Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Contents

List of contributors xxix
Preface xli

1. Tissue engineering: current status and future perspectives 1

Prafulla K. Chandra, Shay Soker and Anthony Atala

Clinical need 1
Current state of the field 1
Smart biomaterials 2
Cell sources 4
Whole organ engineering 8
Biofabrication technologies 9
Electrospinning 9
Inkjet three-dimensional bioprinting 12
Extrusion three-dimensional bioprinting 12
Spheroids and organoids 13
Imaging technologies 16
Tissue neovascularization 16
Bioreactors 16
Organ-on-a-chip and body-on-a-chip 17
Integration of nanotechnology 18
Current challenges 19
Future directions 21
Smart biomaterials 21
Cell sources 22
Whole organ engineering 24
Biofabrication technologies 24
Tissue neovasculatization 25
Bioreactors 25
Integration of nanotechnology 25
Conclusions and future challenges 26
References 26
Further reading 35

2. From mathematical modeling and machine learning to clinical reality 37

Ben D. MacArthur, Patrick S. Stumpf and Richard O.C. Oreffo

Introduction 37
Modeling stem cell dynamics 37
Positive feedback–based molecular switches 38
Variability in stem cell populations 40
Modeling tissue growth and development 41
Monolayer tissue growth in vitro 42
Tissue growth on complex surfaces in vitro 42
Three-dimensional tissue growth in vitro 43
Pattern formation 44
Machine learning in tissue engineering 45
Supervised methods 46
Unsupervised methods 46
Machine learning of cellular dynamics 47
Regulatory network inference 47
From mathematical models to clinical reality 47
References 48

3. Moving into the clinic 53

Chi Lo, Darren Hickerson, James J. Yoo, Anthony Atala and Julie Allickson

Introduction 53
Current state of tissue engineering 53
Pathway for clinical translation 54
Regulatory considerations for tissue engineering 58
Conclusion 60
Acknowledgment 60
References 60
Further reading 60

Part One
The basis of growth and differentiation 63

4. Molecular biology of the cell 65

J.M.W. Slack

The cell nucleus 65
Control of gene expression 66
Transcription factors 67
Other controls of gene activity 67
The cytoplasm 68
The cytoskeleton 69
The cell surface 71

Cell adhesion molecules 71
Extracellular matrix 72
Signal transduction 73
Growth and death 74
Culture media 75
Cells in tissues and organs 76
Cell types 76
Tissues 77
Organs 77
Reference 78
Further reading 78

5. Molecular organization of cells 79

Jon D. Ahlstrom

Introduction 79
Molecules that organize cells 79
Changes in cell–cell adhesion 80
Changes in celleextracellular matrix adhesion 80
Changes in cell polarity and stimulation of cell motility 81
Invasion of the basal lamina 81
The epithelial–mesenchymal transition transcriptional program 82
Transcription factors that regulate epithelial–mesenchymal transition 82
Regulation at the promoter level 82
Posttranscriptional regulation of epithelial–mesenchymal transition transcription factors 83
Molecular control of the epithelial–mesenchymal transition 83
Ligand-receptor signaling 83
Additional signaling pathways 85
A model for epithelial–mesenchymal transition induction 85
Conclusion 86
List of acronyms and abbreviations 86
Glossary 86
References 87

6. The dynamics of cell–extracellular matrix interactions, with implications for tissue engineering 93

M. Petreaca and M. Martins-Green

Introduction 93
Historical background 93
Extracellular matrix composition 93
Receptors for extracellular matrix molecules 94
Cell–extracellular matrix interactions 96
Development 96
Wound healing 100
Signal transduction events during cell–extracellular matrix interactions 104
Relevance for tissue engineering 111
Avoiding a strong immune response that can cause chronic inflammation and/or rejection 111
Creating the proper substrate for cell survival and differentiation 111
Providing the appropriate environmental conditions for tissue maintenance 112
References 113

7. Matrix molecules and their ligands 119

Allison P. Drain and Valerie M. Weaver

Introduction 119
Collagens 120
Fibrillar collagens 121
Fibril-associated collagens with interrupted triple helices (FACIT) 122
Basement membrane–associated collagens 123
Other collagens 123
Major adhesive glycoproteins 123
Fibronectin 123
Laminin 125
Elastic fibers and microfibrils 126
Other adhesive glycoproteins and multifunctional matricellular proteins 126
Vitronectin 126
Thrombospondins 126
Tenascins 126
Proteoglycans 127
Hyaluronan and lecticans 127
Perlecan 128
Small leucine-rich repeat proteoglycans and syndecans 128
Conclusion 128
References 128

8. Morphogenesis and tissue engineering 133

Priscilla S. Briquez and Jeffrey A. Hubbell

Introduction to tissue morphogenesis 133
Biology of tissue morphogenesis 133
Morphogens as bioactive signaling molecules during morphogenesis 134
The extracellular matrix as a key regulator of tissue morphogenesis 135
Cell–cell interactions during tissue morphogenesis 136
Tissues as integrated systems in the body 136
Engineering tissue morphogenesis 138

Cells as building units in tissue engineering 138
Biomaterial scaffolds as artificial extracellular matrices 139
Morphogens as signaling cues in tissue engineering 140
Tissue remodeling in healthy and diseased environments 140
Current focuses and future challenges 141
References 141

9. Gene expression, cell determination, differentiation, and regeneration 145

Frank E. Stockdale

Introduction 145
Determination and differentiation 145
MyoD and the myogenic regulatory factors 147
Negative regulators of development 148
MicroRNAs—regulators of differentiation 148
Pax in development 149
Satellite cells in skeletal muscle differentiation and repair 149
Tissue engineering—repairing muscle and fostering regeneration by controlling determination and differentiation 150
Conclusion 152
References 152

Part Two
In vitro control of tissue development 155

10. Engineering functional tissues: in vitro culture parameters 157

Jennifer J. Bara and Farshid Guilak

Introduction 157
Key concepts for engineering functional tissues 158
Fundamental parameters for engineering functional tissues 158
Fundamental criteria for engineering functional tissues 159
Importance of in vitro studies for engineering functional tissues 159
In vitro studies relevant to tissue engineering and regenerative medicine 159
In vitro platforms relevant for high throughput screening of drugs and other agents 160
Influence of selected in vitro culture parameters on the development and performance of engineered tissues 161
Culture duration 161
Biomaterials 162
Bioreactors and growth factors 166
Bioreactors and mechanical forces 169
Conclusion 171
Acknowledgments 172
References 172
Further reading 177

11. Principles of bioreactor design for tissue engineering 179

Hanry Yu, Seow Khoon Chong, Ammar Mansoor Hassanbhai, Yao Teng, Gowri Balachander, Padmalosini Muthukumaran, Feng Wen and Swee Hin Teoh

Introduction 179
Macrobioreactors 180
Design principles 181
Sustainable bioreactors 188
Cell manufacturing quality attributes and process analytics technology 189
Future outlook 189
Microbioreactors 191
Design principles 191
Types of microreactors 194
Components and integration into microreactors 194
Applications 195
Summary 197
Acknowledgments 197
References 197

12. Regulation of cell behavior by extracellular proteins 205

Amy D. Bradshaw

Introduction 205
Thrombospondin-1 205
Thrombospondin-2 207
Tenascin-C 208
Osteopontin 209
Secreted protein acidic and rich in cysteine 210
Conclusion 212
References 212

13. Cell and matrix dynamics in branching morphogenesis 217

Shaimar R. González Morales and Kenneth M. Yamada

Introduction 217
The basis of branching morphogenesis 217

Branching morphogenesis in the lung 218
Branching morphogenesis in the salivary gland 220
Branching morphogenesis in the kidney 222
Contributions of other cell types 224
MicroRNAs in branching morphogenesis 225
Extracellular matrix components in branching morphogenesis 226
Laminin 226
Collagen 226
Heparan sulfate proteoglycan 227
Fibronectin and integrins 228
Basement membrane microperforations 228
Mathematical and computational models 230
Geometry 230
Mechanical forces 230
Signaling mechanisms 230
Conclusion 231
Acknowledgments 232
References 232

14. Mechanobiology, tissue development, and tissue engineering 237

David Li and Yu-li Wang

Introduction 237
Mechanical forces in biological systems 237
Tension 237
Compression 238
Fluid shear 238
Cellular mechanosensing 238
The cytoskeleton 239
Stretch-activated ion channels 239
Cell–cell adhesions 240
Cell–substrate adhesions 240
The extracellular matrix 241
Cellular effects of mechanotransduction 243
Substrate adhesion, spreading, and migration 243
Cell–cell interactions in collectives 243
Proliferation and differentiation 244
Mechanotransduction in biological phenomena 245
Wound healing 245
Tissue morphogenesis 247
Cancer metastasis 248
Mechanobiology in tissue engineering 248
Bone-implant design 248
Organs-on-a-chip 250
References 252

Part Three
In Vivo Synthesis of Tissues and Organs 257

15. In vivo engineering of organs 259

V. Prasad Shastri

Introduction 259
Historical context 259
Nature's approach to cellular differentiation and organization 260
Conceptual framework of the in vivo bioreactor 261
In vivo bone engineering—the bone bioreactor 261
In vivo cartilage engineering 264
Induction of angiogenesis using biophysical cues—*organotypic vasculature engineering* 265
De novo liver engineering 267
Repairing brain tissue through controlled induction of reactive astrocytes 269
Conclusions and outlook 269
References 270

Part Four
Biomaterials in tissue engineering 273

16. Cell interactions with polymers 275

W. Mark Saltzman and Themis R. Kyriakides

Methods for characterizing cell interactions with polymers 275
In vitro cell culture methods 275
In vivo methods 278
Cell interactions with polymers 280
Protein adsorption to polymers 280
Effect of polymer chemistry on cell behavior 280
Electrically charged or electrically conducting polymers 284
Influence of surface morphology on cell behavior 284
Use of patterned surfaces to control cell behavior 285
Cell interactions with polymers in suspension 286
Cell interactions with three-dimensional polymer scaffolds and gels 287
Cell interactions unique to the in vivo setting 287
Inflammation 287
Fibrosis and angiogenesis 288
References 289

17. Polymer scaffold fabrication 295

Matthew L. Bedell, Jason L. Guo, Virginia Y. Xie, Adam M. Navara and Antonios G. Mikos

Introduction 295
Design inputs: materials, processing, and cell types 297
Materials and inks 297
Processing and cell viability 299
Cell types and biological interactions 300
Assessment of cell viability and activity 301
3D printing systems and printer types 302
Inkjet printing 303
Extrusion printing 304
Laser-assisted bioprinting 305
Stereolithography 305
Open source and commercial 3D printing systems 306
Print outputs: patterning, resolution, and porous architecture 307
Printing/patterning of multiple inks 308
Print resolution 308
Porous architecture 309
Assessment of scaffold fidelity 309
Printing applications: vascularized and complex, heterogeneous tissues 310
Conclusion 310
Acknowledgments 311
Abbreviations 311
References 311

18. Biodegradable polymers 317

Julian Chesterman, Zheng Zhang, Ophir Ortiz, Ritu Goyal and Joachim Kohn

Introduction 317
Biodegradable polymer selection criteria 317
Biologically derived polymers 318
Peptides and proteins 318
Biomimetic materials 322
Polysaccharides 322
Polyhydroxyalkanoates 325
Polynucleotides 326
Synthetic polymers 326
Aliphatic polyesters 326
Aliphatic polycarbonates 330
Biodegradable polyurethanes 330
Polyanhydrides 331
Polyphosphazenes 331
Poly(amino acids) and pseudo-poly (amino acids) 332
Combinations (hybrids) of synthetic and biologically derived polymers 333
Using polymers to create tissue-engineered products 333
Barriers: membranes and tubes 334
Gels 334
Matrices 334
Conclusion 335
References 335

19. Three-dimensional scaffolds 343

Ying Luo

Introduction 343
Three-dimensional scaffold design and engineering 343
Mass transport and pore architectures 344
Mechanics 346
Electrical conductivity 348
Surface properties 349
Temporal control 352
Spatial control 354
Conclusion 355
References 355

Part Five
Transplantation of engineered cells and tissues 361

20. Targeting the host immune response for tissue engineering and regenerative medicine applications 363

Jenna L. Dziki and Stephen F Badylak

Introduction 363
Immune cells and their roles in building tissues after injury 363
Neutrophils 364
Eosinophils 364
Macrophages 364
Dendritic cells 364
T and B cells 365
Specialized immune cell functions beyond host defense 365
Tissue engineering/regenerative medicine strategies as immunotherapy 365
Future considerations for immune cell targeting tissue engineering/regenerative medicine therapies 366
References 366
Further reading 368

21. Tissue engineering and transplantation in the fetus 369

Christopher D. Porada, Anthony Atala and Graça Almeida-Porada

Introduction 369
Rationale for in utero therapies 370
In utero transplantation 371
Early murine experiments with in utero transplantation 372
In utero transplantation experiments in large preclinical animal models 372
Barriers to in utero transplantation success 373
Clinical experience with in utero transplantation 376
Rationale for in utero gene therapy 376
Hemophilia A as a model genetic disease for correction by in utero gene therapy 377
The need for better hemophilia A treatments 378
Preclinical animal models for hemophilia A and recent clinical successes 378
Sheep as a preclinical model of hemophilia A 379
Feasibility and justification for treating hemophilia A prior to birth 380
Mesenchymal stromal cells as hemophilia A therapeutics 383
Preclinical success with mesenchymal stromal cell–based hemophilia A treatment 384
Risks of in utero gene therapy 385
Genomic integration–associated insertional mutagenesis 385
Potential risk to fetal germline 386
Conclusion and future directions 387
References 388

