the age of 3 years. In contrast, SSDs are usually first diagnosed during late adolescence or early adulthood. However, cases meeting diagnostic criteria for SSD clearly occur during childhood (Rapoport, 2009) and mounting evidence suggests that neurobehavioral impairments often precede the onset of full-blown SSD, a clinical phenomenon known as the schizophrenia prodrome (Thomas and Woods, 2006). Manifestations of the schizophrenia prodrome include unusual beliefs and patterns of thought, learning disabilities, minor neurological abnormalities, social withdrawal, and problems with peer relationships. Such differences are readily detectable in many cases, such as in a classic study in which raters, unaware of current diagnosis, observed childhood home movies of patients' families and were able reliably to identify the child destined to develop SSD years later (Walker and Lewine, 1990). Thus, as with ASD, neurodevelopmental dysfunction is often evident early in the lives of patients with SSD.

ASDs are approximately fourfold more common in males than females (Control, 2009). In contrast, there appears to be little to no difference in the prevalence of SSD in males versus females (Saha et al., 2005). However, good evidence supports the conclusion that SSD in males tends to be earlier in onset with a less favorable course over the lifespan than in females (Angermeyer et al., 1990; Hafner et al., 1993), so there

is some degree of sexual dimorphism in SSD. The range of impairment in psychosocial function across affected individuals is broad for both ASD and SSD, with some patients able to integrate into society and function independently, most exhibiting substantial and lifelong need for help in coping with being part of society, and severely affected individuals exhibiting profound impairment that destroys their abilities to care for themselves or function even minimally in society. From the information just reviewed, it is reasonable to view ASD and SSD as partially distinct sets of neurodevelopmental disorders (NDDs) that share a variety of phenotypic features.

35.3 GENETIC MECHANISMS IN ASD AND SSD

35.3.1 Heritability of Risk for ASD and SSD

ASD and SSD exhibit similar degrees of risk heritability. Family studies show that the recurrence risk for ASD and SSD in siblings of affected individuals is approximately 5–10%, which is substantially greater than the ~1% prevalence of either set of disorders in the general population. Additionally, twin studies show concordance rates in monozygotic twins to be substantially higher than in dizygotic twins for both ASD (up to 90% vs. ~10%) and SSD (up to 80% vs. ~10%), leading to heritability estimates of 0.8–0.9 (Folstein and Rosen-Sheidley, 2001; Losh et al., 2008; Riley and Kendler, 2004).

35.3.2 Overlapping Molecular Genetic Associations in ASD and SSD: Single Genes

In some cases, SSD and ASD appear to share common, or at least substantially overlapping, genetic etiologies. Table 35.1 shows a list of genes in which mono- or biallelic mutations or loss-of-function, single-gene copy number variants (CNVs) have been involved in the etiology of both ASD and SSD. Interestingly, these genes encode synaptic or cell adhesion molecules, which play important roles in neural development and therefore appear to be excellent candidates as key players in the pathophysiology of ASD and SSD (Guilmatre et al., 2009).

At the moment, however, the greatest apparent overlap of genetic factors in ASD and SSD comes from recent discoveries regarding the role of genomic CNV (defined below) in both sets of disorders as well as in other neurodevelopmental conditions including Ep and ID. Although CNVs have thus far been associated with ASD and SSD only in small proportions of patients, the number of CNVs associated with both sets of disorders continues to grow. Even if they account only for a minority

TABLE 35.1 Genes Associated with Both ASD and SSZ Through Loss-of-Function Single-Gene CNVs and/or Functional Mutations

Gene symbol	Chromosomal location	Gene name	OMIM ID	ASD references	SSD references
SHANK3	22q13.3	SH3 and multiple ankyrin repeat domains 3	606230	Durand et al. (2007) and Gauthier et al. (2009)	Gauthier et al. (2010)
CNTNAP2	7q35	Contactin-associated protein-like 2	604569	Strauss et al. (2006) and Zweier et al. (2009)	Friedman et al. (2008)
NRXN1	2p16.3	Neurexin 1	600565	Ching et al. (2010), Wisniowiecka-Kowalnik et al. (2010), and Zweier et al. (2009)	Ikeda et al. (2010) and Rujescu et al. (2009)

of cases, CNV-associated cases of ASDs and SSDs promise to be invaluable for understanding specific relationships between genetic differences and disorder-related phenotypes, by virtue of the clarity with which associations can be established between genetic differences (i.e., presence vs. absence of a CNV) and individual patients. Thus, by understanding similarities and differences among patients carrying a common CNV but diagnosed clinically with an ASD, an SSD, or both, we may be able to elucidate meaningful differences, and commonalities, in developmental and pathophysiological processes leading to one set of disorders or the other.

35.4 CNV IN THE GENOME: KNOWN FOR DECADES, UNDERAPPRECIATED UNTIL RECENTLY

Large-scale variation in the genome, such as chromosomal rearrangements, duplications, and deletions, has been known to cytogeneticists for many decades. However, the recent advent of molecular methods allowing high-resolution examination of the entire genome, such as array comparative hybridization (aCGH; Cowell, 2004) and genome-wide single-nucleotide polymorphism (SNP)-genotyping platforms (Ding and Jin, 2009), has led to a much fuller appreciation of how common and how relevant to complex neurobehavioral disorders such large-scale variation actually is. CNVs comprise a class of genomic variants in which long stretches of DNA, ranging in size from thousands to millions of base pairs (bp), occur in variable numbers of contiguous copies on chromosomes from different individuals (Zhang et al., 2009). While some CNV appears to be 'private,' occurring only within a single individual or family, recurrent CNV can be identified at specific locations in the genome in unrelated individuals.

35.4.1 Genomic Architecture Predisposing to Recurrent CNV

The most frequent overlapping rearrangements are usually recurrent and arise from nonallelic homologous recombination (NAHR), where a segment of unique DNA sequence (50 kb–10 Mb) is lost or duplicated due to the presence of flanking segmental duplications, or low-copy repeats (LCR) – large (>10 kb), highly repetitive (>95% homology), DNA sequences that predispose to genomic instability (Dibbens et al., 2009). When two of these paired segmental duplications are found in the same orientation along the chromosome, they can be improperly aligned during meiosis, leading to the duplication of the intervening sequence in one allele and the deletion of this same region in the other; this is the mechanism behind NAHR. Interestingly, some of the regions in which these recurrent deletions occur also harbor inversion polymorphisms which change the orientation of the paired LCR from inverted, or facing on different directions along the chromosome, to aligned, hence greatly increasing the chance of NAHR occurring. In some instances, the presence of the appropriate inversion allele is necessary for the CNV to occur, as is the case for the 17q21.31 region (Alkan et al., 2009; Sharp et al., 2006).

LCR-mediated NAHR thus repeatedly generates within the population recurrent CNV that is identical or nearly so in size and location. Recognition of recurrent CNV in research and clinical settings has increased tremendously over the past few years, leading to the identification of several previously unknown genomic disorders in which autism and/or schizophrenia is part of the phenotype. As the number of array-based research studies and diagnostic procedures increases, and collaborative pooling of information across research and clinical laboratories grows, more recurrent the CNV that causes or predisposes to NDD.

35.5 RECURRENT CNV ASSOCIATED WITH ASD, SSD, AND OTHER NDDS

The remainder of this chapter will focus on recurrent CNVs and their associations to ASD, SSD, and often other NDDs such as Ep (see Chapter 36) and ID. Emerging evidence implicates a growing list of CNVs that associate with ASD, SSD, and other NDDs. This emerging pattern of common CNVs playing a

presumably causal role in diverse phenotypic outcomes suggests that subgroups of patients with clinically different disorders manifest variable phenotypes arising from common underlying genetic disturbances. It appears likely that at least some of the commonality of risk elevation in ASD, SSD, and other NDDs reflects disruption in fundamental brain developmental processes, some of which might be responsive to specific environmental conditions, epigenetic events, or influences of specific loci distant from the CNV that could influence the trajectory of phenotypic outcome. Identifying and disentangling factors associated with variation in phenotypic outcomes among carriers of specific recurrent CNVs are a major challenge, yet meeting that challenge promises to shed light on the basis for ASD, SSD, and other NDDs. Phenotypic studies of participants specifically ascertained by CNV status will be an important first step toward understanding the phenotypic variability associated with recurrent CNVs. We propose that studies ascertaining participants according to the presence or absence of specific sets of CNVs and focusing on a broad variety of behavioral, cognitive, physiological, metabolic, cellular, and molecular phenotypes are likely to be productive strategies for understanding the relationship of ASDs to SSDs and other NDDs.

In other words, if the goal is to organize developmental and neurobiological analysis of NDDs according to biologically meaningful criteria, then direct ascertainment of cases by CNV status will be superior to doing so by phenomenology. The former approach offers the opportunity to ascertain cases on the basis of likely molecular etiology, while the latter has proved unreliable for classifying cases according to similar mechanisms of clinical risk. Where cost, ethical concerns, and territoriality in scientific funding priorities are not important

constraints, CNV would ideally be ascertained in population-based samples of infants at birth, and cases defined by CNV status would be followed prospectively together with demographically matched noncarrier controls. Although in the short-term ascertainment of CNV within large phenotypically identified collections, such as the AGRE resource (Lajonchere, 2010), is the most practical approach to studying CNV and NDD, the ascertainment bias inherent in identifying cases by nonspecific behavioral phenotypes will plague the field until unbiased molecular ascertainment of CNV carriers (some of whom will have only very mild, or absent, clinical phenotypes) becomes a reality in neurodevelopmental epidemiology.

Table 35.2 lists recurrent CNV associated with ASD and SSD, as well as other NDDs (most commonly ID or Ep). Note that most of these pathogenic recurrent CNVs also associate with a large variety of medical and anatomic disorders (the list of such associated disorders probably remains incomplete). Although a detailed discussion of the medical complications of CNV disorders is beyond the scope of this chapter, their presence is very important because it emphasizes the urgent need to begin training clinicians and educators who evaluate ASD, SSD, and other NDDs to include CNV disorders in the differential diagnosis so that appropriate referral for cytogenetic evaluation can be made, and medical as well as behavioral interventions can be instituted. Recently, Miller and colleagues (Miller et al., 2010) suggested that testing for CNV by microarray be made standard of care for evaluation of ASD and ID. No such suggestion has been published for SSD, although in our view, such testing should at least be considered when there is clinical evidence suggesting CNV (e.g., the simultaneous presentation of psychosis and ID). Bassett and Chow (1999)

have elaborated specific clinical criteria indicating testing by fluorescent *in situ* hybridization (FISH) for 22q11 deletion syndrome (22q11DS) in patients with SSD. Such criteria need reevaluation and expansion as microarrays are rapidly supplanting FISH as the primary molecular–cytogenetic diagnostic procedure (FISH remains essential for confirmation of positive microarray results). The need to consider genome-wide testing for recurrent and rare CNV during the work-up of SSD is, in our view, a critical area for future translational research.

In the following sections, we briefly review current knowledge regarding the relationship of specific recurrent CNV to ASD and SSD. The discussion begins with a review of the 22q11 deletion syndrome (22q11DS) because the molecular basis of 22q11DS has been known for 2 decades, and its associations to NDDs have been most extensively studied. We regard 22q11DS as a prototypic CNV disorder, as it exhibits the phenotypic heterogeneity (i.e., variable expressivity) and variable penetrance that appear to be common to all SSD- and ASD-related CNV disorders thus far described. Following discussion of the 22q11DS, we will review the other disorders listed in Table 35.3 in order of the chromosomes they affect, and then will conclude with remarks on implications and future directions for neurodevelopmental research.

35.5.1 22q11.2 Deletion Syndrome: The Prototypic CNV Disorder

First described in an autopsy series of four infants (Kirkpatrick and DiGeorge, 1968), DiGeorge syndrome (DGS) referred to a constellation of severe immune deficiency and findings suggestive of maldevelopment of the third and fourth pharyngeal arches, including thymic aplasia, parathyroid hypoplasia, and abnormalities of the aortic arch. Additional syndromes, called conotruncal anomaly face (CTAF) syndrome in a case series from Japan (Kinouchi et al., 1976) and velocardiofacial syndrome (VCFS) in another series from the United States (Shprintzen et al., 1978), consisted of velopharyngeal anomalies, cardiac anomalies, typical facial appearance, learning disabilities, and speech and language problems. In 1991, Scambler and colleagues reported that microdeletions at 22q11.2 associated with sporadic and familial DGS, and subsequent studies soon showed the majority of cases of DGS, CTAF, and VCFS were all associated with similar deletions (Burn et al., 1993; Carey et al., 1992; Scambler et al., 1992). Although all the foregoing syndrome designations are still in use, it is clear that the term 22q11DS subsumes almost all of the cases meeting the various phenotype definitions just reviewed and is therefore the most appropriate designation for this common CNV disorder (estimated at 1/4000 live births; Botto et al., 2003).

Behavioral manifestations in 22q11DS vary widely (Ousley et al., 2007) but are common in children and adults. By the mid-1980s, behavioral difficulties in children with VCFS had been described (Golding-Kushner et al., 1985), and psychosis in adolescents with the disorder was reported in 1992 (Shprintzen et al., 1992). Pulver and colleagues confirmed that schizophrenia was common in patients with 22q11DS (Pulver et al., 1994), and Karayiorgou and colleagues found several previously undiagnosed cases of 22q11DS in a series of patients with schizophrenia diagnosed solely on the basis of clinical presentation (Karayiorgou et al., 1995). The latter study was a landmark because it raised the prospect that a small but clinically and epidemiologically significant proportion of the SSD population carried undiagnosed 22q11 deletions. It is now clear that 22q11DS occurs at a low but nontrivial rate (~0.75%, about 30-fold more

TABLE 35.3 Candidate Genes in the 22q11 Deletion Region Plausibly Contributing to Risk for SSD or ASD

frequently than in the population at large; Hoogendoorn et al., 2008) in clinically diagnosed SSD patients. Selecting specific phenotypic characteristics prior to molecular testing (e.g., facial dysmorphology, conotruncal heart defects, high-arched palate or cleft palate, ID) can substantially increase the diagnostic yield for the deletion in cohorts of patients with SSD (Bassett and Chow, 1999).

The most common 22q11 deletion (~80% of cases) is approximately 3 megabases (Mb) long, occurring between two LCRs flanking the deletion (Edelmann et al., 1999a, 1999b). Two additional LCRs lie within the 3 Mb deletion region and account for the majority of remaining deletions (~10% of 1.5 Mb and the rest of varied size). The 3-Mb region encompasses 40 genes, and several of these appear to be compelling candidates as genes contributing to SSD risk. However, none of them has yet been confirmed with sufficient confidence to call them 'schizophrenia genes.' Table 35.3 summarizes candidate genes residing within the 22q11DS region for which there is some evidence (usually mixed positive and negative results) supporting associations to risk for SSD.

It is worth noting that even accepting only the positive evidence supporting associations of individual loci within the 22q11DS region as the truth, the effect sizes of those associations are much smaller than the magnitude of the association of the 22q11 deletion itself with SSD (OR <1.5 for any given locus vs. OR ~20 for 22q11DS). It is thus possible that hemizygosity of multiple genes within the 22q11DS region, each of small individual effect, somehow synergizes to produce a more substantial influence on brain development when risk genes in the region are affected simultaneously. Alternatively, it is possible that deletion of single copies of multiple genes creates numerous opportunities for deleterious effects of risk loci elsewhere in the genome. While speculative, such hypotheses are useful because they suggest specific strategies for examining how 22q11DS elevates risk for SSD, ASD, or other NDDs. For example, a genome-wide analysis of variants in 22q11DS patients affected or unaffected by ASD, SSD, or both could identify specific loci elsewhere in the genome that elevate developmental sensitivity to the effects of hemizygosity of loci at 22q11.

The above summary shows that exciting progress has been made in understanding potential genetic mechanisms in SSD related to 22q11DS. Several genes involved either in neurotransmission, neuronal function, or development may be contributing to risk for SSD. The association of 22q11DS to ASD was described only relatively recently (Antshel et al., 2007; Vorstman et al., 2006), so fewer studies of ASD and individual genes within the deletion region have been published.

However, a recent study comparing symptom profiles among ASD patients with 22q11DS, those with Klinefelter syndrome (KS: karyotype 47 XXY), and ASD patients with no specifically defined genetic syndrome suggested that the ranges of overall ASD symptoms in both 22q11DS and KS were narrower than in the idiopathic group and differed from each other (Bruining et al., 2010). Discriminant function analysis of symptom scores (derived from the Autism Diagnostic Interview, Revised) showed clear distinctions in the profiles of each group. While the study can be criticized for several methodological difficulties (e.g., the patient samples were ascertained separately, thus introducing the possibility of selection bias), it is an important step forward because the results suggest that specific aspects of the broad ASD phenotype may specifically associate with definable genetic differences among patients. If true, such associations could form the basis for dissection of genetically regulated developmental pathways leading to specific 'points' in the 'phenotypic space' of ASD and may also provide a basis for comparing pathways leading to ASD versus SSD.

Finally, 22q11DS may serve as an important prototype for demonstrating the clinical importance of diagnosing specific CNV disorders in patients whose clinical presentation is entirely or predominantly behavioral. From the earliest days, DGS was known to associate with hypocalcemia that in its most severe form could lead to fatal status epilepticus. Hypocalcemia in 22q11DS results from the variable degree of parathyroid hypoplasia that occurs in those afflicted and can vary over an individual patient's lifetime. The condition can usually be corrected by dietary supplementation with vitamin D and calcium, but to establish the diagnosis, clinicians must test ionized serum calcium levels, rather than rely on the total calcium levels available in standard metabolic panels. The failure to test specifically for ionized calcium in patients with 22q11DS can lead to poor clinical outcomes. For example, SSD patients are almost always treated with antipsychotic medications. As a class, those agents tend to lower the seizure threshold. Clozapine is an antipsychotic medication that is among the worst offenders in terms of its effect on seizure threshold but remains a uniquely effective treatment in some patients whose psychotic symptoms do not respond well to other antipsychotic medications (Kane et al., 1988). Patients with SSD, 22q11DS, and untreated hypocalcemia who are given clozapine will be at extremely high risk for seizures owing to the synergistic effects of low calcium and the medication. Clinicians unaware of the patient's 22q11DS diagnosis would almost certainly discontinue clozapine when the patient has a seizure after starting clozapine. In that scenario, prophylactic administration of vitamin D and calcium, rather than discontinuation of clozapine, would have been an unexplored therapeutic alternative. Failure to diagnose 22q11DS in the ~0.75% of SSD patients who carry such deletions can thereby deprive

them of potentially effective treatments. Such cases have been documented, so this matter is of more than theoretical interest (Caluseriu et al., 2007). As we learn more about the large variety of clinical management issues associated with each CNV disorder, moving from phenomenological diagnosis to molecular diagnosis of NDD promises to become increasingly valuable for patient care.

35.5.2 1q21 Deletions

With the advent of cytogenomic array testing, recurrent deletions of 1q21, as well as several other genomic disorders that went previously undetected, have been identified in the last few years. This CNV spans 1.35 Mb and was originally identified in a large cohort of patients with schizophrenia (Stefansson et al., 2008). The 1q21 deletion was detected in 11 out of 4718 cases with schizophrenia (0.23%), compared to 8 of 41199 controls (0.02%), providing compelling evidence of the association of this CNV and schizophrenia. Almost simultaneously, the identical CNV was identified in patients referred for clinical testing with a wide array of phenotypic features, which include isolated heart defects, cataracts, Müllerian aplasia, and microcephaly (Mefford et al., 2008). It is noteworthy that patients with the reciprocal 1q21 duplication have macrocephaly, pointing toward a dosage-sensitive gene involved in head growth. Additionally, several of these patients had a behavioral phenotype manifesting as ASD (Brunetti-Pierri et al., 2008; Mefford et al., 2008). Differing from other well-known microdeletion syndromes, such as Angelman and Prader-Willi (15q11.q13 deletions), but similar to 22q11DS, deletions in 1q21 lead to wide phenotypic variability and are sometimes found in apparently unaffected parents of affected individuals. However, a thorough phenotypic assessment in these apparently unaffected parents frequently reveals a subclinical neurocognitive or behavioral phenotype (Girirajan and Eichler, 2010).

There are at least seven genes in the 1q21 deleted interval, although the one responsible for the behavioral phenotype of patients with this CNV has not been identified. *GJA5* and *GJA8* are both part of the connexin family of genes and play an important role in membrane junctions. Mutations in *GJA5* are known to cause atrial fibrillation, whereas mutations in *GJA8* give rise to cataracts. Interestingly, GJA8 has been previously associated with schizophrenia (Ni et al., 2007). However, the gene responsible for the neurobehavioral phenotype of these patients remains unknown.

35.5.3 3q29 Deletions

Causing another novel genomic disorder, microdeletions of 3q29 have been associated with a variable array of phenotypes, including mild-to-moderate mental retardation, slightly dysmorphic facial features, gate ataxia, and long tapering fingers (Willatt et al., 2005).

Also mediated by segmental duplications, this recurrent deletion is 1.6 Mb in size and contains 21 genes, several of which are interesting candidates for NDD. *DLG1* and *PAK2* are interesting candidates, as they are both autosomal homologs of well-described X-linked ID genes *DLG3* and *PAK3*. *DLG1*, also known as synapse-associated protein 97, also interacts directly with *PTEN* to inhibit axonal stimulation of myelination. This molecular brake is important in maintaining proper myelin thickness and, when removed, produces myelin outfoldings and demyelination. In fact, this brake ceases to function in peripheral neuropathies such as Charcot–Marie–Tooth (Cotter et al., 2010). Additionally, and perhaps most importantly, DLG1 interacts directly with AMPA and NMDA receptors, both key components of the glutamatergic synapse (Howard et al., 2010), in line with recent research showing the role of glutamatergic dysfunction in schizophrenia (Gaspar et al., 2009). *PAK2* also appears as an interesting candidate, as it regulates cytoskeleton dynamics, consequently regulating the morphology of the synapse and glutamate receptor complexes in the process (Kreis and Barnier, 2009).

35.5.4 15q13.2–13.3 Deletions

The proximal region of the long arm of chromosome 15 contains a series of five highly similar LCRs, which predispose this region of the genome to a variety of rearrangements (Mignon-Ravix et al., 2007: see Chapter 32). The most well known of such rearrangements consist of deletions between the two most proximal LCRs, giving rise to the imprinted disorders Prader-Willi syndrome or Angelman syndrome, depending on whether the deletion is paternally or maternally inherited, respectively. More distal deletions on chromosome 15, involving loss of DNA between the third and fifth or fourth and fifth LCRs, give rise to 15q13.2–13.3 deletion syndrome (15q13DS). Such deletions have consistently been identified in genome-wide association study (GWAS) of ASD (Miller et al., 2009; Pagnamenta et al., 2009) and SSD (Consortium, 2008; Stefansson et al., 2008). ID is common in 15q13.2–13.3 DS, as are difficulties with aggressive behavior and rage outbursts (Ben-Shachar et al., 2009; Miller et al., 2009; Sharp et al., 2008). Ep is also common in 15q13DS, with one study estimating this single set of CNVs to account for ~1% of idiopathic cases of Ep (Dibbens et al., 2009).

Among the loci deleted in 15q13DS is *CHRNA7*, encoding the α7 nicotinic acetylcholine receptor (α7nAChR). This observation is of great interest for at least two reasons. First, linkage and association studies have implicated *CHRNA7* as an important genetic modifier of an SSD-related physiological phenotype known as gating of the P50 auditory-evoked potential (P50-AEP). The P50-AEP is a positive deflection on EEG that

occurs ~50 ms after a brief auditory stimulus. Gating of the P50-AEP refers to the phenomenon in which an auditory stimulus shortly before the index stimulus attenuates the P50-AEP. Such gating is often impaired in persons with SSD, as well as in their unaffected relatives. Freedman and colleagues reported linkage between markers on 15q13 and P50-AEP gating in families segregating SSD (Freedman et al., 1997), and subsequent association studies suggested that variation at *CHRNA7* accounts for this linkage (Leonard et al., 1998). Together with the foregoing results, the association of 15q13DS with ASD and SSD suggests *CHRNA7* as a prime candidate gene relevant to altered development and function of the brain in ASD and SSD.

The second reason for specific interest in *CHRNA7* is that the pharmacology of the α7nAChR is well developed, with many compounds available for use in animal models and in some cases humans, which could be used as probes with which to examine the role of the receptor in development and possibly even for therapeutics. We recently described an adult male patient with 15q13DS, SSD, rage outbursts, and Ep, whose aggressive behavior was substantially attenuated by treatment with an acetylcholinesterase-inhibiting positive allosteric regulator of the α7nAChR, galantamine. The case provides at least a single example in which diagnosis of a CNV disorder led directly to altered pharmacotherapy in a clinical situation (Cubells et al., 2011).

35.5.5 16p11.2 Duplications

Weiss and colleagues (Weiss et al., 2008) performed a genome-wide search for recurrent CNV associated with ASD, using data from SNP-genotyping arrays from several large GWAS of ASD. They noted significant associations of *both* deletions and duplications in a ~590-kb region flanked by LCRs, located on chromosome 16p11.2. The finding was even more noteworthy because macrocephaly (enlarged head circumference), an endophenotype observed in a substantial minority of children with ASD, was also associated with the deletion at 16p11.2.

Simultaneously with the report of the Weiss et al. group, two other research teams reported associations between ASD and CNV at 16p11.2 (Kumar et al., 2008; Marshall et al., 2008). Importantly, one of those studies (Kumar et al., 2008) confirmed an association between 16p11.2 deletions and ASD using an independent molecular approach: array comparative hybridization. Although those investigators also found a single case of 16p11.2 duplication in their sample, they observed the duplication in two of their control subjects and therefore did not conclude the duplication associated with ASD. However, other studies have confirmed both the deletion and duplication as clearly associated with ASD

(Fernandez et al., 2010; Marshall et al., 2008), despite the variable expressivity highlighted by observations of apparently unaffected individuals occasionally carrying the duplication. Detailed examination of ASD probands carrying CNV at 16p11.2 revealed that the heterogeneous phenotypic spectra associated with these genomic variants include ID and variable facial dysmorphology (Fernandez et al., 2010). That study also found evidence suggesting that 16p11.2 deletions may be more penetrant with regard to ASD than are duplications. Another study confirmed the phenotypic heterogeneity associated with CNV at 16p11.2, adding Ep and motor delay to the manifestations associated with either the deletion or duplication, and attention deficit hyperactivity disorder to those associated with the duplication (Shinawi et al., 2010). Interestingly, that same study found macrocephaly to associate with the deletion and microcephaly (diminished head circumference) with the duplication.

McCarthy and colleagues reported that SSD are also associated with duplications (but not deletions) at 16p11.2 (McCarthy et al., 2009). Interestingly, consistent with earlier results in ASD, this group also observed an association of the 16p11.2 duplication with head circumference in the SSD sample, suggesting this endophenotype may not be specific to ASD but rather associated with the duplication and a broader risk for NDDs. If the 'specificity' of the association between SSD and only the duplication at 16p11.2 withstands more extensive study in additional cohorts of patients, such an observation could help distinguish genes within the CNV region that might more specifically predispose to ASD (when haploinsufficient) rather than SSD (when present in excess). However, more data are necessary before it is clear that only the duplication associates with SSD.

35.5.6 16p13.11 Deletions and Duplications

The short arm of chromosome 16 is particularly rich in LCRs (Martin et al., 2004), with the result that nonhomologous recombination events in the region are common. Thus, another set of recurrent CNVs distal to the 16p11.2 region just discussed occurs on 16p13.11. These CNVs vary somewhat in length, due to the complexity of the region, but most are ~1.4–1.65 Mb in length. Both duplications and deletions were originally described as associated with ASD and ID (Pinto et al., 2010; Ullmann et al., 2007), although apparently unaffected carriers of the duplications were identified in several families with affected members. However, a study that screened a large cohort of patients with ID or multiple congenital anomalies (MCA), as well as two cohorts of European-ancestry adults with no known evidence of NDD (but who were not specifically evaluated) found only the deletions to occur significantly more frequently in patients than in

the control individuals. Those observations led the authors of that study to suggest that duplications at 16p13.1–13.2 might be nonpathogenic variants. A more recent study, of >4300 patients with SSD and >35 000 controls ascertained in several European countries and evaluated using SNP-genotyping arrays, found an overall association between duplications at 16p13.1 and SSD, with approximately a threefold excess observed in the patient group. When the investigators classified the duplications according to their positions across three subregions of 16p13.1, they found a stronger association with duplications residing in the proximal two subregions (with respective odds ratios increasing from 3.27 to 7.27). The authors of the latter study, while acknowledging the difficulty of declaring duplications at 16p13.1 to be pathogenic, given heterogeneity in duplication size and the prior inconclusive results with regard to ID and MCA, argue that additional factors add to evidence that such duplications are pathogenic. They point out that the subregion analysis just summarized, in addition to strengthening the statistical association also identifies a strong candidate locus, *NDE1*. That gene encodes a protein that interacts with *DISC1*, which itself is the product of a strongly supported 'schizophrenia gene.' Another binding partner of *NDE1* is the gene product of *LIS1*, which is strongly associated with the severe NDD, lissencephaly.

35.5.7 17q12 Deletions

Deletions in 17q12 were until recently believed to be one of the few recurrent genomic disorders that spared the central nervous system. This 1.4-Mb recurrent deletion harbors the *HNF1B* gene, which is responsible for the renal cysts and diabetes (RCAD, MIM ID #137920) syndrome. Generally, affected patients have various degrees of renal compromise, including renal cysts and hyperechogenic kidneys that might progress to renal failure (Sovik et al., 2002). Additionally, maturity-onset diabetes of the young type 5 is usually seen by early adulthood. Affected females may have uterine malformations such as bicornuate uterus and Müllerian aplasia (Bellanne-Chantelot et al., 2004). This clinical presentation is often accompanied by a characteristic facial gestalt that includes macrocephaly and prominent forehead, downslanting palpebral fissures, depressed nasal bridge, and protruding maxilla in adulthood (Moreno-De-Luca et al., 2010). However, patients with a milder phenotype, even without these core clinical features and hence without a diagnosis of RCAD, are not infrequent (Moreno-De-Luca et al., 2010).

As alluded to previously, until recently, there was no evidence that a central nervous system phenotype is associated with 17q12 deletion syndrome. However, recent studies have shown that ID, ranging from mild to moderate, is common in patients with 17q12DS. More interestingly, behavioral anomalies have been identified in small cohorts of these patients, particularly involving problems in social interactions reminiscent of ASD. A recent report (Moreno-De-Luca et al., 2010) found that six of nine patients with 17q12DS met DSM-IV TR criteria for ASD. This finding was then confirmed in larger cohorts of patients with ASD (Moreno-De-Luca et al., 2010). Additionally, given the clinical and genetic overlap between ASD and SSD, large cohorts of patients with schizophrenia were investigated to assess the frequency of the deletion. A strong association was identified between 17q12DS and SSD. This CNV was absent from a very large sample of control individuals (52 448), which could be interpreted as a strong impact of this CNV over the phenotype of affected individuals, albeit with variable expressivity (Moreno-De-Luca et al., 2010).

Interestingly, the 17q12 region overlaps with a replicated linkage and association peak found in families with ASD (IMGSAC, 2001; McCauley et al., 2005; Stone et al., 2004, 2007; Yonan et al., 2003). It is tempting to hypothesize that one of the genes within this region is responsible for that linkage signal. However, the frequency of the deletion across different populations is 1 in 900 on average, and the frequency of yet-undiscovered mutations in one of the genes, which would account for a similar phenotype, is very likely rare as well and might not fully explain the linkage signal.

The 17q12DS region harbors 15 genes, and haploinsufficiency in one or more of these likely accounts for the neurocognitive phenotypes observed in these patients. *HNF1B* is responsible for the core features of RCAD (Bellanne-Chantelot et al., 2004); however, patients with point mutations or single-gene deletions do not appear to have a behavioral phenotype, which would mean that one of the other genes within the region might be responsible for the central nervous system findings. *LHX1* is a transcription factor involved in brain development and axonal guidance (Avraham et al., 2009) and appears as an interesting candidate. Knockout mice lack proper patterning of the midbrain–hindbrain barrier (Shawlot and Behringer, 1995). Nevertheless, no mutations in humans have been documented, so the pathogenic role of haploinsufficiency cannot be clearly established. More studies are needed to clarify this issue.

35.6 CONCLUSIONS AND FUTURE DIRECTIONS

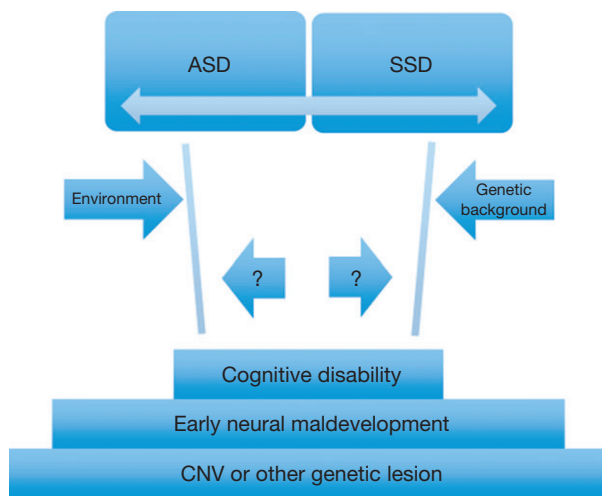
The information just summarized illustrates exciting progress in understanding genomic mechanisms contributing to ASD, SSD, and other NDDs. While our current, very incomplete, knowledge of the roles of CNV in ASD and SSD suggests common pathways of risk for


FIGURE 35.1   A heuristic model relating CNV to risk for ASD and SSD. The model is based on the premises that (i) genes within CNV participate in gene networks regulating neural development; (ii) specific factors, including environmental events, epigenetic factors, and stochastic processes can alter developmental trajectories, thereby influencing phenotypic outcomes; and (iii) timing of such events may be critical, especially relative to key developmental epochs such as the prenatal, early childhood, and adolescent periods. Note that the model posits ID as an outcome that precedes ASD or SSD. That component of the model reflects the virtual universal association of some form or degree of ID (or at least learning disorders) with CNV. Thus, we hypothesize that impaired abilities to engage in social learning, probably beginning at birth or possibly earlier, contribute cumulatively to the development of ASD and SSD. Fundamentally, however, such learning difficulties arise from suboptimal function at the cellular and molecular levels.

these two sets of disorders, a major challenge is to understand how similar or identical CNV results in widely different clinical outcomes in different individuals. In Figure 35.1, we summarize a heuristic model for generating testable hypotheses regarding the developmental impact of CNV on risk for ASD, SSD, and other NDDs (although for simplicity, we include only ASD and SSD in the diagram). The model incorporates the following three hypotheses:

1. CNV predisposing to ASD, SSD, and other NDDs do so by altering the function of gene-regulatory networks in which loci at or near the particular CNV participate. Note that a variety of mechanisms could alter such networks, including under- or overexpression of the products of dosage-sensitive genes within a CNV region; unmasking (in the case of deletion) or enhancement (in duplications) of expression of recessive deleterious alleles within the CNV region; effects of CNV on chromatin structure, leading to 'spreading' effects on regulation of genes in *cis* near the CNV or altered *trans* regulation via mechanisms such as chromatin looping (Miele and Dekker, 2009); or the presence of risk alleles at loci

elsewhere in the genome but involved in the same regulatory networks as those within the CNV.

2. Specific environmental factors might interact with CNV-associated gene-regulatory networks to alter developmental trajectories. A well-known (and therapeutically modifiable) environmental factor affecting neural development, for example, is maternal intake of folic acid during pregnancy, which strongly impacts the risk of open neural tube defects in offspring (Berry and Li, 2002; see Chapter 27). Understanding how such factors interact with genetic networks at the cellular level during development of the brain could lead to effective preventive or ameliorative strategies in patients with CNV disorders.

3. Variability in the timing or magnitude of specific environmental exposures in the context of specific CNVs might alter developmental trajectories. As noted above, ASD and SSD differ in their typical timing of clinical presentation. However, the typical epochs of presentation (early childhood for ASD, or during or just after puberty for SSD) are periods of profound developmental changes in brain structure or function. It is possible that specific CNVs set up carriers for vulnerability to specific risk factors occurring during these critical periods.

Future research is needed at all levels on CNVs and their association to risk for NDD. To date, patients with CNV have been ascertained almost entirely within clinical contexts or in case–control studies where cases have been selected based on phenomenology. 'Unaffected' (or more likely, mildly enough affected to escape clinical notice) carriers have generally been discovered upon family testing once a proband has been identified, or in the context of case–control studies where 'controls' may not represent the general population, but rather are ascertained for absence of a particular set of syndromes. Current literature, while extremely valuable, is therefore almost certainly laden with biased ascertainment and other difficulties that preclude rigorous epidemiological delineation of the role of CNV in public health. The availability of relatively low-cost methods for scanning the genome for CNV (e.g., aCGH) should support the development of sampling strategies in which molecular rather than phenomenological criteria drive case and control ascertainment. Such studies would be particularly valuable for clarifying factors that distinguish clinical subtypes of specific CNV disorders from each other. As alluded to in examples from 22q11DS and 15q13.3 DS, the clear fact that subsets of patients diagnosed according to phenomenological schema such as the DSM-IVTR are at elevated risk for carrying specific CNV has potentially profound implications for diagnosis and treatment of behavioral disorders.

Another exciting direction enabled by expanding knowledge of CNV-associated behavioral disorders is that credible animal models for fundamentally human disorders become possible. Thus, while nobody will ever be able to guess what constitutes psychosis or autism in a mouse, experiments on rodents carrying engineered syntenic CNVs are shedding light on specific neural and developmental mechanisms likely to be relevant to behavioral deficits in SSD and ASD (Meechan et al., 2009; Sigurdsson et al., 2010). Animal models of neuro-developmentally important CNV promise to introduce novel strategies for understanding pathological neural development as well as new platforms for testing therapeutic drugs.

While political and economic barriers, such as insurance discrimination against behavioral disorders and (at least in the United States) inadequate or absent health coverage for large proportions of the population, will continue to impede progress in the diagnosis and treatment of behavioral disorders, the emerging literature on CNV as causative factors in mental illness adds to overwhelming evidence that NDDs are every bit as 'biological' and therefore medically 'real' as other complex disorders. Hopefully, the mountain of evidence supporting such a proposition will eventually get large enough that even the American Congress will be unable to continue ignoring it, thus leading to the elimination of barriers to healthcare access that currently severely impact patients with ASD and SSD. In this regard, the ongoing explosion of knowledge on CNV disorders will benefit patients with NDD whether or not they carry associated CNV.

CHAPTER

36

Excitation–Inhibition Epilepsies

A.X. Thomas, A.R. Brooks-Kayal

University of Colorado, Aurora, CO, USA

OUTLINE

36.1 INTRODUCTION

Epilepsy affects more than 50 million people across the world, making it the second most common neurological disorder (Hauser et al., 1993). Children in particular are at high risk for seizures, and 5 out of every 1000 children will develop epilepsy in any given year. Known risk factors can account for only 25–45% of cases of early-life epilepsy, including congenital malformations of the central nervous system (CNS), moderate to severe head trauma, CNS infections, hypoxic–ischemic encephalopathy, inherited metabolic conditions, and genetic predisposition (Cowan, 2002).

To begin the discussion of epilepsy research, it is important to define the terms *epilepsy* and *epileptogenesis. Epilepsy*

is a neurological disorder that is characterized by recurrent spontaneous seizures. *Epileptogenesis* is defined as the process during which changes occur in the brain after a precipitating injury or insult that results in the development of spontaneous recurrent seizure activity or epilepsy. The time period between the initial insult and the onset of epilepsy is referred to as the latent period. Much of the research in epilepsy is geared toward understanding the underlying molecular mechanisms associated with epileptogenesis. It is important to elucidate the underlying mechanisms of epileptogenesis both to identify better treatments for existing epilepsy and to develop new therapies to prevent epilepsy, as well as the associated neurocognitive disorders that afflict many individuals with epilepsy (LaFrance et al., 2008).

Although epilepsy is defined by the presence of recurrent seizures, it is often associated with cognitive or behavioral dysfunction, particularly in children, among whom 30% of epilepsy patients will have comorbid autism, intellectual or developmental disabilities, or both (Nolan et al., 2003; Tuchman et al., 2009). Children with epilepsy also show higher rates of attention deficit/hyperactivity disorder, learning disorders, and behavioral problems, as well as depression and anxiety (Beghi et al., 2006; Dunn et al., 2002; Gonzalez-Heydrich et al., 2007; Jones et al., 2007; Laurent and Arzimanoglou, 2006). A number of well-known genetic disorders share epilepsy, intellectual disability, and autism as prominent phenotypic features, including tuberous sclerosis, Rett syndrome, fragile X, Angelman syndrome, and genetic disorders of cortical development/migration with mutations such as aristaless-related homeobox (ARX), DCX, and Lis1 (reviewed in Brooks-Kayal, 2011; Deonna and Roulet, 2006; Guzzetta, 2006; Wolff et al., 2006). Seizures themselves, particularly when occurring during early life, may also produce a variety of cellular and molecular changes in the hippocampus that may contribute to an enhanced risk of cognitive or behavioral dysfunction (reviewed in Brooks-Kayal, 2011). Comorbid changes can be progressive, both over periods of years and over the course of the lifespan, and their severity has been correlated with age of onset, seizure frequency, total number of seizures, and increasing age (Dam, 1990; Hermann et al., 2002, 2003).

36.2 DIFFERENCES BETWEEN THE DEVELOPING AND MATURE BRAIN

To understand the complex effects of seizures on the developing brain, it is imperative to understand the differences between the developing and the adult brain. The functional development of inhibitory and excitatory neurons is an important part of the physiology of the normal developing neonatal brain. Three different types of pyramidal neuronal populations have been identified

in the newborn rat hippocampus (Tyzio et al., 1999). These early neurons are described by their responsiveness to the neurotransmitters GABA and glutamate, and the populations consist of silent neurons, neurons that respond to only GABA, and neurons that respond to GABA and glutamate. The silent neurons lack spontaneous or evoked postsynaptic currents (PSCs), even in the presence of toxins that would normally stimulate transmitter release. These neurons have functional $GABA_A$ and glutamate receptors. The neurons that respond to only GABA demonstrate GABA-mediated but not glutamate-mediated PSCs. The neurons that respond to GABA and glutamate demonstrate both GABA-mediated and glutamate-mediated PSCs. These three populations of pyramidal neurons also differ morphologically. The silent neurons have a small soma and an axon with no apical dendrites. The neurons that respond to only GABA are more differentiated and have a larger soma and a small apical dendrite with no basal dendrite. The neurons that respond to GABA and glutamate are even more differentiated and have a basal dendrite and an apical dendrite that reaches the distal part of the stratum lacunosum moleculare (Tyzio et al., 1999).

Even more pertinent to human development is a similar observation made with respect to macaque monkey embryos in utero (Khazipov et al., 2001). In macaque monkeys, neurogenesis is complete in the hippocampus at E165 and morphological differentiation of the hippocampal pyramidal neurons occurs during the second half of gestation. The neurons are highly mature at the time of birth. Embryonic recordings conducted in the second half of gestation from embryonic day (E) 85 to E154 demonstrated that at E85 the CA1 pyramidal neurons were silent, with some neurons that respond to only GABA starting to form. At E105, the proportion of these neurons that respond to only GABA had increased and penetrated deeper into the stratum radiatum with a small proportion of neurons that respond to GABA and glutamate. From E119 and onward, the recorded pyramidal neurons exhibited both GABAergic and glutamatergic PSCs. The ability of $GABA_A$ receptor antagonist bicuculline to initiate epileptiform activity during various stages of development also was studied. At mid-gestation, epileptiform activity was not seen after the administration of the $GABA_A$ antagonists bicuculline but was observed at E105–109, which coincides with the appearance of neurons that respond to only GABA with axonal collaterals and the appearance of spines and glutamatergic PSCs. The occurrence and severity of the epileptiform events coincided with the development of the pyramidal neurons and the increase in the number of spines. Therefore, in primates, maturation of GABAergic and glutamatergic neurotransmission emerges early in utero. The CA1 pyramidal neurons are initially silent and then mature and differentiate to acquire morphological and physiological properties needed to generate

network-driven epileptiform activities well before birth. Early hippocampal development is conserved throughout mammalian development. The steps in hippocampal development seem to be similar in rodents and primates but occur at a faster rate in primates (Khazipov et al., 2001).

The first synapses of the principal neurons in the hippocampus are formed on the apical dendrites (Dupuy and Houser, 1997; Rozenberg et al., 1989). Glutamatergic synapses are formed after the maturity of their postsynaptic target, whereas GABAergic synapses are formed between the axons of GABA neurons and the dendrites of pyramidal neurons. Inhibitory neurons play an important role in normal development of the neocortex and in regulating the critical period. The critical period is defined as a window of time during which experience provides input that is essential for normal development and permanently alters function (Hensch, 2005). During the critical period of rodent visual cortex development, GABA release is important for ocular dominance plasticity (Fagiolini and Hensch, 2000; Hensch et al., 1998). Enhanced inhibition with administration of benzodiazepines just after eye opening is able to accelerate the onset of the critical period (Fagiolini and Hensch, 2000; Fagiolini et al., 2004; Iwai et al., 2003). Tonic GABA

release is sufficient to trigger the completion of the critical period even with the complete absence of visual input (Hensch, 2005).

36.2.1 GABAergic Neurotransmission

GABA and glutamate receptors undergo dramatic changes over the course of postnatal development (Figure 36.1). GABAergic neurotransmission provides very important functions in the brain that differ between immature and mature neurons (Ben-Ari, 2002). GABA is a neurotransmitter that acts in an excitatory manner in the immature brain, while acting in an inhibitory manner in the mature brain (Ben-Ari et al., 1989) and is tied to the temporally regulated expression of K^+–Cl^--coupled cotransporter (KCC2) (Rivera et al., 1999). There is also a developmentally regulated shift in the expression of GABA receptor subunits (Brooks-Kayal and Pritchett, 1993; Brooks-Kayal et al., 2001; Fritschy et al., 1999; Wisden et al., 1992).

Ben-Ari et al. first reported that GABA functioned as a depolarizing, or excitatory, neurotransmitter in young neurons from neonatal hippocampal slices, unlike those of adults (Ben-Ari et al., 1989). In disassociated

Schematic depiction of maturational changes in glutamate and GABA receptor function in the developing brain
FIGURE 36.1 Equivalent developmental periods are displayed for rats and humans on the top and bottom *x*-axes, respectively. Activation of GABA receptors is depolarizing in rats early in the first postnatal week and in humans up to and including the neonatal period. Functional inhibition, however, is gradually reached over development in rats and humans. Before full maturation of GABA-mediated inhibition, the NMDA and AMPA subtypes of glutamate receptors peak between the first and second postnatal weeks in rats and in the neonatal period in humans. Kainate receptor binding is initially low and gradually rises to adult levels by the fourth postnatal week. Abbreviations: AMPA, -amino-3-hydroxy-5-methyl-4-isoxazole propionate; GABA, γ-aminobutyric acid; NMDA, *N*-methyl-D-aspartate; P, postnatal day. *Reprinted with permission of John Wiley & Sons, Inc. Neonatal seizures.* Annals of Neurology *62(2): 2007, 112–120 © 2007 Wiley-Liss, Inc., A Wiley Company.*

embryonic spinal cord neurons, the opening of a single GABA channel is enough to trigger a sodium action potential (Serafini et al., 1995). The activation of GABA receptors also has the ability to generate calcium currents by directly activating voltage-dependent calcium channels (Fukuda et al., 1998; Leinekugel et al., 1995, 1997). The developmental shift in GABA function has been observed in a wide range of species and has been accepted as a general rule that has been conserved throughout vertebrate evolution. Glutamatergic neurons, which are the main excitatory neurons in the adult brain, are formed after GABAergic neurons (Ben-Ari et al., 1989). Thus, in the immature brain, GABA release and activation of $GABA_A$ receptors initiate depolarization and increased concentration of calcium, whereas glutamate serves this function in the adult brain (Ben-Ari, 2002).

$GABA_A$ receptor activity is sufficient to drive synchronous neuronal activity and can be inhibited by $GABA_A$ receptor blockade (Ben-Ari et al., 1989). In cultured hippocampal slices from young rats, elevated extracellular potassium-induced ictal-like epileptiform activity was blocked by $GABA_A$ receptor antagonists, bicuculline and gabazine, and increased in frequency and duration by $GABA_A$ receptor agonists, isoguvacine and muscimol (Dzhala and Staley, 2003). This exacerbation of epileptiform activity with $GABA_A$ receptor agonists and blockade with $GABA_A$ receptor antagonists is opposite to that seen in adult rats.

36.2.1.1 Chloride Gradient

To understand the implications of the chloride gradient on GABAergic transmission, it is important to compare the influx and efflux of chloride ions in neonatal and mature neurons. In neonatal hippocampal slices,

Ben-Ari et al. used electrochemical methods to observe an increase in chloride ions in neonatal hippocampal neurons as compared to the adult (Ben-Ari et al., 1989). The increase in chloride concentration by 20–40 mM is sufficient to shift the function of GABA from inhibition in the adult to excitation in the neonate (Ben-Ari, 2002). There are two main families of chloride transporters responsible for influx and efflux of chloride ions in neurons. The chloride gradient is driven by the Na^+–K^+–$2Cl^-$ cotransporter (NKCC1), which imports two ions of chloride for every ion of sodium and potassium exported, and KCC2, which exports one ion of potassium and chloride. Therefore, the activation of NKCC1 allows for the accumulation of intracellular chloride and the activation of KCC2 decreases the concentration of intracellular chloride. NKCC1 is expressed at early developmental stages and is responsible for the high intracellular chloride concentration inside immature neurons (Fukuda et al., 1998). Expression of KCC2 mRNA levels slowly increases to adult levels at 2 weeks postnatally in various brain regions, which coincides with the functional maturation of these areas. The transfection of immature hippocampal neurons with KCC2 caused an early switch of GABA function from excitatory to inhibitory. GABA also remains excitatory in mice that lack KCC2 expression (Rivera et al., 1999). Thus, the key transporter implicated in the developmentally regulated switch from the excitatory to the inhibitory effects of GABA is KCC2 (Figure 36.2).

The developmental shift from excitatory to inhibitory GABAergic currents is regulated by GABA itself (Ganguly et al., 2001). Blocking $GABA_A$ receptors with bicuculline and picrotoxin prevented KCC2 increases and GABA remained excitatory. The developmental

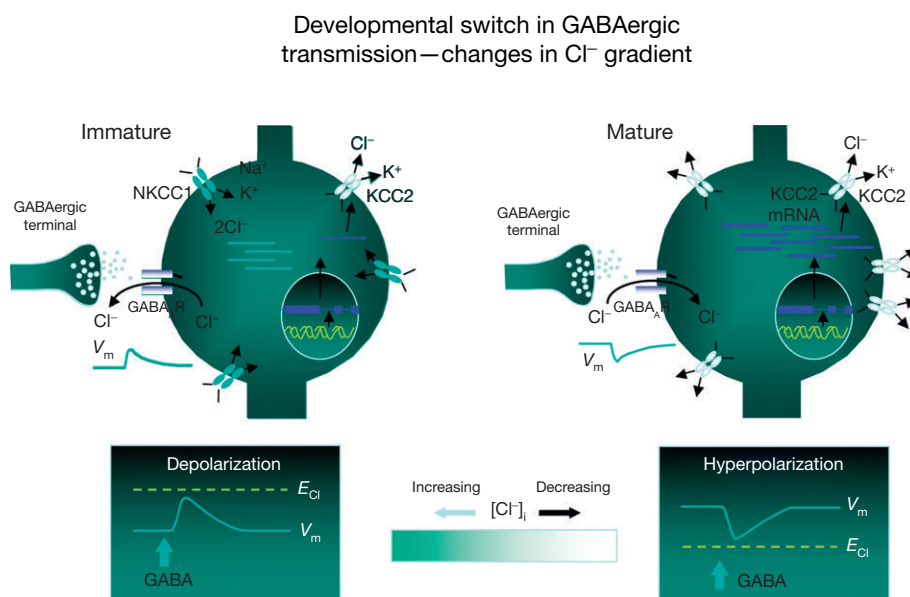
Developmental switch in GABAergic transmission—changes in Cl^- gradient


FIGURE 36.2 This schematic illustrates how the developmental shift in the chloride gradient (Cl^-) affects GABAergic transmission in the immature and mature brain. $GABA_{AR}$, $GABA_A$ receptor; KCC2, transports Cl^- out of the cell; NKCC1, transports Cl^- into the cell; mRNA, messenger RNA; V_m, membrane voltage; E_{Cl}, chloride equilibrium potential. *Reprinted from Brooks-Kayal AR (2005) Rearranging receptors.* Epilepsia *46(supplement 7): 29–38, with permission.*

shift is independent of action potentials, since tetrodo-toxin, a sodium channel blocker, had no effect on the shift from excitation to inhibition. Therefore, an action potential-independent quantal release of GABA resulting in miniature PSCs is sufficient to cause the expression of KCC2 and reduce $[Ca^{2+}]_i$ and appears to be required. Blocking glutamate activity had no effect on the developmental shift of GABA (Ganguly et al., 2001). Taken together, the studies demonstrate that the shift in GABA function from excitatory to inhibitory is primarily caused by the temporally regulated expression of KCC2 which is downstream of GABA$_A$ receptor activation.

36.2.1.2 GABA Receptor Subunit Changes

There are three main GABA subtypes: GABA$_A$, GABA$_B$, and GABA$_C$. GABA$_A$ receptors are ligand-gated ion channels composed of heterogeneous pentameric protein complexes. The pentameric receptors are formed by various combinations of different subunits: α, β, γ, δ, ε, π, and θ. The various combinations of GABA subunits bestow certain physiological characteristics as well as pharmacological properties. GABA$_A$ receptors are typically located postsynaptically and mediate fast synaptic inhibition in the adult brain and excitation in the developing brain. The GABA$_A$ receptors are primarily anion selective, and typically gate chloride ions but, in certain conditions, gate bicarbonate ions as well. GABA$_A$ receptors are typically composed of two α subunits, two β subunits, and one γ subunit. The γ subunit can be replaced by a δ, an ε, a θ, or a π subunit, depending on the neuronal subtype and subcellular localization of the receptor (McKernan and Whiting, 1996; Rudolph and Möhler, 2004). GABA$_B$ receptors are G-protein-coupled metabotropic receptors that are located both presynaptically and postsynaptically and exhibit longer-duration slow inhibitory currents through K^+ and Ca^{2+} channels. GABA$_B$ receptors are composed of a heterodimer consisting of GABA$_{B1}$ and GABA$_{B2}$. The molecular diversity seen in the GABA$_B$ receptors arises from the splice variants of the GABA$_{B1a}$ and GABA$_{B1b}$ subunit isoforms (Bettler and Tiao, 2006; Couve et al., 2000). GABA$_A$ and GABA$_B$ receptors are distributed across the CNS (Bowery et al., 1987).

There are significant spatiotemporal differences in the subunit expression of GABA$_A$ receptors. Alpha$_2$, α_3, and α_5 subunits peak early in development and stabilize or decline, whereas the expression of α_1 and γ_2 is at low levels early in development and increases to adult levels (Fritschy et al., 1994; Wisden et al., 1992). In rats, there is a greater than twofold increase in mRNA expression of α_1, α_4, and γ_2 from postnatal day (P)7 to adulthood and a tenfold decrease in the expression of α_5 mRNA during the same period (Brooks-Kayal et al., 2001). Developmentally regulated changes in GABA$_A$ receptor

subunit composition have also been observed in humans. Between the 36th week of gestation and adulthood, there is a threefold increase in the expression of α_1 mRNA levels in the cortex and cerebellum (Brooks-Kayal and Pritchett, 1993). There are also spatiotemporal differences in the subunit expression of GABA$_B$ receptors. In rodents, the presynaptic subunit of GABA$_B$, GABA$_{B1a}$, is high at birth and progressively declines to adult levels by P14 (Fritschy et al., 1999). However, the postsynaptic GABA$_B$ subunit, GABA$_{B1b}$, is low at birth, progressively increases in the first two postnatal weeks, and then declines to adult levels (McLean et al., 1996). There is some presynaptic GABA$_B$ receptor activity at birth, but no postsynaptic activity until the second or third postnatal week (Fukuda et al., 1993; Gaiarsa et al., 1995).

36.2.2 Glutamatergic Neurotransmission

Excitation outweighs inhibition during the first few years of life in the cerebral cortex and limbic structures in humans and rodents (Fox et al., 1996; Huttenlocher et al., 1982). Glutamate receptors are the main excitatory receptors in the adult brain and are divided into two main classes: ionotropic and metabotropic. Most pertinent to the discussion on developmental epilepsies is the ionotropic class of glutamate receptors. These ionotropic glutamate receptors activate cation-selective ion channels permeable to Na^+, K^+, and Ca^{2+} possessing varying degrees of permeability and blockade by the divalent cation Mg^{2+} (Mayer and Westbrook, 1987). There are three main types of ionotropic glutamate receptors: α-amino-3-hydroxyl-5-methyl-4-isoxazole-propionate (AMPA), kainate, and N-methyl-D-aspartic acid (NMDA) (Mayer, 2005). NMDA receptors are mainly located postsynaptically, require glycine as a coagonist, and have a voltage-dependent magnesium blockade that must be released before agonist binding can open the channel to allow gating of calcium and sodium. NMDA receptors are composed of an obligatory NR1 subunit with a combination of NR2A, NR2B, NR2C, and/or NR3A subunits (Lau and Zukin, 2007). AMPA receptors are typically located on the postsynaptic membrane and are composed of various combinations of GluR1, GluR2, GluR3, and/or GluR4 (Shepherd and Huganir, 2007). Kainate receptors are located presynaptically and postsynaptically on both neurons and glia. Kainate receptors are almost exclusively composed of various combinations of GluR5, GluR6, GluR7, KA1, and/or KA2 and gate sodium (Pinheiro and Mulle, 2006). NMDA receptors are always permeable to calcium ions, whereas AMPA and kainate receptors are selectively permeable to divalent cations depending on their subunit compositions. When AMPA receptors contain low levels of GluR2 or lack it

entirely, the receptors are calcium-permeable (Shepherd and Huganir, 2007). When kainate receptors have low levels of GluR5 or GluR6 or lack these subunits altogether, they allow increased gating of calcium ions (Pinheiro and Mulle, 2006).

The expression of glutamate receptor subunits is spatially and developmentally regulated and has important functional implications. In the mature brain, NR2A is present in almost all areas of the brain, while NR2B is located in the forebrain, NR2C is limited to the cerebellum, and NR2D is restricted to the thalamus and subthalamus (Monyer et al., 1994). In the immature brain, NMDA receptors have high levels of NR2B, NR2D, and NR3A subunits. Elevated levels of NR2B subunits extend current decay times, and the high levels of NR2D and NR3A reduce NMDA receptor sensitivity to magnesium ions (Lau and Zukin, 2007). The increased expression of the NR2B, NR2D, and NR3A subunits is implicated in increased NMDA receptor-mediated calcium influx, lower threshold for seizures, and excitotoxic hypoxic–ischemic injury during development (Rakhade and Jensen, 2009). AMPA receptor subunit composition is also developmentally regulated. The immature rat brain has lower GluR2 expression and a higher prevalence of GluR2 subunit-deficient receptors, which causes an increased calcium and sodium influx. When GluR2 is present in the receptor, AMPA receptors primarily gate sodium (Kumar et al., 2002; Sanchez and Jensen, 2001). In the developing human brain, there is a relative deficiency in GluR2 subunit-expressing AMPA receptors in cortical neurons during term and the early postnatal period. There is a direct correlation between the expression of GluR2-deficient AMPA receptors and vulnerability to hypoxic/ischemic injury (Talos et al., 2006a,b).

36.2.2.1 GABA, NMDA, and AMPA

In the developing brain, GABAergic and glutamatergic synapses work in conjunction with each other. Early glutamatergic neurotransmission is solely NMDA-receptor mediated, without any significant contribution of AMPA receptors (Durand et al., 1996; Isaac et al., 1997; Wu et al., 1996). Voltage-dependent Mg^{2+} blockade of NMDA receptors takes place in both neonates and adults (Khazipov et al., 1995; Swann et al., 1999); however, the degree varies across development, since NMDA receptors containing NR2D and NR3A are expressed in immature neurons and are less sensitive to Mg^{2+} blockade (Lau and Zukin, 2007). In the CA1 region of the hippocampus, the first glutamatergic synapses formed at P2 are silent at resting potential; however, the proportion of silent synapses progressively decreases from P2 to P5 (Durand et al., 1996; Liao and Malinow, 1996). Typically, the activation of AMPA receptors is sufficient to remove the Mg^{2+} blockade of NMDA channels in adult neurons,

resulting in their activation. However, in neonatal hippocampal slices, AMPA activation is not sufficient to remove Mg^{2+} blockade of NMDA channels (Liao and Malinow, 1996); instead, $GABA_A$ receptor activation serves this role (Leinekugel et al., 1995). The opposite is true in the adult brain, where $GABA_A$ receptor activation prevents the activation of NMDA receptors, thereby inhibiting NMDA-dependent forms of synaptic plasticity (Artola and Singer, 1987; Wigström and Gustafsson, 1983). GABA-dependent activation of P2–P5 CA3 pyramidal neurons by the $GABA_A$ receptor agonist, isoguvacine, is sufficient to remove the voltage-dependent Mg^{2+} blockade of NMDA receptors, thereby increasing the affinity of NMDA channels for magnesium and increasing calcium ion influx (Leinekugel et al., 1995). Therefore, in the developing brain, $GABA_A$ receptor activation acts synergistically with NMDA receptor activation, providing the same function that AMPA receptors offer in the adult brain.

36.3 EXPERIMENTAL MODELS OF DEVELOPMENTAL EPILEPSY

Epilepsy is a very complex disease with many different causes and pathologies; therefore, it is important to develop research models that try to mimic the various types of human epilepsies. Many of the research models of seizures and epilepsy have been thoroughly reviewed (Pitkänen et al., 2005; Table 36.1).

36.3.1 Environmental/Perfusion

36.3.1.1 Hypoxia

The most common cause of neonatal seizures is hypoxic encephalopathy (Aicardi and Chevrie, 1970; Hauser et al., 1993). The neonatal rodent hypoxia model has been utilized to elucidate how global hypoxia in neonates leads to increased susceptibility to seizures later in life. Humans and rodents have a similar age-dependent susceptibility to hypoxia-induced seizures early in life, which can cause long-term susceptibility to seizure and neuronal death. P9–P12 Long–Evans rats demonstrate a high susceptibility to hypoxia-induced seizures, with a peak in P10 pups. Sprague–Dawley rats exhibit peak seizures at P8–P9 (Owens et al., 1997). Similar windows of susceptibility are also seen in mice. The hypoxia model uses a brief 15-min exposure to a graded global hypoxia (7–4% O_2) by altering the levels of O_2 and N_2 in an airtight chamber. The acute hypoxia-induced seizures lead to a long-term increase in the susceptibility to seizures, which is usually ascertained through the use of threshold doses of various chemoconvulsants,

TABLE 36.1 Animal Models of Neonatal Seizures and Epilepsy

Age	Experimental model	Human condition Acute model	Recurrent spontaneous seizures (epilepsy)
Neonatal			
P0–P5	Flurothyl	Neonatal seizures	No
P3–P7	Hypoxic ischemia	Hypoxic–ischemic encephalopathy and perinatal stroke	Yes
Adolescent			
P8–12	Hypoxia	Hypoxic encephalopathy	Yes
P7–P14	Hypoxic ischemia	Hypoxic–ischemic encephalopathy and perinatal stroke	Yes
P10–P11	Hyperthermia	Febrile seizures	Yes
P10	Tetanus toxin single dose	Complex partial seizures	Yes
P10–P12	Tetanus toxin continuous infusion	Infantile spasms	Yes
P7–P10	Lithium–pilocarpine	Neonatal seizures	No
P12–P20	Lithium–pilocarpine	Neonatal seizures	Yes*
P7–P10	Kainate	Neonatal seizures	No
P20–Adult	Kainate	Neonatal seizures	Yes[a]

[a]*The increase in rate of epilepsy development directly correlates with the age.*

including pentylenetetrazol (PTZ), flurothyl, and kainate (Jensen et al., 1992; Rakhade et al., 2008b), as well as to spontaneous epileptiform/ictal EEG discharges in a subset of exposed animals (Rakhade et al., 2008a).

36.3.1.2 Hypoxic Ischemia

Neonatal seizures also occur after hypoxic–ischemic encephalopathy and perinatal stroke modeled by the hypoxic–ischemic rodent model of neonatal seizures. Typically, this method is used with P3–P14 rodents by ligating a cerebral artery, usually a unilateral carotid or middle cerebral artery. After ligation, the rodents are allowed to recover and are then subjected to 15–30 min of hypoxia (8% O_2) (Jensen et al., 1994; Rice et al., 1981; Vannucci et al., 1999). Similar to the hypoxia model, the hypoxic–ischemic model results in long-term increases in seizure susceptibility as assessed by injections of chemoconvulsants, as well as emergence of epilepsy later in life (Wirrell et al., 2001; Yager et al., 2002).

36.3.1.3 Hyperthermia

The most common type of seizure in infants and young children is febrile seizures, with a prevalence of 2.3–4%. Simple febrile seizures are short and generalized and occur with high fevers in infants and young children from ~3 months to 5 years of age, peaking between 6 months and 2 years of age. Complex febrile seizures are prolonged or focal seizures or seizures that recur within a single febrile episode. Although the majority of simple febrile seizures are benign, complex prolonged febrile seizures have been associated with an increased risk of later epilepsy development (Cowan, 2002; Hauser, 1994). The model for prolonged febrile seizures was first developed in the immature rat (Baram et al., 1997; Toth et al., 1998) and then adapted for mice (Dubé et al., 2005). The febrile seizure model induces hyperthermia to produce prolonged seizures. The core temperature of P10–11 rats or P14–15 mice is increased gradually and maintained at hyperthermia (40–42 °C) for 30 min, with the animal's core temperature being tightly regulated. The rodents are then allowed to recover for 1 h. In this model, approximately 24% of rats go on to develop spontaneous temporal lobe seizures in adulthood. If the duration of hyperthermia is increased to 64 min, then 45% of rats develop spontaneous seizures in adulthood (Dubé et al., 2010).

36.3.2 Toxin

36.3.2.1 Tetanus Toxin

The ability of tetanus toxin to induce chronic epilepsy was first described by Roux and Borrel (1898). The modern form of the tetanus toxin model of epilepsy involves stereotaxic injection of minute amounts of tetanus toxin into the brain to create an epileptic focus that spontaneously discharges. After interhippocampal infusion of tetanus toxin in P10 rats, anywhere from one to seven seizures are typically observed during the first week, with each seizure lasting from a few seconds to several minutes. The seizure frequency usually peaks on day two and declines over the week following infusion (Benke and Swann, 2004). When the immature rats become adults, they can exhibit unprovoked seizures, typically with a low prevalence (Lee et al., 1995).

36.3.3 Chemoconvulsant

36.3.3.1 Lithium–Pilocarpine

The lithium–pilocarpine model is a variation of the pilocarpine model used in adults. Honchar et al. determined that systemic activation of the cholinergic system in lithium-treated rats induced seizures (Honchar et al., 1983). Typically, lithium is administered 24 h before administration of pilocarpine. The pretreatment with lithium greatly decreases the amount of pilocarpine needed to

induce status epilepticus (SE). There are two dosing regimens, the first with a high dose of pilocarpine (25–60 mg kg^{-1}) 24 h after lithium treatment and the other with divided doses (10 mg kg^{-1}) administered 24 h after lithium treatment every 30 min until SE is induced (Glien et al., 2001). In P12 rats, 25% of the rats experience spontaneous electrographic seizures of limbic onset (i.e., temporal lobe epilepsy (TLE)) 3 months after SE (Kubová et al., 2004). By P20, this percentage increases to 67% (Raol et al., 2003).

36.3.3.2 Kainate

The seizure-inducing properties of kainate were first reported by Nadler et al. (1978). The kainate model is another useful model of TLE, because the rats experience an episode of SE on the order of hours after injection with kainate, followed by days to weeks of a seizure-free latent period, finally ending with progressive recurrent spontaneous seizures, typically when SE occurs in rodents ≥P20. Spontaneous recurrent seizures do not develop in P0 and P5 kainate-induced rats (Stafstrom et al., 1992). There are two main dosing regimens for kainate-induced SE, one using a single high dose (Meier et al., 1992) and the other using repetitive low doses (Meier and Dudek, 1996).

36.3.3.3 Flurothyl

Flurothyl is an inhaled GABAergic antagonist that induces seizures within minutes (Truitt et al., 1960). This method can be used to induce seizures up to five times per day (Cha et al., 2002; Holmes et al., 1998). Seizures are arrested within 30 s of returning the rats to room air; therefore, it is a useful model to study the effect of recurrent seizures. Continuous exposure to flurothyl is able to produce SE (Sperber et al., 1999). Immature rats (P0–P5) that receive recurrent flurothyl seizures do not go on to develop spontaneous recurrent seizures; however, the rats do have a reduced seizure threshold later in life (Holmes et al., 1998; Sogawa et al., 2001).

36.3.4 Kindling

The phenomenon of kindling was first described by Graham Goddard (1967). Goddard studied the effect of repeated hippocampal electrical stimulation on learning in rats. The small electrical insults led progressively to greater severity of seizures and resulted in a permanent increase in seizure susceptibility (Goddard et al., 1969). Kindling is initiated by periodic insults that result in network synchronization that are accompanied by behavioral seizures. There are two main methods of kindling, electrical and chemical. The electrical model of kindling uses repetitive electrical stimulation to various brain centers including the amygdala, perforant

pathway, dorsal hippocampus, olfactory bulb, and perirhinal cortex. Chemical kindling utilizes repetitive administration of chemical agents that evoke repetitive epileptic spiking such as carbacol, acetylcholine, bicuculline, lidocaine, cocaine, and PTZ.

36.3.5 Infantile Spasms Models

Infantile spasms are a severe form of developmental epilepsy that begins between 3 and 12 months of age and has numerous etiologies, including a wide range of acquired and congenital causes (Frost and Hrachovy, 2005). Infantile spasms are associated with specific and unique electroencephalogram (EEG) findings, consisting of chaotic, high-voltage slow background activity intermixed with multifocal spikes and generalized slow waves (hypsarrhythmia), followed by generalized voltage attenuation during the spasm seizures. Only a few medications are effective for infantile spasms (glucocorticoids, adrenocorticotropic hormone, and vigabatrin), and the outcome of infantile spasms is usually poor, with other seizure types occurring after the first year of life and severely abnormal neurological development. The prognosis is especially poor in cases where delay is noted prior to the onset of spasms and the spasms do not disappear with therapy (Stafstrom, 2009). Recently, several animal models have been developed that recapitulate many of the features of infantile spasms, including the NMDA model (Kábová et al., 1999), the tetrodotoxin infusion model (Lee et al., 2008), and the multiple injury model (Scantlebury and Moshé, 2006). In addition, two genetic models of infantile spasms have been developed, the ARX model and the Ts65Dn Down syndrome model, which are discussed later. These new models should provide insights that will improve the understanding, treatment, and prevention of this devastating early-childhood epilepsy syndrome.

36.3.6 Genetic

In humans, mutations in the X-linked ARX gene are linked to structural brain abnormalities, including lissencephaly and abnormal migration of inhibitory interneurons, and neurological deficits, including severe intellectual disability and early-life epilepsy (known as an infantile epileptic encephalopathy). Conditional ARX knockouts exhibit behavioral and electrographic early-life seizures resembling infantile spasms (Marsh et al., 2009; Price et al., 2009). The administration of GABA$_B$ agonists to a mouse model of Down syndrome Ts65Dn mice between 1 week and 2 months old causes them to develop clusters of extensor spasms, which resemble infantile spasms, accompanied by polyspike-wave bursts and electrodecremental responses on EEG (Cortez et al., 2009).

Transgenic mice with mutations in KCNQ3 are known to develop seizures within the first 2 weeks of life. Mutations of KCNQ2 and KCNQ3 are linked to benign familial neonatal convulsions in humans (Castaldo et al., 2002). $K_v1.1$ knockouts exhibit a seizure-sensitive predisposition at P10, demonstrating an increase in early-life seizure susceptibility. Mutations in KCNA1, the human homolog of $K_v1.1$, can lead to episodic ataxia and seizures in humans (Rho et al., 1999). There are many other genetic mouse models with genes that are implicated in human early-life seizures, including SCN2A, SCN1B, and KCNQ2, to name a few. However, these mouse models do not demonstrate early-life seizures but rather develop seizures later in life (Chen et al., 2004; Kearney et al., 2001; Peters et al., 2005).

36.4 SEIZURE-INDUCED CHANGES IN THE BRAIN

The changes in the brain due to seizures can be divided into three overlapping temporal groups: acute, subacute, and chronic. Acute changes are those changes that occur in the brain within the first few minutes to days after a seizure. The subacute changes take place from hours to weeks with the chronic changes taking place over weeks to months. The acute changes that occur are activation of immediate early genes (IEGs), posttranslational protein modifications, and changes to ion channel activity. The subacute changes in the brain include neuronal death, activation of neurotrophic factors, inflammation, neurogenesis, and alterations in transcription factors. The chronic changes include mossy fiber sprouting, dendritic plasticity, and increased susceptibility to recurrent seizures (Rakhade and Jensen, 2009).

36.4.1 Acute

36.4.1.1 Immediate Early Genes

IEGs are genes that are rapidly transcribed in response to cellular stimuli, such as neuronal activity, and are implicated in synaptic plasticity and synaptogenesis. Many IEGs are transcription factors and DNA-binding proteins and have the ability to activate specialized signaling cascades. Repeated synaptic activity induces IEG activation which leads to depolarization and opening of NMDA receptor channels. The calcium influx following NMDA receptor activation can cause activation of kinase cascades that result in phosphorylation of specific transcription factors such as cyclic-AMP response element-binding protein (CREB) and CREB-binding protein (CBP) (Greer and Greenberg, 2008). CREB is a bZIP transcription factor that is activated when phosphorylated at its Ser133 site. The phosphorylated CREB (pCREB) then translocates into the nucleus and dimerizes and binds to the promoter consensus sequence TGACGTCA, which is known as the cAMP response element (CRE) motif. pCREB along with CBP, a chromatin regulator, has the ability to upregulate transcription of target genes (Lonze and Ginty, 2002). The upregulated IEGs can activate secondary response genes that have the ability to modulate synaptic activity (Greer and Greenberg, 2008). IEGs, including *Fos, Jun, EGr1, Egr4, Homer1, Nurr77, Arc,* and *CREB,* have been identified as activated in adult animal models of epilepsy (Herdegen and Leah, 1998), some as early as 30 min after seizure induction (Honkaniemi and Sharp, 1999). IEG activation has also been seen in the developing brain, but to a lesser degree. *Fos* and *Jun* activation has been seen in hypoxia-induced seizures and lithium–pilocarpine SE models (Dubé et al., 1998; Jensen et al., 1993). Activation of *Fos* differs based on age and mode of seizure induction. PTZ- and flurothyl-induced seizures show similar patterns of *Fos* activation in the amygdala, piriform cortex, and hypothalamus, but patterns in the cortex vary based on the age of the rat. *Fos* activation in adults is seen in the superficial layers of the cortex, whereas in P10 rats the activation is seen in the deep layers of the neocortex. Hypoxia-induced seizures demonstrated that *Fos* activation is confined to layer VI of the neocortex and is rarely involved in the limbic structures as seen with chemoconvulsant models (Jensen et al., 1993).

36.4.1.2 Ion Channel and Receptor Posttranscriptional Regulation

The calcium influx after a seizure has the ability to activate phosphatases and kinases that alter ion channel and neurotransmitter receptor function. The calcium-calmodulin-activated phosphatase, calcineurin, can lead to $GABA_A$ receptor endocytosis, decreased inhibitory postsynaptic potential frequency, and reduced network inhibition after early-life hypoxia-induced seizures (Sanchez et al., 2005) and adult pilocarpine-induced SE *in vivo* (Kurz et al., 2001). The same observation of calcineurin-regulated $GABA_A$ receptor-mediated synaptic inhibition has also been seen in neuronal culture and whole hippocampal slices (Khalilov et al., 2003). Seizure-induced calcineurin activation causes dephosphorylation and endocytosis of $GABA_A$ receptors (Blair et al., 2004; Sanchez et al., 2005) and $K_v2.1$ channels (Bernard et al., 2004). Pretreatment with FK506, a calcineurin inhibitor, reversed SE-induced dephosphorylation of $GABA_A$ receptor 2/3 subunits. Calcineurin-mediated dephosphorylation and endocytosis of $GABA_A$ receptors reduce their inhibitory function and may contribute to neuronal excitability in the hippocampus after seizures and epileptogenesis (Wang et al., 2009).

Glutamate receptors contain kinase phosphorylation sites that can be activated by seizures in the developing

brain. Within minutes after a seizure in juvenile rats, protein kinase C activity and calcium–calmodulin-dependent kinase II activity cause an increase in phosphorylation of Ser831 on GluR1 and Ser880 on GluR2 subunits of the AMPA receptor. Protein kinase A activity and phosphorylation of Ser845 on GluR1 are also observed (Rakhade et al., 2008a,b). The phosphorylation of Ser831 on GluR1 is known to increase channel conductance and phosphorylation of Ser845 on GluR1 increases open-channel probability (Shepherd and Huganir, 2007), which can lead to AMPA receptor-mediated potentiation (Rakhade et al., 2008a,b). The administration of AMPA receptor antagonists 48 h after a seizure is sufficient to prevent kinase activation, phosphorylation of Ser831 and Ser845 on GluR1, altered AMPA receptor activity, and increased seizure susceptibility later in life (Rakhade et al., 2008a,b). Increased phosphorylation of Ser880 on GluR2 is known to cause endocytosis of GluR2 subunit and increased Ca^{2+} permeability (Shepherd and Huganir, 2007). Activation of cellular sarcoma kinases can induce phosphorylation of NR2A and NR2B receptor subunits in NMDA receptors in the hypoxic–ischemic model of developmental epilepsy (Jiang et al., 2008).