22. Challenges in the development of immunoisolation devices 403

Matthew A. Bochenek, Derfogail Delcassian and Daniel G. Anderson

Introduction 403
Rejection and protection of transplanted cells and materials 403
Rejection pathways 404
Cellular nutrition 404
Therapeutic cells 405
Primary cells 405
Immortalized cell lines 406
Stem cells 407
Device architecture and mass transport 407
Transplantation site 408
Improving oxygenation of immunoprotected cells 409
Controlling immune responses to implanted materials 410
Steps in the foreign body reaction 411
The role of geometry in the foreign body reaction 411
Tuning chemical composition to prevent attachment 412
Directing immune cell behavior in the transplant niche 412
References 412

Part Six
Stem cells 419

23. Embryonic stem cells 421

Irina Klimanskaya, Erin A. Kimbrel and Robert Lanza

Introduction 421
Approaches to human embryonic stem cell derivation 421
Maintenance of human embryonic stem cell 425
Subculture of human embryonic stem cell 425
Nuances of human embryonic stem cell culture 426
Directed differentiation 426
Safety concerns 430
Conclusion 431
Acknowledgment 431
References 431

24. Induced pluripotent stem cell technology: venturing into the second decade 435

Yanhong Shi, Haruhisa Inoue, Jun Takahashi and Shinya Yamanaka

Disease modeling 435
Drug discovery 436
Stem cell–based therapeutic development 438
Concluding remarks 440
Acknowledgements 440
References 440

25. Applications for stem cells 445

Andres M. Bratt-Leal, Ai Zhang, Yanling Wang and Jeanne F. Loring

Introduction 445
Reprogramming of somatic cells into induced pluripotent stem cells 445
Epigenetic remodeling 446
Reprogramming techniques 446

Induced transdifferentiation 448
Genomic stability 448
Applications of induced pluripotent stem cells 448
Disease modeling 448
Challenges and future possibilities in disease modeling 450
Disease-modifying potential of induced pluripotent stem cells 451
Other applications for induced pluripotent stem cells 452
Conclusion 452
List of acronyms and abbreviations 453
References 453

26. Neonatal stem cells in tissue engineering 457

Joseph Davidson and Paolo De Coppi

Introduction 457
Stem cells 457
Embryonic stem cells 457
Induced pluripotent stem cells 458
Perinatal stem cells 458
Scaffolding specifics in fetal and neonatal tissue engineering 459
Synthetic materials 459
Natural materials 459
Relevance to prenatal therapy 460
Immunology 460
Physiology 460
Conditions of interest 461
Spina bifida 461
Gastroschisis 461
Congenital diaphragmatic hernia 461
Esophageal atresia 461
Congenital heart disease 462
Congenital airway anomalies 462
Bladder 463
Bone and bone marrow 463
Conclusion 463
References 463

27. Embryonic stem cells as a cell source for tissue engineering 467

Ali Khademhosseini, Nureddin Ashammakhi, Jeffrey M. Karp, Sharon Gerecht, Lino Ferreira, Nasim Annabi, Mohammad Ali Darabi, Dario Sirabella, Gordana Vunjak-Novakovic and Robert Langer

Introduction 467
Maintenance of embryonic stem cells 468
Directed differentiation 471
Genetic reprogramming 471
Microenvironmental cues 472
Three-dimensional versus two-dimensional cell culture systems 475
High-throughput assays for directing stem cell differentiation 475
Physical signals 477
Isolation of specific progenitor cells from embryonic stem cells 479
Transplantation 480
Transplantation and immune response 481
Future prospects 482
Conclusion 483
Acknowledgments 483
Conflicts of interest 483
References 483
Further reading 490

Part Seven
Gene therapy 491

28. Gene therapy 493

Stefan Worgall and Ronald G. Crystal

Strategies of gene therapy 493
Ex vivo versus in vivo gene therapy 494
Ex vivo 494
In vivo 495
Chromosomal versus extrachromosomal placement of the transferred gene 495
Gene transfer vectors 495
Nonviral vectors 497
Adenovirus 497
Adeno-associated virus 499
Retrovirus 500
Lentivirus 501
Cell-specific targeting strategies 502
Targeting of Ad vectors 502
Targeting of adeno-associated virus vectors 505
Targeting of retroviral and lentiviral vectors 505
Regulated expression of the transferred gene 505
Using gene transfer vectors for gene editing 507
Combining gene transfer with stem-cell strategies 508
Gene transfer to stem cells 508
Gene transfer to control uncontrolled stem-cell growth 508
Gene transfer to instruct stem-cell differentiation 508
Gene transfer to regulate gene expression 509
Challenges to gene therapy for tissue engineering 509
Acknowledgments 510
References 510

29. Gene delivery into cells and tissues 519

Christopher E. Nelson, Craig L. Duvall, Aleš Prokop, Charles A. Gersbach and Jeffrey M. Davidson

Introduction **519**
Fundamentals of gene delivery **519**
Biodistribution, targeting, uptake, and trafficking **521**
Tissue biodistribution/targeting 521
Cellular uptake and intracellular trafficking 523
Viral nucleic acid delivery **526**
Introduction to viral gene therapy 526
Types of viral vectors 527
Engineering viral vectors 528
Nonviral nucleic acid delivery **530**
Introduction to nonviral nucleic acid delivery 530
Oligonucleotide modifications 531
Conjugates 531
Synthetic polymers 531
Polymers derived from natural sources or monomers 534
Lipid-based delivery systems 536
Inorganic nanoparticles 537
High-throughput screening 537
Engineering tissues with gene delivery **538**
Introduction to engineering tissue with gene delivery 538
Viral delivery to engineer tissues 538
Nonviral delivery from scaffolds 540
Nucleic acid delivery for tissue engineering advances into the clinic 541
Future challenges 541
Outlook **542**
Acknowledgments **543**
References **543**

Part Eight
Breast **555**

30. Breast tissue engineering: implantation and three-dimensional tissue test system applications 557

Karen J.L. Burg and Timothy C. Burg

Introduction **557**
Breast anatomy and development **557**
Breast cancer diagnosis and treatments **558**
Breast reconstruction **558**
Synthetic implants 559
Tissue flaps 559
Cell transplants 559
Cellular scaffolds 560
Special considerations 565
Breast cancer modeling **565**
Animal models 565
Breast tissue test systems 566
In silico breast cancer models **570**
Concluding remarks **571**
Acknowledgement **571**
References **571**

Part Nine
Cardiovascular system **577**

31. Cardiac progenitor cells, tissue homeostasis, and regeneration 579

Wayne Balkan, Simran Gidwani, Konstantinos Hatzistergos and Joshua M. Hare

Origin of cardiac stem/progenitor cells **579**
Modeling cardiac development with pluripotent stem cells **581**
In vivo fate mapping of cardiac progenitors **582**
Neonatal cardiac repair **582**
Reprogramming cardiac fibroblasts **584**
Cardiac resident mesenchymal stem cells 584
Cardiomyocytes and cardiac repair/regeneration **585**
Cell-based therapy **585**
Cardiac progenitor/stem cell therapy 586
Combination stem cell therapy 586
Pluripotent stem cells 586
Future directions **588**
References **588**

32. Cardiac tissue engineering 593

Yimu Zhao, George Eng, Benjamin W. Lee, Milica Radisic and Gordana Vunjak-Novakovic

Introduction **593**
Clinical problem **593**
Engineering cardiac tissue: design principles and key components **594**
Cell source 594
Scaffold 598
Biophysical stimulation 599
Directed cardiac differentiation of human stem cells **599**
Derivation of cardiomyocytes from human pluripotent stem cells 599
Purification and scalable production of stem cell–derived cardiomyocytes 601
Scaffolds **601**
Decellularization approach 601
Artificial scaffolds 602

Biophysical cues 604
Electrical stimulation 604
Mechanical stimulation 604
Perfusion 606
In vivo applications of cardiac tissue engineering 606
Engineered heart issue 606
Vascularized cardiac patches 608
Electrical coupling of cardiomyocytes on the heart 608
Modeling of disease 609
Generation of patient-specific cardiomyocytes 609
Engineered heart tissue models 609
Cardiac fibrosis 609
Titin mutation–related dilated cardiomyopathy 611
Diabetes-related cardiomyopathy 611
Chronic hypertension induced left ventricle hypertrophy 611
Barth syndrome 611
Tissue engineering as a platform for pharmacologic studies 611
Summary and challenges 612
Acknowledgments 612
References 612

33. Blood vessels 617

Luke Brewster, Eric M. Brey and Howard P. Greisler

Introduction 617
Normal and pathologic composition of the vessel wall 617
Developmental biology cues important in vascular tissue engineering 618
Conduits 618
Arteries 618
Veins 618
Current status of grafts in patients 618
Conduit patency and failure 618
Venous reconstruction 619
Hemodialysis vascular access 619
Inflammation and the host response to interventions and grafts 620
Host environment and the critical role of the endothelium 621
Prevalent grafts in clinical use 622
Vascular tissue engineering 623
Early efforts—in vitro tissue-engineered vascular grafts 623
Endothelial cell seeding 623
In vitro approaches to tissue-engineered vascular grafts 624
In vivo tissue-engineered vascular grafts 625
Bioresorbable grafts 625
The living bioreactor 626
Cellular and molecular mediators of graft outcome 626
Conclusion and predictions for the future 630
References 630

34. Heart valve tissue engineering 635

Kevin M. Blum, Jason Zakko, Peter Fong, Mark W. Maxfield, Muriel A. Cleary and Christopher K. Breuer

Introduction 635
Heart valve function and structure 635
Cellular biology of the heart valve 636
Heart valve dysfunction and valvular repair and remodeling 637
Heart valve replacement 638
The application of tissue engineering toward the construction of a replacement heart valve 640
Tissue engineering theory 640
Biomaterials and scaffolds 640
The search for appropriate cell sources 643
Cell seeding techniques 644
Bioreactors 645
Neotissue development in tissue engineered heart valves 645
Clinical applications of the tissue engineered heart valve 647
Conclusion and future directions 648
References 649

Part Ten
Endocrinology and metabolism 655

35. Generation of pancreatic islets from stem cells 657

Bárbara Soria-Juan, Javier López-Beas, Bernat Soria and Abdelkrim Hmadcha

Introduction 657
State-of-the-art 657
The challenge of making a β-cell 658
Recent achievements (first generation of pancreatic progenitors used in the clinic) 658
Need of late maturation: cabimer protocol 659
Strategies to maintain cell viability 659
Encapsulation and tolerogenic strategies 661
The concept of cellular medicament 661
Conclusion 662
Acknowledgments 662
References 662

36. Bioartificial pancreas: challenges and progress 665

Paul de Vos

Introduction 665
History of the bioartificial pancreas 666
Replenishable cell sources and encapsulation 666
Macro- or microedevices 667
Factors contributing to biocompatibility of encapsulation systems 669
Avoiding pathogen-associated molecular patterns in polymers 670
Natural and synthetic polymers 670
Multilayer capsule approaches 670
Antibiofouling approaches 671
Formation of polymer brushes 671
Immunomodulatory materials 672
Intracapsular environment and longevity of the encapsulated islet graft 672

Part Eleven Gastrointestinal system 707

38. Stem and progenitor cells of the gastrointestinal tract: applications for tissue engineering the intestine 709

Kathryn M. Maselli, Christopher R. Schlieve, Mark R. Frey and Tracy C. Grikscheit

Introduction 709
Stem cells of the intestine 709
Cell types of the epithelial layer 709
Stem and progenitor cell types 710
Signaling pathways in the intestinal epithelium 712
The Wnt pathway 712
The Notch pathway 713
Epidermal growth factor receptor/ErbB signaling 713
The Hedgehog pathway 714
The BMP pathway 714
Tissue engineering the intestine with stem/progenitor cells 714
Organ-specific stem cell progenitors versus pluripotent stem cells 714
Synthetic and biological scaffolds 715
Primary intestinal-derived organoid units 716
Pluripotent stem cell approaches—human intestinal organoids 717
Remaining barriers to the generation of tissue-engineered intestine 718
Conclusion 718
Acknowledgment 718
References 718

39. Liver stem cells 723

Dagmara Szkolnicka and David C. Hay

Introduction 723
Liver architecture and function 723
Liver development 723
Fetal liver stem cells 724
Hepatocytes and liver progenitors in organ regeneration 724

Molecular signaling and processes involved in liver regeneration 724
Hepatocytes' role in liver regeneration 725
Cholangiocytes and liver stem cells in liver regeneration 725
Pluripotent stem cell–derived hepatoblasts and hepatocytes 726
3D liver organoids and expansion 727
Pluripotent stem cell–derived liver organoids 728
Bile duct–derived organoids 728
Hepatocyte-derived organoids 728
Novel scaffolds for liver organoids 729
Organoids as a model to study liver cancer disease 730
Reprogramming of human hepatocytes to liver progenitors using different culture conditions 730
Conclusion 731
References 731