36.4.2 Subacute

36.4.2.1 Neuronal Death

Adult models of epilepsy have shown progressive loss of CA3 and CA1 neurons via necrosis and apoptosis in the hippocampus in response to electrical or chemoconvulsant stimulation (Henshall and Murphy, 2008; Henshall and Simon, 2005). Models of early-life seizures have failed to demonstrate neuronal loss in the amygdala, hippocampus, or temporal cortical regions of animals younger than 2 weeks of age (Holopainen, 2008). There is limited neuronal death seen in the hippocampal neurons of immature brains in the flurothyl-induced seizure model (Wasterlain et al., 2002) and in the febrile seizure model (Toth et al., 1998). In the lithium–pilocarpine model, regional and age-related differences in neuronal cell loss have been demonstrated. In P14 and P21 rats exposed to lithium–pilocarpine-induced seizures, few damaged neurons were seen in the CA1 region of the hippocampus, whereas some neuronal damage was observed in the hilar and CA3 regions at P14, with extensive damage at P21 in some, but not all, animals (Raol et al., 2003; Sankar et al., 1998). The damage is thought to be mediated via necrosis, as demonstrated by eosinophilic cell infiltration, and apoptosis, as demonstrated by terminal deoxynucleotidyl transferase-mediated biotinylated UTP nick end labeling (TUNEL) stain. A direct relationship between age and vulnerability of neurons in the amygdala and dentate gyrus was also observed (Sankar et al., 1998). Interestingly, the degree of cell loss did not correlate with the risk

of later development of epilepsy (Raol et al., 2003). Some variability in neuronal death in chemoconvulsant models has been seen with different routes of administration. Intracerebroventricular (i.c.v.) delivery of kainic acid causes more severe acute and progressive damage than an intraperitoneal (i.p.) route of delivery. Administration of kainic acid in P7 rats i.c.v. causes a dose-dependent acute neuronal loss in the CA3 region of the hippocampus with apoptosis seen in CA3 and CA1 as demonstrated by electron microscopy and TUNEL staining (Humphrey et al., 2002). However, kainic-acid-induced SE in P9 rats delivered by i.p. did not produce neuronal damage (Rizzi et al., 2003).

There is another population of neurons, the subplate neurons, that is susceptible to neuronal loss in the hypoxic–ischemic model of developmental epilepsies (McQuillen et al., 2003). The subplate neurons are located in the deep gray matter proper of the neocortex and become interstitial neurons of the subcortical white matter during the prenatal and neonatal periods. They are important for normal maturation of cortical networks, such as the visual cortex (Kanold et al., 2003; Kostovic and Rakic, 1980; Rakic, 1977). Subplate neurons also possess high levels of NMDA and AMPA receptors (Talos et al., 2006a,b) but lack oxidative stress defense mechanisms, making them especially susceptible to hypoxic–ischemic insults (McQuillen et al., 2003). Administration of antioxidants, such as erythropoietin, after acute hypoxia increased the latency of seizures, reduced the duration of seizures, protected against hippocampal cell loss, and decreased apoptosis in P10 rats (Mikati et al., 2007).

36.4.2.2 Neurotrophic Factors

Neurotrophic factors are important mediators of normal synaptogenesis and are expressed at higher amounts during postnatal development than in the adult (Greer and Greenberg, 2008). Early-life seizures in animal models have been shown to increase neurotrophic factor expression (Tandon et al., 1999). Chronic intrahippocampal injection of brain-derived neurotrophic factor (BDNF) results in spontaneous limbic seizures through TrkB signaling in adult animals, suggesting that BDNF is sufficient to produce epileptogenesis (Scharfman et al., 2002). Mice with a conditional knockout of TrkB in neurons have been shown to be protected from epileptogenesis (McNamara et al., 2006). In the adult rat kindling model, BDNF/TrkB activation suppresses the surface expression of KCC2, thereby suppressing chloride-dependent fast GABAergic inhibition (Rivera et al., 2002). However, BDNF has also been demonstrated to play a neuroprotective role during seizures in immature brains. During kainate-induced seizures in P19 rats, BDNF concentrations increase twofold and the administration of antisense oligodeoxynucleotides

specific to BNDF increased seizure duration and loss of CA1 and CA3 pyramidal cells and hilar interneurons. The neuronal loss was determined not to be dependent on seizure duration (Tandon et al., 1999).

36.4.2.3 Inflammation

The inflammatory processes that occur after seizures in the adult brain are important contributors to neuronal cell death (Kunz and Oliw, 2001); however, the role of inflammatory processes in the developing brain is less well understood. SE-induced glial activation and cytokine transcription are age-dependent. At P9, there is very little increase in the activation of glia and cytokine induction after kainate-induced seizures. At P15, immunostaining of microglia and astrocytes increased, as did IL-1β mRNA expression and CA3 neuronal injury. At P21, the immunostaining of microglia and astrocytes was significantly increased, as were IL-1β, TNF-α, IL-6, and Ra (endogenous IL-1 receptor antagonist). The neuronal injury in CA1 and CA3 was also significantly increased (Rizzi et al., 2003). The precise mechanism of neuronal death is poorly understood; however, increase in cytokine expression may play a role. One possible mechanism may involve IL-1β, as IL-1β is known to initiate phosphorylation of NMDA receptors (Viviani et al., 2003), thereby altering the receptor channel-gating properties to favor Ca^{2+} influx (Ali and Salter, 2001). In the rodent model of prolonged febrile seizure, hippocampal levels of IL-1β were significantly elevated after prolonged febrile seizures for a period of over 24 h. Chronically, IL-1β levels were elevated only in the subset of rats that developed spontaneous limbic seizures after febrile SE, consistent with a role for this inflammatory mediator in epileptogenesis (Dubé et al., 2010).

Microglia are a glial cell type that reside in the brain and spinal cord and function, in a manner similar to macrophages, as active immune defense for the CNS. Microglia reach maximal density in the brain during early development in humans (Billiards et al., 2006) and rodents (Dalmau et al., 2003). In addition to the phagocytic role of microglia, they are able to produce neurotrophic molecules, cytokines, and chemokines (Kim and de Vellis, 2005). Microglia are also involved in classical complement cascade-mediated CNS synapse elimination in the developing brain (Stevens et al., 2007). Seizures can directly activate microglia that trigger a cytokine-mediated inflammatory response, as well as complement factors and major histocompatibility class factors (Vezzani et al., 2008). In adult rats, the administration of the microglial inactivators minocyclin and doxycycline has been shown to protect against neuronal death in the kainate-induced SE model (Heo et al., 2006). This observation could not be reproduced in juvenile rat kainate-induced seizures because of the lack of neuronal cell loss during the second postnatal week in this model (Holopainen, 2008).

Cytokine activation can induce two main developmentally regulated inflammatory pathways: inducible nitric oxide synthesis (iNOS) (Romero et al., 1996) and/or the cyclooxygenase (COX) pathway (Tocco et al., 1997). COX-2 is the rate-limiting enzyme for conversion of arachidonic acid to prostaglandins. The enzyme is upregulated in response to seizures and may contribute to SE-induced CA3 hippocampal neuron damage in adult rats (Kawaguchi et al., 2005; Tu and Bazan, 2003). The expression of COX-2 markedly increases between P7 and P14 and reaches adult levels at P21 (Tocco et al., 1997). The developmentally regulated nature of COX-2 expression may in part explain the age-dependent effect of inflammation and neuronal death. In P9 rats, iNOS and COX-2 were upregulated after NMDA injection-induced excitotoxic shock. iNOS was observed in infiltrated neutrophils and in ramified protoplasmic astrocytes closely associated with blood vessels, whereas COX-2 was observed in active microglial and neuronal cells (Acarin et al., 2002). In P21 KA-induced rats, two phases were seen after seizure induction. The first phase occurs within 30 min, is localized to the hippocampus, and is caused by kainic acid receptor activation. Pretreatment with a selective COX-2 inhibitor, NS398, is able to inhibit the inflammatory process almost entirely. The late phase of the inflammatory process seems to be due to prolonged COX-2 expression localized to the hippocampus (Yoshikawa et al., 2006). Pretreatment with celecoxib, a selective COX-2 inhibitor, in flurothyl-induced P7 rats is able to delay signs of seizure and attenuate COX-2 expression (Kim and Jang, 2006). Interestingly, inflammatory mediators can affect neuronal function by altering activity-dependent long-term synaptic plasticity, neuronal excitability, and synaptic transmission in CA1 pyramidal neurons (Chen and Bazan, 2005).

36.4.2.4 Alteration in Transcription of Receptors

In addition to acute changes in posttranslational regulation of ion channels and neurotransmitter receptors, seizures can induce transcriptional changes in GABA and glutamate receptors (Holopainen, 2008). Kainate-induced seizures in P9 rats are sufficient to alter the normal maturation of $GABA_A$ receptor expression by altering region-selective expression of α_1, α_2 β_3, and γ_2 subunit mRNAs in the hippocampus that can last up to a week (Laurén et al., 2005). In addition to acute and subacute changes in $GABA_A$ receptor composition in young rats, long-term alterations in $GABA_A$ receptor α_1 subunit mRNA and protein expression persisted up to 3 months in the dentate gyrus of the hippocampus in SE-induced P10 and P20 rats (Raol et al., 2006; Zhang et al., 2004). The shifting role of $GABA_A$ receptors

from excitatory to inhibitory in the developing brain is demonstrated when seizures generated by functional excitatory GABAergic synapses cause fast oscillations that are necessary to transform normal network activity to an epileptic network (Khazipov et al., 2004). Interestingly, in the immature brain, inhibition of GABA$_A$ receptors can prevent long-lasting sequelae of seizures, whereas in the adult brain GABA$_A$ receptor inhibition leads to high-frequency seizures (Khalilov et al., 2005).

Seizures also affect the expression of both ionotropic and metabotropic glutamate receptor subunits. Downregulation of kainate receptors in the CA3 and dentate gyrus was observed in recurrent kainate-induced seizures in P12 rats (Tandon et al., 2002). In addition, elevation of mGluR1$_\alpha$ protein expression was seen in the inhibitory interneurons of the CA1 stratum oriens–alveus, amygdala, and piriform cortex of the same kainate-induced model. This change in mGluR1$_\alpha$ expression may induce synchrony of the limbic network suppression that can prevent further seizure propagation (Avallone et al., 2006). There is a decrease in GluR2 protein levels at P10 after lithium–pilocarpine (Zhang et al., 2004) and hypoxia-induced seizures (Sanchez et al., 2001). The decrease in GluR2 levels could be explained by excitotoxicity, which activates the repressor element 1-silencing transcription factor that suppresses GluR2 promoter activity, leading to AMPA receptor-mediated neuronal death (Calderone et al., 2003). Ionotropic glutamate receptors such as NMDA receptors are responsible for the excitotoxicity seen with prolonged receptor activation and Ca^{2+} influx in seizure-related neuronal death in adult rats (Furukawa et al., 1997).

Pilocarpine-induced SE in P14 rats showed increased AMPA GluR2 and kainate KA2 subunit mRNAs with decreases in AMPA GluR3 and kainate GluR6 mRNAs, but only in mature dentate granule cell neurons. In the study, immature dentate granule cells showed a decrease only in kainate GluR6 mRNA levels (Porter et al., 2006). These changes to kainate receptor subunits may play a role in the altered kainate receptor conductance and dentate granule cell excitability seen in chronic epilepsy (Epsztein et al., 2005). At P7, a single kainate-induced seizure has the ability to cause a long-term decrease in expression of GluR1 and NR2A subunits and an increase in PSD-95, a primary subsynaptic scaffold, in CA1 (Cornejo et al., 2007).

36.4.2.5 Neurogenesis

Increased neurogenesis has been seen in autopsy specimens and tissue biopsies from pediatric epilepsy surgery patients (Takei et al., 2007). Timing of the seizure insult plays a very important role in seizure-induced neurogenesis. There is a significant decrease in the neurogenesis observed in the granule cell layer of the dentate gyrus following a series of 25 flurothyl-induced seizures at P0–P4 as determined via 5-bromo-2′-deoxyuridine-5′-monophosphate (BrdU) and NeuN co-labeling (McCabe et al., 2001; Schmid et al., 1999). The decrease in BrdU labeling continued for 6 days after the last seizure. A single flurothyl-induced seizure showed no difference in BrdU-labeled cells when compared to controls. Adult rats that were subjected to a series of 25 flurothyl-induced seizures showed a marked increase in dentate gyrus neurogenesis when compared to controls (McCabe et al., 2001). Between 1 and 4 weeks of age, chemoconvulsant-induced seizures cause long-term increases in dentate granule cells after flurothyl-induced seizures (Holmes et al., 1998) and lithium–pilocarpine-induced seizures (Porter et al., 2004; Sankar et al., 2000). Lithium- and pilocarpine-induced SE rats at P20 showed a sixfold increase in BrdU labeling 8 days after SE induction in the dentate gyrus, which decreased to a threefold increase 3 weeks after induction. In addition to increased neurogenesis, an increase in apoptosis was observed in the same samples as determined by a threefold increase in TUNEL staining 8 days after induction as compared to controls. Only a subset of the newborn cells actually went on to become mature neurons as demonstrated by NeuN staining (Porter et al., 2004). The number of episodes of SE and type of chemoconvulsant also have important implications for neurogenesis. One or two episodes of kainate-induced seizures showed no difference at P6 and P9 in BrdU labeling in the dentate gyrus when compared to controls. However, three episodes of kainate-induced seizures demonstrated a decrease in BrdU labeling in the dentate gyrus at P6, P9, and P13 at 48 h after seizure. No difference in cell death or apoptosis was observed in the kainate-induced SE rats when compared to controls; however, the newly born cells demonstrate irregular morphology (Liu, 2003). Alterations in neurogenesis may have a significant functional impact on normal brain development since 80% of granule cells develop after birth, and about half develop after P5 in normal rat brain development (Bayer, 1980).

36.4.3 Chronic

36.4.3.1 Sprouting

In adult rodent models of epilepsy and chronic epileptic foci removed from adult and older pediatric patients, hippocampal granule cell mossy fibers 'sprout' aberrant collaterals to the inner molecular layer of the dentate gyrus, forming monosynaptic connections and a positive feedback loop that may contribute to the seizure focus (Williams et al., 2007). The degree and localization of mossy fiber sprouting differ greatly with age (Holmes et al., 1998, 1999; Liu et al., 1999). In neonatal seizures, much of the sprouting is minimal and located in the CA3 (Holmes et al., 1998, 1999). The adult has a greater

amount of sprouting, which is localized to the supragranular region and results from cell loss in the hilus and CA3 (Liu et al., 1999). The pattern of mossy fiber sprouting in early-life seizures is distinct from adult patterns in that the mossy fiber synapses terminate on the basal dendrites in the CA3 region and the stratum oriens (Holmes et al., 1999). There is some controversy regarding the effect of sprouting on epileptogenesis. Early studies have demonstrated that direct infusion of the protein inhibitor cyclohexamide was able to block pilocarpine- and kainate-induced mossy fiber sprouting in adult rats but not epileptogenesis (Longo and Mello, 1997). However, more recent studies have demonstrated that direct infusion of cyclohexamide to the dentate gyrus of adult rats spanning the period of pilocarpine treatment was unable to block mossy fiber sprouting or epileptogenesis (Toyoda and Buckmaster, 2005; Williams et al., 2002). The mechanism of mossy fiber sprouting is still unclear. Some hypothesize that the sprouting is caused by hyperexcitability; however, recent studies do not support this hypothesis. In adults, blocking L-type calcium channels and sodium channels is unable to stop mossy fiber sprouting in the pilocarpine model (Buckmaster, 2004; Ingram et al., 2009). However, in P14 mice, pilocarpine-induced L-type calcium channel blockade was able to inhibit mossy fiber sprouting (Ikegaya et al., 2000). Early treatment with rapamycin, an inhibitor of the mammalian target of rapamycin, was able to decrease seizure susceptibility in a transgenic mouse model of tuberous sclerosis (Meikle et al., 2008) and block mossy fiber sprouting in the pilocarpine model only with constant infusion, as the sprouting developed again after the cessation of infusion (Buckmaster et al., 2009).

36.5 TREATMENTS

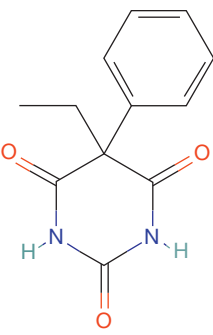
The most challenging aspect of pediatric epilepsy treatment is to identify drugs that can protect against seizures while allowing normal functioning and development of the nervous system. Bromide was the first effective epilepsy treatment. Bromides act by augmenting $GABA_A$ receptor-mediated inhibition by increasing $GABA_A$-mediated currents due to a threefold increase in receptor permeability to Br^- over Cl^- (Bormann et al., 1987; Gallagher et al., 1978). Bromide has been replaced with less toxic antiepileptic drugs (AEDs), some of which target the same GABAergic pathway. Many newer AEDs work through non-GABAergic pathways or possess mixed mechanisms of action. The three main mechanisms of AEDs include enhancement of synaptic inhibition, reduction of synaptic excitation, or modulation of voltage-gated ion channels. Molecular targets of AEDs include voltage-gated sodium channels, voltage-gated calcium channels, GABAergic neurotransmission, and glutamatergic neurotransmission (Rogawski and Löscher, 2004; Table 36.2).

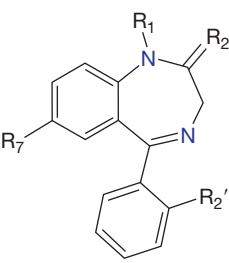
Methods of AED discovery have been recently reviewed by Bialer and White (2010). It is important to note that AED drug testing is typically studied in the adult rat brain. Drugs that pass this first level of screening are then studied in models of epilepsy, typically first in adult models and only later (if at all) in developmental epilepsies. There are three main types of drug-testing modalities used currently: maximal electroshock, subcutaneous PTZ injection, and electric kindling. The maximal electroshock modality utilizes electrical pulses delivered via ear clips or corneal electrodes to cause tonic extension of the hind limbs. If the administration of the drug inhibits the extension of the hind limbs, then the potential AED is thought to prevent the spread of seizure activity through neural tissue and is useful in screening AEDs effective against generalized tonic–clonic seizures. In the subcutaneous PTZ injection, animals are evaluated for clonic seizures. The effectiveness of a drug is determined by its ability to suppress these clonic seizures, making the model useful for finding AEDs effective against generalized myoclonic seizures. The drug discovery model of electrical kindling uses corneal electrodes to deliver 6 Hz electrical signals to induce complex partial seizures. Animals that do not display a clonic phase and automatisms are thought to be protected, making this method useful in screening drugs effective against partial seizures (Bialer et al., 2002; Holmes and Zhao, 2008). Unfortunately, these methods are not always accurate in their predictive efficacy. Levitacetam failed the subcutaneous PTZ and maximal electroshock models, but has proven to be a very effective AED (Klitgaard et al., 1998; Löscher et al., 1998). Therefore, new models of drug screening will be important in the future discovery of effective AEDs, especially for pediatric epilepsies.

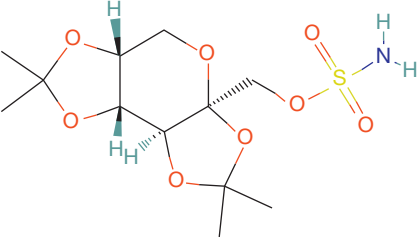
36.5.1 GABA

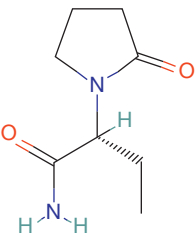
36.5.1.1 Phenobarbital

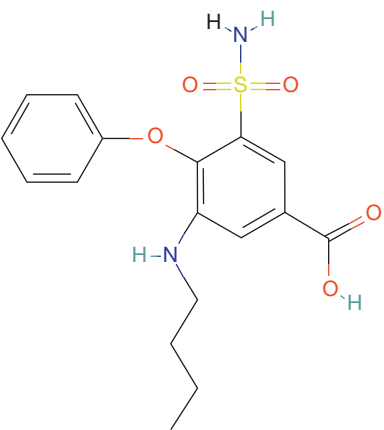
Phenobarbital is a positive allosteric modulator of $GABA_A$ receptors that works by increasing channel-opening probability (Macdonald and Olsen, 1994). In addition to its primary GABAergic effect, phenobarbital can also block sodium channels and T-type calcium channels (Ffrench-Mullen et al., 1993). Phenobarbital is currently used as a first-line therapy for pediatric seizures but is mostly ineffective due to the shift in chloride gradient previously described. The effects of prenatal exposure to phenobarbital on CNS development have been studied extensively (Fishman and Yanai, 1983; Yanai et al., 1979) and have been reviewed (Kaindl et al., 2006). Perinatal and early-life exposure to phenobarbital can reduce brain

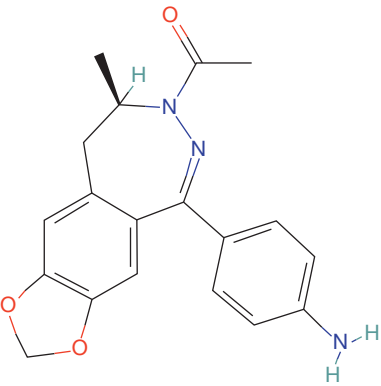
TABLE 36.2 Antiepileptic Drugs Used to Treat Neonatal Seizures and Pediatric Epilepsies


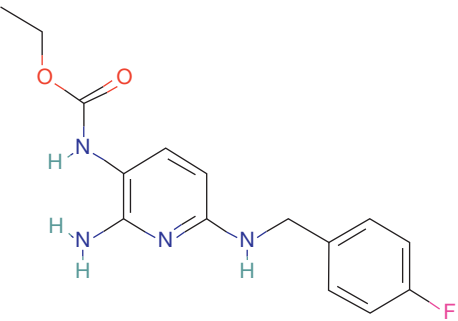












Structure	Drug	Primary effect	Site of action
	Phenobarbital	Enhances inhibition	GABA(A) – Mature brain
	Benzodiazepines	Enhances inhibition	GABA(A) – Mature brain
	Topiramate	Decreases excitation and enhances inhibition	Voltage-dependent sodium channels, Calcium channels, AMPA, and Kainate receptors/ GABA(A)
	Levetiracetam	Decreases excitation and enhances inhibition	Calcium channels, and SV2A/ GABA(A)
	Bumetanide	Enhances inhibition	NKCC1 (chloride gradient)

TABLE 36.2   Antiepileptic Drugs Used to Treat Neonatal Seizures and Pediatric Epilepsies—cont'd

Structure	Drug	Primary effect	Site of action
	Talampanel	Decreases excitation	AMPA receptors
	Flupirtine	Decreases excitation and enhances inhibition	NMDA receptors/KCNQ channels

weight in infant rats, with reductions in DNA, RNA, protein, cholesterol, neuronal number, and neurogenesis occurring, as well as enhanced apoptosis and alterations in gene expression (Bittigau et al., 2002; Diaz and Schain, 1978; Pick and Yanai, 1985; Raol et al., 2005; Stefovska et al., 2008; Yanai et al., 1989). Behavioral studies evaluating the morphological and neurochemical effects of perinatal and early-life exposure to phenobarbital, including deficits in various spatial-learning tasks and memory (Mikati et al., 1994; Pick and Yanai, 1985; Rogel-Fuchs et al., 1992; Yanai et al., 1989). Perinatal exposure to phenobarbital also increased aggression and activity levels in neonatal rats (Diaz and Schain, 1978; File and Wilks, 1990). Phenobarbital also has effects on synaptogenesis and myelination. The administration of phenobarbital to neonatal rats resulted in persistent abnormalities in mitochondria, myelin sheaths, and lamellar inclusion bodies in the cerebellum when compared to controls (Fishman et al., 1989).

36.5.1.2 Benzodiazepines

Benzodiazepines are first-line drugs in the treatment of SE. The actions of benzodiazepines are mediated by allosterically modulating GABA$_A$ receptors that contain the γ_2 with the $\alpha 1$, $\alpha 2$, $\alpha 3$, and $\alpha 5$ subunits (Rudolph et al., 1999; Smith, 2001), increasing GABA$_A$ receptor currents

(Bai et al., 2001). Behavioral deficits have been attributed to the effects of benzodiazepines on memory, possibly due to an alteration in attention (Pereira et al., 1989). The administration of a single dose of diazepam to P11 rats caused a significant decrease in cell proliferation (Pawlikowski et al., 1987). Diazepam and clonazepam administration to P7 rats caused widespread apoptotic neurodegeneration, which is associated with reduced expression of neurotrophins and other prosurvival proteins (Bittigau et al., 2002). Diazepam administration from P10 to P40 in rats permanently altered the expression of genes for GABA receptor subunits, GABA transporters, and GABA-synthesizing enzymes in hippocampal dentate granule neurons (Raol et al., 2005). Diazepam also affects cell proliferation, cell differentiation, and myelination making it less than ideal for treating pediatric epilepsies (Stefovska et al., 2008).

36.5.2 Non-GABA

36.5.2.1 Topiramate

Topiramate works through many pharmacological mechanisms including modulation of voltage-dependent sodium channels, modulation of calcium channels, enhancement of the effect of GABA on GABA$_A$ receptors,

and modulation of AMPA and kainate receptors, all of which have been demonstrated to possess possible neuroprotective qualities. The administration of topiramate before hypoxia-induced seizures suppressed acute seizures in a dose-dependent manner. In addition to blocking acute seizures, topiramate administration was also able to eliminate the long-term susceptibility to kainate-induced seizures and the seizure-induced neuronal injury observed after acute hypoxia (Koh and Jensen, 2001). In lithium–pilocarpine-induced seizures in P20 rats, topiramate treatment resulted in an improved visuospatial performance in the water maze test when compared to saline-treated controls; however, no differences were found in histological examination of the hippocampus. The administration of topiramate in seizure-free neonatal rats resulted in no difference in water maze or histological studies (Cha et al., 2002). Topiramate demonstrates no neurotoxicity to the developing brain at anticonvulsant doses in P7 rats, in stark contrast to phenobarbital (Glier et al., 2004). The administration of topiramate to cultured fetal rat hippocampal and cortical neurons showed an increase in neurite outgrowth (Smith-Swintosky et al., 2001).

36.5.2.2 Levetiracetam

The mechanism of levetiracetam is not fully understood. The drug can block N-type calcium channels and reverse the inhibition by negative allosteric modulators such as zinc and beta-carbolines on neuronal GABA and glycine-gated currents (Rigo et al., 2002). Another pharmacological function distinct to levetiracetam is its binding to synaptic protein SV2A (Lynch et al., 2004). Recent studies have determined that SV2A is an important broad-spectrum anticonvulsant target (Kaminski et al., 2008). More studies are needed to elucidate the role of SV2A in ictal events. The administration of levetiracetam resulted in no deficits in visuospatial memory as observed via water maze testing in amygdala-kindled rats (Lamberty et al., 2000). In neonatal rats, levetiracetam resulted in no neurotoxicity when administered from P0 to P7 and analyzed from 2 to 5 days after administration (Manthey et al., 2005). Levetiracetam is effective in treating tonic convulsions and absence-like seizures in spontaneously epileptic rats during drug administration for up to 8 days after final administration, possibly demonstrating an antiepileptogenic effect (Ji-qun et al., 2005). Levetiracetam administration resulted in no alteration in hippocampal cell proliferation; however, significant effects in protein expression associated with the cytoskeleton, energy metabolism, neurotransmission, signal transduction, myelination, and stress response were observed (Paulson et al., 2010).

36.5.2.3 Bumetanide

Bumetanide is a well-known loop diuretic that is a specific inhibitor of NKCC1. Since enhanced expression of NKCC1 relative to KCC2 is responsible for the excitatory actions of GABA in the developing brain, it is easy to hypothesize that inhibiting NKCC1 would result in decreased excitatory actions of GABA. Dzhla et al. demonstrated the ability of bumetanide to shift the chloride gradient in immature neurons, suppress the epileptiform activity in hippocampal slices, and attenuate electrographic seizures in neonatal rats *in vivo* (Dzhala et al., 2005). Recent *in vitro* studies have shown that bumetanide can enhance the efficacy of phenobarbital in a neonatal seizure model. In the study, phenobarbital alone was able to abolish recurrent seizures in only 30% of the hippocampal slices, whereas the administration of bumetanide with phenobarbital was able to abolish recurrent seizures in 70% of the hippocampal slices. In addition to preventing recurrent seizures, the coadministration of bumetanide and phenobarbital also reduced the frequency, duration, and power of seizures in the remaining 30% (Dzhala et al., 2008). Bumetanide is able to block focal epileptic seizures in immature rat hippocampus, but is not able to prevent the formation of an epileptogenic mirror focus *in vitro* (Nardou et al., 2009).

36.5.2.4 Talampanel

Talampanel is a noncompetitive antagonist of the AMPA receptor and possesses anticonvulsant and neuroprotective properties. Talampanel administration to P10 rats in the hypoxia-induced seizure model suppressed seizures in a dose-dependent manner. Pretreatment of P10 rats before hypoxia prevented increases in seizure-induced neuronal injury later in life (Aujla et al., 2009). Talampanel is also neuroprotective in the CA1 region of the hippocampus in the fluid percussion traumatic brain injury model when administered within 30 min of injury but not when administered at 3 h (Belayev et al., 2001).

36.5.2.5 Flupirtine

Flupirtine, a selective neuronal potassium channel opener, activates KCNQ channels (G-protein-regulated inward rectifying K^+ channels) and stabilizes the resting membrane potential. Flupirtine also works via NMDA receptor antagonism by enhancing Mg^{2+} blockade (Kornhuber et al., 1999). The anticonvulsant properties of flupirtine have only recently been studied. Flupirtine proved successful in completely suppressing seizures in the flurothyl model of neonatal seizures and in preventing electrographic and behavioral seizures in the kainic-acid-induced SE model in P10 rats (Raol et al., 2009). Further studies are necessary to determine the long-term effects of flupirtine treatment of neonatal seizures.

36.6 CONCLUSION

Epilepsy is a very complex disease that affects millions of people worldwide. There are many different types of epilepsy, with various animal models used to elucidate the molecular mechanisms of epileptogenesis. The developing brain is especially sensitive to seizures and epilepsy due to the early enhancement of excitation in the immature brain. The acute and chronic effects of SE are quite complicated and include alterations in ion channels and neurotransmitter receptors, neuronal death, neurotrophin expression, inflammation, and mossy fiber sprouting. Since the development of the human brain is quite dynamic, the same therapeutic modalities used in adults have proved unsuccessful in controlling neonatal seizures. Newer therapeutics that act via novel mechanisms and are more effective in the developing brain are needed in order to treat those suffering from neonatal seizures and pediatric epilepsies adequately.

Sensory Organ Disorders (Retina, Auditory, Olfactory, Gustatory)

D.C. Gillespie

McMaster University, Hamilton, ON, Canada

37.1 INTRODUCTION

Over the past several decades, many common historical causes of congenital sensory impairment have been eradicated or diminished by economic growth and by targeted programs combating disease and maternal health, among others. As a result, at some point in the last few decades, and perhaps for the first time in human history, inherited disorders have become the most common cause of congenital sensory impairment. Over the past 15 years, specific genes, protein function, and disease etiology have been identified at an accelerating rate.

The growing number of animal models for developmental sensory disorders has been tremendously useful for understanding both normal and abnormal development and sensory processing.

37.2 HEARING IMPAIRMENT

Developmental auditory disorders may involve defects at any stage from the moment sound enters the external ear to the sensorineural synapse to the

downstream processing pathways of the central nervous system. Disorders of the auditory organ are thus roughly classified as *conductive*, affecting primarily the mechanical structures of the external and middle ear; *sensorineural*, affecting primarily the sensory, neural, and supporting structures of the inner ear and central auditory pathway; or *mixed.* Because hearing impairment that precedes language acquisition can be especially significant, hearing loss is often characterized as *prelingual*, occurring before 2 years of age, or *postlingual.* Severity of hearing loss may be mild (<40 dB), moderate (40–70 dB), severe (70–90 dB), or profound (>90 dB).

37.2.1 Acquired Hearing Loss

Many forms of hearing loss are preventable. The hair cells, for example, are particularly vulnerable to acoustic trauma and to a wide range of ototoxic drugs (e.g., cisplatin, isoretinoin, alcohol, aminoglyocoside antibiotics, loop-diuretics), and as mammalian hair cells do not regenerate, the inner hair cells constitute a scarce resource at only about 3500 cells per human cochlea. Infection has long been a major cause of hearing loss. Both acquired and congenital syphilis can produce otosyphilis, which if untreated causes endolymphatic hydrops (fluid accumulation) and subsequent degeneration accompanied by hearing loss and vestibular dysfunction. Although reports of congenital otosyphilis are rare in the current literature, there is concern that this disorder could rise with the reemergence of syphilis. Historically, rubella (German measles) was a major cause of hearing loss, and over half of all cases of congenital rubella syndrome, acquired through maternal infection, still lead to hearing loss. Vaccination programs have largely eliminated rubella from high-income countries, though the disease and its consequent hearing loss are still common in many low-income countries (Tucci et al., 2010). Hearing loss as a result of anoxia, maternal diabetes, and maternal herpes simplex virus are also still seen.

The infectious agent with greatest relevance to childhood hearing loss is perhaps the herpes virus cytomegalovirus (CMV), which is now considered a leading cause of congenital developmental disorders. CMV is widespread in humans, with CMV infection rates at birth estimated at 0.2–1%, and sensorineural hearing loss may develop in children who appear healthy at birth. Congenital CMV is estimated to cause 6% of hearing impairment in newborns and 15–25% of sensorineural hearing loss in children in the United States, and is now the primary cause of noninherited sensorineural hearing loss in children. Despite the incidence of this disorder, and the recent introduction of mouse models for CMV-induced hearing loss, the pathology of this CMV-induced hearing loss is still not well understood,

and control remains focused on hygiene and on development of a vaccine or antiviral.

37.2.2 Inherited Hearing Loss

While a significant proportion of human congenital hearing loss was once due to disorders associated with maternal infection, in middle- and high-income countries today, the majority of congenital hearing loss has a genetic component. The most common form of sensory impairment, hearing loss, is also one of the most common birth abnormalities. Clinically, the various sensory disorders are typically categorized as nonsyndromic or primary (e.g., isolated deafness not accompanied by other apparent abnormalities) and syndromic (e.g., deafness accompanied by other sensory, morphological, or physiological abnormalities). Nonsyndromic disorders, though less numerous, account for a majority of cases of deafness of genetic origin; the various nonsyndromic disorders are identified by inheritance pattern, with DFN, DFNA, and DFNB referring to X-linked, autosomal-dominant, and autosomal-recessive deafness disorders (see Table 37.1). In practice, this increasingly long list can be confusing due to genetic heterogeneity and to overlap with some of the syndromic forms of deafness. As the list of mapped loci and identified genes for inherited deafness disorders is still growing, any attempt to encompass the known hereditary hearing disorders is quickly made obsolete by the description of new disorders in mouse and human. A selection from the wide range of auditory disorders will be briefly described here, and the reader is encouraged to consult updated websites and reviews for the most current, in-depth information (Dror and Avraham, 2009; Petit and Richardson, 2009).

37.2.2.1 Hereditary Conductive or Mixed Hearing Loss

In normal hearing, sound is collected at the external ear and focused into the external ear canal. The sound waves set up vibrations of the tympanic membrane that are transmitted by the three small bones of the ossicular chain through the air-filled cavity of the middle ear to the membranous oval window at the border between the middle and inner ear. The hinged lever-like mechanical advantage system of the interconnected ossicles, together with the reduction in surface area between the tympanic membrane and the oval window, allow pressure at the tympanic membrane to be amplified sufficiently to drive compressive waves in the fluid-filled cochlea of the inner ear. When conductive hearing loss presents in children, it is most often associated with otitis media, or middle ear infection, and its sequelae, which can include chronic perforation, mastoiditis, cholesteatoma, ossicular fixation, or tympanic membrane

retraction, among others. Congenital conductive hearing loss most often results from malformations of the middle ear that cause fixation or disruption of the ossicular chain. As a group, the conductive losses are relatively tractable, as the various forms can often be successfully treated with surgery.

Deafness with perilymphatic Gusher is an X-linked disorder that involves congenital mixed conductive and sensorineural hearing loss and is caused by mutation of Brain 4 (Brn4, or POU3F4), a POU-domain transcription factor expressed in the developing otic mesenchyme. The conductive hearing loss results from stapes fixation to the oval window (with the name of the disorder arising from perilymph that gushes out from the cochlea during surgery to free the stapes). The sensorineural hearing loss in the mouse model likely results from a critical role of *Brn4* in establishing the endocochlear potential. Female carriers have been reported to have milder hearing loss that may be conductive or sensorineural. Mutation of the T-box transcription factor gene TBX1 is associated with velocardiofacial syndrome/DiGeorge syndrome, which is often accompanied by chronic otitis media. In mice, *Brn4* has been shown to interact with *Tbx1* to specify cochlear structure (Braunstein et al., 2008).

Several syndromes involving joint disorders, such as Cushing symphalangism, multiple synostoses, and the recently described Teunissen–Cremers syndrome ('stapes ankylosis with broad thumbs and toes'), result in moderate conductive hearing loss. These disorders can be caused by mutations affecting noggin (NOG) or growth and differentiation factor 5 (GDF5), both of which interact with bone morphogenetic proteins (BMP) during development. The secreted signaling proteins BMPs and GDFs induce bone formation, whereas the BMP antagonist NOG halts cartilage production at the site of joint initiation and is thus a critical player in joint development. GDF5 gain of function mutations and NOG loss of function mutations are both associated with ossicular fixation. In heterozygous $Nog^{+/-}$ mice

with varying degrees of hearing loss, impairment is associated with the presence of an extra bone fragment of the stapes that interferes with normal stapedial movement, and complete loss of *Nog* results in a more extreme phenotype with fused ossicles (Hwang and Wu, 2008). Thus, in the developing middle ear, *Bmp4*, *Gdf5*, and *Nog* may cooperate to establish the stapes and to separate it from the styloid process during ossicular development.

As much as 2% of profound deafness in childhood may be caused by the autosomal-dominant disorder branchio–oto–renal syndrome (BOR), which is characterized by branchial arch and renal abnormalities, together with variable hearing loss of sensorineural, conductive, or mixed origin. BOR can include structural anomalies of the external, middle, and inner ear and is associated with mutations of *Drosophila* eyes-absent homolog 1 (EYA1). In mouse, *Eya1* is expressed in adult hair cells, as well as in the developing mouse otocyst, and deletion of *Eya1* halts development at the otocyst stage. The *Eya1* gene product is a transcriptional coregulator that translocates to the nucleus together with sineoculis *Six1*, and mutations in SIX1 result in both BOR and the closely related branchiootic syndrome 3 (BOS3) (Kochhar et al., 2007).

Cholesteatoma occurs when keratin-producing squamous epithelium develops within the temporal bone or middle ear; as this mass expands, it impinges on nearby structures, causing conductive hearing loss. This disorder, which can present in childhood or adulthood, most often occurs after otitis media or injury to the tympanic membrane, occurring as a uni- or bilateral conductive hearing loss, and may result from a genetic predisposition to otitis media. A rare congenital cholesteatoma has also been reported in cases of BOR and in adenomatous polyposis coli, a disorder associated with mutations of the adenomatous polyposis coli (APC) gene, multiple adenomatous polyps, and colorectal cancer. Several forms of nonsyndromic and syndromic hearing loss may involve chronic otitis media. For example,

sensorineural hearing loss DFNA10 is a postlingual progressive hearing loss that typically presents late, in at least the second decade. This disorder involves the eyes-absent homolog EYA4, and the $Eya4^{-/-}$ mouse model displays a predisposition to otitis media. Several additional, as yet unidentified genes that function during development to direct middle ear anatomy likely also result in a susceptibility to otitis media (Rye et al., 2011). The rare autosomal-dominant craniofacial disorder, Treacher–Collins syndrome, is often accompanied by conductive hearing loss due to abnormalities of the ossicular chain. The syndrome is caused by a mutation affecting the nucleolar phosphoprotein treacle (TCOF1), which controls ribosome production and is required for proliferation of neural crest cells.