40. Hepatic tissue engineering 737

Amanda X. Chen, Arnav Chhabra, Heather E. Fleming and Sangeeta N. Bhatia

Liver disease burden 737
Current state of liver therapies 738
Extracorporeal liver support devices 738
Biopharmaceuticals 738
Liver transplantation 738
Hepatocyte transplantation 740
Current clinical trials 740
In vitro models 740
Two-dimensional liver culture 741
Three-dimensional liver constructs 741
Physiological microfluidic models of liver 742
Controlling three-dimensional architecture and cellular organization 742
In vivo models 743
Cell sourcing 743
Cell number requirements 743
Immortalized cell lines 744
Primary cells 744
Fetal and adult progenitors 744
Reprogrammed hepatocytes 744
Extracellular matrix for cell therapies 744
Natural scaffold chemistry and modifications 745
Synthetic scaffold chemistry 745
Modifications in scaffold chemistry 745
Porosity 746
Vascular and biliary tissue engineering 746
Vascular engineering 746
Host integration 747
Biliary network engineering 747
Conclusion and outlook 747
References 748

Part Twelve
Hematopoietic system 755

41. Hematopoietic stem cells 757

Qiwei Wang, Yingli Han, Linheng Li and Pengxu Qian

Introduction 757
Hematopoietic stem cells and hematopoietic stem cells niche 757
Effects of biomaterials on hematopoietic stem cells 758
Applications 759
Engineering hematopoietic stem cells niche for in vitro expansion 759
Manipulation of the multilineage differentiation of hematopoietic stem cells 760
In vivo tracking hematopoietic stem cells 761
Future perspectives 761
Acknowledgments 761
References 761

42. Blood components from pluripotent stem cells 765

Erin A. Kimbrel and Robert Lanza

Introduction and history of modern hematology 765
Red blood cells 765
Megakaryocytes/platelets 769
White blood cells 770
Lymphocytes—T cells 770
Lymphocytes—NK cells 773
Lymphocytes—NKT cells 775
Monocyte-derived dendritic cells 776
Monocyte-derived macrophages 777
Granulocytes—neutrophils 778
Perspectives 779
References 779

43. Red blood cell substitutes 785

Andre Francis Palmer and Donald Andrew Belcher

Introduction 785
Replicating red blood cell functions 785
Hemoglobin-based oxygen carriers 785
Hemoglobin toxicity 787
Oxygen delivery 789

Viscosity and colloid osmotic pressure 789
Cross-linked and polymeric hemoglobin 790
Surface conjugated hemoglobin 790
Encapsulated hemoglobin 791
Sources of hemoglobin 791
Recombinant hemoglobin 792
Erythrocruorins 792
Perfluorocarbons 793
Perspectives 794
Organ transplant preservation 794
Cancer treatment 795
Tissue-engineered construct oxygenation 795
References 795

Part Thirteen
Kidney and genitourinary system 803

44. Stem cells in kidney development and regeneration 805

Kyle W. McCracken and Joseph V. Bonventre

Kidney development 805
Early embryonic origins of nephrogenic tissues 806
Development of the nephric duct and ureteric bud 808
Maintenance and differentiation of the nephron progenitor cell 809
Role of stromal lineages in kidney organogenesis 811
Nephron endowment 812
Kidney repair and regeneration 813
Stem cells in kidney repair 813
Sources of nephrogenic cells 814
Differentiation of renal tissue from pluripotent stem cells (organoids) 815
Conclusion 817
Disclosures 818
Acknowledgements 818
References 818

45. Tissue engineering of the kidney 825

Ji Hyun Kim, Anthony Atala and James J. Yoo

Introduction 825
Cell-based tissue engineering of the kidney 826
Cell sources 826
Tissue-engineered cellular three-dimensional renal constructs 830
Cell-free tissue engineering of the kidney 835
In situ kidney regeneration 835
Granulocyte-colony stimulating factor 835
Stromal cell–derived factor-1 837
Conclusion and future perspectives 837
Acknowledgment 838
References 838

46. Tissue engineering: bladder and urethra 845

Yuanyuan Zhang, James J. Yoo and Anthony Atala

Introduction 845
Cell sources 846
Bladder and ureter cells 846
Stem cell sources 846
Mechanism of cell therapy 848
Biodegradable biomaterials 850
Synthetic scaffolds 850
Natural collagen matrix 851
Preclinical models 854
Tissue regeneration models 854
Fibrotic bladder model 854
Clinical trials 856
Clinical translation 856
Clinical studies 857
Conclusion 858
References 858

47. Tissue engineering for female reproductive organs 863

Renata S. Magalhaes, James K. Williams and Anthony Atala

Introduction 863
Uterus 863
Acellular tissue engineering approaches for uterine tissue repair 864
Cell-seeded scaffolds for partial uterine repair 864
Scaffold-free approaches for partial uterine repair 865
Uterine cervix tissue engineering 865
Ovary 865
Tissue engineering ovarian follicles 866
Vagina 866
Tissue engineering approaches for neovagina reconstruction 866
Conclusion and future perspectives 867
References 867

48. Male reproductive organs 871

Hooman Sadri-Ardekani, John Jackson and Anthony Atala

Introduction 871
Testes 871

Spermatogonial stem cell technology 871
Androgen-replacement therapy 873
Ejaculatory system 874
Engineering vas deferens 874
Spinal ejaculation generator 875
Penis 875
Penile reconstruction 875
Penile transplantation 876
Stem cell therapy for erectile dysfunction 876
Conclusion 877
References 877

Part fourteen
Musculoskeletal system 881

49. Mesenchymal stem cells in musculoskeletal tissue engineering 883

Yangzi Jiang, Dan Wang, Anna Blocki and Rocky S. Tuan

Introduction 883
Mesenchymal stem cell biology relevant to musculoskeletal tissue engineering 883
Mesenchymal stem cell identification 883
Tissue sources of mesenchymal stem cells 885
Mesenchymal stem cell isolation and in vitro culture 886
Mesenchymal stem cell self-renewal and proliferation capacity 887
Skeletogenic differentiation of mesenchymal stem cells 888
Plasticity of mesenchymal stem cells 888
Mesenchymal stem cell heterogeneity 889
Mesenchymal stem cell effect on host immunobiology 889
Safety of using mesenchymal stem cells for transplantation 891
Mesenchymal stem cells in musculoskeletal tissue engineering 891
Cartilage tissue engineering 891
General properties of articular cartilage 892
Cells for cartilage tissue engineering 892
Bone tissue engineering 897
Osteochondral tissue engineering 898
Engineering other skeletal tissues with mesenchymal stem cells 899
Tendon/ligament 899
Meniscus 900
Gene therapy in musculoskeletal tissue engineering 901
Conclusion and future perspectives 901
Acknowledgments 902
References 902

50. Bone tissue engineering and bone regeneration 917

J.M. Kanczler, J.A. Wells, D.M.R. Gibbs, K.M. Marshall, D.K.O. Tang and Richard O.C. Oreffo

Introduction 917
Skeletal stem cells 917
Fracture repair—the (limited) self-reparative capacity of bone 919
A framework for bone repair: biomaterial-driven strategies for bone regeneration 922
Growth factors: biomimetic-driven strategies for bone regeneration 923
Bone biofabrication 924
Development of vascular bone 925
Preclinical development—ex vivo/in vivo small and large animal preclinical models 926
Clinical translation 929
Summary and future perspectives 931
Acknowledgments 931
References 931

51. Tissue engineering for regeneration and replacement of the intervertebral disk 937

Stephen R. Sloan Jr., Niloofar Farhang, Josh Stover, Jake Weston, Robby D. Bowles and Lawrence J. Bonassar

Introduction 937
Intervertebral disk structure and function 938
Cell-biomaterial constructs for intervertebral disk regeneration 940
Nucleus pulposus cell-biomaterial implants 940
Annulus fibrosus repair and regeneration 942
Composite cell-biomaterial intervertebral disk implants 944
Cellular engineering for intervertebral disk regeneration 945
Cell therapy preclinical studies 946
Cell therapy clinical studies 947
Growth factors and other biologics for intervertebral disk regeneration 948
In vitro studies 948
In vivo studies: growth factors 952
In vivo studies: other biologics 953
Gene therapy for intervertebral disk regeneration 953
Gene transfer studies: viral 954
Gene transfer studies: nonviral 954
Endogenous gene regulation 955
Gene therapy in summary 955

In vivo preclinical models for intervertebral disk regeneration and replacement 955
Concluding remarks 957
Acknowledgment 957
References 957

52. Articular cartilage injury 967

J.A. Martin, M. Coleman and J.A. Buckwalter

Introduction 967
Articular cartilage injury and joint degeneration 968
Mechanisms of articular cartilage injuries 968
Response of articular cartilage to injury 970
Matrix and cell injuries 970
Chondral injuries 971
Osteochondral injuries 971
Preventing joint degeneration following injury 972
Promoting articular surface repair 972
Penetration of subchondral bone 972
Periosteal and perichondrial grafts 973
Cell transplantation 973
Artificial matrices 973
Growth factors 973
Antiinflammatories 974
Conclusion 974
Acknowledgments 974
References 974
Further reading 977

53. Engineering cartilage and other structural tissues: principals of bone and cartilage reconstruction 979

Batzaya Byambaa and Joseph P. Vacanti

Introduction 979
Biomaterials for cartilage tissue engineering 979
Cell sources for cartilage tissue engineering 980
Biofabrication of cartilage tissue 981
Magnetic resonance imaging and computerized tomography scans 981
Scaffolds for cartilage tissue engineering 981
Bioprinting techniques for fabrication of cartilage constructs 982
Bioinks for cartilage tissue printing 982
Osteochondral tissue engineering 985
References 985

54. Tendon and ligament tissue engineering 989

Spencer P. Lake, Qian Liu, Malcolm Xing, Leanne E. Iannucci, Zhanwen Wang and Chunfeng Zhao

Introduction 989
Tendon and ligament composition, structure, and function 990
Composition 990
Structure 990
Function 990
Requirements for a tissue-engineered tendon/ligament 991
Scaffold 992
Cell 994
Bioactive factors 995
Three-dimensional bioprinting and bioink 996
Bioink inspired from ligament and tendon structures 997
Tissue engineering tendon and ligament in clinical application 998
Summary 999
References 1000

55. Skeletal tissue engineering 1007

Matthew P. Murphy, Mimi R. Borrelli, Daniel T. Montoro, Michael T. Longaker and Derrick C. Wan

Introduction 1007
Distraction osteogenesis 1008
Critical-sized defects 1010
Cellular therapy 1010
Cytokines 1013
Scaffolds 1014
Tissue engineering in practice 1016
Conclusion 1017

57. Brain–machine interfaces 1037

José del R. Millán and Serafeim Perdikis

Introduction 1037
Brain–machine interface signals 1037
Voluntary activity versus evoked potentials 1038
Mutual learning 1040
Context-aware brain–machine interface 1040
Future directions 1041
References 1042

58. Spinal cord injury 1047

Nicolas N. Madigan and Anthony J. Windebank

Introduction 1047
Epidemiology 1047
Spinal cord organization 1047
Spinal cord injury 1048
Available clinical interventions 1049
The continuum of physical, cellular, and molecular barriers to spinal cord regeneration 1049
The role of tissue engineering in spinal cord injury repair 1051
Bioengineering for integrated spinal cord biocompatibility 1052
Animal models of spinal cord injury 1052
Principles of biomaterial fabrication for spinal cord injury repair 1054
Biomaterials for spinal cord tissue engineering: natural polymers 1058
Extracellular matrix polymers 1058
Polymers from marine or insect life 1065
Polymers derived from the blood 1071
Biomaterials for spinal cord tissue engineering: synthetic polymers 1072
Poly α-hydroxy acid polymers 1073
Nonbiodegradable hydrogels 1077
Conclusion and future directions: the promise of clinical translation 1080
References 1080

59. Protection and repair of hearing 1093

Su-Hua Sha, Karl Grosh and Richard A. Altschuler

Introduction 1093
Protection from "acquired" sensory hair cell loss 1093
Oxidative stress and stress-related mitochondrial pathways 1094
Calcium influx 1094
Endoplasmic reticulum stress 1094
Prevention of ototoxicity 1094
Prevention of acoustic trauma 1096
Antiinflammatory agents 1097
Heat shock proteins 1097
Neurotrophic factors 1098
Protection from excitotoxicity: "acquired" loss of auditory nerve connections to hair cells 1098
Gene transfer for the prevention and treatment of genetic deafness 1099
Interventions for hair cell repair: gene therapy for transdifferentiation 1099
Interventions for repair: hair cell and auditory nerve replacement—exogenous stem cells 1101
Interventions for repair/replacement: cochlear prostheses 1101
Fully implantable cochlear prostheses 1101
Interventions for repair/replacement: central auditory prostheses 1102
Local delivery to cochlear fluids 1103
Conclusion 1103

67. Cell- and tissue-based therapies for lung disease 1253

Jeffrey A. Whitsett, William Zacharias, Daniel Swarr and Vladimir V. Kalinichenko

Introduction: challenges facing cell and tissue-based therapy for the treatment of lung disease 1253
Lung morphogenesis informs the process of regeneration 1254
Integration and refinement of signaling and transcriptional pathways during lung formation 1256
The mature lung consists of diverse epithelial and mesenchymal cell types 1256
Structure and function of pulmonary vasculature 1257
Embryonic development of alveolar capillaries 1258
Evidence supporting lung regeneration 1259
A diversity of lung epithelial progenitor/stem cells is active during regeneration 1260
Role of lung microvasculature in lung repair 1262
Endothelial progenitor cells in lung repair 1262
Pulmonary cell-replacement strategies for lung regeneration 1263
Induced pluripotent stem cells for study of treatment of pulmonary disease 1263
Differentiation of induced pluripotent stem and embryonic stem cells to pulmonary epithelial cell lineages 1264
Bioengineering of lung tissues 1265
Mesenchymal stromal cells and mesenchymal stromal cell products for the treatment of lung disease 1265
Important role of the extracellular matrix in lung structure and repair 1265
Tissue engineering for conducting airways 1266
Pulmonary macrophage transplantation for the treatment of interstitial lung disease 1266
Conclusion 1266
Acknowledgments 1266
References 1266

68. Lung tissue engineering 1273

Micha Sam Brickman Raredon, Yifan Yuan and Laura E. Niklason

Introduction 1273
Design criteria for pulmonary engineering 1273
Decellularized scaffolds and biofabrication approaches 1274
Pulmonary epithelial engineering 1276
Proximal airway engineering 1276
Distal airway engineering 1276
Mesenchymal support of pulmonary epithelium 1277
Pulmonary endothelial engineering 1277
Endothelial cell sources for lung tissue engineering 1278
Endothelial seeding into lung scaffolds 1278
Organomimetic endothelial culture 1279

Mesenchymal support of pulmonary microvasculature 1280
Bioreactor technologies for pulmonary engineering 1280
Conclusion 1281

70. Wound repair: basic biology to tissue engineering 1309

Richard A.F. Clark, Michael Musillo and Thomas Stransky

Introduction 1309
Basic biology of wound repair 1310
Inflammation 1310
Transition from inflammation to repair 1310
Reepithelialization 1310
Granulation tissue 1312
Wound contraction and extracellular matrix organization 1316
Chronic wounds 1317
Scarring 1318
Pathological scars 1318
Scarless healing 1319
Tissue engineered therapy with skin cells 1320
Engineered epidermal constructs 1320
Engineered dermal constructs 1321
Engineered skin substitutes 1321
Skin autograft harvesting without scarring 1322
Tissue-engineered therapy with stem cells, bioactives, and biomaterials 1322
References 1324

71. Bioengineered skin constructs 1331

Vincent Falanga

Introduction 1331
Skin structure and function 1331
The epidermis 1331
The dermis 1332
The process of wound healing 1333
Impaired healing and its mechanisms 1333
Acute versus chronic wound healing 1333
Bacterial colonization 1333
Growth factor imbalances 1334
Matrix metalloproteinase activity 1334
Moist wound healing in chronic wounds 1334
Ischemia 1334
Abnormalities at the cellular level 1335
Engineering skin tissue 1335
Design considerations 1335
Commercial considerations 1336
Process considerations 1337
Regulatory considerations 1337
Immunological considerations 1338
Summary: engineering skin tissue 1338
Epidermal regeneration 1338
Dermal replacement 1339
Bioengineered living skin equivalents 1339
Bioengineered skin: FDA-approved indications 1340
Cutaneous indications 1340
Oral indications 1341
Apligraf and Dermagraft: off-label uses 1341
The importance of wound bed preparation 1344
Proposed mechanisms of action of bioengineered skin 1345

Construct priming and a new didactic paradigm for constructs 1347
Other considerations 1348

Part Twenty
Tissue-engineered food 1353

72. **Principles of tissue engineering for food** 1355

Mark Post and Cor van der Weele

Introduction 1355
Why tissue engineering of food? 1355
Specifics of tissue engineering for medical application 1356
Uniqueness 1356
Function 1356
Skeletal muscle and fat tissue engineering 1357
Tissue engineering of skeletal muscle 1357
Tissue engineering of fat 1359
Specifics of food tissue engineering 1361
Scale 1361
Efficiency 1362
Taste, texture, juiciness 1362
Enhanced meat 1363
Other foods 1363
Consumer acceptance 1364
Regulatory pathway 1365
Conclusion 1365
References 1365

73. **Cultured meat—a humane meat production system** 1369

Zuhaib F. Bhat, Hina Bhat and Sunil Kumar

Introduction 1369
Need and advantages of cultured meat 1370
Cultured meat 1372
Scaffolding techniques 1372
Self-organizing tissue culture 1373
Organ printing 1375
Biophotonics 1375
Nanotechnology 1375
Challenges and requirements for industrial production 1375
Generation of suitable stem cell lines from farm-animal species 1376
Safe media for culturing of stem cells 1377
Safe differentiation media to produce muscle cells 1377
Tissue engineering of muscle fibers 1378
Scaffolds 1378
Industrial bioreactors 1379
Fields 1380
Atrophy and exercise 1380
Senescence 1381
Meat processing technology 1381
Associated dangers and risks 1381
Regulatory issues 1381
Consumer acceptance and perception 1382
Role of media in publicity of cultured meat 1382
Market for cultured meat 1382
Conclusion 1383
References 1384

Part Twentyone
Emerging technologies 1389

74. **Three-dimensional bioprinting for tissue engineering** 1391

Jun Tae Huh, James J. Yoo, Anthony Atala and Sang Jin Lee

Introduction 1391
3D Bioprinting strategy: from medical image to printed bioengineered tissue 1391
Three-dimensional bioprinting techniques 1392
Jetting-based bioprinting 1392
Extrusion-based bioprinting 1394
Laser-assisted bioprinting 1394
Laser-based stereolithography 1395
Digital light processing 1395
Hybrid and other techniques 1396
Biomaterials as bioinks for three-dimensional bioprinting 1396
Hydrogel-based bioinks for cell-based three-dimensional bioprinting 1396
Biodegradable synthetic polymers for structure-based three-dimensional bioprinting 1399
Scaffold-free cell printing 1399
Three-dimensional bioprinting in tissue engineering applications 1400
Three-dimensional bioprinted vascular structures 1400
In vitro tissue models 1400
Three-dimensional bioprinted implantable tissue constructs 1403
Conclusion and future perspectives 1409
Abbreviations 1410
Glossary 1410
References 1411

75. Biofabricated three-dimensional tissue models 1417

David B. Berry, Claire Yu and Shaochen Chen

Introduction 1417
Current methods of three-dimensional biofabrication 1418
Biomaterials for three-dimensional fabrication 1421
Three-dimensional tissue models for drug screening, disease modeling, therapeutics, and toxicology 1425
Conclusion and future directions 1435
Acknowledgments 1435
References 1435

76. Body-on-a-chip: three-dimensional engineered tissue models 1443

Thomas Shupe, Aleksander Skardal and Anthony Atala

Introduction 1443
Advanced in vitro modeling systems—progression from two-dimensional to three-dimensional models 1444
Organ-on-a-chip technologies and their applications 1445
Microengineering and biofabrication 1446
Liver-on-a-chip 1447
Vessel-on-a-chip 1447
Lung-on-a-chip 1448
Heart-on-a-chip 1448
Cancer-on-a-chip 1448
Body-on-a-chip: integrated multiorgan systems and future applications 1449
The importance of multiorganoid integration 1449
Cutting edge body-on-a-chip: the first highly functional multiorganoid systems 1452
Conclusion and perspectives 1455
References 1456

77. Monitoring and real-time control of tissue engineering systems 1459

Jean F. Welter and Harihara Baskaran

Introduction 1459
Current state-of-the-art 1460
General environmental monitoring and real-time control 1460
Tissue-level monitoring 1462
Mechanical properties 1462
Cell-level monitoring 1463
Reporter-based gene expression imaging 1463
Tissue-specific 1463
Cartilage monitoring and real-time control 1463
Skin 1464
Concluding remarks 1464
Acknowledgments 1465
References 1465

78. Biomanufacturing for regenerative medicine 1469

Joshua G. Hunsberger and Darren H.M. Hickerson

Current landscape of biomanufacturing 1469
Highlighting current workflows for biomanufacturing 1470
Current challenges in biomanufacturing for regenerative medicine 1470
Current platform technologies enabling biomanufacturing 1472
Regulatory challenges for biomanufacturing 1473
Food and Drug Administration guidance documents 1474
Creating standards 1475
The future: envisioned advanced biomanufacturing 1476
Closed-modular biomanufacturing systems 1476
Off-the-shelf products 1477
Preservation advances 1477
Synthetic biology advances 1477
Cell banking advances 1477
Medical applications for biomanufacturing in regenerative medicine 1477
Space exploration 1478
References 1479

Part Twentytwo Clinical experience 1481

79. Tissue-engineered skin products 1483

Jonathan Mansbridge

Introduction 1483
Types of therapeutic tissue-engineered skin products 1484
Components of tissue-engineered skin grafts as related to function 1484
Scaffold 1484
Keratinocytes 1485
Fibroblasts 1485
Extracellular matrix 1485
Subcutaneous fat 1485
Components of the immune system 1486
Melanocytes 1486
Adnexal structures 1487

Commercial production of tissue-engineered skin products 1487
Regulation 1487
Product development 1487
Overall concept 1487
Allogeneic cell source 1488
Viability of product and avoidance of a final sterile fill 1488
Shelf life 1488
Size, user convenience 1489
The manufacture of Dermagraft and TransCyte 1489
Cells 1489
Medium 1489
Bioreactor design 1490
The Dermagraft and TransCyte production processes 1490
Release specifications 1491
Distribution and cryopreservation 1491
Problems with commercial culture for tissue engineering 1492
Clinical trials 1492
Immunological properties of tissue-engineered skin 1493
Commercial success 1494
Mechanism of action 1494
Future developments 1495
Conclusion 1496
References 1496

80. Tissue-engineered cartilage products 1499

Henning Madry

Introduction 1499
Cartilage defects, osteoarthritis, and reconstructive surgical options 1499
Cartilage defects pathophysiology 1499
Surgical treatment options for articular cartilage defects 1500
Tissue-engineered cartilage products for orthopedic reconstruction 1500
Cells for tissue-engineered cartilage repair 1500
Scaffolds for clinical tissue-engineered cartilage repair 1501
Collagen scaffolds 1501
Hyaluronan 1502
Synthetic polymers 1502
Agarose and alginate 1502
Scaffold-free three-dimensional systems 1502
Bioreactors for tissue-engineered cartilage repair 1502
Clinical nomenclature of scaffold-based techniques 1503
Clinical generations of autologous chondrocyte implantation 1503
Acellular, scaffold-based products 1503
Particulated autologous or allogenic articular cartilage 1503
Commercial autologous chondrocyte implantation products 1503
MACI (Vericel, Cambridge, MA, United States) 1503
ChondroCelect (TiGenix, Leuven, Belgium) 1504
Spherox (Co.don, Berlin, Germany) 1504
Novocart 3D (Tetec, Reutlingen, Germany) 1504
BioSeed C (Biotissue, Geneva, Switzerland) 1504
Novocart Inject (Tetec, Reutlingen, Germany) 1504
Chondron (Sewon Cellontech, Seoul, Korea) 1505
Cartipatch (Tissue Bank of France, Génie Tissulaire, Lyon, France) 1505
CARTISTEM (Medipost, Seongnam, Korea) 1505
Clinical application of autologous chondrocyte implantation in reconstructive articular cartilage surgery 1505
Indications for autologous chondrocyte implantation 1505
Contraindications 1505
Surgical steps 1506
Clinical results of autologous chondrocyte implantation 1506
Overview 1506
Data from prospective randomized clinical trials 1507
Long-term results of autologous chondrocyte implantation 1508
Clinical factors affecting the clinical outcomes of autologous chondrocyte implantation 1508
Conflict of interest 1509
References 1509

81. Bone tissue engineering 1511

Hani A. Awad, Regis J. O'Keefe and Jeremy J. Mao

Introduction 1511
Conventional bone tissue engineering strategies: cells, scaffolds, and biofactors 1511
Delivery of molecules and/or scaffolds to augment endogenous bone regeneration 1512
Biomaterials development and three-dimensional printing 1513
Clinical successes and opportunities in regenerative repair of craniofacial defects 1516
Conclusion 1517
Acknowledgments 1517
References 1517

82. Tissue-engineered cardiovascular products 1521

Doris A. Taylor, Camila Hochman-Mendez, Joern Huelsmann, Abdelmotagaly Elgalad and Luiz C. Sampaio

Clinical situation/reality **1521**
Considerations for tissue-engineered cardiovascular constructs **1521**
Components for tissue-engineered cardiovascular constructs **1521**
Cell sources 1521
Scaffolds 1524
Tissue-engineered cardiovascular constructs **1525**
Vascular grafts 1525
Valves 1526
Cardiac patches 1527
Building the next level of complexity: whole heart 1529
Pathway to approval and commercialization **1530**
Future perspectives **1532**
References **1532**

83. Tissue organoid models and applications 1537

Timothy S. Leach, Anthony Dominijanni, Sean V. Murphy and Anthony Atala

Introduction **1537**
Cell sources **1537**
Types of organoid models **1538**
Cardiac organoid **1539**
Liver organoid **1540**
Brain organoid **1540**
Lung organoid **1541**
Gastrointestinal tract organoid **1541**
Other organoid models **1542**
Applications **1542**
Tumor and disease models 1542
Drug analysis 1543
Organ-on-a-chip 1544
Developmental biology 1544
Conclusion **1545**
References **1545**