Semicircular canal dehiscence is a rare condition in which an opening in the bone of the semicircular canal effectively creates a third window in the inner ear. This extra outlet acts as a relief valve, such that oval window vibrations that would normally drive only the cochlear perilymph toward the round window are transmitted in part toward this third window, stimulating the vestibular organs. In patients with this condition, acoustic stimuli or fullness of the middle ear can produce dizziness and nystagmus. Otopalatodigital syndrome and frontometaphyseal dysplasia are X-linked skeletal dysplasias that also result in moderate to profound conductive deafness and are linked to the actin-binding protein filamin A (FLNA). Finally, congenital atresia of the oval window and perilymph fistula (loss of perilymph into the middle ear) are rare conductive disorders of unknown etiology.

37.2.2.2 Hereditary Sensorineural Hearing Loss

Sensorineural hearing loss is most commonly related to defects within the cochlea, though a small percentage of hearing loss is more central. The mammalian inner ear, encased in the temporal bone, comprises six sensory organs: five belonging to the vestibular system and one, the cochlea, to the auditory system. The cochlea coils about 2.5 times in humans (less in certain disorders), narrowing toward its apex, and in cross section is divided into three fluid-filled ducts that run in parallel nearly the length of the coiled cochlea. Two of these ducts, the perilymph-filled scala vestibuli and scala tympani, join at the apical end of the cochlea to form a continuous chamber with the oval window at one end and the membranous round window at the other. The endolymph-filled scala media is sandwiched between the scalae vestibuli and tympani and contains the receptor organ itself, the organ of Corti, which comprises the mechanosensitive hair cells – one row of inner hair cells, the actual sensory receptor cells along the inside of the cochlear spiral, and three rows of outer hair cells that provide cochlear amplification – as well as several types of supporting cells. Each hair cell is a polarized neuroepithelial cell whose apical, mechanotransducing pole contains the stereocilia hair bundle, and whose basal, synaptic pole is surrounded by supporting cells of the basilar membrane. The stereocilia project into the endolymph, and the tallest stereocilia of the outer hair cells are inserted in the tectorial membrane, a gelatinous extracellular matrix. At the inner, coiled, core of the cochlea lies the spiral ganglion, containing the cell bodies that give rise to the afferent fibers of the auditory nerve.

Vibrations of the oval window are transmitted to the perilymph in the scala vestibuli, setting up a traveling wave that propagates along the basilar membrane, which is tuned by mechanical properties along its length to map low-frequency sounds near the apex and high-frequency sounds near the base of the cochlea. The traveling wave at the basilar membrane induces movement relative to the hair cell bundle. Tethered only at one end, the tectorial membrane can move in part independently of the organ of Corti, and the shearing motion of the tectorial membrane against the organ of Corti causes deflection of the hair bundles. Outer hair cells actively amplify the cochlear mechanics through a mechanism that is still controversial.

Inward current through the mechanoelectrical transduction channels produces a receptor potential that alters the tonic release of glutamate at the hair cell–ganglion cell synapse; the majority of hair cells innervated by ganglion cells of the cochlear nerve are inner hair cells. The active mechanical properties of the cochlea cause the healthy cochlea to emit faint sounds, both spontaneously and in response to auditory stimuli. These otoacoustic emissions (OAEs) can be recorded and used clinically to assess outer hair cell motility and/or to identify whether the site of hearing loss is cochlear. As a noninvasive test that does not require a behavioral response, OAE recording is also commonly used to screen newborns for hearing loss. Central dysfunction is indicated by abnormal auditory brainstem responses (ABRs), auditory evoked potentials recorded at surface electrodes. Auditory neuropathy refers to any one of several forms of nonsyndromic sensorineural hearing loss in which the deficit is localized to the inner hair cell–ganglion cell synapse, or to neurons of the auditory nerve and auditory brain stem.

37.2.2.3 Hearing Loss and the Tectorial Membrane

The longest stereocilia of each outer hair cell contact the tectorial membrane, a specialized extracellular matrix consisting of collagen fibril bundles, together with three non-collagenous glycoproteins – otogelin, α-tectorin, and β-tectorin – that are expressed only in the inner ear. As mRNA for both tectorins is only transiently expressed during cochlear development, whatever form the tectorial membrane takes during that

period likely persists for the lifetime of the organism. Though loss of otogelin in mouse causes early vestibular dysfunction, followed by a variable, progressive hearing loss and subtle abnormalities of the tectorial membrane, no human deafness associated with otogelin mutations has yet been identified (Simmler et al., 2000). In contrast to the subtle changes caused by the lack of otogelin, the absence of α-tectorin results in a failure to form the striated sheet matrix, the non-collagenous portion of the tectorial membrane. Mutations affecting α-tectorin (TECTA) are found in prelingual mid-frequency hearing loss of mild to profound severity, in both autosomal-dominant (DFNA8/12) and autosomal-recessive (DFNB21) forms of nonsyndromic hearing loss. In animal models lacking α-tectorin, otogelin and β-tectorin are not incorporated in the tectorial membrane and the tectorial membrane fails to associate normally with the spiral limbus and the organ of Corti, with the result that basilar membrane sensitivity is reduced and OAEs are abolished (Legan et al., 2000). To date, no mutations affecting β-tectorin (TECTB) have been associated with human hearing loss, though loss of *Tectb* in mouse results in a low-frequency hearing loss.

Two additional genes expressed uniquely in the inner ear are associated with sensorineural hearing loss. Otoancorin (OTOA) mutations associate with moderate to severe prelingual autosomal-recessive hearing loss DFNB22. Otoancorin is expressed at the apical surface of supporting cells adjacent to hair cells, but its role at the interface between the tectorial membrane and the sensory epithelium remains to be identified. Stereocilin (STRC) localizes to the distal portion of outer hair cell stereocilia. In humans, STRC mutations are associated with the early postlingual hearing loss DFNB16. In the mouse model $Strc^{-/-}$, which also experiences early hearing loss, the stereocilia array is established, but without the apical connectors between stereocilia or the links attaching stereocilia to the tectorial membrane, the stereocilia array rapidly deteriorates (Verpy et al., 2011).

37.2.2.4 Hypothyroidism and Hearing Loss

Congenital hypothyroidism in humans has been associated with a range of conductive and sensorineural hearing loss. Though none of these pathologies is entirely clear, animal studies point to a few possible pathways for hypothyroidism-induced hearing loss. The transcription factors thyroid receptor TRα1 (*Thra*) and T3 thyroid receptor TRβ (*Thrb*) are variably expressed during embryogenesis in the cochlea, *Thra* throughout the cochlea, and *Thrb* at high levels in the organ of Corti and at lower levels in the stria vascularis. Embryonic hypothyroidism delays development of the organ of Corti and prevents the normal transient developmental upregulation of β-tectorin mRNA. The Snell dwarf $Pou1f^{dw}$ mouse model highlights several effects of congenital hypothyroidism: (1) the tectorial membrane is abnormal, possibly due to altered β-tectorin expression; (2) KCNQ4 expression and function in outer hair cells is reduced; and (3) the endocochlear potential is decreased due to reduced expression of the inwardly rectifying K^+ channel KCNJ10 in intermediate cells of the stria vascularis (Mustapha et al., 2009).

37.2.2.5 Pendred Syndrome

Pendred syndrome (deafness with goiter) is the most common syndromic form of deafness, accounting for up to 7.8% of cases of congenital deafness and occurring in an estimated 7.5 of 100,000 births. Patients inheriting this autosomal-recessive disorder have variable degrees of deafness at birth and typically develop goiter in the second decade. The syndrome is accompanied by structural defects of the temporal bone such as Mondini dysplasia and enlarged vestibular aqueduct (EVA) that are likely driven in part by accumulation of endolymph. The vestibular aqueduct, embedded within the temporal bone, is a small canal containing the endolymphatic duct and extending from the vestibule between the cochlea and the labyrinth to the endolymphatic sac. In Mondini dysplasia, the apical turn of the cochlea fails to form, and patients are profoundly deaf at birth. In EVA, vestibular dysfunction may be present and the hearing loss is variable. The mutated Pendred syndrome gene PDS (SLC26A4) is a member of the solute carrier protein 26 anion transporter family, and the gene product pendrin is a transmembrane $Cl^-/I^-/HCO_3^-$ transporter. Allelic heterogeneity produces some SLC26A4 variants with Pendred syndrome and others with non-syndromic deafness with EVA (DFNB4).

Pendrin is expressed in the inner ear and kidney, and in the thyroid, where it mediates apical iodide transport in thyroid follicular cells (Kopp et al., 2008). Although Pendred syndrome is sometimes accompanied by hypothyroidism that could itself contribute to hearing loss, the distribution of the mouse pendrin throughout the endolymphatic duct and sac, and in specific areas of utricle, saccule, and external sulcus, points to a specific role of pendrin in fluid resorption and in regulating the ionic composition of the cochlear endolymph. The cochlear endolymph of the scala media is a unique extracellular fluid of high K^+ concentration and low Na^+ and Ca^{2+} concentrations. The unusual ionic makeup of the cochlear endolymph gives rise to a positive 'endocochlear potential' of about $+80$ mV and provides the driving force responsible for the large receptor potentials recorded from inner hair cells. Maintaining the ionic composition of the endolymph that underpins the endocochlear potential is critical to the generation of receptor potentials; this is a primary role of the stria vascularis, the extensively vascularized epithelium in the lateral wall of the scala media (Hibino et al., 2010).

Loss of pendrin in the knockout $Pds^{-/-}$ mouse leads to a thinned stria vascularis and a markedly reduced endocochlear potential. The Pendred syndrome alleles cause a complete loss of function, due to the retention of pendrin protein in the endoplasmic reticulum, whereas the nonsyndromic EVA alleles result in reduced anion transport and a less severe phenotype. In the absence of pendrin, both $Kcnj10$ expression in the stria vascularis and the endocochlear potential are lost in early postnatal life. The decreased K^+ concentration of $Pds^{-/-}$ endolymph may be explained by the loss of $Kcnj10$ expression, while the increased Ca^{2+} concentration results from disruption of pendrin-mediated transport of HCO_3^- into the endolymph. Loss of HCO_3^- exchange lowers the pH of the endolymph and can inhibit TRPV5/6 Ca^{2+} channels, increasing the endolymphic Ca^{2+} concentration (Nakaya et al., 2007). The winged helix/forkhead protein *Foxi1* has similar expression patterns to pendrin and may be an upstream regulator, as $Foxi1^{-/-}$ mice lack pendrin transcripts and display an enlarged endolymphatic chamber. Mutations of FOXI1 are also found in human patients with Pendred syndrome or nonsyndromic enlarged vestibular aqueduct.

To maintain the endolymphic concentration necessary for transduction, K^+ must be actively recycled; K^+ exits the hair cells and diffuses through the perilymph to the lateral wall, where it is transported by N^+–K^+–ATPase and/or Na^+–K^+–Cl^- cotransporter (NKCCl) into the stria vascularis, from which it is reintroduced into the endolymph by the voltage-gated K^+ channel KCNQ1. NKCCl is expressed during development in the stria vascularis and in immature epithelial cells lining the developing scala media, and its removal causes the collapse of the cochlear ducts. Mutations of KCNQ1 are also associated with the cardio-auditory Jervell and Lange-Nielsen syndrome, an autosomal-recessive disorder characterized by congenital deafness, prolonged QT syndrome, ventricular arrhythmia, and sudden death (Wangemann, 2006). Mouse models of this disorder display similar, though somewhat variable, defects.

Autosomal-dominant deafness DFNA2A – mild to severe progressive hearing loss with widely variable age of onset (early childhood to sixth decade) and occasional tinnitus – is associated with mutations affecting the voltage-gated potassium channel KCNQ4. In mouse, the native $Kcnq4$ is expressed at high levels at the base of outer hair cells, where it forms a depolarization-activated K^+ channel with relatively slow kinetics. The slow progressive hearing loss seen in $Kcnq4^{-/-}$ mice may be due to degeneration of outer hair cells that are chronically depolarized (Kharkovets et al., 2006).

Mutations involving the connexins Cx26 (GJB2) and Cx30 (GJB6) may account for half of all cases of prelingual autosomal-recessive hearing loss, with loss of Cx26/30 leading to hair cell degeneration and subsequent degeneration of the spiral ganglion cells. The precise functions of Cx26 and 30 in the inner ear are unknown, though they are important for maintaining the high K^+ concentration of the endolymph. Cx26 and Cx30 are both highly expressed in adults in the supporting cells of the organ of Corti and in the stria vascularis, and though the connexins are not found in the developing hair cells themselves, both connexins are required for the survival of hair cells and the organ of Corti. Extensive gap junction coupling in the neonatal organ of Corti is likely supported by Cx26/30 gap junctions; the function of this coupling is unknown. In mice lacking Cx30, the capillary endothelial barrier in the stria vascularis breaks down, the endocochlear potential disappears, and the hair cells degenerate (Cohen-Salmon et al., 2007).

The SLC26 family protein prestin (SLC26A5), which is closely related to pendrin, is linked to mild to profound hearing loss DFNB61, presenting from birth to the fourth decade. Prestin is expressed specifically in cochlear outer hair cells, where it functions as an anion transporter in the lateral membrane of outer hair cells. Electromotility, the hair cells' ability to change shape in an applied electric field, is driven by a physical change in the lateral membrane of outer hair cells and underlies cochlear amplification. Prestin is likely the critical voltage-driven motor protein for electromotility, and the loss of prestin and hair cell electromotility may yield a loss in cochlear amplification of 40–60 dB (Liu et al., 2003).

37.2.2.6 Other Hearing Disorders

Although hereditary hearing loss affecting primarily low frequencies (<2 kHz) is rare, a few distinct forms have been reported. The nonsyndromic hearing loss DFNA1 is an autosomal-dominant sensorineural disorder that manifests at about 10 years with low-frequency hearing loss and progresses to entail profound deafness at all frequencies by age 30. The disorder results from mutations affecting the homolog of *Drosophila* diaphanous (DIAPH1), which is widely expressed in many tissues in addition to the cochlea. As diaphanous is a member of the family of highly conserved formin proteins, which stabilize microtubules and regulate actin nucleation and elongation (Chesarone et al., 2010), the disorder likely affects the actin skeleton of hair cells or stereocilia. A second form of low-frequency sensorineural deafness, DFN6/14/38, results in moderate hearing loss with occasional tinnitus. Little is known of the pathology of this disorder, which involves wolframin (WFS1), a membrane glycoprotein found at the endoplasmic reticulum.

Several forms of inherited hearing loss are associated with mutations in mitochondrial DNA and can present as prelingual or postlingual hearing loss. In particular, Mohr–Tranebjaerg syndrome (MTS), or dystonia–deafness

syndrome, is an X-linked progressive syndrome (DFN1) involving early postlingual hearing loss and dystonia that can also be accompanied by myopia, cortical blindness, and mental impairment. The mutation is due to a loss of function in the TIMM8A gene (translocase of inner mitochondrial membrane 8), but the mechanism of hearing loss is unknown. Additional disorders linked to mutations in mitochondrial genes include diabetes–deafness syndrome, Ballinger–Wallace syndrome, multisystem disorder, and a number of nonsyndromic sensorineural deafness disorders.

37.2.2.7 Auditory Neuropathy

Auditory neuropathy accounts for about 10% of profound childhood hearing loss. Some of the major preventable causes of auditory neuropathy include anoxia, certain infectious diseases, and hyperbilirubinemia. Neonatal hyperbilirubinemia is easily treatable, but it is also common, and bilirubin neurotoxicity may account for 50% of all cases of auditory neuropathy. Various genetic mutations underlying auditory neuropathies of mild to profound hearing loss have also been identified.

One of the first auditory neuropathy genes identified was found in a candidate gene search for the profound prelingual hearing loss DFNB9 (Yasunaga et al., 1999). The membrane-anchored Ca^{2+}-binding protein otoferlin (OTOF) is expressed in hair cells and in the spiral ganglion during development in the mouse, and in adult localizes to vesicles of the ribbon synapses at the basal pole of the inner hair cells. Though otoferlin is not required for the development of ribbon synapses, it is required both for Ca^{2+}-dependent exocytosis at ribbon synapses of inner hair cells and at ribbon synapses that are transiently expressed during development at the outer hair cells. Otoferlin mutations may also result in minor defects in hair bundle structure.

The postlingual progressive hearing loss of variable severity DFNA15 is linked to mutations in POU4F3. Brn-3.1, a member of the Class IV POU-domain transcription factor family, is expressed exclusively in hair cells of the inner ear; $Brn-3.1^{-/-}$ mice show severe balance deficits and are completely deaf at a young age. In $Brn-3.1^{-/-}$ mice, the overall structure of the cochlea and spiral ganglion is normal at birth, but the hair cells do not differentiate and extend stereocilia; within a short period, the hair cells and supporting cells of the cochlea and the neurons of the spiral ganglion, degenerate (Erkman et al., 1996). Brn-3.1 likely mediates terminal differentiation of the hair cells, and the failure of hair cell differentiation may lead to secondary degeneration of supporting cells and postsynaptic neurons.

Glutamate release at the synapse between inner hair cell and spiral ganglion cell requires the vesicular glutamate transporter VGLUT3 (SLC17A8), and mutation of the SLC17A8 gene in humans is associated with the progressive sensorineural hearing loss DFNA25. Loss of SLC17A8 in mouse results in deafness, seizing, and deficits in central auditory circuit refinement; the central deficits may be due to a role for VGLUT3 in inhibitory synapse maturation (Seal et al., 2008). The gene for SLC17A8 is one of a few known to have effects both early in the cochlea and more centrally in the auditory pathway. Another is pejvakin (Persian for "echo"), which is associated with recessive auditory neuropathy DFNB59, causing prelingual severe hearing impairment. Pejvakin is expressed in cell bodies in the cochlea, spiral ganglion, and neuronal subpopulations in the auditory brain stem and midbrain in mouse, and though the function is unknown, the pathology likely affects both outer hair cells and downstream auditory pathways.

Charcot–Marie–Tooth disease describes a diverse group of inherited peripheral neuropathies, with onset in the first or second decade, of which the most common is the demyelinating form CMT1. About 5% of patients with CMT exhibit sensorineural hearing loss, with a likely locus in the cochlear nerve, specifically those with point mutations or deletions in the genes for peripheral myelin protein 22 (PMP22), myelin protein zero (MPZ), or connexin-32 (GJB1).

37.3 MIXED AUDITORY AND VISUAL IMPAIRMENT – USHER SYNDROME

Hereditary deafness–blindness in its most common form, Usher syndrome, is an autosomal-recessive disorder that involves bilateral sensorineural hearing loss and retinitis pigmentosa, in addition to vestibular deficits in some cases. Over half of all cases of hereditary deafness–blindness are associated with Usher syndrome, which has an estimated global prevalence of 1:16,000–1:50,000. The three clinically recognized subtypes of the syndrome are distinguished from one another by severity of hearing loss, age of onset of retinitis pigmentosa and the presence or absence of vestibular dysfunction. Usher syndrome types 1 and 2 are most common, type 1 being more severe and type 2 more frequent. Patients with the rarer form of type 3 Usher syndrome exhibit progressive hearing loss of intermediate severity, together with vestibular dysfunction and retinitis pigmentosa of varying severity and onset. Examination of the hair cells in Usher syndrome reveals significant disorder of the hair bundles, and the syndrome is considered a ciliopathy, as the primary deficit is at hair cell stereocilia in the cochlea and at the ciliated stalk connecting inner and outer photoreceptor segments in the retina.

Usher syndrome can result from mutations in any one of at least nine genes, all of which are involved in the

organization of the stereocilia during development of the hair bundle. The stereocilia are not true cilia, but rather are specialized microvilli formed of tightly packed cross-linked actin filaments. During development, however, each hair bundle expresses a single true cilium, the kinocilium, which in mammalian cochlear hair cells eventually degenerates. During early development of the hair bundle, a central kinocilium, surrounded by microvilli at apparently random locations, is first extended at the apical pole of the hair cell. The kinocilium migrates to one side of the hair bundle, and then the kinocilia of all hair cells align to the same side of their hair cells. A height-ordered array of stereocilia begins to form, with those stereocilia nearest the kinocilium elongating first, followed sequentially by stereocilia farther removed from the kinocilium, and an organized, hexagonal array of stereocilia forms, in stepwise order of increasing height. Stereocilia are continually extended from the apical surface during this period, many to be later resorbed. Once elongation is complete, the addition of actin filaments to the stereocilia increases stereocilia width, the stereocilia extend actin rootlets into the cytoplasm of the hair cell, and the basal ends of the stereocilia taper to a point (Goodyear et al., 2006; Tilney et al., 1992).

Mature stereocilia are linked at their apical tips by tip links, filamentous strands oriented in parallel with the direction of hair bundle deflection that connect the tip of each stereocilium to the side of its taller, adjacent stereocilium. In addition to the tip links, several additional filamentous links between stereocilia are also expressed, especially during development. In the E17.5 mouse, lateral links, tip links, and some kinociliary links are present. Ankle links appear at around P2 and remain until about P9. The different links can be distinguished by their position along the stereocilia, from apical tip to basal ankle, and by their distinct antibody binding.

37.3.1 Usher Syndrome Type 1

Individuals with USH1 typically exhibit severe hearing loss ($\geq$90 dB) and vestibular dysfunction at birth. Balance problems contribute to an average 12-month delay in walking, and onset of retinitis pigmentosa occurs before puberty. Although Usher type 1 is genetically heterogeneous, all identified relevant gene products are expressed in cochlear hair cells, where they function during development to organize and hold together the hair bundle. The five known gene products are myosin VIIa (USH1B), an actin-based motor protein, harmonin (USH1C), cadherin 23 (USH1D), protocadherin-15 (USH1F), and the putative scaffolding protein Sans (USH1G). Harmonin can bind to F-actin, as well as to the four other USH1 proteins. Harmonin, cadherin 23, and protocadherin-15 are expressed at the hair bundle as soon as stereocilia are extended, and cadherin 23 and protocadherin-15 together

form the tip link connecting the tip of one stereocilia to its taller neighbor. The various *Pcdh15* isoforms differ in sites of expression along the stereocilia and in timing of expression during development, and may direct distinct aspects of hair bundle development. Myosin VIIa is expressed throughout the hair cell, and likely plays several roles in development of the hair bundle. One function involves directing harmonin to its appropriate position on the stereocilia, as harmonin remains at the base of the hair bundle in the absence of *Myo7a* (Boeda et al., 2002). Sans function is less well understood; this transiently expressed protein can interact with myosin VIIa or with harmonin and may be a component of the developmentally expressed lateral links.

37.3.2 Usher Syndrome Type 2

Usher syndrome type 2, which accounts for 3–6% of congenital hearing loss, is characterized by mild congenital nonprogressive hearing loss, onset of retinitis pigmentosa in the first to second decades, and a lack of vestibular dysfunction. Three causative genes have been identified for USH2; all proteins are expressed in the cochlea during development. Type 2A, the most common form of Usher syndrome, results from mutations in usherin (USH2A), type 2C from mutations in GPR98, and type 2D from mutations in whirlin (WHRN).

The highly conserved 600 kDa long usherin variant is transiently associated with the growing stereocilia of inner and outer hair cells. The long isoform, found in both retina and inner ear, contains a PDZ-binding motif on its cytoplasmic tail, as do harmonin b and whirlin, which are also present in the differentiating hair bundle. GPR98 (VLGR1) is a transmembrane, calcium-binding G protein-coupled receptor that is transiently expressed at the base of the hair bundle during development. Both usherin and Vlgr1 bind to whirlin and myo7a, and association of Vlgr with usherin allows the formation of the ankle links at the base of the hair bundle. Ankle links are required for controlling the shape of the hair bundle, and loss of Vlgr during development leads to reduced transduction currents in the outer hair cells, alteration of the overall hair bundle structure, and deafness. Whirlin localizes to the stereocilia tips, where it interacts with myo15a or with myo7a in the control of stereocilia length during the growth of the hair bundle. In mice, targeted N-terminus whirlin mutants exhibit loss of both vision and hearing, whereas C-terminus mutants exhibit an isolated auditory disorder (Yang et al., 2010).

37.3.3 Usher Syndrome Type 3

Type 3 (USH3) is a relatively rare form of Usher syndrome reported primarily in Finland and among Ashkenazi Jewish populations, usually diagnosed in

the first decade. The disorder results from mutations in the transmembrane protein clarin-1 (CLRN1), most instances occurring due to a single amino acid substitution that affects glycosylation and membrane insertion of the protein. *Clarin-1* is expressed transiently in the cochlea during development, and in Muller cells of the retina. In the Clrn1 knockout mouse, loss of clarin-1 results in disorganized stereocilia of the outer hair cells, followed by slow progressive disorganization of the hair bundle and age-related stereocilia lengthening and eventual hair cell degeneration, leading to vestibular dysfunction and complete loss of hearing (Geller et al., 2009). The protein's ability to interact with cell adhesion molecules and induce actin filament reorganization suggests that the pathology results from disruption of interactions between cell-adhesion molecules and the actin cytoskeleton.

37.3.4 Retinitis Pigmentosa in Usher Syndrome

As this disease is characterized by the progressive degeneration of the rod photoreceptors, the cone photoreceptors, and finally retinal pigment epithelium (RPE) cells, patients present first with night blindness (nyctalopia). Progressive loss of peripheral vision leads to tunnel vision, whereas central vision (color and high acuity) may be compromised after a variable period. The pigment deposits for which the disorder is named appear late in the disease, after photoreceptors degenerate and cells of the RPE detach and migrate through the eye (Milam et al., 1998).

The ciliary defect in hearing loss in Usher syndrome, and the existence of a ciliary stalk between the inner and outer segments of retinal photoreceptors, points to photoreceptors as the primary site of the visual deficit in Usher syndrome, and the first measurable retinal loss in humans with USH 1B, 1 F, 2A, and 2C is of photoreceptors. Despite the existence of various animal models for Usher syndrome, an ongoing challenge has been that affected animals exhibit hearing loss and vestibular dysfunction but most mouse models fail to develop the retinitis pigmentosa characteristic of Usher syndrome in humans. Additionally, many well-known mouse models of deafness (e.g., waltzer, shaker-1, deaf circler, Ames waltzer, and Jackson shaker) possess mutated USH1 genes and exhibit vestibular but not visual impairment. In the retina, usherin is expressed at all ages at the connecting cilium in photoreceptors, and one promising development is the mouse model for USH2A, which loses large numbers of photoreceptors (Liu et al., 2007).

37.4 VISUAL IMPAIRMENT

Many historical forms of childhood blindness have been largely eradicated in middle- and high-income countries, and are being eliminated from low-income countries, where programs combating measles and vitamin A deficiency have been especially successful. Corneal disorders still account for 19% of childhood blindness worldwide, however, and are disproportionately common in the developing world, amounting to perhaps 1% of all cases of blindness in the highest income regions and as much as 36% of all cases in sub-Saharan Africa (Gilbert, 2009). Most of these cases are preventable, resulting from vitamin A (retinol) deficiency, measles, and/or use of traditional treatments. Prenatal or neonatal lack of dietary vitamin A, increased demand for vitamin A during infection, and malabsorption of vitamin A due to illness can singly or together lead to retinol deficiency, a risk factor for xerophthalmia (dry eye), which commonly leads to corneal ulceration and scarring. Corneal ulceration and scarring can also result from measles infection, an effect that is potentiated if vitamin A deficiency is already present.

Microphthalmia, an abnormally small eye with normal structure, develops in response to genetic or environmental factors, and may be present in as much as one-tenth of all childhood blindness. Microphthalmia most often occurs bilaterally as part of a heritable syndrome, and most of the genes linked to this disorder code for transcription factors and homeobox genes involved in early development of the eye, for example in neuronal differentiation, proliferation of retinal progenitor cells, or formation of the lens placode. Some of the known genes include transcription factor SOX-2 (SOX2), retina homeobox protein Rx (RAX), and visual system homeobox 2 (VSX, also CHX10), among others (see Table 37.2).

37.4.1 Disorders of the Anterior Segment

The anterior segment of the eye includes the cornea, iris, and lens, together with their supporting structures. As the first structure through which light passes, and as part of the interface with the most refractive power, the cornea occupies a special position; hence, environmental insults or genetic disorders that affect the cornea can profoundly affect visual sensation. Transparency of the lens also plays a critical role in conducting light to the retina. Disorders of the anterior segment can commonly include glaucoma of unknown etiology. Aniridia, for example, the complete or partial absence of the iris, may occur with glaucoma, as well as with cataracts or photophobia. Aniridia is associated with over 100 different mutations of the transcription factor paired box 6 (PAX6), which is linked to several additional disorders of abnormal eye development, such as morning glory disc (a dysplasia of the optic disc), ectopic pupil, optic nerve hypoplasia, and foveal hypoplasia. Corneal dystrophy refers to a group of disorders that lead to accumulation of deposits in the corneal layers and to a loss of corneal transparency; depending on the specific type of dystrophy, the

disorder can manifest as early as the first decade. Genes encoding a sodium borate cotransporter (SLC4A11) and transforming growth factor, beta-induced (TGFBI) have been implicated in multiple corneal dystrophies; however, relatively few animal models exist, corneal transparency itself is not well understood, and both the normal functions and the pathologies of these gene products are largely unknown (Klintworth, 2009).

Cataract, an opacification of the lens, occurs congenitally in 1–6 of 10,000 births. Worldwide, congenital cataract may account for 15% of childhood blindness, and if left untreated, this peripheral disorder can induce significant central visual deficits such as amblyopia. Inherited congenital cataract in humans is commonly autosomal-dominant and phenotypically variable, as cataracts appear with varying densities, colors, and locations within the lens.

The lens itself consists primarily of lens fiber cells surrounded by an epithelial cell layer on the outer surface; this structure continues to grow throughout life from the inside out, adding new lens fiber cells, formed from the outer epithelial cell layer to the body of the lens underneath the epithelial cell layer. Lens transparency is ensured in part by the loss of all intracellular organelles in lens fiber cells as they differentiate from the epithelial cell layer. In the avascular lens, homeostasis is maintained through a gap–junction coupled network. The cytosolic crystallins form the principal protein component of lens fiber cells, and the inside–out growth process of the lens dictates that the crystallins be extremely stable, as they cannot be replaced during the life of the lens. Furthermore, the crystallins play a role in setting refractive index and maintaining transparency of the lens. The α-crystallins are heat-shock proteins and chaperones, with α-crystallin making up almost half of the total lens protein by weight. Both αA-crystallin and αB-crystallin are found in the developing lens, and β- and γ-crystallins are also present in the adult lens (Andley, 2007; Bassnett, 2009).

Mutations of several of the crystallins, including αA, αB, βA1, βB1, βB2, γC, γD, and γS, have been associated with hereditary congenital cataracts as well as with a developmental cataract that is absent at birth but develops in early childhood. The pathologies of the crystallin mutations are incompletely understood; they may involve several distinct pathways that ultimately affect solubility and transparency of the crystallins. For example, levels of the chaperone αA-crystallin may control the ratio of soluble to insoluble αB protein, as the loss of αA-crystallin in mice leads to higher levels of insoluble αB-crystallin and reduced lens transparency (Brady et al., 1997). Additional mutations may alter protein transparency by actions on protein folding or protein solubility, or through effects on crystallin–crystallin interactions.

Connexins expressed in the lens, Cx46 (GJA3) and Cx50 (GJA8), allow gap–junction coupling of both lens fiber cells and lens epithelial cells. Although it is still not precisely understood how gap–junction coupling maintains transparency, gap–junction coupling provides a circulation system for the avascular lens, promoting homeostasis among the anuclear lens fiber cells and promoting crystalline solubility, and mutations of Cx46 and Cx50 are associated with congenital cataract. In mice, knockouts for Cx46 and for Cx50 exhibit different cataract phenotypes; nevertheless, it appears that Cx50 and Cx46 are functionally redundant and that the number of gap junctions is more critical than the specific connexin components for preserving transparency (White, 2002).

37.4.2 Disorders of the Retina

37.4.2.1 Retinopathy of Prematurity

Retinopathy of prematurity (ROP) is a disorder of retinal vascularization that first appeared in high-income countries in the 1940s, when advances in neonatal care led to increased survival rates for premature infants. Today, global incidence of this disorder describes an inverse U-shape as a function of economic context. Low-income countries typically have high infant mortality rates, which are associated with very low ROP incidence because premature infants do not survive. High-income countries also have low rates of ROP, and it is middle-income countries with variable quality in neonatal care that have the highest rates of ROP. Oxygen exposure

was identified as a risk factor early on, but the survival of increasingly smaller infants in the developed world has kept ROP incidence high. Although genetic factors may play a role in developing ROP, the primary risk factors remain oxygen exposure, degree of prematurity, and low birth weight. By current estimates, a majority (68%) of premature infants born in first-world countries and weighing 1250 g or less at birth will develop ROP (Good et al., 2005).

Two phases of ROP are seen, the first characterized by a loss of vascularization and the second by a pathological angiogenesis. In normal development, the retinal vasculature develops radially, reaching the peripheral extent of the retina at about 36 weeks gestation. Thus, in premature infants, an avascular area, with extent determined by gestational age at birth, surrounds the central vascularized retina. At birth, retinal vascularization slows, possibly in response to the relatively hyperoxic environment outside the uterus. During the first phase of ROP, the avascularized retina, unable to meet metabolic demand, becomes hypoxic until about 32 weeks gestational age. The second phase begins at 32–34 weeks gestation and involves neovascularization in response to hypoxia. In more extreme cases, the pathological blood vessel growth can pull the retina away from the RPE, leading to retinal detachment and blindness; prevention consists of careful monitoring and laser photocoagulation to prevent retinal detachment. Less extreme forms of ROP that resolve spontaneously are associated with abnormally thick retinae with broad, shallow foveal pits, and with altered rod photoreceptor development. Vascular endothelial growth factor (VEGF), which can be regulated by hypoxia, plays a critical role in vascularization of the retina. The proximal cause of the first phase of ROP may be hyperoxic downregulation of VEGF-induced vascular growth, whereas the second stage is likely caused by hypoxic upregulation of VGEF to stimulate angiogenesis. VEGF activity requires insulin-like growth factor (IGF-1), in a permissive or added manner. Thus, the loss of maternally supplied IGF-1 at birth in premature infants may abolish VEGF activity (Smith, 2008). Potential preventative treatments for ROP include supplemental IGF-1 in the preterm infant and the development of small-molecule antagonists to VEGF receptors.

The primary ROP risk factors of gestational age and oxygen exposure can be potentiated by genetic background; in particular, several mutations in the Wnt–beta-catenin pathway affect development of retinal vasculature and may also increase risk for developing ROP. These include the Norrie disease protein norrin, the canonical Wnt receptor *Frizzled-4* (*Fz4*; gene FZD4), and the Wnt coreceptor Lrp5. Norrin, normally produced in the Muller glia, is a high-affinity ligand for the canonical Wnt receptor *Fz4* at retinal epithelial cells. Additional inherited pathologies of retinal vascularization that are associated with this group of proteins include X-linked familial exudative vitreoretinopathy (FEVR), Coats' disease, and persistent fetal vasculature syndrome (PFVS).

37.4.2.2 *Retinitis Pigmentosa*

Retinitis pigmentosa occurs frequently in isolation; the term refers to a large group of genetically heterogeneous degenerative disorders with a prevalence of 2–3 in 10,000. The disease may be inherited in X-linked, autosomal-dominant, or autosomal-recessive mode, and age of onset is variable after the first year. Diagnosis typically occurs in young adulthood, but early-onset forms may manifest in the first 5 years. This disorder is essentially a rod–cone dystrophy, in that rod photoreceptors degenerate before cone photoreceptors, resulting in a loss of peripheral and night vision.

Over 10% of retinitis pigmentosa patients have the most severe, X-linked form (XLRP), which is associated with mutations in retinitis pigmentosa 2 (RP2) or in retinitis pigmentosa GTPase regulator (RPGR). RP2 is a membrane-associated protein that is found throughout the retina and in the RPE. RP2 shares sequence homology with tubulin-specific cofactor C, a GTPase activator for tubulin, and regulates the GTP-bound form of the microtubule-associated protein ADP ribosylation factor-like 3 (Arl3). RP2 and Arl3 are localized to the connecting cilium between inner and outer photoreceptor segments, where they mediate trafficking of vesicles from the Golgi (Evans et al., 2010).

RPGR interacts with the delta subunit of rod cyclic phosphodiesterase (PDE), which mediates transport of certain proteins to photoreceptor outer segments, and retinitis pigmentosa alleles of RPGR exhibit reduced binding to PDE/delta. RPGR also interacts with a protein localized to the connecting cilia of photoreceptors: PPGR-interacting protein 1 (RPGRIP1), and its expression overlaps that of usherin.

The photopigment of the photoreceptor outer segment consists of a transmembrane opsin (in cones) or rhodopsin (in rods) G-protein-coupled receptor and a covalently attached small organic moiety, 11-*cis*-retinal, that determines the photoreceptor's wavelength sensitivity. Absorption of a photon isomerizes the 11-*cis*-retinal, causing a conformational change in the opsin that leads to activation of the membrane-bound G protein transducin. Transducin activation turns on a cGMP PDE that hydrolyzes cGMP, causing the normally open cGMP-gated cation channels in the outer segment plasma membrane to close. Closure of the cation channel hyperpolarizes the photoreceptor and leads to a decrease in tonic neurotransmitter release at the photoreceptor–bipolar cell synapse. Inactivation of opsin is accomplished in part by S-arrestin, while 11-*cis*-retinal is regenerated through the retinoid cycle. Well over 100 mutant

rhodopsin (RHO) alleles, some with mouse models, can cause retinitis pigmentosa. These alleles may cause protein misfolding that prevents formation of a functional photopigment, interfere with trafficking to the outer segment, affect activation of transducin, and/or initiate the formation of stable rhodopsin that is constitutively active in the dark. Protein misfolding can underlie certain forms of retinitis pigmentosa, though the mechanism of degeneration is unknown. Mutations of S-arrestin (SAG) are also associated with retinitis pigmentosa, probably due to constitutive rhodopsin activation. The cyclic nucleotide channels in photoreceptor outer segment membrane are heteromeric tetramers composed of A (CNGA1) and B (CNGB1) subunits; each subunit has been linked to retinitis pigmentosa (Wright et al., 2010).

The RPE plays a critical role in retinal health, phagocytosing about 10% of the photoreceptor outer segments daily and performing many of the steps necessary in the retinoid cycle in which 11-*cis*-retinal is regenerated from the all-*trans*-retinal product of photoisomerization in the outer segments, and mutations affecting the retinoid cycle are associated with many retinal disorders. One such mutation in retinitis pigmentosa affects the retinoid isomerase RPE65, which is normally expressed in RPE and in cone photoreceptors and is necessary for the isomerization of all-*trans*-retinyl to 11-*cis*-retinal. Loss of RPE65 results in a gradual disorganization of the outer segments and a slow degeneration of photoreceptors, loss of the rod ERG and of rhodopsin, and an accumulation in the RPE of all-*trans*-retinyl esters. The rhodopsin homology RGR (retinal G-protein-coupled receptor) is another RPE protein involved in the retinoid cycle that has been implicated in retinitis pigmentosa. The retina-specific ATP-binding cassette transporter ABCA4 gene encoding the photoreceptor Rim protein also functions in the retinoid cycle, though it is expressed in the disk membrane of photoreceptor outer segments, where it is involved in active transport of retinoids from the lumen of the disk to the cytoplasm. The all-*trans*-retinal product of photoactivation is a precursor for potentially toxic diretinal compounds. Loss of ABCA4 activity allows accumulation of diretinal compounds that are then incorporated in the RPE during outer segment phagocytosis. Finally, mutations of the anion channel bestrophin 1 (BEST1), which is also expressed in RPE cells, lead to a retinitis pigmentosa of unknown pathology.

The tubby-related protein TULP1 is expressed in the photoreceptor inner segments where it can bind dynamin, a critical endocytosis protein. In mouse, loss of Tulp1 results in the loss of ribbon synapses at photoreceptor terminals, the mislocalization of the visual pigment rhodopsin to the inner segment, and photoreceptor degeneration. The transcription factor neural retina leucine zipper (NRL) is expressed primarily in rod photoreceptors. The retinae of mice lacking *Nrl* develop with no rod photoreceptors and with more short-wavelength cones than normal, a phenotype similar to that seen in humans with retinitis pigmentosa caused by mutations of NRL (Mears et al., 2001).

Retinitis pigmentosa is distinguished from other retinal dystrophies in that cone photoreceptor death follows the main phase of rod photoreceptor death, and little is currently known about the events that initiate cone photoreceptor death. Several models of retinitis pigmentosa share a common metabolic pathway for cone death, however, suggesting that in diverse cases the late loss of foveal vision may be caused by cell starvation.

37.4.2.3 Cone–Rod Dystrophy

Cone–rod dystrophy is distinguished from retinitis pigmentosa by the order in which photoreceptors are lost. The cone–rod dystrophies are less prevalent than retinitis pigmentosa, but can be severe because the loss of high-acuity, color vision precedes night blindness and the loss of peripheral vision. The transcription factor cone–rod homeobox (CRX) is a member of the orthodenticle family that is expressed primarily in photoreceptor inner segments. Crx transactivates photoreceptor-specific genes including rhodopsin and arrestin, and was the earliest gene identified in cone–rod dystrophy. Additional causes of cone–rod dystrophy are similar to those discussed earlier with retinitis pigmentosa.

37.4.2.4 Leber Congenital Amaurosis

The most severe of the retinal diseases, Leber congenital amaurosis (LCA), underlies about 5% of inherited retinopathies; it includes a heterogeneous group of severe inherited disorders in which nystagmus and retinitis pigmentosa are present, the ERG response is absent, and pupils are amaurotic (i.e., they do not respond to light shining directly in the same eye) (Walia et al., 2010). Identified mutations include the photoreceptor transcription factor Crx, which leads to a failure to form photoreceptor outer segments and the formation of abnormal photoreceptor synapses, and the Crumbs protein (CRB1), a regulator of cell polarity and morphology whose loss leads to dysmorphic Muller glia cells, retinal disorganization, and subsequent degeneration.

Another subgroup of LCA cases results from mutations of visual cycle proteins, either RPE65 or retinol dehydrogenase 12 (RDH12). The role of RDH12 in LCA is still unclear, however, as the Rdh12 deficiency appears to be compensated for in the mouse knockout. Maintenance of the cGMP-gated current in the photoreceptor outer segments requires local cGMP synthesis, and the membrane-bound retinal guanylate cyclase GUC2D has been associated with LCA. *In vitro* results suggest that a GUC2D mutation commonly found in LCA impairs cyclase activity and causes the constitutive closure of the cGMP-gated channels.

37.4.2.5 Stargardt's Disease

Stargardt's disease, an autosomal-recessive juvenile-onset macular dystrophy, presents with loss of central vision and progressive atrophy of the RPE at the fovea. Known causes include mutations of ABCA4 and of the cyclic-nucleotide-gated channel, discussed earlier under retinitis pigmentosa.

37.4.2.6 Night Blindness

The inherited night blindnesses typically cause myopia, reduced visual acuity, and nystagmus in addition to reduced vision in dim light (nyctalopia). Complete congenital stationary night blindness (cCSNB), or type 1 CSNB, is a nonprogressive X-linked or autosomal-recessive disorder that affects the photoreceptor–bipolar cell synapse and can be seen on electroretinogram (ERG). Different forms of cCSNB have been linked with mutations to genes encoding a leucine-rich proteoglycan, nyctalopin (NYX), the metabotropic glutamate receptor mGluR6 (GRM6), and the transient receptor potential channel melastatin (TRPM1). In addition to numerous transgenic mouse models for night blindness, naturally occurring animal models exist in the Nob mouse ("no b-wave," a Nyx mutant) and certain colorations of appaloosa horse (Trpm1 mutant).

In the normal retina at rest, glutamate tonically released from the photoreceptor activates the retina-specific Group III metabotropic glutamate receptor mGluR6, which is expressed specifically on the dendrites of an ON bipolar cell, to cause the closure of a nonspecific cation channel. The reduction in glutamate release with light stimulation causes the mGluR6-coupled cation channels to open, depolarizing the ON bipolar cell. Though the function of nyctalopin is unknown, it is expressed in close proximity to mGluR6 in dendrites of rod bipolar cells, TRPM1 is likely regulated by mGluR6 activity, and loss of *Trpm* causes an abnormal ERG characteristic of ON bipolar dysfunction; in fact, depolarizing bipolar cells from Nob mouse retina show no response to glutamate application. Thus, the cCSNB defect appears to be localized to a site on the ON bipolar cell postsynaptic membrane where nyctalopin, mGluR6, and TRPM1 are likely functionally linked.

Congenital stationary night blindness type-2 (CSNB2) is an X-linked disorder caused by a presynaptic channelopathy at the rod–bipolar synapse. CSNB2 is caused by mutations that affect the $\alpha 1$ subunit of the retinal L-type calcium channel $Ca_v 1.4$ ($Ca_v 1.4\alpha 1$; gene CACNA1F) or the calmodulin-like calcium-binding protein-4 (CABP4), which modulates $Ca_v 1.4$ function. The $Ca_v 1.4$ channel inactivates slowly in response to depolarization and it lacks calcium-dependent inactivation; both qualities contribute to the photoreceptor's ability to release glutamate tonically, and both the $\alpha 1$ subunit and CABP4 are necessary for transmitter release at the photoreceptor–bipolar synapse.

37.5 DISORDERS OF CHEMICAL SENSATION

Recognized disorders or chemical sensation usually present after infection or after use of certain drugs, and developmental disorders of the chemical senses are rare.

37.5.1 Taste

One well-studied taste 'disorder' is the inability to taste the synthetic compound phenylthiocarbamide (PTC). PTC and 6-n-propylthiouracil (PROP) are members of a class of thiourea compounds that are perceived bimodally, a large number of individuals tasting these compounds as very bitter, and somewhat fewer individuals failing to taste them at all; PTC nontasters exist in nearly every population tested. Bitter tastes are transduced by receptors in the Taste Receptor 2 (TAS2R) family of 7-transmembrane, G-protein-coupled receptors, which are coexpressed with the G protein α subunit gustducin in a subset of taste receptor cells within the taste buds. The TAS2R38 gene is not highly conserved across species, and like other members of the TAS2R gene family, the human PTC (TAS2R38) gene shows broad allelic heterogeneity. Though the lack of PTC conservation across species and the broad distribution of non-tasting PTC alleles might suggest that PTC sensing is less a disorder than an interesting genetic oddity, the PTC-sensing phenotype may confer certain benefits. It has been suggested, for example, that PTC tasters might enjoy an evolutionary advantage by avoiding bitter-tasting toxic compounds, and also that a genetically encoded ability to taste bitter compounds could be protective against nicotine and alcohol consumption that might otherwise lead to addiction. Indeed, specific single-nucleotide polymorphisms in TAS2R38 are associated with a higher incidence of nicotine use in certain populations (Mangold et al., 2008). Interestingly, TAS2R38 and several other bitter-taste receptors are also expressed in ciliated cells of the airway epithelium. When stimulated with bitter compounds, these cells show an increase in ciliary beating (Shah et al., 2009), a response that may play a role in protecting the lungs from exposure to noxious compounds. Variability is not restricted to the bitter receptors, and altered taste perception of sucrose correlates with single-nucleotide polymorphisms in the promoter region of the TAS1R3 gene. Taste anomalies or deficits are exhibited by many of the knockout mice for gustducin, various members of

the TAS1R (sweet) and TAS2R (bitter) families, the taste tissue-specific phospholipase Cβ2 (Plcb2), and the TRP channel Trpm5, and several human taste preferences correlate with polymorphisms in various TAS2Rs (Hayes et al., 2011). Whether or not genetic variability in taste should be considered a disorder is unclear; nevertheless, the broad variability of genetically encoded taste perception offers opportunities for further study.

37.5.2 Olfaction

37.5.2.1 Kallmann Syndrome

Kallmann syndrome encompasses a heterogeneous group of disorders that include severe hypogonadotropic hypogonadism (impaired or absent function of the testes or ovaries) and hyposmia or anosmia. Diagnosis is typically made when patients fail to enter puberty due to a deficiency of gonadotropin-releasing hormone (GnRH). Olfactory impairment, anosmia or hyposmia, is typically discovered only at this time. The sensory impairment results from the absence or hypoplasia of the olfactory bulbs, which are the principal target of the olfactory epithelium, and of the lateral olfactory tracts. A broad range of additional, variable neurological deficits may also be present. Kallmann syndrome is not precisely a disorder of the olfactory organ, as the deficit is one of axon migration and neurogenesis in central pathways, but is worth mention here as one of very few identified olfactory disorders. Much about this disorder is still unclear, and in fact the genes that have been identified to date represent a minority of all cases (Dode and Hardelin, 2009).

The principal known genes for Kallmann syndrome include KAL1, which shows X-linked inheritance and codes for anosmin-1; KAL2, an autosomal-dominant form associated with mutations of fibroblast growth factor receptor 1 (FGFR1); KAL3 and KAL4, encoding prokineticin receptor-2 (PROKR2) and prokineticin-2 (PROK2); and KAL6, encoding fibroblast growth factor 8 (FGF8). Anosmin-1 is a secreted glycoprotein of embryonic olfactory bulb, tract, and cortex that acts as a chemoattractant and promotes neurite branching of olfactory neurons, possibly signaling through FGFR1, which is co-expressed with anosmin-1 in the olfactory bulbs during development. PROK2 is a secreted ligand for PROKR2, a G protein-coupled membrane receptor necessary for differentiation and migration of neural progenitor cells to the olfactory bulb. It is likely that many of the still unidentified gene products underlying Kallmann syndrome will be proteins that interact with FGFR1 – possibly FGF2 – or with PROKR2.

37.5.2.2 Other Congenital Olfactory Disorders

Hyposmia has also been reported in a few additional syndromic disorders. CHARGE (coloboma, heart disease, atresia choanae, retardation, genital and ear anomalies) syndrome, with an estimated incidence on the order of 10^{-4}, is related to the less severe Kallmann syndrome, type 5. CHARGE syndrome is typically diagnosed in infancy, may be accompanied by deaf–blindness, and nearly always involves olfactory deficits. Over 50% of CHARGE cases are caused by mutations in chromodomain helicase DNA-binding protein 7 (CHD7), and several mouse models of this disorder are associated with *Chd7* mutations. *Chd7* and the transcription factor *Sox2* form a transcriptional network for regulating several target genes in neural stem cells (Engelen et al., 2011).

In both humans and mice, PAX6 mutations and aniridia may be accompanied by olfactory bulb hypoplasia

TABLE 37.3 Disorders of chemical sensation

Name	Gene	Gene product	Reference
PTC non-taster			
PTC	TAS2R38	Taste receptor, type 2, member 38	Kim et al. (2003)
Kallmann syndrome			
KAL1	KAL1	Kallmann syndrome 1 protein; anosmin-1	Franco et al. (1991) Legouis et al. (1991)
KAL2	FGFR1	Fibroblast growth factor 1	Dode et al. (2003)
KAL3	PROKR2	Prokineticin receptor 2	Dode et al. (2006)
KAL4	PROK2	Prokineticin-2	Dode et al. (2006)
KAL5	CHD7	Chromodomain helicase DNA-binding protein 7	Kim et al. (2008)
KAL6	FGF8	Fibroblast growth factor 8	Falardeau et al. (2008)
Aniridia and hyposmia	PAX6	Paired box 6 protein Pax-6	Sisodiya et al. (2001)

OMIM gene symbols are used throughout.

and hyposmia, whereas mutation of SOX 9 (campomelic dysplasia) or SOX10 (Waardenburg syndrome) may be accompanied by a complete absence of the olfactory bulbs. Finally, hyposmia has been reported in some cases of pseudohypoparathyroidism, Bardet–Biedl syndrome, and Leber congenital amaurosis (Table 37.3).

37.6 CONCLUSION

Congenital sensory impairment is widespread. With the success of vaccination, maternal health, and perinatal care programs worldwide, the incidence of congenital sensory impairment has decreased greatly, and inherited disorders are now the most common form of congenital sensory loss. This is both a challenge and a boon: a challenge because these disorders can be quite heterogeneous; a boon because the growth of animal models for specific genetic disorders offers rich opportunities for research into normal and pathological sensory development.

The Developmental Neurobiology
of Repetitive Behavior

S.-J. Kim[1], M. Lewis[2], J. Veenstra-VanderWeele[3]

Nashville, TN, USA

OUTLINE

38.1 INTRODUCTION

Repetitive behavior can be expressed as a variety of topographies, ranging from very simple motor behaviors to extremely complex rituals. The most succinct terminology for these related behaviors comes from the autism literature, where restricted, repetitive behavior (RRB) refers to a broad class of behaviors linked by repetition, inflexibility, and lack of obvious purpose or function. As detailed later, RRB is characteristic of a number of neurodevelopmental and neuropsychiatric disorders, but various forms of aberrant RRB also occur in a significant percentage of individuals without cognitive or neuropsychiatric impairment (Castellanos et al., 1996; Rafaeli-Mor et al., 1999; Singer, 2009). A number of neurobiology research tools have improved the understanding of the mediation of RRB, including molecular genetics, neuroimaging, and animal models. Data from these different methodological domains are beginning to coalesce, resulting in the identification of key brain regions, circuits, and neurotransmitter systems.

38.2 PHENOMENOLOGY OF REPETITIVE BEHAVIOR

38.2.1 Normative Developmental Pattern of Repetitive Behavior

Repetitive motor behavior, compulsions, and rituals are well documented in normative development, and some attempts have been made to chart the developmental trajectory of such behaviors. For example, Thelen (1980) demonstrated that specific rhythmical, stereotyped movements in infants have a clear onset, peak (at about 2 years of age), and decline coincident with emerging voluntary motor control. Whereas very young children engage in a number of repetitive motor behaviors (e.g., swaying, rocking, and flapping), older children display a variety of behaviors that are compulsive and ritualistic (e.g., insistence on certain clothing or foods and bedtime rituals), reflecting an insistence on sameness (IS), rigidity, and ritualization of daily activities (Thelen, 1980). Attachment to a favorite object, perseverating on certain thoughts and topics, and having intense, restricted interests are also common in preschoolers. Evans et al. (1997) have shown that such behaviors peak at about 2–3 years of age and begin to decline after about age 5.

38.2.2 Phenomenology and Treatment of Repetitive Behavior in Tourette Syndrome

Tourette syndrome (TS) is defined by repetitive behaviors that include both motor and vocal tics (American Psychiatric Association, 2000). Motor tics are stereotyped movements that range from very simple, such as an eye blink, to more complex, such as a full body salute. Vocal tics similarly range from very simple, such as throat clearing, to more complex, including complete phrases. Although patients often describe a premonitory urge or sensory experience preceding a tic, no description of an internal experience is necessary to make the diagnosis. Men are more likely to be affected, and TS follows a developmental time course, with onset typically in middle childhood and slow improvement of behavior in many patients as they enter adulthood (Bloch and Leckman, 2009).

Many people with TS do not require medical care, but treatment is often helpful. Behavioral therapy, which includes monitoring of urges and the use of voluntary replacement behaviors, has been shown to be effective in many patients (Piacentini et al., 2010). A variety of medications have been tested in patients with TS, with most data favoring dopamine receptor D2 antagonist drugs that were developed as antipsychotics (reviewed in Swain et al., 2007). Data also support the use of norepinephrine alpha-2 agonist drugs, such as clonidine, in the treatment of TS (Leckman et al., 1991). Importantly, patients with TS are often more severely impaired by comorbid conditions, such as attention deficit hyperactivity disorder (ADHD) or obsessive–compulsive disorder (OCD), than by the tics themselves.

38.2.3 Phenomenology and Treatment of Repetitive Behavior in OCD

OCD is characterized by repetitive, distressing thoughts and accompanying repetitive behaviors that relieve distress (American Psychiatric Association, 2000). OCD can emerge during childhood or adulthood, with men more likely to have earlier onset and an associated tic disorder or TS. Most people with OCD experience both obsessive thoughts and compulsive behaviors, but some, particularly children, manifest only compulsions. In turn, some, particularly adults, manifest only obsessions, often with compulsive thoughts but no outward compulsive behavior. Unlike the repetitive tics of TS, repetitive behavior in OCD is typically purposeful, such as hand washing to eliminate germs. Obsessions and compulsions can be divided into a variety of semi-independent symptom dimensions, including forbidden thoughts, symmetry, cleaning, and hoarding (Bloch et al., 2008).

Treatment for OCD is often partially effective but rarely relieves symptoms completely. Cognitive behavioral therapy (CBT), which involves exposure to the obsessive stimulus without engaging in the compulsive response, has been shown to be helpful in many patients (Foa et al., 2005). Serotonin reuptake inhibitors (SRIs),

but not other monoamine reuptake inhibitors (Leonard et al., 1989), are also helpful, particularly when combined with CBT (Pediatric OCD Treatment Study Team, 2004). Dopamine receptor D2 antagonist drugs can also be helpful when added to SRIs (Bloch et al., 2006). More recent data suggest that medications acting on the glutamate system may also be helpful for some people with OCD (Pittenger et al., 2006). Severe cases of OCD have also been treated successfully with a variety of neurosurgical approaches, including cingulotomy and deep brain stimulation (DBS) in the ventral internal capsule/ventral striatum region (Greenberg et al., 2008).

38.2.4 Phenomenology and Treatment of Repetitive Behavior in Autism Spectrum Disorder

As a cluster of positive symptoms, RRB rather than general developmental delay is often the first clue that a child has an autism spectrum disorder (ASD) (Pediatric OCD Treatment Study Team, 2004). The category of RRB in ASD is broad and heterogeneous, including (1) encompassing preoccupation; (2) apparently inflexible adherence to specific, nonfunctional routines or rituals; (3) stereotyped and repetitive motor mannerisms; and (4) persistent preoccupation with parts of objects (American Psychiatric Association, 2000). Turner (1999) conceptualized repetitive behaviors as falling into two clusters: 'lower order' motor actions that are characterized by repetition of movement, and more complex or 'higher order' behaviors that have a distinct cognitive component. Since then, several groups (Cuccaro et al., 2003; Lam et al., 2008; Szatmari et al., 2006) have examined the structure of RRB as measured on the Autism Diagnostic Interview-Revised (ADI-R) (Lord et al., 1994), the gold standard instrument for autism ascertainment. These studies have identified a three-factor model of RRB: repetitive sensory and motor behavior (RSMB), which corresponds to 'lower order' RRB, IS, and circumscribed interest (CI).

Further support for a developmental pattern of repetitive behavior emergence and resolution can be found in studies of children with developmental disorders. For example, Esbensen et al. (2009) assessed individuals with autism across a wide range of ages (2–62 years) using a modified cross-sectional design. They found that repetitive behaviors decreased across age regardless of subtype of repetitive behavior. Somewhat different results were obtained by Richler et al. (2010), who assessed the development of RRB longitudinally at 2, 3, 5, and 9 years of age in children with autism and developmental delay. They measured two major subtypes of repetitive behaviors (repetitive sensorimotor behavior and IS), and reported decreased sensorimotor repetitive behaviors and increased IS behaviors with increasing age. Further research is needed to understand the

transition between normative developmental RRB and pathological RRB that exceeds the expected level of RRB at a particular developmental stage. Such information would allow for identification of environmental and neurobiological mechanisms that mediate this transition and the persistence of repetitive behavior.

The occurrence of RRB in normative development, as well as in TS and OCD, raises the question of whether there is a unique pattern of behavior in ASD. Most data suggest that RRB is quantitatively increased at each developmental stage in ASD, but without a unique topography that distinguishes this behavior from normative development or OCD (Bartak and Rutter, 1976; Bodfish et al., 2000; Freeman et al., 1981; Hermelin and O'Connor, 1963; Lord, 1995; Lord and Pickles, 1996; Russell et al., 2005; Szatmari et al., 1989; Watt et al., 2008; Wing and Gould, 1979). Instead, an elevated pattern of occurrence and severity of RRB, particularly rituals and restricted interests, appears to distinguish autism from other disorders (Bartak and Rutter, 1976; Bodfish et al., 2000; Lam et al., 2008). Most attempts to treat RRB in ASD center on the same systems and approaches used in OCD and TS, with most data favoring the use of dopamine D2 antagonist drugs (McDougle et al., 2005) and not so much supporting SRIs (King et al., 2009).

38.2.5 Cognitive, Sensory, and Motor Correlates of RRB in Typical and Atypical Development

Deficits in executive function are often reported in individuals with RRB (Turner, 1997). Executive function is defined as a broad category of cognitive processes involved in the planning and execution of flexible, goal-directed behavior (O'Hearn et al., 2008). Evans et al. (2004) demonstrated that some executive function tasks, such as set shifting and response inhibition/motor suppression, were related to the frequency and intensity of compulsive behaviors in typically developing children. In individuals with ASD, positive correlations are seen between executive function deficits and RRB symptoms (Lopez et al., 2005; Turner, 1997). Furthermore, Lopez et al. (2005) reported that the degree of RRB in individuals with autism was positively correlated with deficits in cognitive flexibility, even after controlling for level of cognitive function. However, other groups have had mixed results in ASD (Joseph and Tager-Flusberg, 2004; South et al., 2005). Consistent with results in typical development and in ASD, individuals with OCD also show deficits in executive function, including response inhibition, set shifting, and reversal learning (Menzies et al., 2008). Some executive function deficits are also reported in TS, particularly in response inhibition, although these studies may be complicated by the common comorbidity with ADHD (Eddy et al., 2009).

38.2.6 Medication-Induced Repetitive Behavior

A number of medications have been observed to cause or exacerbate repetitive behavior in clinical populations. This is most commonly seen in the context of an existing neuropsychiatric disorder that has led to medication treatment in the first place. One obvious appeal to these observations is the opportunity to translate these induced repetitive behavior symptoms into animal models that could probe the underlying mechanisms of action, as well as potential treatments.

The most common scenario is the child with ADHD who develops a motor tic after starting a dopamine reuptake-inhibiting stimulant medication, such as methylphenidate, or a dopamine-releasing medication, such as amphetamine or dextroamphetamine. Given the frequency of comorbid tic disorder or TS in ADHD, many instances of tics emerging during stimulant treatment may not be due to the medication. Overall, the data suggest that it is no more common for tics to worsen than to improve on methylphenidate, and that high doses of dextroamphetamine appear to worsen tic severity (Bloch et al., 2009).

In addition, chronic dopaminergic replacements, such as L-DOPA (L-3,4-dihydroxyphenylalanine) treatment for Parkinson's disease (PD) or high-dose psychostimulants (e.g., cocaine and amphetamine), have been shown to cause dyskinesias, compulsions, and punding (i.e., abnormal repetitive nongoal-oriented behavior) (Fasano and Petrovic, 2010; O'Sullivan et al., 2007; Voon et al., 2009). Treatment strategies include a gradual reduction in dopamine dosage and N-methyl-D-aspartate (NMDA) blockers (e.g., amantadine) in PD patients.

Two other medications have been reported to either trigger or increase OCD symptoms in some, but not all, studies. At high doses, clozapine and, to a much lesser extent, other atypical antipsychotics can lead to repetitive behaviors or OCD symptoms (Sa et al., 2009). The complex pharmacology of clozapine, with actions on multiple receptors in the serotonin, dopamine, and histamine systems, makes it difficult to assess what particular receptors are responsible for this effect. Susceptibility to clozapine treatment-emergent OCD symptoms was associated in one study with polymorphisms in the neuronal glutamate transporter SLC1A1 gene (Kwon et al., 2009), which is also associated with idiopathic OCD, as reviewed later. Finally, serotonin receptor $5-HT_{1B}$ agonists, including sumatriptan, have been reported to cause worsened OCD symptoms in some patients with existing OCD (Gross-Isseroff et al., 2004), but reports are mixed across studies.

38.2.7 Autoimmune-Mediated Repetitive Behavior

Interest in the relationship between repetitive behavior and immune system response to infection first emerged from the observation of tics and compulsions in some children with Sydenham's chorea (SC), a movement disorder that emerges during poststreptococcal infection rheumatic fever (RF). Swedo and colleagues assessed whether some children may have OCD or tic symptoms without manifesting the full symptoms of SC or RF, identifying a subset of children who follow a pattern that they termed postinfections autoimmune neuropsychiatric disorders associated with group A streptococcal (PANDAS) infection (Swedo et al., 1998). In addition to tic or compulsive symptom onset soon after a strep infection, individuals who fit the PANDAS pattern are typically prepubertal, often show additional comorbidities such as hyperactivity, and are more likely to show a variable, intermittent pattern of symptoms (Murphy et al., 2010). Plasma exchange and intravenous immunoglobulin showed promise in an initial randomized, controlled trial in the PANDAS population (Perlmutter et al., 1999). Similarly, one study shows successful prevention of symptom exacerbations with antibiotic treatment (Snider et al., 2005). While these preliminary treatment studies are encouraging, it has been more difficult to connect symptom exacerbations to strep infections or to connect PANDAS pattern to a specific autoimmune mechanism. While some studies show increased antistreptolysin O titers in children with tics (Cardona and Orefici, 2001), prospective data are limited and do not yet show a clear relationship between strep infections and symptom exacerbations (Leckman et al., 2011). Considerable effort has gone into pursuing the specific antibody or immune cell response that may mediate PANDAS (reviewed in Murphy et al., 2010), with some promising, but not yet consistent, findings.

38.3 GENETICS OF REPETITIVE BEHAVIOR

A variety of approaches has been brought to bear on understanding the genetic susceptibility to repetitive behavior across neurodevelopmental and neuropsychiatric disorders. Twin studies are the gold standard for evaluating the genetic contribution to susceptibility. Family studies can offer further support for genetic susceptibility and allow for modeling of inheritance patterns, but environmental effects within families can confound results. A variety of molecular approaches is applied to try to locate genes that may contribute to susceptibility. Chromosomal rearrangements, deletions, or duplications that are detected by karyotyping can point to regions of interest or even implicate single genes that are disrupted. Linkage mapping within extended families or sibling pairs can identify chromosomal regions that are shared more often than chance among affected family members. Association studies can identify particular alleles that are more common among people with a disorder than in the general population. Each of these

approaches has strengths and weaknesses, and multiple approaches are often required to identify a gene of interest. Technology is moving rapidly in this arena, with the promise of whole-genome sequencing in the near future. The limiting factor in gene identification may be collecting samples of sufficient size to apply the latest technologies while correcting for the huge number of statistical tests performed across the genome. Given the rapid movement in this area, only those studies with the highest impact or replication across multiple samples are reviewed below.

38.3.1 Genetic Susceptibility to TS

TS affects approximately 1% of the population (Robertson, 2008), with isolated motor and vocal tic disorders affecting a larger number. The largest twin study suggests that TS is strongly heritable, with 53% of monozygotic twins (MZ) sharing the diagnosis compared to only 8% of dizygotic twins (DZ) (Price et al., 1985). These numbers rise when chronic tics are included, suggesting that isolated motor tics or, less commonly, vocal tics share a genetic susceptibility with TS. Family studies also support a significant role for heritability in TS (reviewed in O'Rourke et al., 2009). In addition to chronic tic disorders, OCD is also more common in the relatives of probands with TS (Pauls et al., 1986). While early segregation analysis suggested dominant inheritance of TS (Pauls and Leckman, 1986), genetic linkage studies have not yet revealed a major susceptibility gene.

The initial molecular genetic studies in TS used candidate gene association approaches with little success. Several small- to medium-sized genetic linkage studies have been conducted, with only one achieving genome-wide statistical significance on chromosome 2p23 (Tourette Syndrome Association International Consortium for Genetics, 2007). Linkage mapping in a single family followed by full exon sequencing of 51 genes on chromosome 15q led to the identification of a nonsense mutation in the L-histidine decarboxylase gene (*HDC*) in all affected family members (Ercan-Sencicek et al., 2010). Expression of this HDC nonsense variant interfered with the activity of the wild-type allele, suggesting that it acts in a dominant negative fashion to decrease synthesis of histamine (Ercan-Sencicek et al., 2010). Recurrent chromosomal rearrangements have been reported at a number of sites, and copy number variants may also play a role in TS susceptibility (Sundaram et al., 2010). A chromosome 13q inversion in one patient with TS pointed toward the slit- and trk-like 1 neuronal trophic factor (*SLITRK1*) as a positional candidate gene (Abelson et al., 2005). One frameshift mutation and a recurrent rare variant at a microRNA-binding site were identified in a group of TS patients, although subsequent studies have provided only mixed support (O'Roak et al., 2010). Despite their rarity, the promising findings at *HDC* and *SLITRK1* may point toward molecular mechanisms involved in the larger group of patients with TS.

38.3.2 Genetic Susceptibility to OCD

OCD affects approximately 2% of the population, with similar numbers of females and males, but with an earlier onset in males. Twin studies with modern diagnostic criteria are lacking, but more recent twin studies based upon OCD symptoms rather than diagnosis suggest a strong heritability (Hudziak et al., 2004). Family studies strongly favor genetic susceptibility, with most evidence coming from families of probands with childhood-onset OCD (Nestadt et al., 2000). TS and chronic tic disorders are also more common in first-degree relatives of probands with OCD (Grados et al., 2001), paralleling what is seen in probands with TS.

Most molecular genetics studies in OCD have focused on candidate genes, with mixed success. Based on response to the SRIs, the most studied candidate gene is the serotonin transporter (SERT, *SLC6A4*). Studies of common *SLC6A4* polymorphisms also favor a role for the serotonin transporter gene (SERT, *SLC6A4*) in OCD, but different polymorphisms have been associated across studies, with some suggestion of sex differences (Voyiaziakis et al., 2011; Wendland et al., 2008). Ozaki et al. (2003) identified a rare, hyperfunctioning Ile425Val variant of *SLC6A4* in two families with OCD and other psychiatric disorders, although subsequent studies have provided mixed support (Voyiaziakis et al., 2011). Only three small- to medium-sized genome-wide linkage studies have been carried out, with no statistically significant findings in any study (Hanna et al., 2002, 2007; Shugart et al., 2006). A follow-up linkage study for hoarding symptoms in OCD families yielded a significant linkage finding on chromosome 14q (Samuels et al., 2007). Additionally, one suggestive linkage finding on chromosome 9p24 (Hanna et al., 2002) was replicated in an independent linkage sample (Willour et al., 2004). Follow-up studies of the neuronal glutamate transporter EAAC1 gene (*SLC1A1*) have revealed a significant association in multiple samples, although different polymorphisms in the 3′ region of the gene have been associated across studies (reviewed in Wendland et al., 2009). Single candidate gene association studies have pointed to other genes in the glutamate system, converging on the finding that cerebrospinal fluid glutamate levels are elevated in OCD patients (Chakrabarty et al., 2005).

38.3.3 Genetic Susceptibility to Repetitive Behavior in ASD

ASD is a highly heritable complex genetic disorder with much higher concordance rates in monozygotic twins (64–91%) than in dizygotic twins and siblings

(0–9%) (Bailey et al., 1995; Bolton et al., 1994; Steffenburg et al., 1989). The ADI-R and Autism Diagnostic Observation Schedule (ADOS) (Lord et al., 1999, 2000), the gold standard instruments for ASD ascertainment, have been used extensively to reduce phenotypic heterogeneity in ASD research (Hus et al., 2007; Veenstra-VanderWeele and Cook, 2004). In addition, researchers have applied a stratification strategy by using 'subphenotypes' to enhance the ability to dissect the genetic etiology of ASD (Buxbaum et al., 2001; Cuccaro et al., 2003; Lam et al., 2008; Shao et al., 2002). Since RRB is one of the core domain features of ASD, specific forms of RRB can be used as a 'subphenotype' to identify a common genetic etiology in ASD. For example, Shao et al. (2003) have found increased linkage evidence at the *GABRB3* locus in the15q11-q13 region in families sharing high IS factor scores. Brune et al. also reported an association between the 5-HTTLPR long/long genotype of the serotonin transporter gene (*SLC6A4*) and RSMB (Brune et al., 2006).

Several groups have reported that RRB has a strong tendency to run within ASD families, indicating separate genetic factors for RRB. For instance, Silverman and colleagues examined the variance of the RRB subdomain scores on the ADI-R in 212 ASD sibling pairs (Silverman et al., 2002). They found statistically significant familiality in two ADI-R subdomains that captures the RRB similar to the CI and IS factors. In line with the Silverman study, Tadevosyan-Leyfer and colleagues also reported the familiality of the 'compulsion' factor derived from the ADI-R that captures both CI and IS factors (Tadevosyan-Leyfer et al., 2003). However, the RSMB factor did not appear to be familial in these studies. Instead, the RSMB factor was associated with individual characteristics, such as IQ, age, social/communication impairments, and the presence of regression (Lam et al., 2008). In summary, 'higher order' RRBs, such as IS and CI, appear to be under genetic control, whereas the 'lower order' RSMB factor reflects variation in developmental levels. Moreover, genetic factors for RRB are likely independent of those that influence the social or communication deficits in ASD (Mandy and Skuse, 2008; Ronald et al., 2006; Silverman et al., 2002).

38.3.4 Simple Genetic Disorders with Repetitive Behavior Phenotypes

RRB is also common in specific, relatively rare, genetic syndromes including but not limited to the genetic syndromes detailed below. A few example syndromes are reviewed briefly here, but further details can be found on the Online Mendelian Inheritance in Man (OMIM), which provides a comprehensive review of individual genetic syndromes. These individual syndromes may

provide insight into the molecular pathways and brain systems involved in RRB in the larger group of patients with developmental or neuropsychiatric disorders. Syndromes other than those highlighted below, including Angelman syndrome, Cornelia de Lange syndrome, Down syndrome (DS), and Cri-du-Chat syndrome, also include RRB as a significant part of their clinical profile. Each of these syndromes includes some degree of intellectual impairment, which raises the issue of interpretation of RRB in the developmental context. Importantly, individuals with each of these syndromes appear to have more RRB than IQ-matched peers.

Prader–Willi syndrome (PWS, OMIM #176270) is a rare genomic imprinting disorder with an estimated incidence rate of ~1 in 15 000 (Butler, 1990). PWS occurs when the *paternal* contribution is absent in the 15q11-q13 region. Interestingly, studies have reported a higher rate of ASD among individuals with PWS (Veltman et al., 2005). In addition, PWS has been associated with clinically significant RRB (Bittel and Butler, 2005; Dykens and Shah, 2003; Dykens et al., 1999; State and Dykens, 2000). For example, skin picking is reported in most individuals with PWS (Dykens et al., 1999; Thompson and Gray, 1994; Torrado et al., 2006; Veltman et al., 2004; Webb et al., 2002; Whitman and Accardo, 1987). A sizable group of individuals with PWS has prominent OCD symptoms, such as hoarding, ordering/arranging, concerns with symmetry/exactness, rewriting, and need to tell/know/ask (Dykens et al., 1996).

Rett syndrome (RS, OMIM #312750) is classified as one of the pervasive developmental disorders in the Diagnostic and Statistical Manual of Mental Disorders, 4th Edition (DSM-IV) (American Psychiatric Association, 2000). RS is caused by mutations in *MECP2*, located on the X chromosome (Xq28), and occurs almost exclusively in females with an estimated prevalence of ~1 in 20 000 females (Kozinetz et al., 1993; Leonard et al., 1997). The affected infants show normal prenatal and postnatal development for the first 5 months, followed by a deceleration of head growth rate, loss of acquired skills, impairments in social communication, and characteristic stereotypic repetitive hand movements such as mouthing or hand-wringing (Ben Zeev Ghidoni, 2007). Interestingly, an increase in *MECP2* gene dosage also appears to be pathological. Ramocki and colleagues described clinical characteristics of nine boys with duplication of the chromosomal interval including *MECP2* (Ramocki et al., 2009). This *MECP2* duplication syndrome is associated with severe to profound mental retardation, as well as repetitive behaviors including hand stereotypies and resistance to changes (Ramocki et al., 2010).

Smith–Magenis syndrome (SMS, OMIM #182290) is most commonly caused by a 3.7-Mb interstitial deletion in chromosome 17p11.2. SMS can also be caused by

mutations in *RAI1* within the chromosome 17p11.2 region. The individuals with SMS show brachycephaly, midface hypoplasia, prognathism, hoarse voice, and speech delay with or without hearing loss, psychomotor and growth retardation, as well as RRB, such as stereotypic body movements (e.g., mouthing objects, hand biting, teeth grinding, body rocking, spinning/twirling, and lick and flip), restricted interests, obsessions, repetitive speech, ritualistic behavior, and attachment to people (preference for adults) (Clarke and Boer, 1998; Dykens and Smith, 1998; Dykens et al., 1997; Moss et al., 2008).

Smith–Lemli–Opitz syndrome (SLOS, OMIM #270400) is an autosomal recessive genetic disorder caused by a defect in cholesterol biosynthesis due to mutations of *DHCR7*. The estimated incidence of SLOS varies, ranging from 1 in 20 000 to 1 in 80 000 births (Kelley and Hennekam, 2000; Lowry and Yong, 1980; Ryan et al., 1998). The SLOS phenotypes vary but include microcephaly, mental retardation, hypotonia, facial dysmorphism, digital anomalies, and ambiguous genitalia. In addition, various forms of RRBs are common in SLOS. For instance, Tierney and colleagues reported repetitive forceful and rapid backward head/trunk arching and backward thrusting (opisthokinesis) in 50% of their study subjects, stereotypic stretching with brief and rapid hand movements, as well as self-injurious behavior, such as biting themselves or banging their heads on objects (Tierney et al., 1999, 2000).

38.4 NEUROPATHOLOGY AND NEUROIMAGING OF REPETITIVE BEHAVIOR

Neuropathology studies of RRB in human samples have been limited by sample availability. Even in TS, where a number of studies have been published, there are not sufficient samples to allow for replication of key findings. Neuroimaging techniques are a promising avenue and are yielding some consistent findings across studies. A variety of structural and functional neuroimaging techniques have been applied to the study of repetitive behavior in defined neurodevelopmental or neuropsychiatric syndromes. The structural techniques include variations on magnetic resonance imaging (MRI), including structural MRI, magnetic resonance spectroscopy (MRS), and diffusion tensor imaging. A variety of techniques is also used to evaluate functional activity of particular brain regions, including positron emission tomography (PET), which is typically used as a measure of brain metabolism, as well as single-photon emission computed tomography (SPECT) and functional MRI, which are used as measures of regional blood flow. Additionally, each of these functional measures can be applied in the resting state or during the performance of particular cognitive tasks, making the resulting findings quite difficult to evaluate for consistency. Finally, various PET ligands can be used to evaluate the availability or binding of specific receptor or transporter proteins. The summaries that follow reflect findings that have emerged in large sample sizes or across multiple studies. Except where noted, most of these studies have been conducted in older children, adolescents, and adults because of the difficulties in imaging younger children. Importantly, data across these disorders point to common brain regions, including the basal ganglia, but findings are sometimes in opposite directions in different disorders, making it difficult to draw clear lines between RRB and specific regional alterations.