Part Twenty three
Regulation, commercialization and ethics 1551

84. The regulatory process from concept to market 1553

Kyung Eun Sung, Judith Arcidiacono, Donald W. Fink Jr., Andrea Gray, Johnny Lam, Winson Tang, Iwen Wu and Raj K. Puri

Introduction **1553**
Regulatory background **1553**
Overview of development and approval process **1554**
Early-stage development **1554**
Chemistry, manufacturing, and controls 1555
Pharmacology and toxicology 1555
Clinical 1556
US Food and Drug Administration/sponsor meetings **1557**
Submitting an investigational new drug application **1557**
Required US Food and Drug Administration forms 1557
Investigational new drug application contents 1558
US Food and Drug Administration review of an original investigational new drug application submission 1559
Later-stage development topics **1559**
Compliance with current good manufacturing practice 1559
Product readiness for Phase 3 1559
Potency assay 1560
Pharmacology and toxicology 1560
Phase 3 clinical development 1560
Combination products **1561**
Tissue-engineered and regenerative medicine products **1562**
3D bio-printed tissue-engineered/regenerative-medicine products 1563
Medical devices **1563**
Least burdensome principles 1563
Breakthrough device program 1563
Evaluation of devices used with regenerative medicine advanced therapy 1564
Expedited review programs **1564**
Other regulatory topics **1565**
Minimal manipulation and homologous use of human cells, tissues, and cellular and tissue-based products 1565
Clinical research involving children 1566
Expanded access to investigational drugs for treatment use 1566
Charging for investigational drugs under an investigational new drug application 1566
Responsibilities of sponsors and investigators 1566
Clinical research conducted outside of the United States 1568
Use of standards 1568
US Food and Drug Administration international regulatory activities 1568
The role of cell-based products in medical product testing 1568
Conclusion **1568**
Acknowledgments **1568**

Appendix I: Code of Federal Regulations citations relevant to cellular product development 1569
Appendix II: The list of acronyms 1569
References 1570

85. Business issues 1573

Matthew Vincent

Introduction 1573
The aging population 1573
Rise of regenerative medicine 1575
Product development 1577
Embryonic stem cells 1578
Induced pluripotent stem cells 1579
Direct reprogramming of differentiated cells 1580
Small molecule-induced differentiation 1580
Reimbursement 1580
Conclusion 1582
References 1582

86. Ethical issues 1585

Laurie Zoloth

Introduction 1585
Duty and healing: natural makers in a broken world 1587
To make is to know: notes on an old problem about knowledge 1587
What is a thing? The perils of deconstruction 1588
What contextual factors should be taken into account, and do any of these prevent the development and use of the technology? 1588
What purposes, techniques, or applications would be permissible and under what circumstances? 1589
On what procedures and structures, involving what policies, should decisions on appropriate techniques and uses be based? 1590
Conclusion 1590
References 1590
Index 1593

Preface

The first edition of *Principles of Tissue Engineering* was published almost a quarter-of-a-century ago—back in the 1990s when the term "tissue engineering" was first coined—and quickly became the most widely relevant and cited textbook in the field. Since that time there have been powerful developments, including breakthroughs at all stages of development, ranging from two Nobel Prizes for pioneering work in the area of stem cells, which could be used as an unlimited source of cells for repair and engineering of tissues and organs, to actual clinical therapies, ranging from skin and bladder replacement to cartilage, bone, and cardiovascular repair.

The fifth edition of "Principles" covers all of this tremendous progress as well as the latest advances in the biology and design of functional tissues and organs for repair and replacement, from mathematical models to clinical reality. We have also added Anthony Atala, the W.H. Boyce Professor and Director of the Wake Forest Institute for Regenerative Medicine, as a new editor and have expanded the book to include a new section on emerging technologies, including 3D bioprinting and biomanufacturing for tissue-engineering products. As in the previous editions, the book attempts to simultaneously connect the basic sciences with the potential application of tissue engineering to diseases affecting specific organ systems. While the fifth edition furnishes a much needed update of the rapid progress that has been achieved in the field in the last 6 years, we have retained the fundamentals of tissue engineering, as well as those facts and sections which, while not new, will assist scientists, clinicians, and students in understanding this exciting area of biology and medicine.

The fifth edition of "Principles" is divided into an introductory section, followed by 23 parts starting with the basic science of the field and moving upward into applications and clinical experience. The organization remains largely unchanged, combining the prerequisites for a general understanding of cellular differentiation and tissue growth and development, the tools and theoretical information needed to design tissues and organs, as well as a presentation by the world's experts of what is currently known about each specific organ system, including breast, endocrine and metabolism, ophthalmic, oral/dental applications, skin, and the cardiovascular, gastrointestinal, hematopoietic, kidney and genitourinary, musculoskeletal, nervous, and respiratory systems. We have again striven to create a comprehensive book that, on one hand, strikes a balance among the diversity of subjects that are related to tissue engineering, including biology, chemistry, material science, medicine, and engineering, while emphasizing those research areas that are likely to be of clinical value in the future.

While we cannot describe all of the new and updated material of the fifth edition, we continue to provide expanded coverage of stem cells, including neonatal, postnatal, embryonic, and induced pluripotent stem cells and progenitor populations that may soon lead to new tissue-engineering therapies for cardiovascular disease, diabetes, and a wide variety of other diseases that afflict humanity. This up-to-date coverage of stem cell biology and other emerging technologies is complemented by updated chapters on gene therapy, the regulatory process, and the challenges of tissue engineering for food and in vitro meat production, which someday may end up a routine part of our food system, potentially reducing environmental pollution and land use. As with previous editions, we believe the result is a comprehensive textbook that will be useful to students and experts alike.

Robert Lanza, Robert Langer, Joseph Vacanti and Anthony Atala

Chapter 1

Tissue engineering: current status and future perspectives

Prafulla K. Chandra, Shay Soker and Anthony Atala
Wake Forest Institute for Regenerative Medicine, Wake Forest University, Winston-Salem, NC, United States

Clinical need

Tissue and organ failure due to disease, injury, and developmental defects has become a major economical and healthcare concerns [1]. At present, use of donated tissues and organs is the clinical practice to address this situation. However, due to the shortage of organ donors, the increasing number of people on the transplant waiting lists, and an ever-increasing aging population, dependence on donated tissues and organs is not a practical approach. In addition, due to severe logistical constraints, many organs from donors cannot be matched, transported, and successfully transplanted into a patient within the very limited time available. In the United States alone, more than 113,000 people are on the National Transplant Waiting list and around 17,000 people have been waiting for more than 5 years for an organ transplant (US Department of Health and Human Services, Organ Procurement and Transplantation network; https://optn.transplant.hrsa.gov; data as of February, 2019). To address this critical medical need, tissue engineering (TE) has become a promising option. TE and regenerative medicine (RM) are multidisciplinary fields that combine knowledge and technologies from different fields such as biology, chemistry, engineering, medicine, pharmaceutical, and material science to develop therapies and products for repair or replacement of damaged tissues and organs [2,3].

The process of TE is multistep and involves engineering of different components that will be combined to generate the desired neo-tissue or organ (Fig. 1.1). Today, this field has advanced so much that it is being used to develop therapies for patients that have severe chronic disease affecting major organs such as the kidney, heart, and liver. For example, in the United States alone, around 5.7 million people are suffering from congestive heart failure [5], and around 17.9 million people die or cardiovascular diseases globally (World Health Organization data on Cardiovascular disease; https://www.who.int/cardiovascular_diseases/en/). TE can help such patients by providing healthy engineered tissues (and possibly whole organ in future) to replace their diseased tissue for restoring function. For example, chronic kidney disease (CKD) is a worldwide health crisis that can be treated, but it also depends on organ donation. In the United States alone, around 30 million people are suffering from CKD (Center for Disease Control & Prevention; National Chronic Kidney Disease Fact Sheet 2017; https://www.cdc.gov/kidneydisease/pdf/kidney factsheet), while close to 10% of the population is affected worldwide. Liver disease is another healthcare problem, which is responsible for approximately 2 million deaths per year worldwide [6]. Other diseases or conditions that can benefit from TE technologies include skin burns, bone defects, nervous system repair, craniofacial reconstruction, cornea replacement, volumetric muscle loss, cartilage repair, vascular disease, pulmonary disease, gastrointestinal tissue repair, genitourinary tissue repair, and cosmetic procedures. The field of TE, with its goal and promise of providing bioengineered, functional tissues, and organs for repair or replacement could transform clinical medicine in the coming years.

Current state of the field

TE has seen continuous evolution since the past two decades. It has also seen assimilating of knowledge and technical advancements from related fields such as material science, rapid prototyping, nanotechnology, cell biology, and developmental biology. Specific advancements that have benefited TE as a field in recent years include novel

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00004-6

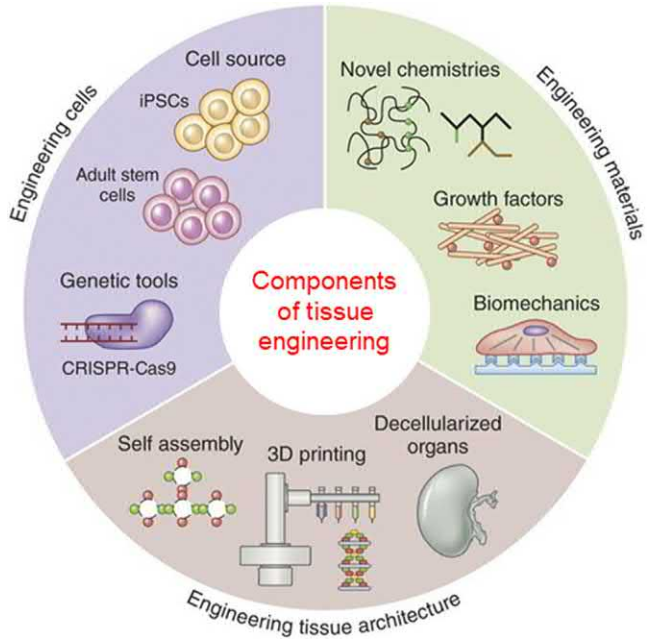

FIGURE 1.1 Schematic representation of different aspects of tissue engineering. Each component (materials, cells, and tissue architectures) can be engineered separately or in combination to achieve the therapeutic goals. *Reprinted with permission from Khademhosseini A., Langer R. A decade of progress in tissue engineering. Nat Protoc 2016;11 (10):1775–81. doi: 10.1038/nprot.2016.123 [4]. ©2016 Springer Nature Publishing AG.*

biomaterials [7], three-dimensional (3D) bioprinting technologies [8], integration of nanotechnology [9], stem-cell technologies such as induced pluripotent stem cells (iPSCs) [9,10], and gene editing technology such as Clustered Regularly Interspaced Short Palindromic Repeats (CRISPR) [11]. All these have led to promising developments in the field that include smart biomaterials, organoids, and 3D tissue for disease modeling and drug development, whole organ engineering, precise control and manipulation of cells and their environments, and personalized TE therapies.

Biomaterials are critical components of many current TE strategies. Recent developments in this field that are benefiting TE include synthesis of new biomaterials that can respond to their local environment and cues (smart biomaterials). Advancements in 3D bioprinting technologies are at the core of many developments in TE. It is now possible to print multiple biocompatible materials (both natural and synthetic), cells, and growth factors together into complex 3D tissues, many with functional vascular networks, which match their counterparts in vivo. We have also learned a great deal about cell sourcing, culture, expansion, and control of differentiation. This is also true for stem cells, where new sources such as placenta, amniotic fluid, and iPSCs have been explored and optimized for use. Vascularization and innervation in bioengineered tissue is a continuing challenge essential to warrant sustained efforts success of tissues implanted in vivo would be very low. Therefore there is a need for greater understanding of vascularization and innervation as applied to bioengineered tissues. This is an ongoing effort, and the results we are seeing from various studies are encouraging. Biofabrication technologies are playing a great role in this regards.

Several engineered tissues are moving toward clinical translation or are already being used in patients. These include cartilage, bone, skin, bladder, vascular grafts, cardiac tissues, etc. [12]. Although, complex tissues such as liver, lung, kidney, and heart have been recreated in the lab and are being tested in animals, their clinical translation still has many challenges to overcome. For in vitro use, miniature versions of tissues called organoids are being created and used for research in disease modeling, drug screening, and drug development. They are also being applied in a diagnostic format called organ-on-a-chip or body-on-a-chip, which can also be used for the above stated applications. Indeed, the development of 3D tissue models that closely resemble in vivo tissue structure and physiology are revolutionizing our understanding of diseases such as cancer and Alzheimer and can also accelerate development of new and improved therapies for multiple diseases and disorders. This approach is also expected to drastically reduce the number of animals that are currently being used for testing and research. In addition, 3D tissue models and organ-on-a-chip or body-on-a-chip platforms can support advancement of personalized medicine by offering patient-specific information on the effects of drugs, therapies, environmental factors, etc.

Development of advanced bioreactors represent another recent developments that are supporting clinical translation of TE technologies. Such bioreactors can better mimic in vivo environments by provide physical and biochemical control of regulatory signals to cells and tissue being cultured. Examples of such control include application of mechanical forces, control of electrical pacing, dynamic culture components, induction of cell differentiation. Incorporation of advanced sensors and imaging capabilities within these bioreactors are also allowing for real-time monitoring of culture parameters such as pH, oxygen consumption, cell proliferation, and factor secretion from a growing tissue. 3D modeling is also a new tool relevant to TE that provides great opportunities and better productivity for translational research, with wide clinical applicability [13]. Recent advancements in specific field that are helping advance TE are discussed next.