38.4.1 Neuropathology and Neuroimaging in TS

A limited number of postmortem cases are available in TS. In small sample studies, two findings have emerged with evidence across at least two studies or different brain regions. First, dopamine transporter binding density is decreased in both the basal ganglia and the frontal cortex (Singer et al., 1991; Yoon et al., 2007). Although this finding provides further support for the involvement of the dopaminergic system in TS and RRB, it is difficult to evaluate whether it is a primary or secondary change due to exposure to medications acting on the dopamine system as well as chronic TS. Second, two studies have found a decrease in parvalbumin-positive interneurons in the caudate (Kalanithi et al., 2005; Kataoka et al., 2010). As detailed below, this may point to a more specific population of neurons than can be identified in structural neuroimaging studies.

The presence of frequent motor tics may limit the ability of patients with TS to remain in the scanner. Perhaps as a result, relatively few structural neuroimaging studies have been performed in TS, with little consistency among studies to date (Plessen et al., 2009). The largest structural MRI study pointed to decreases in caudate volume in children and adults with TS (Peterson et al., 2003). A follow-up study provided further support for the importance of caudate volume, observing that lower caudate volume during childhood predicted higher tic severity in young adulthood (Bloch et al., 2005). The same large study found increased volumes in the orbitofrontal and parietal cortex of children with TS but decreased volumes in adults (Peterson et al., 2001). Furthermore, cortical volumes correlated inversely with symptom severity, suggesting that these alterations may serve to compensate for the primary deficit in TS (Peterson et al., 2001). Abnormalities have also been reported in other brain regions, including the corpus callosum, the limbic system, and the thalamus, but

consistent findings have yet to emerge (Plessen et al., 2009). A variety of PET ligands has been used to examine monoamine receptors and transporters in TS, with a particular focus on the basal ganglia. The most consistent finding to emerge from these studies is an increase in amphetamine-induced release of dopamine, as assessed by a change in receptor binding after drug administration (Singer et al., 2002; Steeves et al., 2010; Wong et al., 2008).

Functional neuroimaging studies in TS have shown little consistency, likely because of variation in methodologies and subject populations (Rickards, 2009). If subjects are able to remain still in the scanner to allow adequate image acquisition, they will, as a result, be scanned in the act of tic suppression, regardless of what other cognitive task may be assigned. Perhaps as a result, PET, SPECT, and fMRI studies show considerable variability, with some support for decreased metabolism or blood flow in the basal ganglia (Braun et al., 1993; Eidelberg et al., 1997; Klieger et al., 1997; Peterson et al., 1998; Riddle et al., 1992). When considering the neuroimaging results as a whole, then, there is reasonable evidence favoring the involvement of the basal ganglia and the dopamine system, but much less consistency regarding the importance of other brain regions.

38.4.2 Neuroimaging of OCD

Postmortem studies have not been published to date in OCD. Individual structural MRI studies vary, but the aggregate data provide significant support for cortical–striatal pathology in OCD. Radua and Mataix-Cols (2009) performed a voxel-wise meta-analysis to identify individual regions with consistent findings across 12 MRI studies, including 3 studies of children and adolescents, and 9 of adults. Increased gray matter volume was found in the basal ganglia, including a large portion of the putamen and extending into the caudate. The severity of OCD in the patients included in each study correlated with the severity of this increased basal ganglia volume. Additionally, decreased gray matter volume was found in a continuous region encompassing the dorsal mediofrontal cortex and anterior cingulate cortex. No consistent evidence was obtained for changes in the orbitofrontal cortex (OFC), although individual structural neuroimaging studies do report changes in this region (Pujol et al., 2004; Szeszko et al., 2008), as do the functional neuroimaging studies reviewed later.

MRS has also been applied in OCD to understand the chemical composition of brain regions implicated in functional studies. A couple of studies have reported decreased N-acetylasparate, a putative marker of neuronal integrity, in the anterior cingulate cortex (Jang et al., 2006; Yucel et al., 2007). The Rosenberg group has also reported increased glutamatergic signal, comprising both glutamate and GABA, in the caudate that normalizes with treatment with SRIs in pediatric OCD patients (Rosenberg et al., 2000). This may match one study that found increased glutamate levels in cerebrospinal fluid from patients with OCD (Chakrabarty et al., 2005). PET and SPECT studies have also been used to evaluate ligand binding to particular receptor and transporter proteins in OCD. Despite some inconsistency, a few studies report decreased binding to the serotonin transporter in a number of regions, including the thalamus (Matsumoto et al., 2010; Reimold et al., 2007; Zitterl et al., 2007). Other studies implicate the dopamine system, including decreased ligand binding to the dopamine D2 receptor, suggesting increased dopamine in the synapse (Moresco et al., 2007; Perani et al., 2008).

Functional neuroimaging studies provide further evidence of the involvement of the basal ganglia in OCD and also point to the OFC. Different methodologies have been used to examine functional activation of brain regions in OCD, including PET, SPECT, and fMRI, which are detailed elsewhere in this volume. PET studies emerged first, typically using [18]fluorodeoxyglucose to assess regional brain metabolism. SPECT and fMRI use different measures of regional blood flow, which may correspond to regional activation. Measures of metabolism and blood flow may provide different results, although a few consistent findings have emerged across different modalities. These methods can also be applied in different settings, either to measure baseline activity at rest or to measure changes in activity during particular cognitive tasks. Resting PET studies favor increased brain metabolism in the caudate and the OFC, with some evidence also favoring the thalamus (Baxter et al., 1987, 1988; Whiteside et al., 2004), although findings are not always consistent (Whiteside et al., 2004). fMRI, SPECT, and PET studies have also used symptom provocation or executive function tasks to evaluate differences in brain region activation in particular contexts, with the data again highlighting the importance of the basal ganglia and OFC (Chamberlain et al., 2008; Menzies et al., 2008).

The coupling of functional neuroimaging methodology with successful treatment provides the best evidence for involvement of the corticostriatal pathway in OCD. The first reports of increases of caudate and OFC glucose metabolism by PET were followed quickly by reports of decreased caudate and OFC metabolic activity by PET after successful treatment with SRIs (Baxter et al., 1992; Benkelfat et al., 1990). OCD is not the only disorder to be treated with SRIs; they can also be helpful for depression and anxiety disorders, raising the possibility that changes in regional glucose metabolism could be nonspecific. Saxena et al. (2002) tested this possibility by comparing changes in regional glucose metabolism with an SRI in patients with OCD compared to patients with major depression, finding that the decreased metabolic activity

in the caudate and OFC was specific to OCD. Adding further support to the specificity of this change to OCD treatment response, a decreased caudate glucose metabolism was also seen after successful CBT for OCD (Baxter et al., 1992; Schwartz et al., 1996). Taken as a whole, the structural and functional neuroimaging data support the concept of an OCD circuit including the OFC, the anterior cingulate cortex, the basal ganglia, and the thalamus.

38.4.3 Neuroimaging of Repetitive Behavior in ASD

Little, if any, information is available associating post-mortem findings with RRB in individuals with neurodevelopmental disorders (Amaral et al., 2008). There are some associations, however, between structural neuroimaging findings (i.e., regional volumetric measurements) and repetitive behavior. For example, Sears et al. (1999) reported a significant negative association between caudate volume and three ADI-R repetitive behavior items: difficulties with minor changes in routine, compulsions/rituals, and complex mannerisms. A directionally different result was obtained by Hollander et al. (2005), who found increased right caudate volumes in individuals with autism and a positive correlation between right caudate volumes and ADI-R repetitive behavior domain total scores. Interestingly, no relationship was found between right caudate volume and RSMB. Instead, the association was due to the correlation between right caudate volume and IS/resistance to change factor scores. The same pattern was observed when putamen volumes were correlated with repetitive behavior scores. These findings were largely replicated by Rojas et al. (2006). In addition, significant positive partial correlations with the ADI-R repetitive and stereotyped behavior domain were also found in the left inferior frontal gyrus and right amygdala. Smaller volumes of the superior temporal gyri, left postcentral gyrus, and cerebellar regions were associated with worse repetitive behavior domain scores. Pierce and Courchesne (2001) found a positive correlation between repetitive behavior exhibited in the experimental setting of an exploration task and frontal lobe volume in a study of young children with autism. This measure of repetitive behavior was negatively correlated with cerebellar vermis volume. These neuroanatomic measures were not associated with ADI-R or ADOS repetitive behavior scores, however, Kates et al. (2005) compared boys with stereotypies who had no other known developmental or neurological disorder with matched controls. In this study, decreases in frontal white matter were found even after total white matter volume was taken into account. Caudate volumes did not differ between groups when expressed relative to total brain volume.

There has been little utilization of functional MRI to determine the neurobiological basis of repetitive behavior in neurodevelopmental disorders. One notable exception has been the work of Thakkar et al. (2008) who made use of an antisaccade task, which involves suppression of the prepotent response of looking toward rather than away from a stimulus. High-functioning individuals with ASD exhibited significantly higher error rates in the antisaccade condition and significantly increased anterior cingulate cortex (ACC) activation during correct trials. Moreover, higher ADI-R repetitive behavior scores were associated with greater ACC activation during correct trials, with repetitive sensorimotor behavior scores more strongly related to ACC activation than resistance to change/IS factor scores. An exaggerated ACC response to correct trials has also been observed with OCD subjects. An association between repetitive behavior and ACC activation has also been shown by Shafritz et al. (2008). These investigators used both a response-shifting and a set-shifting cognitive task in individuals with high-functioning autism. Individuals with autism showed deficits in response shifting but, surprisingly, not cognitive set shifting when compared to controls. Reduced activation in frontal, striatal, and parietal regions was observed during these trials in the ASD group. The severity of repetitive behavior was negatively correlated with activation in anterior cingulate and posterior parietal regions.

Despite the paucity of imaging studies related to repetitive behavior, the extant studies, taken together, highlight the importance of corticostriatal-thalamocortical circuitry in the mediation of repetitive behavior, as in TS and OCD. As will be seen in later sections, findings from animal models of repetitive behavior strongly support the involvement of this circuitry. Of particular value for the future would be studies such as the work of Langen et al. (2009), examining trajectories of development of key brain structures such as the caudate. Such work would need, however, to track coincident changes in the expression of RRB (Table 38.1).

38.5 MODELING REPETITIVE BEHAVIOR IN ANIMALS

As reviewed by the authors recently (Lewis et al., 2007), animal models of repetitive behavior that are relevant to clinical disorders can be categorized as follows: repetitive behavior associated with targeted insults to the CNS, repetitive behavior induced by pharmacological agents, and repetitive behavior associated with restricted environments and experience. Since that review, there have been reports confirmed by the authors' own observations of spontaneous repetitive behavior in two inbred mouse strains. As reviewed above, repetitive behavior occurs in multiple clinical populations, and animal models of repetitive behavior are therefore unlikely to be specific to a particular disorder. Even without achieving specificity,

TABLE 38.1 Summary of Clinical Research Areas and Major Findings

Research area	Twin study	Molecular genetic study	Neuropathology and neuroimaging study
TS	53% monozygotic (MZ) versus 8% dizygotic (DZ)	HDC	↓ DAT binding density in basal ganglia and frontal cortex
		SLITRK1	↓ Parvalbumin-positive neuron in caudate
		2p23	↓ Caudate volume
			↓ Caudate volume during childhood ↑tic severity in adulthood
			↑ Orbitofrontal and parietal cortex volume in children versus ↓ in adults
			↓ Cortical volume ↑tic severity
			↓ Metabolism in basal ganglia
OCD	None using DSM criteria	SLC6A4	↑ Glutamate in CSF
		SLC1A1	↓ Binding to 5-HT transporter
		14q	↓ Ligand binding to D2 receptor
		9p24	↑ Gray matter volume in basal ganglia
			↓ Gray matter volume in dorsal mediofrontal cortex and anterior cingulate cortex
			↑ Metabolism in caudate, thalamus, OFC
			↓ Metabolism in caudate and OFC after successful treatment with SRIs
ASD	~91% MZ versus ~10% DZ	GABRB3 – IS	↑ ADI-R RRB item score ↓ caudate volume
		SLC6A4 – RSMB	↑ ADI-R IS score ↑ right caudate and putamen volume
			↑ ADI-R RSMB score ↑ left inferior frontal gyrus and right amygdala volume
			↑ RRB ↑ frontal lobe and ↓ cerebellar vermis volume

however, these models can be very useful in deciphering the circuit or the pharmacological contributions to repetitive behavior across clinical and nonclinical populations.

38.5.1 Repetitive Behavior in Animal Models of Targeted CNS Insult

There are a small number of mouse models that involve mutations of specific genes or chromosomal regions that have been reported to result in specific forms of repetitive behavior as part of the phenotype. For example, compulsive grooming resulting in hair removal and self-inflicted wounds has been observed in the *Hoxb8* homozygous mutant mouse (Greer and Capecchi, 2002) and the *Sapap3* KO mouse (Welch et al., 2007). In the latter model, the SAPAP3 protein is expressed selectively in glutamate synapses in striatum, whereas high levels of expression of *Hoxb8* were observed in brain regions known to comprise circuitry mediating OCD symptoms in patients. These models may have specific relevance to OC spectrum disorders such as trichotillomania or self-injurious behaviors common in individuals with severe neurodevelopmental

disorders. Mice expressing truncated MeCP2 protein, which serve to model RS, exhibit repetitive forelimb movements resembling the distinctive hand stereotypies (e.g., hand wringing, waving, and clapping) observed in patients with this syndrome (Moretti et al., 2005; Shahbazian et al., 2002). PWS patients exhibit a variety of compulsive behaviors including skin picking associated with deletions of the q11–13 region of chromosome 15 (Dykens, 2004). Among the genes that lie within this region is the *GABRB3* gene, which codes for the β3 subunit of the GABAA receptor. The *Gabrb3* homozygous knockout mouse exhibits stereotyped behavior including intense circling or 'tail-chasing' (DeLorey et al., 1998; Homanics et al., 1997). Ts65Dn mice have segmental trisomy for orthologs of a number of genes on human chromosome 21 and thus serve as a model of DS. The authors have shown that such mice exhibit repetitive hindlimb jumping and cage-top twirling (Turner et al., 2001). Similar stereotypies (jumping and cage top circling) have been reported in the amyloid precursor protein transgenic mouse model of Alzheimer disease (TgCRND8) (Ambree et al., 2006). Alterations in the neurexins, neuroligins, and associated proteins including SHANK3 have been implicated in the etiology of

autism. Transgenic animals overexpressing neuroligin 2 (TgNL2) have altered synapse development and neuronal excitability and behaviorally exhibit limb clasping similar to *MECP2* KO mice and stereotyped vertical jumping (Hines et al., 2008). Neurexin 1α (*Nrxn1*), neuroligin 1 (*Nl1*), and *Shank3* KO mice each show increased grooming behavior, potentially pointing to a common repetitive behavior outcome for disruption of this autism-associated synaptic protein system.

CNS insult leading to repetitive behaviors in animals has also included nongenomic factors. Perhaps the most striking demonstration of such factors comes from Martin et al. (2008). These investigators purified antibodies from women who had at least two children with ASD and injected them into pregnant rhesus macaques. The offspring of these macaques were observed to engage in spontaneous whole-body stereotypies that persisted in the 6 months following weaning and were observed in multiple test conditions. Exposure to maternally derived IgGs that cross the placenta has been implicated in other disorders involving tics and compulsive disorders. Prenatal exposure to valproic acid has been linked to autism susceptibility. In rats, exposure to valproic acid on embryonic day 12.5 induces stereotypic activity (Ingram et al., 2000; Rodier et al., 1997; Schneider and Przewlocki, 2005). Repetitive behavior can also be induced by exposure of newborn rats to Borna disease virus (Hornig et al., 1999). In nonhuman primates, early lesions encompassing the amygdala, hippocampal formation, and adjacent temporal cortex result in repetitive behavior (Bachevalier and Loveland, 2006). A delayed (after year 1 of life) emergence of repetitive motor behavior following amygdala or hippocampal lesions in macaque infants has also been reported by Bauman et al. (2008), who also showed that amygdala damage induced self-directed behaviors, whereas hippocampal lesions induced repetitive head twisting.

Although these studies provide potentially valuable models, repetitive behavior has generally not been the focus or rationale for the work. Thus, the repetitive behavior observed has often not been well characterized and little additional work has investigated the specific neurobiological mechanisms associated with the expression of the repetitive behavior.

38.5.2 Animal Models of Drug-Induced Repetitive Behavior

As early as the 1960s, it was known that specific pharmacological agents such as amphetamine and apomorphine can induce repetitive behavior in animals. As these drugs act on dopamine receptors or uptake sites that are enriched in striatum, these findings pointed to the importance of the basal ganglia in the mediation of repetitive behaviors. Confirmation came from experiments showing that dopamine or a dopamine agonist injected

directly into the corpus striatum induced stereotyped behavior in rats (e.g., Ernst and Smelik, 1966). Similarly, intrastriatal administration of the glutamate receptor ligand, NMDA, also induced stereotyped behavior (Karler et al., 1997). Intracortical manipulations enhancing the activity of excitatory corticostriatal projections exacerbate the expression of stereotypy. For instance, administration of either the D_2 antagonist sulpiride or the GABA antagonist bicuculline into the frontal cortex enhances the motor stimulatory effects of amphetamine (Karler et al., 1998; Kiyatkin and Rebec, 1999). Conversely, amphetamine-induced stereotypy can be attenuated via intracortical infusion of DA or GABAergic agonists (Karler et al., 1998). Experiments in which the expression of drug-induced stereotypy was shown to be sensitive to manipulations in the substantia nigra pars reticulata (SNpr) and the subthalamic nucleus (STN) also support the hypothesized role of cortical–basal ganglia circuitry in repetitive behaviors (Barwick et al., 2000; Scheel-Kruger et al., 1978). These, and many other relevant findings, provide clear evidence of the preeminent role played by the cortical–basal ganglia circuitry in the expression of drug-induced repetitive motor behaviors.

38.5.3 Repetitive Behavior and Environmental Restriction

Abnormal repetitive behaviors are considered sentinel behaviors by applied ethologists signaling poor animal welfare. This is not surprising as a wide variety of species of animals housed in restricted or impoverished environments (e.g., zoo, farm, and laboratory) exhibit abnormal repetitive behavior (Mason and Rushen, 2006). In fact, as Wurbel (2001) has pointed out, repetitive behaviors are the most common category of abnormal behavior observed in confined animals. Demonstrations of the attenuation or prevention of repetitive behavior by rearing animals in larger, more complex environments (environmental enrichment) provide strong evidence for the role of environmental restriction in the induction of repetitive behavior. Early social deprivation as a special case of environmental restriction has been shown to have powerful deleterious effects on humans and nonhuman primates including the induction of abnormal repetitive behavior (Carlson and Earls, 1997; Mason and Rushen, 2006).

The authors' own work has involved an animal model that falls under the category of repetitive behavior associated with environmental restriction. In this model, deer mice (*Peromyscus maniculatus*) exhibit repetitive hindlimb jumping and backward somersaulting as a consequence of being reared in standard laboratory caging. These behaviors occur at a high rate, persist across much of the life of the animal, and appear relatively early in development, sometimes as early as weaning. The authors have shown in several studies that environmental

enrichment markedly attenuates the development and expression of the repetitive behavior. This outcome was associated with biochemical and morphological changes in basal ganglia circuitry (Lewis, 2004).

38.5.4 Repetitive Behavior in Inbred Mouse Strains

Examination of inbred mouse strains for autistic-like behavioral traits led to the observation that C58/J mice displayed stereotyped jumping and backward flipping behaviors not observed in other strains (Moy et al., 2008a,b). A similar behavioral phenotype has been reported in the C57BL/10 strain (Deacon et al., 2007), with mice of this strain exhibiting spontaneous repetitive vertical jumping with no such behavior observed in the closely related C57BL/6 strain. The authors have confirmed both sets of observations (unpublished findings). In addition, Crawley and her colleagues have described an excessive grooming phenotype in BTBR (BTBRT+tf/J) mice (Silverman et al., 2010). Thus, several inbred mouse strains display a repetitive behavior phenotype, which should be highly advantageous for addressing the issue of the genetics of repetitive behavior.

38.5.5 Resistance to Change/IS in Animal Models

As the findings in the previous sections make clear, it is the repetitive sensory–motor factor of RRB that is most frequently modeled in animals. This cluster of behaviors is easier to model than behaviors related to the IS or resistance to change factor. Nevertheless, some animal work has addressed cognitive flexibility or resistance to change. This work has entailed a range of behavioral tests from response extinction to reversal learning to intra- and extradimensional set shifting (e.g., Colacicco et al., 2002). In some cases, there has been an attempt to correlate repetitive motor behaviors or stereotypies with measures of cognitive flexibility. For example, the amount of environmental restriction-induced stereotypy observed in bank voles and bears was significantly inversely correlated with extinction learning (Garner and Mason, 2002; Vickery and Mason, 2005). Similar findings were obtained with Orange-wing Amazon parrots using performance on a variation of a gambling task that indexed the tendency to repeat responses or perseverate. Birds with higher stereotypy scores exhibited greater sequential dependency in their responses on this task (Garner et al., 2003). In their own work, the authors have examined the performance of deer mice in a procedural T-maze learning task. Their results indicate that high levels of stereotypy in deer mice were associated with deficits in reversal learning in the T-maze (Tanimura et al., 2008b). The relationship between cognitive rigidity (deficits in set shifting, extinction, and reversal learning) and motor stereotypy is perhaps not surprising given the common mediation by cortical–basal ganglia pathways. Much greater emphasis needs to be placed on modeling 'higher order' repetitive behaviors in animals in future studies, however.

38.6 NEUROCIRCUITRY OF REPETITIVE BEHAVIOR

38.6.1 Basal Ganglia Circuitry and Repetitive Behavior

As reviewed recently by the authors (Lewis and Kim, 2009), neural mediation of the expression of repetitive behavior rests on pathways that project from select areas of the cortex to the striatum and then onto other basal ganglia, then the thalamus, and finally back to the cortex. Medium spiny GABAergic striatal projection neurons receive input from sensory–motor and associative areas of cortex, and, in turn, give rise to the so-called direct and indirect pathways that constitute corticostriatothalamocortical loops. GABAergic medium spiny neurons in the striatum that express the neuropeptides dynorphin and substance P as well as D_1 dopamine receptors and A_1 adenosine receptors constitute striatonigral or direct-pathway neurons. These neurons send projections from the striatum to the internal segment of the globus pallidus (GPi) and SNpr. Striatal medium spiny neurons that express the neuropeptide enkephalin as well as D_2 dopamine receptors and A_2 adenosine receptors constitute striatopallidal or indirect-pathway neurons. Indirect-pathway neurons project to the external segment of the globus pallidus (GPe) and then to STN before projecting to GPi and SNpr. Output from the GPi/SNpr goes to the thalamus and then on to the cortex to complete the circuitry (Gerfen, 2000; Olanow et al., 2000; Steiner and Gerfen, 1998). The classic view has been that the direct pathway facilitates movement via disinhibition of glutamatergic thalamocortical firing, whereas the indirect pathway inhibits ongoing movement via inhibition of thalamocortical afferents (Gerfen et al., 1990).

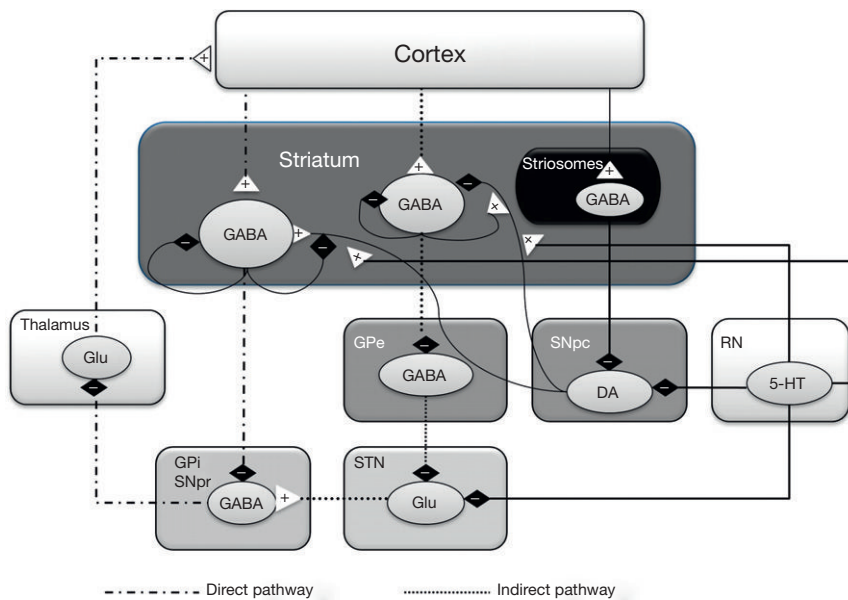
The medium spiny cells that give rise to either the direct or the indirect pathways constitute about 85% of projection neurons and the matrix compartment of the striatum. The remaining projection neurons form patchy areas or striosomes that are distributed throughout the extrastriosomal matrix. Striosomal projection neurons


FIGURE 38.1 Cortical–basal ganglia circuitry. The direct and indirect pathways through the basal ganglia are shown, along with other neurotransmitter systems that impact basal ganglia circuitry. +, excitatory input; −, inhibitory input; Glu, glutamate; 5-HT, serotonin; DA, dopamine; GPe, globus pallidus externa; GPi, globus pallidus interna; RN, raphe nucleus; SNpc, substantia nigra pars compacta; SNpr, substantia nigra pars riticulata; STN, subthalamic nucleus.

receive input preferentially from limbic cortical areas (e.g., OFC, anterior cingulate/posterior medial prefrontal cortex [PFC]) and, in turn, project to the substantia nigra pars compacta (SNpc) (Canales and Graybiel, 2000a,b). Striosomal projections can, therefore, directly mediate nigrostriatal dopamine pathway activity, which, in turn, will strongly influence the activity of direct- and indirect-pathway neurons in the striatum. Moreover, the activity of striosomal projections should strongly impact reward through regulation of ascending DA projections. White and Hiroi (White and Hiroi, 1998) provided some support for this idea by showing that high rates of intracranial self-stimulation were associated with electrode placement either in or next to striosomes. Conversely, 'normal' sensory–motor function (e.g., grooming and locomotion) in rats appears to be mediated by the extra-striosomal matrix (Brown et al., 2002). Findings from nonhuman primates have suggested that striosomal output innervates SNpr and GP as well as SNpc (Levesque and Parent, 2005), so these pathways also may not be as segregated as once believed (Figure 38.1).

38.6.2 Cortical–Basal Ganglia Circuitry and Repetitive Behavior

As many as five parallel information-processing circuits have been identified that make up the cortical–basal ganglia circuitry. These five circuits have been labeled as the motor, oculomotor, dorsolateral prefrontal, lateral orbitofrontal, and anterior cingulate circuits (Alexander et al., 1986). These circuits, though anatomically distinct, are nevertheless not segregated. Of these, the motor

circuit has been the most studied and emerges as the best candidate for mediation of repetitive behavior.

Direct evidence for the role of such circuitry in repetitive behavior is limited. The authors have shown that stereotyped behavior in early socially deprived rhesus macaques was associated with dopamine receptor super-sensitivity (Lewis et al., 1990), loss of dopamine innervation in striatum and dopamine cells in substantia nigra, and decreases in medium spiny striatal projection neurons as indexed by neuropeptide staining (Martin et al., 1991).

The importance of the corticobasal ganglia circuitry in repetitive behavior is further highlighted by the behavioral phenotype of the *Sapap3* knockout mouse (Welch et al., 2007). *Sapap3* encodes a postsynaptic scaffolding protein, highly expressed in the striatum and important in regulating glutamatergic corticostriatal synapses. Mice homozygous for the gene deletion exhibited excessive grooming leading to lesions of the head, neck, and snout. In addition, these animals exhibited alterations in α-amino-3-hydroxy-5-methyl-4-isoxazoleproprionic acid (AMPA) and NMDA-receptor-dependent transmission at corticostriatal synapses. Interestingly, administration of the serotonin uptake inhibitor fluoxetine given systemically for 6 days reversed the compulsive grooming. Finally, the behavioral phenotype was rescued by transduction of the *Sapap3* gene into preweaning mice. This work shows that deletion of even a single protein that functions to maintain the activity of the cortical–basal ganglia circuitry can result in a robust repetitive behavior phenotype. Moreover, an SRI can reverse the effects of loss of a glutamate synapse protein. Further support for the involvement of corticostriatal signaling is evidenced by mice lacking the *Slitrk5* gene, which encodes another

member of the protein family that includes *Slitrk1*, implicated in TS. Like the Sapap3 knockout mouse, the *Slitrk5* knockout mouse also shows increased grooming and anxiety-like behavior that improves with fluoxetine (Shmelkov et al., 2010). It also shows abnormalities in corticostriatal neurotransmission, perhaps due to altered striatal cellular composition, and increased OFC activity. These emerging genetic models, while not yet mapping onto known RRB susceptibility genes, suggest that the complex circuitry underlying RRB can be effectively modulated in multiple ways.

Grabli et al. (2004) have reported induction of stereotyped behavior (e.g., licking and biting of fingers) in monkeys by the GABA antagonist bicuculline microinjected into the limbic aspect of the GPe (part of the indirect pathway). In a follow-up study (Baup et al., 2008), this group showed that DBS applied to the STN dramatically reduced these drug-induced repetitive behaviors. The importance of the STN, and thus the indirect pathway, was also highlighted by Winter et al. (2008). In this study, rats that sustained ibotenic acid lesions to the STN exhibited an increase in compulsive lever pressing in the signal attenuation model of OCD. This same research group has also shown that bilateral high-frequency stimulation of the STN as well as its pharmacological inactivation reduced compulsive checking in rats induced by the dopamine agonist quinpirole (Winter et al., 2008). This latter finding is consistent with clinical observations that DBS applied to the STN reduced the severity of symptoms in previously treatment-refractory OCD patients (Mallet et al., 2008).

The authors have shown, in multiple studies, that early environmental enrichment markedly attenuated the development of repetitive behavior in deer mice. In addition, brain changes associated with this attenuation occurred in brain areas associated with the cortical–basal ganglia circuitry but not in other brain regions (e.g., hippocampus; see Lewis, 2004). In other experiments with deer mice, antagonism of corticostriatal glutamatergic projections or nigrostriatal dopaminergic projections by intrastriatal administration of selective pharmacological agents selectively reduced stereotyped behavior (Presti et al., 2003). Interestingly, the D_1 dopamine receptor antagonist SCH23390 exhibited such effects, whereas no such attenuation was observed following intrastriatal administration of the D_2 dopamine receptor antagonist raclopride (Presti et al., 2004).

Dysregulation of corticostriato-thalamocortical circuitry associated with motor disorders is thought to be due to an imbalance between the direct and indirect pathways comprising this circuit. Because dynorphin and enkephalin serve as markers for direct- and indirect-pathway neurons, respectively, concentrations of these striatal neuropeptides were measured to index the relative activation of these basal ganglia pathways in stereotypic deer mice (Presti and Lewis, 2005). Measurements were made in dorsolateral striatum using deer mice exhibiting different levels of spontaneous stereotypy. Results indicated significantly increased dynorphin/enkephalin content ratios in high-stereotypy mice relative to low-stereotypy mice. This ratio difference was due to significantly lower leu-enkephalin content in high-stereotypy mice. Moreover, a significant positive correlation was found between the dynorphin/enkephalin content ratio and frequency of stereotypy in these mice, whereas a significant negative correlation was found for enkephalin content and stereotypy.

To extend these findings, the authors assessed indirect-pathway activation relative to stereotypy by measuring neuronal metabolic activation of the STN, a key brain region in the indirect pathway (Tanimura et al., 2008a). Using cytochrome oxidase (CO) histochemistry to index long-term neuronal activation, they found that CO staining in the STN was significantly reduced in high-stereotypy mice. Further, CO staining was significantly negatively correlated with the frequency of stereotypy. Thus, higher rates of spontaneous stereotypy were associated with reduced neuronal activation of the indirect pathway.

The authors hypothesized that if high rates of spontaneous stereotypy were associated with decreases in indirect-pathway activation, then stimulation of this pathway by a selective pharmacological agent should attenuate repetitive behavior. As A2A receptors are enriched in striatum, expressed on striatopallidal neurons and activate Gs/olf proteins upon stimulation, activation of these receptors should attenuate stereotypy. When administered alone, however, the selective A2A receptor agonist CGS21680 failed to reduce stereotypy. The addition of the selective A1 agonist N6-cyclopentyladine (CPA) to CGS21680 did selectively attenuate stereotypy in a dose-dependent manner without adverse suppression of general motor activity. The relative efficacy of the combined stimulation of A2A and A1 receptors compared to A2A alone may be explained by the results reported by Karcz-Kubicha et al. (2006). In this work, administration of an A1 or A2A receptor agonist alone did not induce striatal c-Fos expression. Stimulation of both receptor subtypes, however, did induce striatal c-Fos expression and in a selective fashion with activation seen in striatopallidal, but not striatonigral, neurons. This combined treatment of A1 and A2A receptor agonists also increased striatal enkephalin expression. The attenuation by repetitive behavior of this drug combination provides additional evidence for the importance of the indirect pathway and also highlights potential novel therapeutic targets.

38.6.3 Long-Term Neuroadaptations and Repetitive Behavior

The development and persistence of repetitive behavior in neurodevelopmental disorders presumably involve long-term, experience-dependent plasticity in the

cortical–basal ganglia pathways. As yet, there is little information available as to the nature of these neuroadaptations or the mechanisms that mediate such plasticity. There are other models of such long-term basal ganglia neuroadaptations, however, that may be highly informative for the understanding of pathway changes that may mediate the development and expression of repetitive behavior associated with clinical disorders.

One model for such neuroadaptation would be habit learning or habit formation. Habits and repetitive behaviors share a number of important similarities; indeed, as Graybiel (2008) has suggested, repetitive behaviors can be thought of as 'extreme' habits. Habit formation, typically examined in the context of procedural learning, involves adaptations of cortical–basal ganglia loops. Discrete shifts in neural activity patterns associated with the transition from a goal-directed to a habit-driven behavior have been identified using chronic electrophysiological monitoring of ensembles of neurons in rodents and nonhuman primates (reviewed in Graybiel, 2008). Amphetamine sensitization, another model of dopamine-dependent striatal plasticity, involves long-term neuronal changes following repeated, intermittent drug exposure. Amphetamine sensitization accelerates the development of habit learning or formation (Nelson and Killcross, 2006), and also results in significantly increased levels of repetitive motor behavior (Canales and Graybiel, 2000b).

Experience-dependent neuroadaptations are generally thought to be driven by differential gene expression mediated by transcription factors. A leading candidate for mediating long-term striatal plasticity is the transcription factor ΔFosB (Nestler et al., 1999, 2001). ΔFosB undergoes posttranslational modifications that result in highly stable isoforms, which heterodimerize with Jun proteins and bind to AP-1 sites expressed in the promoter regions of genes encoding key striatal proteins (e.g., AMPA glutamate receptor subunit, GluR2, and dynorphin; Bibb et al., 2001; Chen et al., 1997; Kelz et al., 1999). ΔFosB is induced after chronic exposure to stimuli relevant to repetitive behavior (e.g., stress, drugs of abuse, and chronic wheel running) and persists in the brain for long periods of time (McClung et al., 2004). Thus, ΔFosB might have a more general role in the development of repetitive behavior induced by a wide range of stimuli.

Repetitive behavior including compulsions and dyskinesias can be induced by chronic L-DOPA administration to individuals with PD. In rats, L-DOPA-induced dyskinesias have been shown to be associated with increased striosomal FosB relative to matrix FosB (Andersson et al., 1999; Cenci et al., 1999). Pulsatile administration of a D_1 dopamine agonist to parkinsonian nonhuman primates markedly elevated striatal ΔFosB but only in those animals that developed dyskinesias (Doucet et al., 1996). These FosB-related proteins appear to be expressed preferentially in direct-pathway neurons (Andersson et al., 1999). Similarly, in mouse models of L-DOPA-induced dyskinesias, activation of extracellular-signal-regulated kinase (ERK), the extracellular-regulated kinases that mediate downstream transcription, was restricted to direct-pathway neurons (Santini et al., 2009). Selective induction of ΔFosB in striatal direct-pathway neurons is associated with compulsive wheel running in rodents. Transgenic mice that selectively overexpress ΔFosB in these projection neurons display compulsive wheel running, whereas this behavior is significantly inhibited in animals that overexpress the gene in enkephalin-containing or indirect-pathway neurons (Werme et al., 2002).

The various models described in the previous sections provide important candidate mechanisms that may explain the transition from normative behavior to aberrant repetitive behavior. Identification of such mechanisms would provide novel potential therapeutic targets for drug development.

38.7 SUMMARY

Repetitive behavior has been studied using a variety of tools, from molecular genetics to neuroimaging to model organisms, but the wide variety of repetitive behaviors observed across normative development and human disorders presents a substantial challenge. The phenomenology of repetitive behavior reveals a continuum beginning with very simple repetitive motor sequences, such as hand flapping or grunting, that are typically seen in early childhood and also in ASD and TS. At the other end of the continuum are IS and compulsive rituals, which typically emerge in the preschool years and decline thereafter except when seen in ASD and OCD.

Within the human repetitive behavior disorders, some consistent findings have emerged across cognitive, treatment, genetic, and neuroimaging studies. Neuropsychological testing reveals deficits in executive functioning across disorders. Treatment studies point to behavioral therapies that stress response inhibition in each study, although approaches vary quite widely depending upon the RRB target. Pharmacology studies point to dopamine D2 receptor antagonists across disorders, but there is less consistency in response to SRIs, which are useful in OCD but show mixed data in ASD. Genetic studies support substantial heritability for repetitive behavior, both within and across disorders. Initial genetic findings do not show clear consistency across studies, with the exception of the serotonin transporter gene, which has been implicated in OCD and in RRB within ASD. Neuroimaging studies have coalesced to some degree around the corticostriatal circuit, although the strongest structural findings in TS and

OCD are in opposite directions in the caudate. Other inconsistencies have also emerged across disorders. Multiple studies, from genetics to MRS to CSF, point to the glutamate system in OCD. In contrast, postmortem findings in TS point to decreased GABAergic neurons in the caudate.

Ideally, animal models should be used to dissect the ways that genetic and environmental influences impact brain circuits to feed RRB. Initial work using genetic models points to the same corticostriatal circuits that are implicated by neuroimaging studies. Some of the best current models are combinations of environmental deprivation in species or inbred strains that show some baseline repetitive behavior. These naturalistic models have significant potential to translate back to human disorders. For example, the social disconnectedness that is diagnostic in autism may actually parallel the environmental deprivation that triggers RRB in animals. Research in naturalistic and pharmacological animal models of RRB favors imbalance in the direct and indirect pathway of the basal ganglia. As molecular genetic studies yield more RRB susceptibility genes, the different ways in which this imbalance may be triggered could be better understood. With the rapid progress possible using multiple different research approaches, the emerging understanding of the circuits underlying RRB may translate to potential treatments for TS, OCD, or RRB within neurodevelopmental disorders.

Disorders of Cognitive Control

B.J. Casey, N. Franklin, M.M. Cohen

Sackler Institute for Developmental Psychobiology, New York, NY, USA

39.1 INTRODUCTION

A core feature of several neurodevelopmental disorders is the difficulty in overriding or suppressing inappropriate thoughts and behaviors in favor of appropriate ones. This ability is referred to as cognitive control. Examples of disorders of cognitive control include attention deficit hyperactivity disorder (ADHD), which is characterized by both distractibility and impulsivity; Tourette syndrome, which is characterized by difficulty suppressing repetitive movements and vocalizations that may be complex, emotionally provocative, and exacerbated by stressful situations; obsessive–compulsive disorder (OCD), which is characterized by intrusive thoughts and ritualistic behaviors; and schizophrenia, which involves disorganized thoughts, delusions, or hallucinations and difficulty suppressing them. Cognitive control problems are found in a range of disabilities with limited ability to regulate attention, thought, behavior, or emotions. The number of disorders with cognitive control problems underscores the need for a clearer understanding of the development and neurobiological bases of cognitive control.

Most theoretical and neuroanatomical accounts of cognitive control have focused on the role of the prefrontal cortex in this ability. This focus is based largely on the protracted development of the prefrontal cortex that coincides with cognitive maturity and the neuropsychological literature showing that frontal lobe damage impairs the ability to regulate behavior and suppress inappropriate thoughts or actions (e.g., Phineas Gage, as cited in Harlow, 1869). Although the approach has been important in describing problems in cognitive control, it has not captured the biological basis of how behavior is regulated or how it breaks down in disorders of cognitive control.

This chapter integrates findings on the neurobiological basis of disorders of cognitive control, highlighting the role of cortical and subcortical brain regions in signaling and implementing control. At first glance, the involvement of a number of the same brain regions across many disorders would seem too disparate to be informative. However, considering these findings in the context of cognitive control theory and development paints a clearer picture of each region's contribution to the regulation of behavior and potential disruption in different developmental disorders.

39.2 DEVELOPMENT OF COGNITIVE CONTROL

A key feature of cognitive development is a steady increase in the ability to suppress irrelevant information and inappropriate actions in favor of appropriate ones. This ability becomes more efficient throughout childhood and adolescence. Failure to develop this ability results in cognition that is susceptible to interference from competing external or internal information without resolution.

A classic example of the child's developing ability to resolve behavioral conflict is demonstrated by the Piagetian A-not-B task. In this task, the child reaches for a hidden toy in one location (a covered well) and is then required to find the hidden toy in a new location. The infant continues to reach in the old well even though the toy is hidden in full view of the infant and even though the child may look in the correct new direction. This failure has been interpreted as reflecting inhibitory inefficiency rather than a lack of object permanence, as originally proposed by Piaget (Diamond, 1988). As such, obtaining the goal of reaching and finding the toy in the original location biases motor systems in that direction that compete with the new goal and the means to reach in the new opposing direction. Development of the prefrontal cortex has been implicated in the development of this goal-directed behavior.

The development of the ability to override inappropriate actions in favor of appropriate ones has a protracted course of development. In older children, this ability is measured by developmentally appropriate versions of adult neuropsychological tasks including go/no-go, working memory, and attention-switching tasks. In all cases, children have a more difficult time ignoring or suppressing irrelevant salient information or responses in favor of the relevant ones than adults. Performance on these tasks shows a developmental trend over the ages of 4–12 years, approximating adult levels by 12–13 years of age, as indexed by mean reaction times and accuracy rates (Enns and Cameron, 1987).

The age-related differences in performance of cognitive tasks are not observed on tasks in the absence of competing information. For example, tasks that measure the ability to detect and predict statistical regularities in the environment are mastered by infancy (Saffran et al., 1996). This ability is indicated by anticipatory saccades in the direction of the expected stimulus or by a longer duration of looking in the direction of an expected stimulus, when it is not presented (violation in expectation). Learning about one's environment is essential for adaptive functioning, as well as for the development of neural specialization and regulatory ability during toddler, childhood, and adolescent years. Knowing when or what or in which context to expect an event is critical for planning and maintaining appropriate actions in different contexts over time. Adjusting behavior when these expectations are violated is an essential element of cognitive control and an aspect of cognition that shows more protracted development (Mayr et al., 2005).

If this ability develops differently, or along a different trajectory, it may contribute to difficulties in the maturation of self-control abilities (or the concomitant neural systems in which these abilities are instantiated). Thus, with development, these cognitive systems become more differentiated as they are modulated both by experience and by the top-down cortical projections from the prefrontal cortex that help the organism alter behavior when these predictions are violated (Casey, 2005; Casey et al., 2006).

39.3 BRAIN DEVELOPMENT AND COGNITIVE CONTROL

A significant amount of brain development occurs *in utero*, but changes continue postnatally. These postnatal changes coincide with changes in cognitive control. This period is characterized by rapid synapse formation that begins well before birth in nonhuman primates (Rakic, 1974) and results in overproduction of synapses relative to its adult state. This process of synaptogenesis appears to occur concurrently across diverse regions of the nonhuman primate cerebral cortex (Rakic et al., 1986). In both human and nonhuman primate studies, the early synaptic density peaks are followed by a plateau phase that decreases during childhood and into adulthood. The plateau and pruning phases of some cortical regions (e.g., prefrontal cortex) in primates are relatively protracted in comparison to others (e.g., sensorimotor and subcortical regions; Bourgeois et al., 1994; Huttenlocher and Dabholkar, 1997). Positron emission tomography (PET) studies of glucose metabolism suggest that maturation of local metabolic rates parallel the time course of overproduction and subsequent pruning of synapses (Chugani et al., 1987). These studies imply different time courses in regional brain development.

Magnetic resonance imaging (MRI) technologies have introduced a new set of tools for capturing features of brain development in living, developing humans. MRI is particularly well suited to the study of children, as it provides exquisitely accurate anatomical images without the use of ionizing radiation. However, these methods lack the resolution to definitively characterize the mechanism of change with development (e.g., dendritic arborization, synaptic pruning, and myelination). The most informative studies to date are those based on volumetric measures and large sample sizes (Giedd et al., 1999a; Sowell et al., 2003). These studies have yielded three consistent findings. First, total cerebral

volume shows little significant change after 6 years of age. Second, there is a significant decrease in cortical gray matter by approximately 12 years of age in prefrontal and association cortices that is preceded by earlier maturing cortical development in sensorimotor regions. Finally, there is an increase in cerebral white matter throughout childhood and young adulthood, especially in prefrontal white matter tracts (Klingberg et al., 1999).

The protracted development of prefrontal and association cortices, along with white matter fiber tract development in this circuitry, contributes to children's developing capacity for cognitive control, as shown by diffusion tensor imaging (DTI). DTI is a measure sensitive to myelination and neuroanatomical changes in white matter microstructure (Liston et al., 2006). Further, variability in the myelination and regularity of prefrontal white matter fibers contribute to individual differences in cognitive control and have been linked to disorders of cognitive control such as ADHD (Casey et al., 2007a).

To investigate neural circuits underlying disruption of cognitive control in developmental disorders more directly, an *in vivo* assessment of the physiological timecourse of behavior is needed. Functional magnetic resonance imaging (fMRI) provides this ability (Logothetis et al., 2001). These studies show that children recruit distinct but often larger, more diffuse brain regions when performing cognitive control tasks than do adults. The pattern of activity within brain regions central to cognitive control performance, such as prefrontal cortex, becomes more focal or fine-tuned, based on cross-sectional (Brown et al., 2005) and longitudinal studies (Durston et al., 2004). This pattern of activity is suggestive of development within, and refinement of, projections to and from the prefrontal cortex with maturation. Recent developmental functional connectivity data (Kelly et al., 2009) are consistent with this observation of diffuse correlations among frontal brain regions in children, whereas adults exhibit more focal connections with distal regions.

39.4 DOPAMINE AND COGNITIVE CONTROL

Structural and functional changes in the brain with development occur together with changes in neurotransmitter systems. For example, significant changes are observed in the dopamine system that innervates prefrontal circuitry. The development of the dopaminergic system parallels the development of performance on cognitive control tasks; postnatal innervation of dopaminergic neurons to cortical and subcortical targets peaks at times coincident with the development of cognitive control. Such age-dependent effects of dopamine have been best studied in humans using delayed response tasks and Piaget's A not B task in typically developing and phenylketonuria (PKU)-affected children (reviewed in Diamond, 1998). The genetic mutation that causes PKU results in decreased levels of tyrosine, a precursor of dopamine, in the central nervous system. In behavioral tasks such as the A not B task, typically developing children show sharp improvements in the first year of life and gradual improvements in age-appropriate versions of the task until age 10; however, in PKU children, the sharp increase in performance is not observed, and only mild improvements occur. In typically developing children, this task is highly dependent on prefrontal cortex activation, a brain area that shows extremely high dopamine turnover, and is thus impaired in PKU children.

In nonhuman primates, the A not B task also shows a sharp increase in performance during the first 6 months of life. Behavioral performance is paralleled by an observed postnatal increase in dopamine levels and in dopamine receptor gene expression (Goldman-Rakic and Brown, 1982; Lidow et al., 1991). An examination of the laminar distribution patterns of tyrosine hydroxylase (TH)-positive processes in prefrontal regions has revealed that a gradual maturation of axons and varicosities occurs up until 2–3 years of age in the monkey (Rosenberg and Lewis, 1995), which is roughly 10–12 years in the human.

In rats with a pharmacologically induced form of PKU, performance is also altered in delayed alternation tasks (Diamond et al., 1994). Neuroanatomical studies in rats have shown that dopaminergic cells in the ventral tegmental area (VTA) and substantia nigra (SN) are fully differentiated and have axons projecting into the prefrontal cortex by embryonic day 16. Only after birth, however, does a dramatic increase in arborization and innervation into deeper cortical layers occur. This postnatal innervation is also paralleled by an increase in dopamine receptor gene expression and in dopamine levels coincident with a postnatal period of rapid synaptogenesis in dendritic spines followed by a slower plateau phase of growth until adolescence (Granger et al., 1995).

Several dopamine-related hypotheses have emerged in an attempt to explain developmental disorders of cognitive control such as ADHD (Swanson et al., 2007) and schizophrenia (Snyder, 1976) based on pharmacological treatments for these disorders. Computational models of dopamine based on animal and human imaging studies suggest that dopamine controls the flow of information from other areas of the brain to the prefrontal cortex in gating and maintaining information (Braver and Cohen, 2000). Both gating and maintenance are important in overriding or suppressing inappropriate thoughts and behaviors in favor of appropriate ones (i.e., cognitive control). Thus, dysfunction in this system can result in dysregulated attention, behavior, and thoughts.

39.5 BRAIN CIRCUITRY IMPLICATED IN COGNITIVE CONTROL

Most functional and developmental studies have focused on the role of the prefrontal cortex in cognitive control. However, both cortical and deep subcortical structures have been implicated in disorders of cognitive control. Considering these findings in the context of development and cognitive control theory may paint a clearer picture of each region's contribution in regulating behavior and its disruption in developmental disorders.

39.5.1 Disorders of Cognitive Control

As depicted in Figure 39.1, clinical neuroimaging studies have identified several brain regions that appear to be altered in childhood disorders of cognitive control. These regions include the prefrontal cortex, anterior cingulate cortex, posterior parietal cortex, basal ganglia, and cerebellum. Abnormalities in these structures have been reported in ADHD (Bush et al., 1999; Castellanos et al., 1996; Durston et al., 2003; Tamm et al., 2006), Tourette syndrome (Leckman et al., 2010), OCD (Baxter et al., 1988; Fitzgerald et al., 2005; Swedo et al., 1992), and childhood-onset and adult schizophrenia (Carter et al., 2001; Frazier et al., 1996).

Abnormalities in size, asymmetry, function, or glucose metabolism are typically reported. For example, MRI volumetric studies of ADHD have revealed abnormalities in the size of the prefrontal cortex, basal ganglia, and cerebellum, showing decreased volumes in each. Decreased activity in these regions as well as in the anterior cingulate and parietal cortices during performance of cognitive control tasks has been reported (Bush et al., 1999; Tamm et al., 2006). Activity in these regions, and cognitive control, is largely normalized with stimulant medications (Epstein et al., 2007; Vaidya et al., 1998), presumably due to increases in the availability of dopamine (Volkow et al., 2001).
PET studies of OCD have revealed hypermetabolic activity in these regions, particularly in the caudate nucleus, anterior cingulate cortex, and orbitofrontal cortex (Baxter et al., 1988; Swedo et al., 1989). Both pharmacological and behavioral treatments have been shown to normalize these patterns of activity. Abnormalities in the basal ganglia, specifically the striatum, in children with Tourette syndrome have been reported in fMRI studies during provocation of symptoms (Peterson et al., 1998). Structural imaging studies have shown cortical thinning in the frontal and parietal cortices in individuals with Tourette syndrome relative to typically developing children (Sowell et al., 2008).

Individuals with schizophrenia show suboptimal levels of activity in prefrontal and parietal regions when performing cognitive control tasks such as the Wisconsin Card Sorting Task or the n-back working memory tasks (Barch and Csernansky, 2007; Berman et al., 1988). MRI-based decreases in volume of the basal ganglia and cerebellum have been reported in this disorder too, especially in those individuals with childhood onset (Frazier et al., 1996; Giedd et al., 1999b). Therefore, a number of cortical and subcortical regions appear to be significantly involved in a range of disorders that have as a key symptom a problem overriding inappropriate actions (i.e., cognitive control).

The presence of common disturbances in cognitive and neural systems across discrete syndromes may be surprising at first. However, there has been increasing concern regarding the validity of the boundaries between discrete syndromes as well as the underlying dimensional nature of specific functional systems underlying these disorders (Frances et al., 1990). Specific disorders may be associated with differential salience, valence, or combinations of the core underlying functional systems. The identification of core processes involved in a disorder can move a field from a disparate set of data-driven findings to a more theoretically coherent collection of findings. Theoretical understanding and identification of specific neurophysiologic function may provide valuable information for validating the core features of and distinctions between psychiatric disorders.

39.5.2 Theoretical Framework: Signaling and Implementation of Control

Cognitive control processes such as the ability to suppress or override competing attentional and behavioral responses have been included in a number of cognitive theories (Cohen and Servan-Schreiber, 1992; Desimone and Duncan, 1995; Shallice, 1988). For

FIGURE 39.1 Brain regions implicated in disorders of cognitive control.

example, Shallice (1988) proposed a "supervisory attention system" as a system for inhibiting or replacing routine, reflexive behaviors with more appropriate behaviors. Desimone and Duncan (1995) describe top-down biasing signals as important in attending to relevant information by virtue of mutual inhibition or suppression of irrelevant information. Finally, Miller and Cohen (2001) proposed a model of cognitive control based largely on their respective nonhuman primate and computational modeling studies of prefrontal function. According to this theory, the function of the prefrontal cortex in cognitive control is active maintenance of patterns of activity that represent goals and the means to achieve them. The prefrontal cortex biases relevant sensory and motor systems for goal-directed behavior, through the buildup and integration of rules learned throughout development (Bunge and Zelazo, 2006). Functional imaging studies of cognitive control have focused largely on this form of top-down cortical control in trying to understand the breakdown in regulating actions and biasing of attention in favor of relevant information.

The focus on prefrontal brain regions is based on the neuropsychological literature showing that frontal lobe damage impairs the ability to regulate behavior. Although this approach has been important in describing problems in cognitive control, it has not captured the biological basis of how this ability breaks down in such a broad range of clinical disorders. Figure 39.2 illustrates a theoretical framework that includes the popular construct of top-down implementation of control by the prefrontal cortex. In addition, it provides mechanisms by which control is called. Specifically, different brain regions can signal the prefrontal cortex for control. Each of the regions identified is part of unique circuitry that project both to and from the prefrontal cortex, thus providing a means for signaling prefrontal regions to

help impose top-down control of behavior by biasing signals relevant to goal-related behavior.

Immaturity, developmental delay, or dysfunction within these circuits can lead to cognitive control problems. Ineffective signaling of control systems by any one of these regions could lead to poor regulation of attention or behavior, though with subtle differences, depending on the system impacted. Likewise, intact signaling of prefrontal systems in the presence of inefficient top-down control could result in poor regulation of attention or behavior, though presumably in a more general way. This theoretical framework of cognitive control moves findings of a variety of disparate brain regions' involvement in several disorders toward a cohesive understanding of where cognitive control can break down in these disorders.

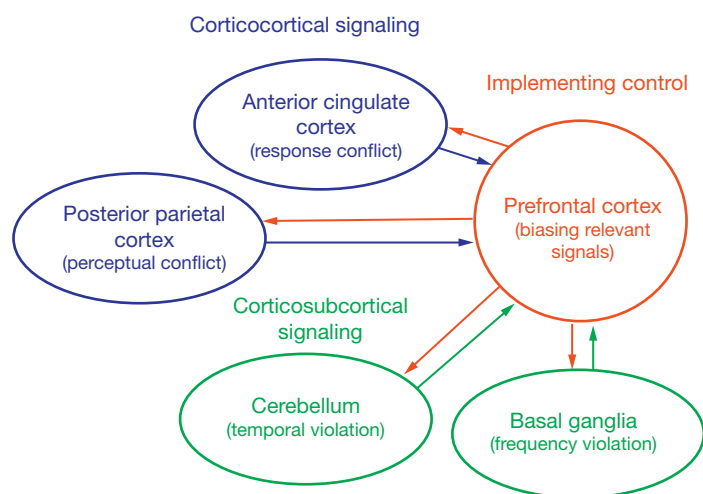
The conditions in which these regions may signal the prefrontal cortex are summarized below in terms of frontocortical and frontosubcortical circuitry. Each circuit is generally described. Examples are provided for how each circuit might break down and lead to what appears to be an implementation of control problem, but which could simply be a signaling problem. For example, prefrontal dysfunction could result in a failure of top-down biasing of attention or behavior. Dysfunction in corticocortical signaling from posterior parietal cortex or from anterior cingulate cortex could result in a failure to resolve perceptual conflict among competing inputs or response conflict among competing outputs, respectively. Dysfunction in corticosubcortical signaling from the cerebellum or from the basal ganglia could result in a failure to detect and alter responses to violations in predicted timing or frequency of events, respectively. Finally, a detailed description of one of the frontosubcortical circuits is provided as an example of how a signaling or implementation problem could occur at one of many different locations within a given circuit. This


FIGURE 39.2 Locations within prefrontal circuitry where control might break down in disorders of cognitive control. Each region is part of unique circuits that project both to and from the prefrontal cortex, thus providing a means for signaling prefrontal regions to help impose top-down control of behavior and a location where control could break down.

example emphasizes the importance of circuit development and function rather than a homunculus approach of emphasizing a single brain region such as the frontal lobes to explain disorders of cognitive control.

39.5.2.1 Frontal Cortical Control Circuitry

There is an expansive literature implicating the prefrontal cortex in cognitive control from imaging studies (Cohen et al., 1994; D'Espostio et al., 1995; Duncan and Owen, 2000; Smith and Jonides, 1999) to studies of patients with frontal lobe lesions (e.g., Milner et al., 1985; Stuss et al., 1982) to electrophysiological and lesion studies in animals (Fuster, 1980; Mishkin and Pribram, 1955) to computational models (Braver and Cohen, 2000). Each of these approaches consistently supports the involvement of the prefrontal cortex in implementation of cognitive control.

Anterior cingulate and posterior parietal cortices have been shown to be involved in aspects of cognitive control too, especially in overcoming prepotent response tendencies and switching attentional sets (Barber and Carter, 2005; Liston et al., 2006). Activity in both regions has been shown to predict increased prefrontal activity and subsequently enhance behavioral performance in switching behavioral and attentional sets (Hedden and Gabrieli, 2010; Liston et al., 2006). These results are consistent with a network of cortical structures that regulate prefrontal activity by signaling the need for greater control (Birrell and Brown, 2000; Blais and Bunge, 2010; Dias et al., 1996a; Fox et al., 2003; McAlonan and Brown, 2003; O'Reilly et al., 2002).

Each of these brain regions has functionally been dissociated. There is a growing consensus that the prefrontal cortex acts to support task-relevant representations of stimulus information and stimulus–response mappings, thus favoring them in competitions with task-inappropriate representations in posterior cortex (Desimone and Duncan, 1995; Miller and Cohen, 2001). The posterior parietal cortex has been implicated in the generation of motor plans via transformations of sensory inputs from multiple modalities (Andersen and Buneo, 2002) in the service of perceptual decision-making (Gold and Shadlen, 2001; Platt and Glimcher, 1999). As such, this region helps to detect and resolve perceptual conflict. The anterior cingulate cortex, in contrast, has been shown to be involved in the response to conflict detection and its resolution (Botvinick et al., 2001; Posner and Petersen, 1990). One influential theory, known as the conflict-monitoring hypothesis, provides a plausible account of how anterior cingulate and dorsolateral prefrontal cortices act in concert to detect conflict and implement control to resolve it. Accordingly, the anterior cingulate cortex monitors conflicts in information processing and recruits lateral portions of the prefrontal cortex to resolve competition as needed (Botvinick et al., 2001).

While the prefrontal cortex, anterior cingulate, and posterior parietal cortex respond to manipulations of conflict, the role of the anterior cingulate is limited to conflict at the level of the response and not at the level of the stimulus representation (Bhanji et al., 2010; Milham and Banich, 2005). Just as the anterior cingulate is anatomically well situated to detect conflicts at the level of a motor response and signal these to the lateral prefrontal cortex (Barbas and Pandya, 1989; Bates and Goldman-Rakic, 1993), several studies suggest that the posterior parietal cortex is anatomically well suited to detect stimulus conflict and signal this to the prefrontal cortex. The primate posterior parietal cortex receives ample, direct input from the extrastriate visual cortex and sends direct projections to the lateral prefrontal cortex (Wise et al., 1997). Previous studies have emphasized a role for the posterior parietal cortex in detecting unexpected or behaviorally relevant stimuli and facilitating goal-directed attention to task-relevant aspects of a visual stimulus (Corbetta and Shulman, 2002; Corbetta et al., 2000). Together, these findings suggest one mechanism by which these processes may be mediated: detection of conflicts in information processing at the level of the stimulus representation may signal to the prefrontal cortex the need for enhanced top-down control (Casey et al., 2000; Desimone and Duncan, 1995; Dias et al., 1996b; O'Reilly et al., 2002).

These findings are consistent with the anterior cingulate and parietal cortex being involved in signaling the prefrontal cortex in the presence of competing inputs and outputs (perceptual or response conflict) as depicted in Figure 39.2. The ability to detect conflict is necessary for triggering cognitive control to bias the relevant input or output being promoted to resolve the conflict (Miller and Cohen, 2001). If conflict is not detected, then the control system is not signaled and competition between inputs or outputs may not be resolved in the goal-oriented direction (e.g., the schizophrenic child attends to intrusive thoughts over appropriate ones).

39.5.2.2 Frontal Subcortical Control Circuitry

Subcortical regions implicated in disorders of cognitive control include the basal ganglia and cerebellum. The basal ganglia and cerebellum have been implicated in learning about the frequency and the timing of events (i.e., learning what to expect and when). These regions make up frontostriatal and frontocerebellar loops that have similar features. For example, both the cerebellum and the basal ganglia project to the prefrontal cortex via the thalamus. The primary neurotransmitter in both the basal ganglia and the cerebellum is GABA, an inhibitory neurotransmitter. Glutamate is found in the prefrontal cortex and thalamus, which is an excitatory neurotransmitter and dopamine is a critical neuromodulator of both circuits (Braver and Barch, 2002; Cohen et al., 1992;

Montague et al., 1996; Schultz et al., 1997) that is expressed preferentially in portions of the prefrontal cortex, basal ganglia, and dentate nucleus of the cerebellum, all regions implicated in disorders of cognitive control.

These circuits have been shown to support both motor and cognitive behavior with cognitive-related actions being driven by projections from the prefrontal cortex and modulated by input from the dentate nucleus of the cerebellum and from the dorsal and ventral striatum of the basal ganglia (caudate and nucleus accumbens). This circuitry is perhaps most well described within the basal ganglia thalamocortical circuitry for which at least five circuits have been identified (Alexander et al., 1986). The basal ganglia thalamocortical circuits include a motor, oculomotor, prefrontal (dorsolateral and lateral orbital), and limbic circuit. These circuits involve the same projection regions (basal ganglia, thalamus, and cortex), but differ in the exact projection zone within each region and in the set of thoughts and actions they support.

The general organization of these circuits involves prefrontal projections to different portions of the striatum (i.e., putamen or caudate nuclei), which then project to either a direct or an indirect pathway (see Figure 39.3). The direct pathway involves an inhibitory projection to the internal capsule of the globus pallidus (GPi) and substantia nigra (SNr) resulting in the dampening of an inhibitory projection to the thalamus (i.e., disinhibition). The indirect pathway consists of an inhibitory GABA projection to the external capsule of the globus pallidus (GPe) that dampens the inhibitory projection to the subthalamic nuclei (STN) resulting in excitation of the internal capsule of the globus pallidus and substantia nigra. This in turn leads to inhibition of the thalamus. The direct pathway presumably facilitates thalamo-cortically mediated behavior, while the indirect pathway is thought to inhibit thalamo-cortically mediated behavior.

As the prefrontal cortex projects directly to the basal ganglia and cerebellum and as both project back to the prefrontal cortex via the thalamus, an account of suppression of competing actions may be described here in somewhat more mechanistic terms. That is, the basal ganglia and cerebellum have been implicated in monitoring the frequency and/or timing of events (Davidson et al., 2003; Hayes et al., 1998; Ivry and Keele, 1989; McClure et al., 2003; Spencer et al., 2003; Van Mier and Petersen, 2002). The ability to predict what and when an event will occur is an essential component of cognitive control, in planning and maintaining appropriate thoughts and actions in different contexts over time. Maintaining representations of such events and information is critical in suppressing competing ones.

Thus, frontocerebellar and frontostriatal circuits may provide neural mechanisms for the maintenance of representations of events over time. In contrast, detecting violations in such predictions (which presumably allows the system to attend to and learn new information) may be linked to intrinsic inhibitory functions of GABA-related functions of the basal ganglia and cerebellum in the absence of frontally driven planned thoughts and actions. Accordingly, the basal ganglia and cerebellum do not generate planned or voluntary movements or behaviors *per se*, but rather the prefrontal cortex generates these voluntary actions. They do, however, detect violations in the timing and nature of events, providing the system with a way to shift out of prefrontally driven behavior when highly salient events occur. The basal ganglia and cerebellum then act broadly to inhibit competing thoughts and behaviors that would otherwise interfere with the prefrontally driven goal or behavior (Casey, 2000; Mink, 1996).

39.6 DISRUPTION OF COGNITIVE CONTROL CIRCUITRY

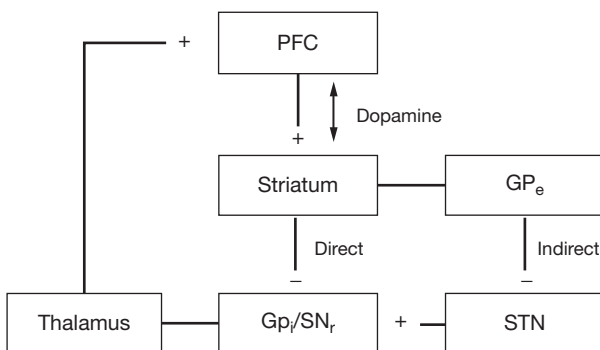
How does the previously described circuitry contribute to the symptoms and behaviors observed in the childhood disorders of cognitive control? First, the typical assumption made when a child presents with a cognitive control problem is that it is due to top-down prefrontal dysfunction or inefficiency. For example, disruption of the prefrontally mediated direct pathway within the basal ganglia corticosubcortical circuit described can result in constantly interrupted behaviors such as those observed in ADHD or constantly interrupted thoughts observed in schizophrenia. In contrast, if the basal ganglia and cerebellum are involved in shifting out of prefrontally driven thoughts or behaviors (Redgrave et al., 1999), then their disruption may result in irrepressible repetitive behaviors and thoughts similar to those observed in OCD and Tourette syndrome. Likewise, disruption in cortical signaling from the posterior parietal and anterior cingulate cortex of perceptual or


FIGURE 39.3 Direct and indirect pathways of the basal ganglia corticosubcortical circuit involved in cognitive control.

response conflict may result in failure of prefrontal systems to bias appropriate signals in favor of goal-directed behavior. As such, inappropriate attentional or behavioral responses (i.e., distractibility and impulsivity) as observed in ADHD may result (Bush et al., 1999; Tamm et al., 2006). Finally, neuromodulatory (e.g., dopamine) imbalances or deficiency in prefrontal circuitry can lead to problems in cognitive control resulting in constantly interrupted behaviors and thoughts as seen in ADHD and schizophrenia. Several psychiatric and neurologic disorders have been linked to disruptions in specific frontostriatal (Alexander et al., 1986, 1991), frontocerebellar (Dum and Strick, 2003; Middleton and Strick, 2002), and corticocortical loops (Bush et al., 2005; Casey et al., 2007b).

The theoretical framework distinguishing between signaling and implementation of control suggests that information is maintained in an active state over time in the prefrontal cortex by means of recurrent excitatory connectivity (Cohen et al., 1992). The prefrontal cortex, which consists primarily of excitatory projections (glutamate), is thus involved in maintenance of relevant information for action and disruption of this brain region results in deficits in the ability to carry out the relevant actions, as evidenced in ADHD. The basal ganglia and cerebellum, which consist primarily of inhibitory projections (GABA), are involved in switching or shifting attention elsewhere when there is a lack of sufficient prefrontal input to drive the behavior in an organized way. Disruption to these brain regions (basal ganglia and cerebellum) or their development may therefore result in cognitive control deficits related to an inability to shift out of particular behavioral sets (Hayes et al., 1998), as evidenced in OCD and schizophrenia. Likewise, disruption in cortical signaling from the posterior parietal and anterior cingulate cortex of perceptual or response conflict may result in failure of prefrontal systems to bias appropriate signals in favor of goal-directed behavior, as observed in ADHD (Bush et al., 1999; Tamm et al., 2006).

39.7 SUMMARY

A key feature of cognitive development is the gradual increase in the ability to suppress competing thoughts and actions in favor of goal-oriented ones, referred to as cognitive control. This ability is disrupted in several neurodevelopmental disorders including ADHD, OCD, Tourette syndrome, and schizophrenia. The protracted development of the prefrontal cortex has made this region a primary candidate in the study of the development of cognitive control. Further, the neuropsychological literature showing that frontal lobe damage impairs the ability to regulate behavior and suppress inappropriate thoughts or actions has driven the focus of clinical studies.

Recent theoretical and empirical studies suggest that the function of the prefrontal cortex in cognitive control relates to the active maintenance of patterns of activity that represent goals and the means to achieve them. The implementation of control requires signaling of the prefrontal cortex to bias relevant sensory and motor systems for goal-directed behavior. These signals may arise from cortical or subcortical regions. Cortical regions include the posterior parietal cortex and anterior cingulate cortex, which have been implicated in detecting perceptual and response conflict and signaling the prefrontal cortex to implement control. Subcortical signaling regions include the basal ganglia and cerebellum. These regions have been implicated in detecting violations in the expected nature and timing of events, providing the system with a way to shift out of prefrontal-driven behavior when highly salient or novel events occur.

Each region is thus unique and part of an interactive circuitry that project both to and from the prefrontal cortex, thus providing a means for signaling prefrontal regions to help impose top-down control of attention and behavior by biasing signals relevant to goal-related behavior. Immaturity, developmental delay, or dysfunction within these circuits can lead to cognitive control problems. Ineffective signaling of control systems by any one of these regions can lead to poor regulation of attention or behavior, but with subtle differences depending on the system impacted. Ineffective biasing of circuits by control systems can likewise lead to poor regulation of attention or behavior, though in a more general way.

In sum, basic learning and attention systems are important in signaling top-down control systems to adjust attention and behavior when predicted outcomes are violated (Botvinick et al., 1999; Casey et al., 2000). The basic assumption is that learning where, when, or what contexts to expect an event is critical for goal-directed behavior across different contexts over time. Deficits in learning to detect regularities in the environment can lead to less signaling of control systems to help alter or adjust behavior when these expectations are violated. Such deficits can mimic those observed when top-down control systems themselves are impaired.

Glossary

ADHD Characterized by both distractibility and impulsivity, with frequent overlap of these behaviors; symptoms usually start before 7 years of age.

Anterior cingulate cortex The frontal part of the cingulate cortex with connections to the prefrontal cortex; implicated in response conflict detection and its resolution.

Basal ganglia A group of nuclei situated at the base of the forebrain with strong connections to the prefrontal cortex and thalamus; implicated in learning about the frequency of events.

Cerebellum It is tucked underneath the cerebral hemispheres at the posterior ventral portion of the brain with connections to the prefrontal cortex and thalamus; implicated in learning about the timing of events.

Cognitive control The ability to override or suppress inappropriate thoughts and behaviors in favor of appropriate ones.

Diffusion tensor imaging (DTI) An imaging technique that enables the measurement of the restricted diffusion of water in tissue in order to produce images of neural tracts in the brain.

Direct pathway Involves an inhibitory projection from the striatum to the internal capsule of the globus pallidus (GPi) and substantia nigra (SNr) resulting in the dampening of an inhibitory projection to the thalamus (i.e., disinhibition); implicated in facilitation of thalamo-cortically mediated behavior.

Dopamine A catecholamine neurotransmitter produced in the substantia nigra and ventral tegmental area; acts as a neuromodulator of the frontostriatal and frontocerebellar loops and is implicated in controlling the flow of information from other areas of the brain to the prefrontal cortex in the service of gating and maintaining information.

Functional magnetic resonance imaging (fMRI) A specialized type of MRI that measures the hemodynamic response (change in blood flow) related to neural activity in the brain or spinal cord of humans or other animals.

Glutamate The most abundant excitatory neurotransmitter in the nervous system with high concentrations in the prefrontal cortex and thalamus; implicated in maintenance of information for action.

Go/No-go task A task assessing cognitive control in which a subject presses a button to each target stimulus and must withhold a response when a rare nontarget stimulus appears on screen.

Indirect pathway Consists of an inhibitory GABA projection from the striatum to the external capsule of the globus pallidus (GPe) that dampens the inhibitory projection to the subthalamic nuclei (STN) resulting in excitation of the internal capsule of the globus pallidus and substantia nigra, leading to inhibition of the thalamus; implicated in the inhibition of thalamo-cortically mediated behavior.

Magnetic resonance imaging (MRI) A noninvasive medical imaging technique used in radiology to visualize the detailed internal structure of the body and brain.

N-back working memory task A task assessing cognitive control in which the participant sees stimuli one at a time and must respond whether the stimulus they see is the same stimulus as they saw a predetermined number of trials back.

OCD An anxiety disorder characterized by intrusive thoughts and ritualistic behaviors; age of onset is seen earlier in men, ranges from childhood to young adulthood, and is often before 15 years of age.

Phenylketonuria (PKU) An autosomal recessive metabolic genetic disorder characterized by a deficiency in the hepatic enzyme phenylalanine hydroxylase, which ultimately results in decreased levels of tyrosine, a precursor of dopamine, in the central nervous system.

Piaget's A-not-B task A classic task demonstrating a child's developing ability to resolve behavioral conflict in which an infant reaches for a hidden toy in one location and is then required to find the toy in a new location hidden in full view.

Positron emission tomography (PET) A nuclear medicine imaging technique which produces a three-dimensional image of functional processes in the body through the detection of gamma rays emitted indirectly by a positron-emitting tracer, which is introduced into the body on a biologically active molecule.

Posterior parietal cortex The posterior section of the parietal cortex with connections to the prefrontal cortex; implicated in the generation of motor plans via transformations of sensory inputs from multiple modalities in the service of perceptual decision-making and detecting and resolving perceptual conflict.

Prefrontal cortex Located in the anterior part of the frontal lobes of the brain with widespread connections to many areas of the brain, including the anterior cingulate cortex, the posterior parietal cortex, the basal ganglia, and the cerebellum; implicated in cognitive control capabilities and biasing relevant signals; development is protracted and maturity is not reached until young adulthood.

Schizophrenia A mental illness characterized by disorganized thoughts, delusions, or hallucinations and difficulty suppressing them; symptom onset typically occurs in young adulthood.

Tourette syndrome Characterized by difficulty suppressing repetitive movements and vocalizations that may be complex, emotionally provocative, and exacerbated by stressful situations; disease onset is usually seen in childhood.

Wisconsin card sorting task A task assessing cognitive control in which the participant sorts cards according to rules that change over the course of the experiment.

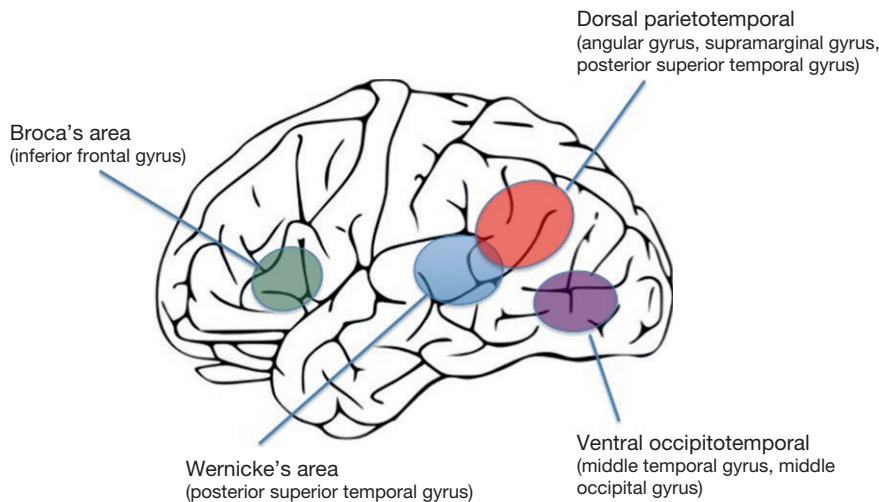
Language Impairment

R.H. Fitch

University of Connecticut, Storrs, CT, USA

40.1 INTRODUCTION

Language represents a complex and unique aspect of human neurocognitive processing and, as such, is vulnerable to disturbance through disruption of or damage to underlying neural systems. Such disruption is generally divided into two types: developmental (encompassing pre- and perinatal brain injury) and acquired.

Acquired disturbances of language generally present as deficits in the comprehension (reception) and/or production (expression) of language following traumatic injury to *established* neural language systems, generally in the left cortical hemisphere (although a minority of individuals seem to have language functions in the right cortical hemisphere; Figure 40.1). These language regions include interconnected areas, such as a left perisylvian posterior lateral temporal (auditory) region called Wernicke's area. This region is believed to mediate the perception and processing of spoken language. Another key language area is Broca's area, found in the left inferior frontal/motor cortex, which generally is thought to mediate production of oral speech. Additional areas routinely activated during neuroimaging measures of language tasks include left parietotemporal and occipitotemporal areas implicated in reading. Damage to these regions results in a range of language deficits collectively termed *aphasias*, with symptoms reflecting the functions mediated by the damaged regions. For example, Wernicke's aphasia presents as a loss in receptive language processing, whereas Broca's aphasia presents as a general deficit in language production (but not comprehension). More recent evidence suggests that these disorders are not as circumscribed as once believed (e.g., Blank et al., 2002), but the terms continue to be used in clinical diagnosis. More global forms of aphasia, encompassing both expressive and receptive language deficits, may also be seen after more extensive damage affecting multiple brain regions. Acquired language disorders may also include deficits in reading skills, termed *acquired dyslexia* or *alexia*. Importantly, all of these disorders are – by definition – confined to the assessment of acquired injury in previously language-competent individuals (older children and adults) and reflect a loss in language skills due to damage of *already-developed* neural systems subserving these processes (see Jordan and Hillis, 2006, for review). Interestingly, language functions do seem to reorganize to the right hemisphere after left-hemisphere damage in young children, evidencing a


high degree of plasticity in language systems during early development. Indeed, young children who undergo left temporal lobectomy because of intractable epilepsy show a surprisingly normal course of language development (Vargha-Khadem et al., 1997). However, comparable injuries in older children and adults with established language functions lead to more permanent language function loss and substantially less reorganization (less plasticity). These early plasticity effects parallel evidence that a second language is acquired more quickly and effortlessly in young children compared with adults.