Smart biomaterials

Smart biomaterials are biomaterials that can be designed to modulate their physical, chemical, and mechanical

properties in response to changes in external stimuli or local physiological environment (Fig. 1.2) [14,15]. Advances in polymer synthesis, protein engineering, molecular self-assembly, and microfabrication technologies have made producing these next-generation biomaterials possible. These biomaterials can respond to a variety of physical, chemical, and biological cues such as temperature, sound, light, humidity, redox potential, pH, and enzyme activity [16,17]. Other unique characteristics displayed by some smart biomaterials are self-healing or shape-memory behavior [18]. The development of biomaterials with highly tunable properties has been driven by the desire to replicate the structure and function of extracellular matrix (ECM). Such materials can enable control of chemical and mechanical properties of the engineered tissue, including stiffness, porosity, cell attachment sites, and water uptake. For hydrogels, use of reversible cross-linking through physical methods, self-assembly, or thermally induced polymer chain entanglement is creating hydrogels that undergo structural changes in response to external stimuli [19,20]. Another class of hydrogels that are recent developments is called self-healing and shear thinning hydrogels. These materials are now being used to develop injectable biomaterials, which have low viscosity during application (injection) due to shear thinning and once at their target site, they self-crosslink (or heal) to fill the defect site [21]. Injectable biomaterials are also often loaded with drugs, biologics, and cells. For example, Montgomery et al. created an injectable shape-memory biomaterial for minimally invasive delivery of functional tissues [22]. In other applications, tissue glues are being developed using smart biomaterials, where they are used to bond and allow the tissue to self-heal. An example of this approach is a study by Bhagat and Becker

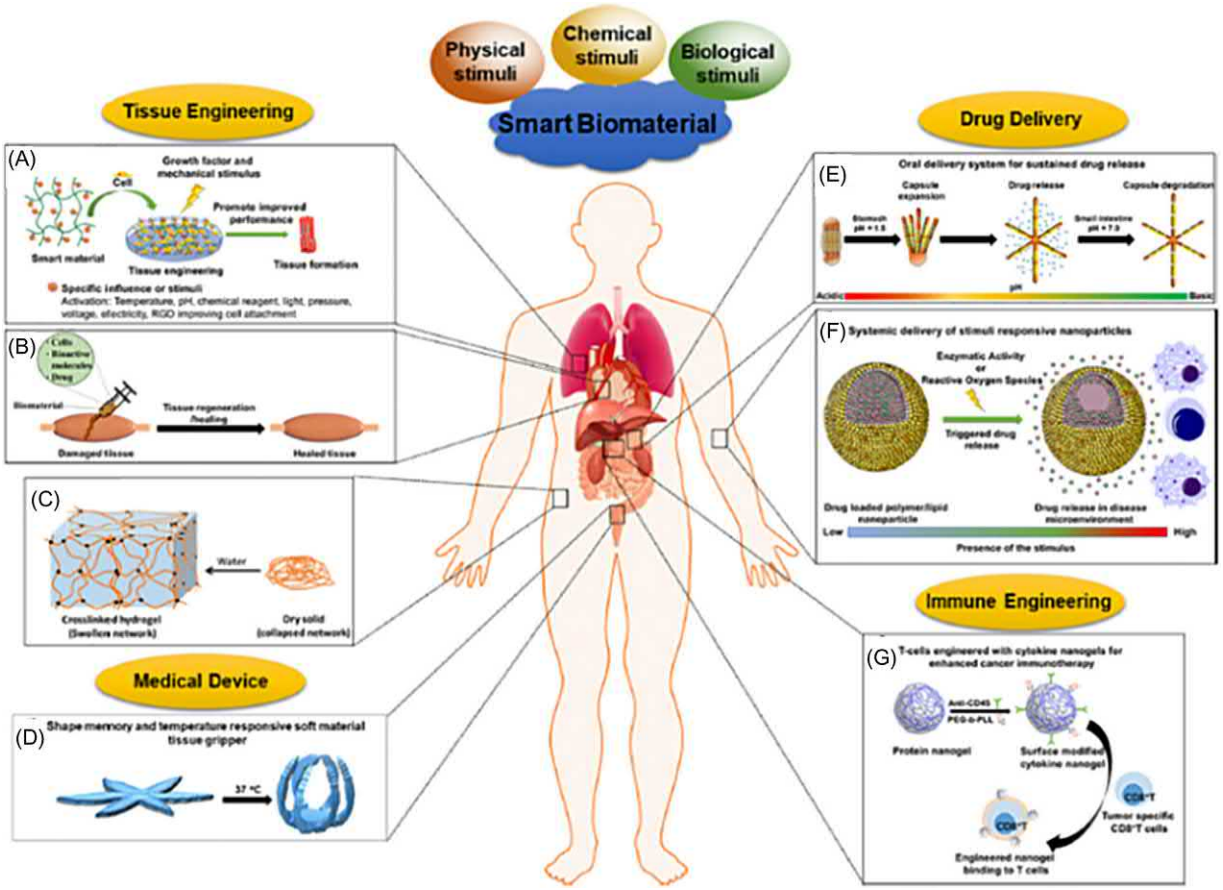

FIGURE 1.2 Different applications of smart biomaterials in the fields of tissue engineering and related fields. (A) Stimuli-responsive material that can promote cell differentiation and tissue growth; (B) injectable biomaterial loaded with cells, drugs, or bioactive molecules can be delivered less-invasively and can promote healing of tissue at the target damage site; (C) swelling polymer can be delivered as small scaffolds but can expand in vivo to achieve 3D structure of the target defect after exposure to water; (D) shape-memory and temperature-responsive soft material can be used as a tissue adhesive; (E) star-shaped delivery system for sustained drug release in the gastrointestinal tract; (F) nanoparticle-based stimuli-responsive drug delivery system for systemic application; (G) materials for enhanced cancer immunotherapy using targeted delivery of chimeric antigen receptor T cell. *3D*, Three-dimensional. *Reprinted with permission from Kowlaski PS, Bhattacharya C, Afewerki S, Langer R. who created a chondroitin-based tissue glue that helps direct improved tissue repair [23].

The ECM is a complex and dynamic structural scaffold for cells within tissues and plays an important role in regulating cell function [1]. Given the role of the ECM in structural support of tissues, there has been significant effort in developing ECM-based scaffolds for TE and RM [24,25]. However, as with all materials implanted into the body, the immune response significantly influences the ability of scaffold-containing engineered tissues to integrate and functionally interact with the host [26]. Thus an emerging strategy in TE is to design materials that can directly control the host immune response [27]. For example, the Arg-Gly-Asp (RGD) of ECM proteins can exert immunomodulatory effects on both innate and adaptive immune cells while also having an inhibitory effect on phagocytosis and neutrophil chemotaxis [28]. In the context of TE, synthetic ECM-mimetic hydrogels containing the RGD sequence have been shown to cause increased cellular adhesion on polymer scaffolds and also have an antiinflammatory effects from macrophages [29,30]. Under certain conditions, the RGD peptides have also been found to effect cytokine secretion from T cells [31]. Therefore use of RGD as part of TE scaffolds or hydrogels can be used to enhance cells adhesion in addition to controlling the ability of macrophages to degrade and remodel the surrounding tissue environment.

Matrix metalloproteinases (MMPs) are a family of proteases that not only selective degrade a wide variety of ECM proteins but also interact with bioactive molecules, some of which have immunomodulatory effects [32,33]. So, another strategy to control the extent of matrix remodeling, integration of engineered tissues into native host tissues or invasion of immune cell into implanted materials could be by incorporating MMP-sensitive peptides into the TE constructs. Examples of this approach include studies by Patterson and Hubbell, who showed that the rate of scaffold material degradation depends on the MMP-sensitive peptide sequence, the type of MMP, and also the MMP concentrations [34]. In a separate study, West and Hubbell created biomimetic poly(ethylene glycol) (PEG) hydrogels that incorporated peptides that could be degraded by either a fibrinolytic protease (plasmin) or a fibroblast collagenase (MMP-1) [35,36]. One drawback of this using MMP-sensitive peptides in TE constructs is their immunogenicity and more work will be needed to get around this issue. Possibly, use of immunomodulatory domains along with MMP-sensitive peptides could support long-term viability and integration within native host tissues.

Another category of smart biomaterials is multidomain peptides (MDPs) hydrogels. These are injectable ECM mimetic materials that are engineered to form self-assembling meshes at the target site [37,38]. These MDPs can also control cellular behavior. For example, in a mouse study by Moore et al., MDPs alone were found to be biocompatible and had prohealing effects in vivo [39]. Hydrogel have also been prepared from multiple ECM mimetic peptides for the purpose of enhancing the viability of the biomaterial in vivo. Smart biomaterials are going to have a big impact on 3D printing of tissues and organs. By combining smart biomaterials with 3D bioprinting, a wide variety of architectures can be created which can further offer control over how these materials perform in a biological environments. Smart biomaterials can also be made from proteins. Some protein−protein interactions can be utilized to physically crosslink protein chains, while small coiled-coil domains within some proteins (called leucine zippers) can self-assemble into superhelical structures. Leucine zippers have been used to make hydrogels by physically crosslinking protein domains [40]. The stability of the leucine zipper self-assembly (and hence the hydrogel) can be controlled by changing the temperature. Another way to control the stability of some protein-based hydrogels is by arrangement of the interacting domains [41].

One drawback of hydrogels made of self-interacting protein domains is their low-to-moderate mechanical properties, which is not ideal for TE applications. However, these week interactions can be reinforced by introducing covalent bonds into the network (e.g., disulfide bonds between cysteine in the protein chains). This will not only improve the mechanical properties of the hydrogel but also its stability [42].

Cell sources

For TE, a variety of cell types are now being used. They include autologous, allogeneic, progenitors, adult unipotent or multipotent stem cells and iPSCs (Fig. 1.3). For some applications, the ability to expand a sufficient number of autologous cells from a small biopsy is well-established [44]. A good example is bladder augmentation, where smooth muscle and urothelium can be easily isolated from then native tissue, expanded in culture and used for engineering a new bladder tissue. However, in many cases, it is challenging to harvest and/or expand enough appropriate autologous cells for this purpose. Examples of such cell types include hepatocytes, kidney cells, insulin-producing pancreatic beta cells, cardiomyocytes, neurons. New sources or methods to obtain these cell types in quantities can advance engineering of these tissues/organs and significantly benefit treatment of associated diseases. Immature precursor cells present within tissue such as skin, cartilage, muscle, and bladder are essential for the expansion of corresponding cells from biopsies and enabling engineering of neo-tissues [45]. The extension of this approach to other tissue and organ

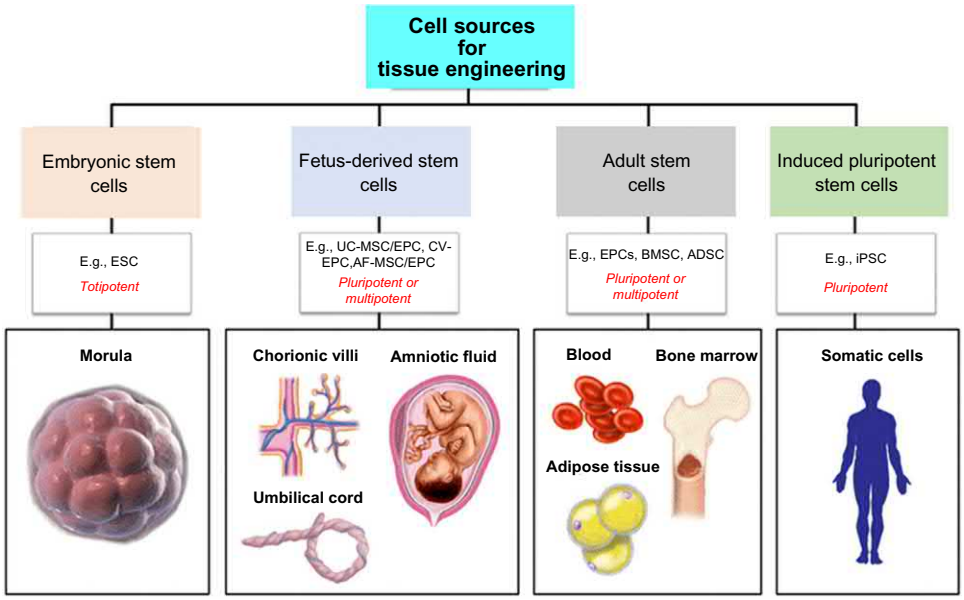

FIGURE 1.3 Different sources of cells for tissue engineering. Fetus-derived and induced pluripotent stem cells are gaining more attention for tissue engineering applications. *Reprinted from Al-Himdani S, Jessop ZM, Al-Sabah A, Combellack E, Ibrahim A, Doak SH, et al. systems will depend greatly on finding sources of appropriate stem and progenitor cells.

Three major stem-cell sources are currently under intensive investigation:

1. embryonic stem (ES) cells, which are derived from discarded human embryos, and the equivalent embryonic germ (EG) cells;
2. iPSCs derived by genetic reprograming of somatic cells; and
3. Autologous or allogeneic adult tissue stem cells (sourced from fetal, neonatal, pediatric, or adult donor tissue).