In contrast to acquired aphasias, *developmental* disruptions to language systems occur as a result of early factors influencing the *initial* establishment of neural systems needed to support emergent language. These disruptions may occur as one component of a more global neural disruption, resulting in overall degradation of cognitive processing (e.g., mental retardation, learning disorders, or pervasive developmental disorders; Broman and Grafman, 1994; Pennington, 1991), or may be *specific* to language systems (meaning overall intellect or IQ is within the normal range). The latter condition is most commonly associated with the term *language impairment* (LI), and therefore the rest of this chapter addresses behavioral features and underlying factors implicated in the developmental disruption of language systems.

40.2 SPECIFIC LANGUAGE IMPAIRMENT AND RELATED DISABILITIES

The ability to understand and produce spoken words represents a profoundly complex process that most young children acquire with remarkable ease, despite a lack of formal instruction (i.e., most young children

are not explicitly taught how to speak). Such evidence of innate predisposition toward language skill has fueled debates about intrinsic 'preadaptations' in the human brain for language, particularly compared with neural substrates underlying other species-specific use of communicative vocalizations or even learned communicative systems (such as sign or computer use in nonhuman primates; see Fischer and Marcus, 2006; Hauser, 1996). Despite the language-ready predisposition seen in most typically developing human children, a subset nonetheless experiences delays in the achievement of language milestones in the absence of known causal factors. That is, even when potential underlying impairments such as epilepsy or other neurologic abnormalities, disorders of vision or hearing, psychiatric impairments, or environmental deprivation are excluded, about 5–10% of children exhibit unexplained deficits/delays in language development (Beitchman et al., 1986; Leonard, 1998; see Heim and Benasich, 2006, for review). These problems are specific to language and occur despite a nonverbal IQ in the normal range. Such language-specific developmental disorders are termed either (LI) or *specific language impairment* (SLI), and deficits associated with SLI can be further subdivided into receptive (*SLI-R*, comprehension), expressive (*SLI-E*, production), or combined deficits.

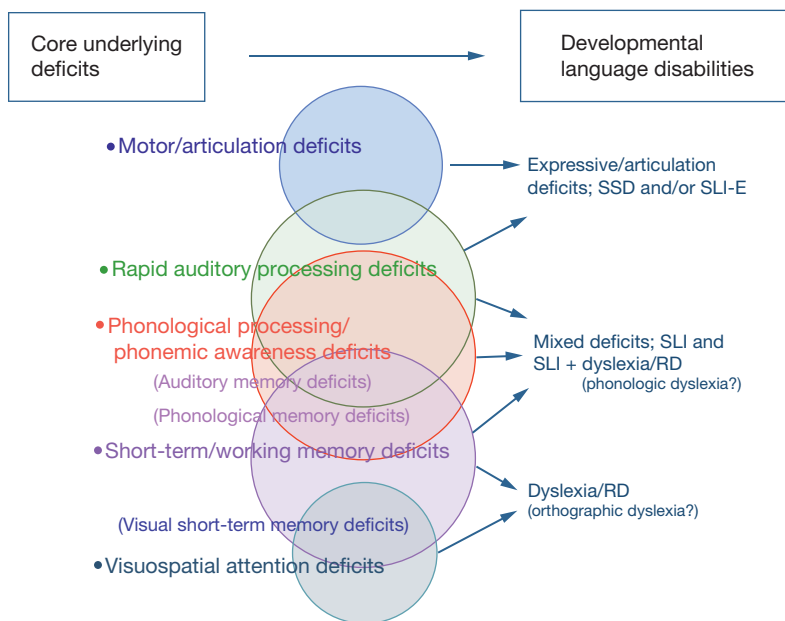
What is implied by SLI being defined, in part, by the *exclusion* of other impairments and disabilities? One example of this 'exclusionary criteria' would be applied when fetal lead or fetal alcohol exposure (FAS) results in generalized cognitive impairments that include impaired language skills. A young child with language delays related to FAS would *not* likely be diagnosed as having SLI, based on the more generalized underlying cognitive deficit. A diagnosis of SLI also requires the exclusion of other related disorders with similar or overlapping symptoms. For example, a subset of exclusively

expressive language difficulties specific to articulation, phonology, and/or oral-motor skills are thought to represent a related but separate disability termed *speech-sound disorder* (SSD; Pennington and Bishop, 2009; Peterson et al., 2007). *Receptive* deficits in language processing may also overlap with central auditory processing disorder (CAPD or APD). However, CAPD generally presents as a broad-based difficulty in listening to and processing sounds that include, but are not limited to, speech sounds. Moreover, CAPD has been characterized by the American Speech & Hearing Association to include deficiencies in 'blocking out' noise and acoustic distracters (Bamiou et al., 2001), which are not diagnostic features of SLI. Therefore, CAPD may be a contributing factor in the development of SLI, but the two disorders are, at least at the present time, considered clinically different.

SLI can also be diagnosed as *comorbid* with other co-occurring developmental disabilities. For example, SLI might co-occur with attention difficulties, as seen in attention deficit disorders with or without hyperactivity (ADD/ADHD) (see Chapter 22). SLI might also be comorbid with SSD or CAPD. From a diagnostic perspective, SLI might further 'overlap' with characteristics of related disorders. For example, autism spectrum disorder (ASD; see Chapter 34) encompasses substantial communicative disabilities, and ASD individuals presenting with significant LI have even been designated as ASD-LI (e.g., Williams et al., 2008). While these overlaps may lead to complications and difficulties in individual diagnosis, when taken from a research perspective, the existence of overlapping phenotypic deficits across SLI and ASD-LI populations presents an opportunity to study potential commonalities in underlying etiology. Such studies have revealed some evidence of phenotypic similarity between ASD-LI and SLI populations (e.g., evidence of common neuroanatomic abnormalities, and similarities in anomalous information processing; Herbert and Kenet, 2007), but others suggest that the underlying etiology (i.e., genetics) leading to language disruptions in these two disorders may follow different neurodevelopmental routes and that ASD-LI versus SLI are in fact likely to stem from very different causes (Williams et al., 2008). Ongoing research in this area will be critical in ascertaining whether common mechanisms across these disorders may account for the similarities in phenotypic language disturbance or whether perhaps differing vectors of disruption to early brain development might exert such fundamental (core) effects on information processing that they ultimately lead to seemingly similar phenotypes in higher-order language processing ('phenocopies').

Overall, the most common comorbidity seen with SLI is the subsequent diagnosis of *dyslexia* or *reading disability* (*RD*, also called *specific reading disability* or *developmental*

dyslexia). Dyslexia is defined by exclusionary criteria (much like SLI), but in this case represents an unexpected delay or deficit in the acquisition and performance of reading, despite an overall nonverbal IQ in the normal range. This prevalent comorbidity between SLI and dyslexia likely reflects the fact that, while most children with SLI do eventually reach normal language milestones (i.e., they learn to understand and produce speech), the subsequent milestones in reading require the translation of learned phonemes (letter sounds) onto orthographic representation (written letters). Since deficits in phonemic representation and/or phonologic processing comprise a core and persisting component of SLI (see below for more discussion), it is not surprising that a large portion (>50%) of children with SLI go on to be diagnosed as dyslexic/RD (Bishop and Snowling, 2004; Catts et al., 2005; Schuele, 2004; Sices et al., 2007). It is a matter of ongoing debate whether those children who are initially diagnosed as SLI but overcome their disorder without further reading difficulties may, in fact, comprise a different subtype of the SLI population as compared to those who go on to be comorbid for dyslexia/RD. Moreover, another subgroup may be comprised of older children/adults diagnosed with dyslexia/RD in the *absence* of any prior history of SLI (see Bishop and Snowling, 2004; Pennington and Bishop, 2009, for discussion). In fact, it has been suggested that the latter subset of dyslexics, generally thought to correspond to a subcategory termed orthographic, or surface, dyslexics, exhibit primarily visual and higher-order reading deficits but lack the core phonological deficits characteristic of SLI. Conversely, the remaining dyslexics do show core phonological deficits and are accordingly designated phonologic dyslexics. Many or most of the dyslexics in this category do have some history of SLI or language-related difficulties.

Ongoing assessment of these various subgroups appears likely to support the existence of core functional components that characterize both SLI and dyslexia/RD, and may speak to the fact that some of these core deficits show a large amount of overlap across the two disorders (Figure 40.2). For this reason – and recognizing the obvious underlying heterogeneity inherent to the term – some researchers have begun to use combined terms such as *language disabilities* (*LD*), *language-learning disabilities*, or *language-learning impairments* to refer to this set of language-related developmental disabilities (Peterson et al., 2007; Tallal et al., 1993; but see Bishop and Snowling, 2004, for an opposing view). The remainder of this chapter will discuss the phenotypic features and underlying genetics for this *common* category of *LD*, inclusive of both SLI and dyslexia/RD. This grouping reflects the fact that much of the pertinent neuroimaging and genetic research has been performed using adult dyslexic and/or combined LD populations, with


a comparatively limited amount of research performed exclusively on SLI children (but see Webster and Shevell, 2004 for data specific to SLI).

40.3 BEHAVIORAL FEATURES OF LD

Behavioral profiles in clinically defined language-disabled groups vary, but are typically characterized by deficits in both lower-order (e.g., sensory/motor) and higher-order (e.g., grammatical, syntactic, and verbal memory) processes (e.g., Menghini et al., 2010). In fact, the LD population appears to be a heterogeneous mix of individuals with an assortment of deficits corresponding to some subset of the following functional core areas (along with other possible deficits not listed here). (1) Oral-motor skills and articulation, as required for tasks such as rapid naming. (2) Rapid auditory processing, as required to discriminate rapidly changing acoustic sounds such as consonant–vowel syllables. (3a) Phonemic awareness, as required to distinguish and identify phonemes, or subunits of words, and (3b) phonological processing, as required to manipulate phonemes within words and perform mapping to-and-from sounds and letters, as required for non-word reading. (4) Short-term and/or working verbal memory and the related auditory and phonological memory, required for nonword repetition. (5) Visuospatial processing, visual memory, and/or visuospatial attention, required for specific reading tasks. Evidence further suggests that unique patterns of these core deficits may characterize specific subsets of

individuals (i.e., SLI/SSD only, SLI + dyslexic/RD, and dyslexic/RD only; see Figure 40.2). Thus, dyslexic/RD-only individuals (orthographic dyslexics) are less likely to show motor/articulation deficits. Conversely, SLI-E populations are less likely to show visual-processing and memory deficits. However, both groups, as well as the comorbid overlapping population, share evidence of *common* deficits in rapid auditory processing (Farmer and Klein, 1995; Fitch and Tallal, 2003), phonemic and phonological processing (Pennington and Bishop, 2009; Schuele, 2004; Shankweiler et al., 1995), and aspects of short-term/working memory (Briscoe and Rankin, 2009; Montgomery et al., 2010). Each of these core functional features of LD (including SLI and dyslexia/RD) is discussed in greater detail below.

40.3.1 Motor/Articulation Deficits, SSD, and the KE family

As young children learn to speak, it is not unusual to hear substitutions of letter sounds (e.g., /w/ for /r/, as in 'wabbit'), lisps, or stutters. Normally, children outgrow these charming but immature articulation patterns. Some children, however, persist with articulation difficulties (lisp, stutter, and other oral mispronunciations) that may reflect chronic defects in oral musculature, vocal apparatus, palate formation, or general oral-motor 'weakness.' When evidenced in the absence of any delays in language comprehension or reductions in vocabulary, these articulation deficits tend to be less predictive of long-term language and literacy

problems, although the chronic incorrect encoding of certain letter sounds may, in fact, lead to some difficulties in the orthographic translation of those same sounds. On the other hand, children with expressive language difficulties characterized by *multiple* speech-sound errors (phonemic omissions, substitutions, and distortions characterized as phonological processing difficulties) exhibit more marked impairment of articulation and expressive language. (In a phonological (or phonemic) disorder (PD), a child has difficulty learning the sound system of the language, and, specifically, fails to recognize and identify specific sounds as unique. For example, the sounds /k/ and /t/ may not be recognized as different and may therefore be substituted for each other). Children exhibiting language difficulties characterized by such deficits in the oral production or expression of language are, depending on other deficits, likely to be diagnosed with *specific expressive language impairment* (*SLI-E*), *PD*, *SSD*, or some combination of these (Fischer and Scharff, 2009; Pennington and Bishop, 2009). Concurrent research also aims to examine a putative role for more generalized motor deficits associated with SLI, and to separate these features from related overlapping disorders such as developmental coordination disorder (e.g., Archibald and Alloway, 2008).

An intriguing series of studies have been performed on a single extended family with an inherited form of expressive LI (also called 'verbal dyspraxia'; Alcock et al., 2000). Half the members of the patient KE's family (so named for anonymity) show this disorder, exhibiting severe impairments in phonology and syntax, as well as oral praxis. Ongoing studies of this family have led to the isolation of a gene termed *FOXP2* that may be associated with the expressive and oral language deficits evidenced in the KE family. Interestingly, animal studies of the *Foxp2* homolog have shown that disruptions of this gene lead to defects in motor learning, including the acquisition of birdsong and the production of vocalizations in mice (reviewed in Fischer and Scharff, 2009; see below for further discussion).

Ongoing research will continue to assess the specific role of articulation and motor-specific deficits in defining subtypes within the heterogeneous LD population.

40.3.2 Rapid Auditory Processing Deficits

A key series of studies by Tallal and colleagues showed that SLI children were unable to discriminate two sequential tones when the interval between the tones fell below a threshold interval and were also impaired in the identification and discrimination of consonant–vowel syllables characterized by short, rapidly changing formant transitions (e.g., /ba/, /da/, /pa/, /ta/; see Tallal, 1977, 1980; Tallal and Newcombe, 1978; Tallal and Piercy, 1973a,b, 1975; Tallal and Stark, 1981; reviewed in Fitch and Tallal, 2003). Additional studies showed that performance on these auditory tasks was correlated not only with speech perception indices, but also with nonword reading scores (Tallal, 1980). Thus, it was posited that basic defects in low-level auditory processing may be associated with deficits in speech perception and phonology and thus could represent a core factor in the development of LD.

This suggestion of a low-level auditory processing deficit as a possible causal factor in developmental LD has elicited some controversy (e.g., Mody et al., 1997; Ramus, 2003; Rosen and Manganari, 2001). However, ongoing behavioral and psychophysical studies of language-disabled subjects appear to support the notion of an auditory processing deficit that may underlie (or at least be related to) some deficits in speech perception and subsequent language development (Au and Lovegrove, 2007; Cardy et al., 2005; Cohen-Mimran and Sapir, 2007; Corbera et al., 2006; Edwards et al., 2004; Farmer and Klein, 1995; Gaab et al., 2007; Hari and Kiesla, 1996; King et al., 2007; Kraus et al., 1996; McAnally and Stein, 1996, 1997; McCrosky and Kidder, 1980; Neville et al., 1993; Reed, 1989; Renvall and Hari, 2002; Robin et al., 1989; Sutter et al., 2000; Watson, 1992; Witton et al., 1998; Wright et al., 1997). Again, while it remains to be determined whether these auditory deficits represent causal or comorbid (parallel but noncausal) deficits (see McArthur and Bishop, 2001; Ramus, 2003; Rosen and Manganari, 2001), an early deficit in auditory processing could reasonably precede observable LI, in which case assessment of auditory processing in at-risk infants would be extremely useful in identifying those likely to develop later language problems. In fact, Benasich et al. (2002) found that infants with a family history of LI or dyslexia (and thus at an elevated risk of developing language problems themselves; Tallal et al., 1991) were impaired relative to controls in their ability to discriminate two-tone sequences when there was a short interval between the tones, but not with a longer interval. Prospective follow-up of these children revealed a predictive relationship between the threshold at which rapidly presented auditory stimuli could be processed in infancy and language outcomes at 12–24 months (Benasich et al., 2006; Choudhury et al., 2007). More recently, a comparable relationship was seen between early auditory-evoked response potential and electroencephalogram (AERP/EEG) scores using these same stimuli and later language outcomes (Choudhury et al., 2007). In addition, predictive associations between early auditory processing skills have been related to language performance later in life in normally developing samples. Trehub and Henderson (1996) found that children who had performed above the median on a variety of

acoustic gap detection tasks at 6 or 12 months were found to have larger productive vocabularies, use longer, more complex sentences, and produce more irregular words compared with children who had scored below the median. Such findings are also supported by evidence from studies recording evoked response potentials (ERPs) to auditory stimuli in infancy. Molfese and Molfese (1997) found that ERPs to consonant–vowel syllables recorded from infants within 36 h of birth differed between children whose verbal IQ was above, versus below, the norm at 5 years of age. Similarly, infants with a family history of dyslexia showed different patterns of ERPs to consonant–vowel stimuli as compared with matched controls when recorded at 1 week and at 6 months (Leppänen and Lyytinen, 1997; Leppänen et al., 1999; Pihko et al., 1999). Importantly, evidence indicates that these group differences do in fact relate to emergent language skills, based on longitudinal analysis (Benasich et al., 2006; Choudhury et al., 2007).

Collective data thus support the notion that the ability to make fine auditory discriminations (rapid auditory processing) is strongly correlated with later language development and that deficits in this basic function may impair subsequent language development, with ultimate implications for higher-order processes seemingly distal to basic acoustic processing (e.g., reading). Ongoing research will continue to evaluate the role of basic auditory processing deficits in the later emergence of language deficits.

40.3.3 Phonemic and Phonological Processing Deficits

A wide variety of language-based developmental disorders appear to encompass a central deficit in the ability to learn to identify and discriminate individual speech sounds as unique (phonemic awareness). Studies of both SLI and dyslexic/RD populations have consistently shown deficits in phonemic awareness, as well as phonological processing (i.e., using and manipulating phonemes and translating them to and from print) within these populations. Tasks that tap such processes include asking individuals to remove phonemes from words (e.g., /slid/ to /lid/), substitute phonemes (e.g., /bat/ to /hat/), map phonemes from or onto letters (phoneme to grapheme), and/or decode phonemes during nonword reading tasks. The consistency of profound deficits observed in such tasks within both SLI and dyslexic populations has led to some speculation that phonological deficits may form a critical core deficit spanning diverse language disorders (e.g., Bradley and Bryant, 1983; Catts et al., 2005; reviewed in Vellutino et al., 2004). However, speculation still continues regarding the putative etiological underpinning of core phonemic and

phonological difficulties. For example, many studies suggest that difficulties with phonological processing in LD populations may reflect underlying deficits in sound processing and identification (or rapid auditory processing deficits, as described above), while others suggest that phonological deficits may arise in parallel with separate auditory problems, but remain specific to linguistic systems (e.g., Ramus, 2003). Still others ascribe core phonological deficits in LD to primary difficulties with phonological memory (e.g., Gathercole and Baddeley, 1990). In fact, a plausible explanation would suggest that the core demands of phonological processing in language development may be such that disruption from a variety of *different* routes or causes (bottom-up or top-down) might lead to impairments in this key process of language development and reading and lead in turn to shared or overlapping phenotypes of language disruption.

Again, ongoing research into the role of core deficits in phonemic awareness and phonological processing will continue to inform the diagnosis, treatment, and etiologic understanding of developmental LD as a whole.

40.3.4 Short-Term/Working Memory Deficits

Evidence has shown consistent evidence of deficits in language processing using working and/or verbal *short-term memory* (*STM*) to process sentence morphology, syntax, and/or semantics in LD populations (Brady et al., 1983; Shankweiler and Crain, 1986; Shankweiler et al., 1995; Smith et al., 1989). Clearly, the effective use of language requires the use of STM to hold letter sounds in memory during word processing (prior to combining the sounds into a meaningful word), as well as in processing complex semantic meaning within sentences, paragraphs, and narratives (e.g., the meaning of later parts of a sentence may be modified by early sentence structure that must be held in STM to fully interpret the complete sentence). Tasks that tap these underlying capacities include digit-span recall tasks, word-memory tasks, and more complex assessments of active narrative comprehension during reading (see Montgomery et al., 2010, for review). Evidence for STM deficits specific to processing phonological information, such as is required for repeating nonwords, has also been reviewed (Gathercole and Baddeley, 1990; see also Catts et al., 2005). In a recent review by Briscoe and Rankin (2009), the authors discuss data dissociating deficits specific to the 'phonological memory loop' versus more generalized deficits in executive working memory systems in SLI subjects, concluding that evidence more strongly supports a deficit in core phonological memory processes (phonological loop) as opposed to overall executive memory. However, these assertions are counted by findings such as those of

Smith-Spark and Fisk (2007), who demonstrated deficits in cross-modal executive working memory, as well as phonological memory, in dyslexics.

An intriguing family-based genetic association study has also shown a genetic–behavioral linkage within a subset of dyslexic individuals, with deficits in STM appearing to correspond to variations in a segment of the dyslexia-risk gene *DYX1C1* (Marino et al., 2007). Specifically, a significant linkage was observed between single-letter backward-span scores and a genetic variant within this segment of the *DYX1C1* gene. Further evidence suggests associations between memory and/or attentional difficulties and anomalies in other dyslexia-risk genes such as *DCDC2* (Berninger et al., 2008). These collective results support the view that ongoing genetic research into LD may eventually reveal a correspondence between specific genes (out of multiple LD risk genes that have been, and are likely yet to be, identified) and specific core functional deficits contributing to LD (e.g., STM).

40.3.5 Visuospatial Processing, Visuospatial Memory, and/or Visuospatial Attention Deficits

A series of studies in the 1990s suggested that, in addition to rapid auditory processing deficits, adult dyslexics might also be characterized by deficits in processing rapidly changing, but not slowly changing (or static), visual information. This assertion was based on evidence of impairments in processing visual rapid change in human dyslexics and led to suggestions that LD may include a core deficit in 'magnocellular' system processing, since rapidly changing visual information is processed in the magnocellular (rather than parvocellular) subsystem of the visual thalamic nucleus (Lehmkuhle et al., 1993; Livingstone et al., 1991; Lovegrove et al., 1990; Slaghuis et al., 1992). Evidence of a 'magnocellular theory' of dyslexia continues to be explored (e.g., Stein, 2001). With regard to visual memory, a recent study of adult dyslexics and age/IQ-matched controls reported evidence of working memory deficits in dyslexics for both verbal and nonverbal (visuospatial) working memory span tasks that encompassed simple, complex, and dynamic span assessments (Smith-Spark and Fisk, 2007). These latter studies were of particular interest in showing that STM deficits in dyslexic populations are *not* seen exclusively in the phonological domain and may therefore reflect a more fundamental defect in neurological memory systems that in turn impacts on language processing (as well as other functions; but see Briscoe and Rankin, 2009). Ongoing research also continues to explore the role of visual memory and/or attention as a feature of LD populations. For example, Shaywitz and Shaywitz (2008) have shown that attentional processing plays a key role in reading for dyslexic individuals as measured by fMRI, further suggesting that this component of LD may even be amenable to pharmacological remediation, similar to treatment for ADHD.

Clearly, research has shown a range of core functional deficits associated with SLI and/or dyslexia/RD (Figure 40.2), and research continues to refine these behaviorally established criteria for reliable subtyping within the LD population. Thus, a very strong impetus exists to establish markers of genetic or neural features that could be used to segregate this heterogeneous LD population. Unfortunately, what are needed first are reliable markers by which to identify homogeneous subgroups for testing, which will in turn yield significance in genetic linkage and neuroimaging studies. This makes the task circular and very difficult. Recognizing these limits, studies have proceeded nonetheless by using heterogeneous populations (i.e., both SLI and dyslexic/RD) with *post hoc* analysis of subgroups, by separating groups based on core behavioral features (e.g., those with/without phonologic deficits), by correlating one putative marker with another (e.g., memory scores and genetic mapping), by using longitudinal analyses of emergent language measures to segregate groups, and by assessing distinctions and overlaps with related disorders (such as ASD-LI and SLI). Each of these approaches (as well as others) moves us forward in understanding the underlying etiology of LD. The following sections will review some of the anatomic, neuroimaging and genetic data that have resulted from these approaches.

40.4 NEUROPATHOLOGY OF LD

To date, structural neuroimaging and *postmortem* studies performed on clinically defined childhood and adult LD populations (SLI and dyslexic/RD) have, by and large, failed to reveal consistent neurological factors as markers for developmental language and reading disabilities. Some evidence of reduced cortical and subcortical volume in children with LD (e.g., Jernigan et al., 1991) has been reported. Others have reported evidence of anomalous hemispheric asymmetry in language-disabled subjects as measured by *postmortem* anatomical analysis (e.g., Galaburda, 1991; Galaburda et al., 1985; Humphreys et al., 1990) and MRI (Hynd et al., 1990, 1991; Jancke et al., 1994; Larsen et al., 1990; Leonard et al., 1993, 2006; Robichon et al., 2000; Schultz et al., 1994). Generally, these studies report greater evidence of abnormal (increased) symmetry in affected populations, specifically in the *planum temporale*, an area between Heschl's gyrus and the sylvian fissure and including Wernicke's area, and, more recently, in the

inferior frontal gyrus (with both regions showing a left greater than right asymmetry in typical populations). Interestingly, these effects appear to be larger and more reliable for SLI subjects, as compared to dyslexics. In fact, recent work by Leonard et al. (1993, 2006) specifically compared cortical asymmetry for SLI and dyslexic populations and found evidence for smaller cerebral volume and greater temporal symmetry only in SLI children. Some evidence also shows reductions in cerebellar volume, as well as in the cortex and caudate nucleus, in individuals with a speech/language disorder (Watkins et al., 2002). The cerebellar deficits are postulated to relate more specifically to motor component deficits in LD. Clearly, more research is needed using homogeneous subtypes of the LD population in order to gain information about the biological underpinnings of identified functional deficits associated with LD.

Notably, failure to identify a consistently observable, gross anatomical neural feature of LD does *not* imply a normal brain, which has led some to investigate more subtle, but no less deleterious, mechanisms of neural disruption in developmental disabilities of language. For example, key neurodevelopmental processes may be disrupted early in life, leading to anomalous neurocircuitry not necessarily evident at the gross anatomical level. Such complex and subtle effects, however, could have potentially severe behavioral consequences. One scenario that could lead to such effects involves a confluence of genetic and/or environmental factors that occurs in the perinatal period, during key periods of neural development that disrupt the cascade of normal developmental events. One such example is neuronal migration disorders (Barth, 1987). Neuronal migration disorders occur when control mechanisms regulating the final positioning of newly generated migrating neural cells are disrupted and can result in permanent cellular/structural anomalies including agyria/pachygyria, microgyria, dysplasia, and neuronal and leptomeningeal heterotopias and focal ectopias (see Barth, 1987 for review). In fact, Galaburda and Kemper (1979) reported the presence of such focal cellular anomalies in the *postmortem* brain of an adult dyslexic male. This subject was characterized by delayed speech development in the preschool period, and difficulties with reading and spelling soon after entering elementary school, despite normal intelligence and special tutoring. These neuroanatomical findings, including the presence of cortical dysplasias and polymicrogyria in the left temporal lobe and cortical dysplasias throughout the left hemisphere, provided one of the first suggestions that language and reading impairments may represent behavioral manifestations of an underlying neuroanatomical disorder. Subsequently, Galaburda et al. (1985) published an account of three additional brains obtained at *post mortem* from adult male dyslexics. One of these subjects exhibited

delayed speech development followed by reading difficulties in school, and the others exhibited early childhood learning disabilities followed by reading difficulties. Again, numerous neuronal ectopias and cortical dysplasias were observed, primarily in left perisylvian/temporal (language) regions. The authors ascribed these cellular anomalies to focal disruption of neocortical neuronal migration, which probably occurred during the prenatal period (see also Chang et al., 2005, 2007; Preis et al., 1998; Rocha de Vasconcelos Hage et al., 2006). This assertion is supported by developmental studies of animal models exhibiting similar neuronal migration disorders.

In addition to neocortical neuronal migration disorders, fMRI studies have revealed clear evidence of abnormal cortical activation in LD subjects during language tasks, which is thought to reveal abnormal cortical connectivity and/or circuitry in these subjects (e.g., Hoeft et al., 2006; Shaywitz et al., 1998, 2002; Temple et al., 2001). In general, these results correspond to anatomic findings, with evidence of reduced activation in left perisylvian, occipitotemporal, and temperoparietal regions during phonological and reading tasks in dyslexic/RD individuals (see Figure 40.1). Abnormalities in white matter tracts connecting anterior and posterior perisylvian regions have also been reported in subjects with impaired reading ability (Klingberg et al., 2000). Anomalous patterns of activation could in turn stem from a common underlying etiology relating to processes involved in neuronal migration, *or* they could reflect aspects of LD largely orthogonal to focal anomalies. An improved understanding of how these disruptions in neural functioning may underlie, or relate to, expressed behavioral deficits would further our understanding of the relationships among and between the behavioral deficits that characterize LD overall (as well as within various subtypes). In other words, the ambiguity in our understanding of the etiology and interrelation of *neural* anomalies characterizing LD parallels clinical controversies regarding the role of core characteristic *behavioral* deficits that define human LD (as discussed above). Are neural anomalies – perhaps with a common underlying etiology – expressed in a variety of interrelated structures and in turn expressed as a cascade of interwoven functional deficits defining the fabric of 'language disability'? Alternatively, can multiple and semi-orthogonal anomalies simultaneously arise in neural development (both cortical and subcortical), leading in turn to semi-orthogonal functional deficits that contribute (in varying degrees) to a heterogeneous behavioral expression of LD (with some features more pronounced in certain subtypes than others)?

As an interesting aside, histopathological analysis of sections from the same *postmortem* brains that had previously shown focal cortical anomalies (Galaburda

et al., 1985) also subsequently revealed abnormalities at the thalamic level, specifically, in the lateral geniculate (visual) nucleus (LGN; Livingstone et al., 1991). The dyslexic brains showed significantly smaller magnocellular LGN cells (28% smaller in surface area), but no size differences in parvocellular LGN neurons, as compared to controls. Concurrent electrophysiological evidence showed that healthy adult dyslexics exhibited anomalies in neural activation during performance of visual tasks known to depend on the magnocellular system. Livingstone and colleagues suggested that the focal cortical anomalies seen in dyslexics were linked to disruptions of thalamic development, including the visual pathways of the LGN responsible for transmission of low spatial frequency, low luminance contrast, and high temporal rate of change of information (magnocellular pathways; see also Lehmkuhle et al., 1993; Lovegrove et al., 1990; Slaghuis et al., 1992). Subsequent analysis of the same brains showed a similar type of anatomical change in the auditory (medial geniculate) nucleus (MGN). Specifically, dyslexics exhibited a significant shift toward more small and fewer large cells in the left MGN as compared to controls (Galaburda et al., 1994). The latter findings have been viewed in light of concurrent data demonstrating that language-disabled subjects also exhibit fundamental defects in the processing of rapidly changing auditory information (discussed above).

40.5 CANDIDATE LD AND DYSLEXIA SUSCEPTIBILITY GENES

Another approach to understanding the basic etiology of language disorders derives from epidemiological and family studies designed to draw linkages between the incidence of specific genetic variants and the incidence of language disorders (including dyslexia/RD). Studies have examined the incidence of LD in families in order to determine estimates of heritability, used linkage analysis to assess genetic 'markers' shared at above-chance levels among affected individuals from the same family, and used genetic association studies to examine correspondence between variations in regions of genes and specific phenotypes within a group (generally a clinically defined group, such as dyslexics). Such studies have revealed that language disorders are characterized by a degree of heritability, but do not conform to any single-gene models. Moreover, a degree of environmental influence seems to exist as well, since affected individuals can appear in families with no history of LD. The etiology of these 'nonheritable' incidences *could* reflect factors such as chronic ear infections (which impair hearing and thus may disrupt language acquisition), perinatal birth incidents, or the cumulative effects

multiple 'risk' genes inherited from parents with subthreshold expression, but expressed in offspring due to recombination or environmental exacerbation.

Cumulative studies appear to implicate a role for regions on chromosomes 1, 3, 6, and 15 for SSD; 13, 16, and 19 for SLI; and 1, 2, 3, 6, 15, 18, and X for dyslexia/RD (reviewed in Bishop, 2009; Gibson and Gruen, 2008; Pennington and Bishop, 2009). Studies honing in on specific genes have further revealed a role for the *FOXP2* gene in the KE family, as associated with the incidence of an expressive language disorder (Fischer and Scharff, 2009). Researchers have also reported on evidence for six candidate dyslexia susceptibility genes. These include *DYX1C1*, *KIAA0319*, *DCDC2*, *ROBO1*, *MRPL19*, and *C2ORF3* (see Anthoni et al., 2007; Brkanac et al., 2007; Cope et al., 2005; Francks et al., 2004; Hannula-Jouppi et al., 2005; Harold et al., 2006; McGrath et al., 2006; Meng et al., 2005; Paracchini et al., 2006; Schumacher et al., 2006; Taipale et al., 2003, see Fischer and Francks, 2006, for review).

Of these genes, *KIAA0319* and *DCDC2* are located on chromosome 6, *FOXP2* is located on chromosome 7, *ROBO1* is located on chromosome 13, and *DYX1C1* is located on chromosome 15. *MRPL19* and *C2ORF3* are coregulated genes on chromosome 2, the function of which is not yet known. Research suggests that each of the remaining genes appears to be involved in early cortical development, including neuronal migration, axon growth, and synaptic plasticity (Wang et al., 2006). Since neurodevelopmental processes such as neuronal migration and axon growth share several common features and requirements, including dependence upon coordinated changes in cell adhesion and cytoskeletal restructuring, the overlapping functions implicated for these genes is not surprising. For example, *ROBO1* has well-understood roles in axon growth and neuronal migration. The proteins in the *DCX* family, of which *DCDC2* is a member, play well-documented roles in neuronal migration to neocortex and may also play a role in the development of the corpus callosum (LoTurco et al., 2006; Miller, 2005; Rosen et al., 2007; Wang et al., 2006). In addition, *KIAA0319* appears to play a role in cortical cell adhesion and migration, as does *FOXP2* (possibly via regulation of contactin-associated protein). Moreover, *FOXP2* appears to specifically modulate cortical synaptic plasticity, and acts as a transcriptional factor (transcriptional repressor) that may further regulate the expression of other genes important to brain development (Fischer and Scharff, 2009). Indeed, research has revealed very minor changes to a promoter sequence in the *FOXP2* gene when comparing humans and nonhuman primates, and this evolutionary change may modulate some aspects of the development of unique human language-processing capabilities (Konopka et al., 2009).

In terms of functional implications, studies using animal models have provided a unique insight into the role of these various genes by linking individual gene actions with core functional deficits characteristic of human LD populations. For example, studies have demonstrated that knockdown of the avian ortholog to *FOXP2* in birds leads to an impairment in the motor learning of birdsong, and also that *Foxp2* knockout mice show anomalous vocalizations (Gaub et al., 2010; Shu et al., 2005). Similarly, recent research has used rodent models to knock down the actions of identified dyslexia-risk genes transiently, specifically through the transfection of 'interference RNA' (RNAi) into the cerebral ventricles of fetal rats. This RNAi is taken up by new neurons in the ventricular zone, thus deactivating the target genes in these specific cells. Behavioral testing of rodents treated using this technology shows that male rats with embryonic cortical RNAi of the homolog *Dyx1c1* exhibit deficits in complex auditory processing later in life (Threlkeld et al., 2007). These results have intriguing implications for the possible role of *DYX1C1* in modulating auditory processing deficits, and perhaps even associated phonemic/phonological deficits. More recent research has extended these findings to rodent models using another dyslexia-risk gene, *KIAA0319*. Specifically, rats with embryonic RNAi for the homolog *Kiaa0319* also showed significant deficits in rapid auditory processing for fast frequency-modulated (FM) sweep stimuli as compared to sham controls (Szalkowski et al., 2012). Again, these effects are interpreted to parallel evidence of rapid auditory processing deficits in LD populations. As an aside, it is important to note that neither group of RNAi animals was categorically impaired in sound processing tasks, and both groups performed quite normally on discrimination tasks with easier/slower stimuli (e.g., single tones). This point is important when developing animal models for clinical conditions, since a genetic defect resulting in comprehensive learning and cognitive impairments would provide a poor model for the relatively specific pattern(s) of deficits seen within the LD phenotype.

More recently, another study examined STM performance on a delayed match to sample radial arm maze task in male rats with or without embryonic RNAi of *Dyx1c1* (Szalkowski et al., 2011). In this study, results showed persistent STM deficits in *Dyx1c1* knockdown rats, as indicated by higher numbers of errors, paralleling evidence of cross-modal STM deficits in human dyslexics (Smith-Spark and Fisk, 2007). These effects were seen despite parallel evidence that *Dyx1c1* RNAi rats do *not* show deficits on basic spatial maze learning (Morris maze) unless migrational anomalies specifically extended into the hippocampus (as was seen in a small subset of subjects; Threlkeld et al., 2007). Interestingly, similar working memory deficits were *not* seen in a sample of *Kiaa0319* knockout rats, suggesting that these genetic risk factors may exert dissociable effects on core behavioral deficits related to dyslexia (Szalkowski et al., 2012). Again, this pattern of behavioral–genetic associations provides a relatively specific profile to model deficits seen in LD (i.e., deficits in STM). Future work will continue to explore a role for animal models in evaluating these gene–brain–behavior relationships.

40.6 CONCLUSIONS

As will by now be readily apparent from the current chapter, research in the field of language-related disabilities represents one of the most comprehensive and complex cross-disciplinary research fields currently confronting the scientific and clinical community. On the one hand, the breadth of expertise and approaches brought to bear on the issue has led to a vast database concerning the behavioral, neural, and genetic features of LD. On the other hand, the field also suffers from the challenge inherent to processing and integrating the enormous amount of information that now exists. These difficulties are reflected in the fact that different researchers have created conflicting acronyms for what appear to be the same terms, that substantial disagreements exist regarding the distinctions and overlap between subgroups as a function of behavioral criteria (leading to studies that use differently defined populations as subjects for assessment and experimentation), and that it remains quite nearly impossible to achieve expertise in fields as diverse as molecular genetics to clinical behavioral evaluation (thus constraining efforts to integrate data on LD populations fully). Nonetheless, researchers continue to move forward in refining and reshaping our conceptions of language-related developmental disorders from a behavioral perspective and in adding new information to the database of neural and genetic features that characterize these populations. Finally, animal studies provide a unique opportunity to test and assess some of the putative genetic–neural–behavioral links in an experimental manner that is virtually impossible to employ with human subjects.

With regard to future directions, two of the most promising goals toward which research efforts continue to strive are (1) the development and implementation of effective early diagnostic criteria that might detect infants at risk for later language problems, and provide an opportunity for very early intervention (while brain systems are still highly plastic), and (2) the development of effective remediation strategies tailored to unique patterns of deficits in subpopulations of LD (Hoeft et al., 2006). Promising efforts currently continue in both respects. For example, studies have shown that measures of acoustic processing obtained from infants as young

as 6 months of age may predict their later risk for language difficulties (Benasich et al., 2006; Choudhury et al., 2007). In addition, intriguing neuroimaging studies have shown that effective intervention strategies can actually shift the abnormal patterns of brain activity in affected subjects observed during language tasks toward more normative patterns following training (e.g., Gaab et al., 2007). All of these promising routes of investigation will continue in the next decade, as we continue to make inroads in our diagnosis, understanding, and treatment of developmental LD.