Shared features of all stem cells include their capacity self-renewal and their ability to give rise to particular classes of differentiated cells. The ES, EG, and iPSCs can serve as precursors for many specialized cell type found during normal development and therefore are pluripotent. Adult stem cells are generally restricted to limited sets of cell lineages, hence called unipotent (constrained to a single fate) or multipotent (can give rise to multiple cell types). It appears likely that multiple tissue-engineered products based on each class of stem-cell source will be tested in the clinic in the coming years. Previous clinical and commercial experience sheds light on key differences between personalized products containing autologous cells and off-the-shelf products containing allogeneic cells. The vast majority of human studies till date have focused on using either adult stem or progenitor cells. More recently, clinical trials have begun with tissue-engineered products derived from pluripotent stem cells and their future looks promising.

The first clinical tissue-engineered products to achieve marketing approval from the US Food and Drug Administration (FDA) were skin substitutes that were used for wound healing. Examples of such products include Dermagraft (Shire Regenerative Medicine Inc., CT, United States) and Apligraf (Organogenesis, MA, United States), which were off-the-shelf products that used cells (fibroblasts for Dermagraft and fibroblasts plus keratinocytes for Apligraf) expanded from donated human foreskins. Whereas fibroblasts have been cultured in vitro since the early 20th century, the successful large-scale culture of human keratinocytes represented an important breakthrough for RM [46]. The success of off-the-shelf skin substitutes can be attributed to the lack of antigen-presenting cells, because of which they were not acutely rejected despite the inevitable histocompatibility mismatches between donors and recipients [47,48]. Eventually, the cells in the skin substitutes could be rejected, but the grafts has enough time for patients' own skin cells to regenerate. This stands in contrast to standard tissue/organ transplantation in which immune rejection is a major concern and immunosuppressive drug therapy is generally part of the application of allogeneic grafts [49]. Tissue-engineered products based on harvesting and expanding autologous cells containing stem and/or progenitor populations have also been developed successfully. Prominent examples include Epicel (Genzyme, MA, United States), a permanent skin replacement product based on expanded keratinocytes for patients with life-threatening burns, and Carticel (Genzyme, MA, United States), a chondrocyte-based treatment for large articular cartilage lesions [50,51].

Embryonic stem cells

ES cells and EG cells are indeed quite similar to early germ cells, with an apparently unlimited self-renewal capacity and pluripotency. Their great degree of plasticity represents both a strongest virtue and a significant potential limitation to their use in TE. A major ongoing challenge is in efficiently obtaining pure populations of specific desired specialized cell types from human ES cells [52,53]. Efforts during recent years have yielded more robust methods to isolate and grow ES cells under conditions consistent with Good Manufacturing Practice (GMP) and to generate differentiated cell products. While initial efforts have focused on cell therapies, these advances will positively impact production of tissue-engineered constructs using ES cells. Human ES cells are considerably more difficult to isolate and maintain stably in culture than the cell types that have previously been used in clinical testing. However, they can now be derived, grown, and cryopreserved without exposure to nonhuman cells or proteins, even under a GMP environment [54,55]. In the future, use of bioreactors, microcarriers, along with improved xeno-free and serum-free media and possibly small molecules that inhibit spontaneous differentiation of these cells would facilitate expansion of these stem cells to population sizes that are normally required for product development and clinical application [56,57].

Human tissues include more than 200 distinct cell types, and ES cells, in principle, can give rise to all of them. The historical approach of allowing ES cells to differentiate spontaneously has now been supplanted. Current strategies employ staged differentiation guided by knowledge of signaling events that regulate normal embryonic development [58]. For example, fine tuning of the exposure of early embryonic cells to the growth factor Nodal (a member of the transforming growth factor beta or TGF-β family) or its analog Activin A, in conjunction with other growth factors or small molecules, can now allow consistent generation of endoderm-specific cells from ES cells in vitro [59,60]. This is an early, but key milestone in a multistep process to generate differentiated cells that can eventually be used for TE of tissues/organs like the liver and pancreas. Conversely, inhibition of Nodal/Activin signaling favors the production of ectoderm specific cells, a precursor for neural lineage cells [61].

Despite substantial challenges, the first ES-cell-derived therapeutic product to enter clinical trials was the human ES-cell-derived oligodendrocyte progenitors (Geron Corporation; CA, United States) for stimulating nerve process growth in subjects with spinal cord injury [62]. Similarly, ES-cell-derived retinal pigment epithelium cells (Advanced Cell Technology, now Astellas Institute for Regenerative Medicine; CA, United States) were used in clinical trials in patients to treat Stargardt's macular dystrophy and dry age-related macular degeneration. Encouraging results from such clinical studies using ES cell-derived product will have a positive impact to develop tissue-engineered products from pluripotent stem cells in the near future. Areas of clear unmet medical need that might benefit from stem-cell-derived products include type 1 diabetes and Parkinson's disease. For type 1 diabetes, research at a biotech company called Viacyte Inc. (CA, United States) similarly pursued the produced progenitors of pancreatic endocrine cells from human ES cells using growth factors and hormones [63]. The progenitor cells from the final-stage differentiation in vitro were able to mature further in vivo to yield glucose-responsive β-like cells [64]. As a potential therapy for Parkinson's disease, significant advances have been made in the production of functional midbrain dopaminergic neurons by staged differentiation from ES cells [65,66]. Studies in the past few years have demonstrated that efficient grafting of these cells can lead to physiological correction of symptoms in several animal models, including nonhuman primates [67]. A particular safety concern is that undifferentiated pluripotent ES and iPS cells form teratomas in vivo. The risk of tumorigenicity makes it essential to rigorously determine the residual level of undifferentiated stem-cell population in any therapeutic product derived from ES or iPS cells [68]. It will also be valuable to determine whether a small number of undifferentiated pluripotent stem cells can be introduced into human patients without significant risk of tumor growth and if this threshold is influenced by use of immune suppressive drugs during treatment.

Induced pluripotent stem cells

Theoretically, the development of iPSCs represent the most direct way to ensure immune compatibility of tissue-engineered products when the recipient themselves serve as the donor. Generation of iPSCs through reprograming of mature somatic cells to a pluripotent state was first accomplished by ectopic expression of four transcription factors: OCT4 and SOX2, both with KLF4 and c-MYC [69] or NANOG and LIN28 [70]. The resulting iPSCs closely resembled ES cells in key properties such as the capacity for extensive self-renewal, ability to differentiate to multiple cell lineages, and generation of teratomas in vivo. Initial studies on reprograming of fibroblasts soon were extended to a variety of other cell types such as peripheral blood cells [71], cord blood cells [72], keratinocytes from hair shafts [73], and urine-derived cells [74]. Many recent developments have advanced this reprograming technology toward a safer, efficient translation toward therapeutic products. Also,

improved methods to deliver the pluripotency factors can minimize the risk of unintended permanent genetic modification of iPSCs, particularly integration of an oncogene such as c-*MYC* and thereby decrease the potential for future tumorigenicity [75]. One approach is being pursued for this is to transiently deliver the factors using various nonintegrating viral or plasmid vector systems. Reprograming also can be achieved by direct delivery of either synthetic messenger RNA (mRNA) encoding the pluripotency factors or of the protein factors themselves [76].

A recent development in the cellular reprograming field has centered on efforts to bypass the circuitous route of resetting cells to a pluripotent ground state and then inducing them to a desired lineage. Instead, there are efforts to achieve directed "trans-differentiation" between cell lineages. A number of studies have reported that fibroblasts or other adult cells can potentially be reprogramed directly to various specialized cell types such as neural progenitors [77], cardiomyocytes [78], endothelial cells [79], and hepatocytes [80]. However, there are still many queries about direct lineage-to-lineage reprogramming must be addressed. Some of these include the following questions: do the differentiated cells accurately mimic the genetic and functional characteristics of the target cells, or is there residual signatures of the original cells? Do the differentiated cells display fully adult phenotypes? Is the risk of introducing unwanted genetic or epigenetic abnormalities less or greater than in reprogramming through a pluripotent state? The answers to these questions will clarify the value of direct cell lineage conversions and the future of this approach for TE and RM applications.

Adult stem cells

Despite the promise of ES and iPSCs for TE and RM, the challenges of controlling lineage-specific differentiation, eliminating residual pluripotent stem cells, and confirming the safety and phenotype accuracy of then final products will likely delay the clinical translation and regulatory approval of such products. By contrast, adult stem cells represent a more straight-forward approach to rapid clinical development of cell-based and tissue-engineered products. Adult stem cells are present in many tissues throughout fetal development and postnatal life and are committed to restricted cell lineages [81,82]. Also, intrinsically they are not tumorigenic. At present, the most commonly used adult stem cells for development of cell therapy and TE applications are bone marrow-derived mesenchymal stromal or stem cells (MSC). MSCs can give rise to a number of tissue types, including cartilage, bone, adipose, and some types of muscle [83]. MSC have also generated considerable interest for musculoskeletal and vascular TE [84,85]. An advantage of using MSCs is that they can be easily harvested from liposuction specimens. An unexpected discovery that is further benefitting the use of MSCs for RM is then observation that they can be readily transplanted into allogeneic recipients without significant immune rejection [86]. This ability to avoid acute immune rejection in the host results from a variety of mechanisms, most notably the secretion of antiinflammatory cytokines [87]. Recent clinical trials have also assessed MSC-based cell therapy to treat graft versus host disease (GvHD) and various inflammatory or autoimmune conditions [88,89]. In fact, the first regulatory approvals for sale of a bone marrow-derived MSC product (Prochymal; Osiris Therapeutics; MD, United States) was for treatment of GvHD.

The therapeutic benefits of MSCs can also be through secretion of trophic factors. This has been seen in MSC-based cell therapy for heart disease, where delivery of autologous or allogeneic cells into the left ventricle wall for treatment of ischemic cardiomyopathy in a large animal model or even human clinical trials showed induction of new cardiomyocytes from endogenous cardiac stem and progenitor cells through trophic effects [90]. The injected MSCs also apparently contribute to positive remodeling of damaged heart tissue long after the initial damage [91]. Another study has demonstrated that combined delivery of MSCs with adult cardiac stem cells can substantially improves outcomes in the porcine model of ischemic cardiomyopathy [92]. This interesting result can be translated to generating improved tissue-engineered cardiac constructs by incorporating both the above stem cell types. Treatment of neurodegenerative conditions remains a challenge. Several years ago a company called Stem Cells Inc. (CA, United States) carried out clinical studies using a brain-derived neural stem-cell preparation called human central nervous system stem cells (HuCNS-SC), in a handful of subjects with neurological degenerative conditions referred to as neuronal lipoid fuscinosis (Batten's Disease) and Pelizaeus–Merzbacher disease [93]. Study data, including magnetic resonance imaging (MRI), demonstrated the durable engraftment of these cells and suggested that they contributed to myelination in recipient's brain tissue. The same company later began clinical trials using the same neural-derived stem cell in human subjects with dry age-related macular degeneration and spinal cord injuries.

Hepatic stem cells (HpSC) represent another human adult stem-cell population that can gives rise to parenchymal cells within tissues and organs [94]. The HpSCs are isolated from the liver and can be enriched from cadaveric fetal, neonatal, or fully mature donors by selection with a monoclonal antibody to the surface marker CD326. Exposure to certain growth factors (such as epidermal growth factor or EGF) or different tissue-specific matrix

molecules (such as liver proteoglycans) can induce efficient differentiation of the HpSC to either hepatocytes or cholangiocytes (bile duct cells) [95]. An early clinical study for the assessment of CD326-positive hepatic stem and progenitor cells on 25 subjects with decompensated liver cirrhosis found that delivery of these cells to the liver was best achieved by infusion via the hepatic artery. Also, at 6 months postinfusion, improvements in a number of clinical parameters were noted, including a significant decrease in the mean Mayo End-stage Liver Disease score ($P < .01$).

Another clinical study with HpSC transplantation achieved encouraging results using allogeneic donors, no human leukocyte antigen (HLA) loci matching, and without the use of immune suppressive drugs [94]. It is conceivable that HpSC (and possibly other fetal liver-derived stem cells) are particularly nonimmunogenic because they express only low levels of major histocompatibility complex (MHC) Class I and lack detectable MHC Class II (similar to ES cells). In addition, the liver is significantly immune privileged with respect to transplant rejection. Another hypothesis for this immune privilege could be that since this particular HpSC population were are isolated by immune-selection using antibody-coated beads specific for CD326, some angioblast-like mesenchymal cells could have copurified. Angioblast-like mesenchymal cells, just like MSC, are known to secrete immunomodulatory factors that could protect the HpSC and differentiated cells derived from them against immune rejection in the liver.

A new source of human adult stem-cell population, which can be used for engineering of pancreatic islet−like structures to treat insulin-dependent diabetes, was identified in peribiliary glands (found in the extrahepatic biliary tree located between the liver and pancreas) [95,96]. Molecular characterization of these biliary tree stem cells suggests that they comprise a population of endodermal stem cells that are more primitive than HpSC identified within the liver. Some of these biliary tree stem cells do not express CD326 but appear to be precursors of the CD326-positive HpSC. The biliary tree stem cells can proliferate extensively when cultured in the serum-free defined medium developed for HpSC.

Whole organ engineering

Tissue and organ failure is currently one of the biggest health issues, whose treatment is still an unmet medical need. This problem is ever increasing, with more than 100,000 patients being on the organ donor waiting lists in the United States alone [97]. Lack of sufficient organ donors and availability of healthy tissues and organs are further complicating this situation. TE is providing hope in this direction, with many efforts directed toward bioengineering tissues and even whole organs [98]. Decellularized tissues are gaining popularity as scaffolds for TE. These are prepared by removing cells from original tissues using mild detergents [99], after which they can be processed into different forms such as blocks, or powder for use. These decellularized materials represent the ECM of tissue from which they are derived and consist mainly of collagen. Since the shape, size, and complex structural properties of the native tissue are also maintained, decellularized tissue represent the ideal scaffolds for TE.

Decellularization can be performed using chemical, physical/ mechanical, or combination methods. Chemical methods include use of mild surfactants such as sodium dodecyl sulfate (SDS), sodium deoxycholate, 3-[(3-cholamidopropyl) dimethylammonio]-1-propanesulfonate, Triton X-100, tridecylalcohol ethoxylate, and acid/bases such as per-acetic acid [100]. Physical/mechanical methods for decellularization are used in situations where there are concerns regarding the possible toxicity of the chemicals and nondesirable destruction of ECM proteins. Physical/mechanical treatments include the use of high hydrostatic pressure, freeze−thaw, or super-critical carbon dioxide (CO_2). The decellularization strategy is being used for TE to treat hernia repair [98,101], periodontal tissue [102], tendon [103], bone [104], vasculature [105], uterine tissue [106], heart valves [107], etc. Recent advancements in decellularized tissue research have resulted in successful decellularization of whole organs for whole organ reconstruction. Examples include liver [108], kidney [109], lung [110], and heart [111].

Clinical applications of decellularized ECM-based scaffolds are also on the rise. However, they have been limited to engineering of less complex tissues related to structural or reconstructive applications. It is noteworthy that many of the FDA-approved products on the market are derived from xenogeneic or allogeneic decellularized tissue ECM. Examples include SynerGraft for repair of human pulmonary heart valve (CryoLife; GA, United States), AlloDerm Regenerative Tissue Matrix (human dermal graft; LifeCell Corp, now Allergen, NJ, United States), and Meso BioMatrix Surgical Mesh (DSM Biomedical; PA, United States). Clinical trials have also been carried out using more complex structures made from decellularized ECM-scaffolds. One examples is a tissue-engineered trachea [112], which had long-term patency (at least 5 years posttransplantation), was completely cellularized and vascularized and did not provoke a significant immunogenic response [113].

Sometimes, the decellularization process can damage certain critical components needed for new tissue formation, such as endothelial basement membrane of the vasculature. In such cases, a practical strategy would be to add synthetic materials to promote functions. For

example, some researchers have used the immobilization of anticoagulants, such as peptides [114] or heparin [115], to the endothelium of the decellularized vessel to prevent blood coagulation inside the blood vessels during the regeneration process. A new avenue in decellularized tissue research is use of a device that links native tissues to synthetic materials. Here the decellularized tissue acts as an intermediate material, and then linking device ensures compatibility between the native tissue and synthetic materials at the molecular level. An example for this approach preparation of a decellularized skin dermis and poly(methyl methacrylate) (PMMA) complex by immersing the decellularized dermis in methyl methacrylate monomers, followed by polymerization [116]. Testing showed that this composite elasticity similar to the skin dermis, while the compressive modulus value was between that of the dermis and PMMA.

Biofabrication technologies

Biofabrication combines the principles of engineering, material science, and biology. It is a great toolbox that promise to change the outcome of many biomedical disciplines, particularly TE and RM. In addition, it also holds great potential for development of physiological 3D in vitro models, where complex tissue constructs are created that have a high degree of structural and functional similarities to native tissues. For TE, the most commonly used biofabrication technologies include (1) electrospinning; (2) drop-on-demand technologies such as ink-jet 3D bioprinting; (3) fused deposition modeling technologies such as extrusion-based 3D bioprinting; and (4) light-based technologies such as stereolithography (SLA) and laser-assisted bioprinting [117] (Fig. 1.4). Recent trends in electrospinning, inkjet printing, and extrusion-based 3D bioprinting are discussed next:

Electrospinning

Electrospinning refers to a technique for fabricating fibrous scaffolds [121] (Fig. 1.4B). The advantages of electrospinning as a scaffold fabrication technique include simple setup, versatility, and relative low-cost, which has supported use in TE applications, from skin grafts to vascular grafts to drug delivery devices [122–125]. For TE, a wide range of fiber architectures have been created, from scaffolds with uniform fibers to fibers with gradient properties, fibers with core–shell morphology, and scaffolds with patterned fiber depositions [126,127]. This has enabled researchers to create complex TE strategies to better mimic in vivo tissue structure and function. In spite of the several advantages of electrospun fibers and their scaffolds, one inherent limitation is the relatively poor cellular infiltration into the depth of these scaffold. This can happen due to high-fiber packing densities resulting in small and uneven pore sizes. Recent approaches in the field of electrospinning that have tried to address these limitations and expand the use of electrospun scaffolds in TE include use of postprocessing procedures and sacrificial components [128,129]. Some recent developments in electrospinning include modification of the electrospinning setup, new electrospinning processes, and new methods to achieve complex mesh composition and architectures (Table 1.1).

Modification of the electrospinning setup have been carried out to provide better fiber orientation, control of fiber blending or cospinning, and targeted fiber collection. Examples include use of a rotating mandrel [130], gap electrospinning [131], and magnetic electrospinning [132,133]. The description of these methods and their specific advantages are listed in Table 1.1. In the past decade, a variety of new electrospinning processes have been developed with the aim of generating more varied and complex fiber geometries. Prominent among these methods are coaxial electrospinning [134], fiber blending [135,136], emulsion electrospinning [137,138], and edge electrospinning [139,140]. The description of the new electrospinning processes and specific advantages of each are listed in Table 1.1. In coaxial electrospinning, since the fiber generation process occurs rapidly, there is no possibility of any mixing of the core and shell polymers. Examples of electrospinning using fiber blending include creation of a polyurethane (PU)-gelatin bicomponent fibrous scaffold for wound dressing applications [146] and formation of an RGD peptide cell-adhesive gradient through the depths of a scaffold to direct cellular migration [147]. Fiber blending represents a future area of advancement for electrospinning and its use in creating more in vivo–like scaffolds.

Emulsion electrospinning is mainly used for delivery applications, where drugs, enzymes, growth factors, etc., are often emulsified within hydrophobic polymers, so that their bioactivity is retained and sustained release can be achieved [137,138]. To address the issue of speed (electrospinning is a slow process), a method called edge electrospinning [139,140] has been developed. An examples is a study by Thoppey et al. who used edge electrospinning of polycaprolactone and saw an increase in the production rate by about 40 folds [140]. New electrospinning methods that have been designed to achieve complex mesh composition and architectures include coelectrospinning [141.142], hydrospinning [143], and 3D electrospinning [144,145]. One example of coelectrospinning is when a natural polymer is used along with a synthetic polymer, the cellular behavior and the mechanical properties of the resulting scaffold can be independently controlled by altering the weight ratio of each material [142]. Examples of hydrospinning include a study where

scaffolds with high porosity were created that allowed for better cellular infiltration [143] and another where anisotropic scaffolds with layers that altered in alignment were created for better tendon TE [148]. Examples of 3D electrospinning include fabrication of interconnected tubes with different structures and patterns [144] and reconstruction of outer ear using an ear-shaped collector to generate the scaffolds [145]. Achieving optimum cellular infiltration within electrospun scaffolds has been a challenge and an intrinsic limitation of the electrospinning method. A variety of methods that are being developed to improve cellular infiltration and direct their behavior within electrospun scaffolds include variations of the electrospinning process (as discussed above), use of postprocessing procedures, and incorporation of biochemical cues.

Another way to decrease packing density and increase pore size within electrospun scaffolds is by using sacrificial components during coelectrospinning [149,150]. After fabrication, the sacrificial component is removed by treating the scaffold with an aqueous solution. Postelectrospinning processing (postprocessing) of the scaffolds is another practical way to enhance cellular penetration. Postprocessing methods include use of laser ablation to pattern pores into the scaffold [151], use of a metal comb to separate fibers after the electrospinning [152], and used of ultrasonic energy to mechanically agitate fibers immersed in a liquid [153]. Till now, the most effective method to enhance cellular infiltration within electrospun scaffolds has been the use of dynamic cell culture. Dynamic cell cultures have been achieved for this purpose by using either simple setups such as an orbital

TABLE 1.1 New methods and recent trends in electrospinning.

Trend	Method	Description	Advantages	References
Modification of the electrospinning setup	Rotating mandrel	A rotating mandrel is used to orient and collect fibers	Controlling fiber alignment	[130]
	Gap electrospinning	Combinations of electrodes and/or electric charges are used to create varied fiber alignments	Creating multilayered scaffolds with varied fiber alignment	[131]
	Magnetic electrospinning	Polymer solution is magnetized and a magnetic field is used to stretched the fibers and align them across a gap	Controlling fiber alignment; collecting fibers over raised topographies; creating wavy or curly fiber architectures	[132,133]
New electrospinning processes	Coaxial electrospinning (also called core–shell electrospinning)	Two separate polymer solutions are fed into concentrically arranged needles, resulting in a compound polymer jet where the core and shell polymers are separate	Creating fibers from difficult to use materials; electrospinning immiscible blend of polymers; creating hollow fibers	[134]
	Fiber blending	Two or more polymer solutions fed through a mixing head to enable complete blending of the materials	Incorporating properties of two or more different polymers in a single fiber; creating bi- or multicomponent fibers; generating gradients of components across the depth of a scaffold	[135,136]
	Emulsion electrospinning	Bioactive reagents are encapsulated within hydrophobic polymers or a dissolvable material is emulsified within the primary polymer and later removed	Incorporation and controlled release of bioactivity compounds within electrospun fibers; creating porous fibers	[137,138]
	Edge electrospinning	High voltage is applied to multiple fluid streams at once so that multiple jets can be produced from a single spinneret	Substantially increases the fiber generation and collection speed; suitable for industrial production of electrospinning	[139,140]
Methods to achieve complex mesh composition and architectures	Coelectrospinning	Simultaneous electrospinning from multiple spinnerets onto the same collector	Fabricating composite scaffolds that have more than one type of polymer fiber; controlling ratio and gradient of different materials within the scaffold; increasing mesh pore to allow for cell infiltration	[141,142]
	Hydrospinning	Electrospun fibers are collected on the surface of a water bath instead of the traditional conductive metal	Creating scaffolds with layers that have altered alignments; increasing scaffold porosity for better cellular infiltration	[143]
	3D electrospinning	3D collectors are used to form fibrous architectures such as multilayered stacks or tubes		[144,145]

3D, Three-dimensional.

shaker [154] or a complex system such as a flow perfusion bioreactor [155].

Inkjet three-dimensional bioprinting

3D bioprinting is a process in which biomaterials or biomaterials combined with cells are deposited in predefined patterns, layer-by-layer using a bottom-up assembly approach to create a 3D biological structure [8]. This technology is making it possible to recapitulate the structure, composition, and complexity of human tissues and, ultimately, may lead toward whole organ engineering for clinical use. Inkjet 3D bioprinting is a method that uses droplets of inks (polymers, cells, or combinations of the two) to create 3D cellular or tissue structures (Fig. 1.4C). The first attempts to print live cells using then inkjet method was carried out using a modified commercially available inkjet printer [8]. However, due to severe limitations in that approach, special 3D printers were designed to dispense cells and biological materials into a desired pattern using droplets that were ejected via thermal or piezoelectric processes. The main advantages of inkjet printing is their high resolutions (5−50 μm), high cell viability, high print speeds, and low costs. However, there are problems too, including less control of droplet directionality, unreliable cell encapsulation due to the low viscosity of the ink material, restrictions on the viscosities of materials that can be used, and limitations of vertical printing. Some examples of tissue fabrications using inkjet include full thickness skin models with pigmentation [156], cardiac tissue with a beating cell response [157], neural tissue [158], and a bone-like tissue [159].

Extrusion three-dimensional bioprinting

Extrusion-based bioprinting is focused on the printing of biomaterials, cells, bioactive molecules, or combinations thereof by extruding continuous cylindrical filaments using pneumatic, piston-driven, or screw-assisted systems (Fig. 1.4C). This technology supports precise deposition of materials/cells and formation of complex 3D structures. Extrusion-based bioprinted structures have better structural integrity compared to inkjet-printed structures and can be used to form porous 3D scaffolds. The resolution that can be achieved with extrusion-based systems are relatively low as compared inkjet or laser-based systems, but anatomically shaped structures can best be generated using this technology. In the past several years, extrusion-based 3D bioprinting has been receiving considerable attention for creating artificial tissues or organs [160,161]. This technology has been supported by development of new bioink materials that can mimic many features of native ECMs while at the same time support cell adhesion, proliferation, and differentiation [162,163].

Extrusion-based bioprinting systems (bioprinters) rely on continuous dispensing of polymer and/or hydrogel filaments through a micro-nozzle (about 25−300 μm or larger pore diameter) and positioning them according to a 3D digital design file, via computer-controlled motion either of the printing heads or collecting stage or both. New technological advances in the past decade include development of advanced extrusion 3D bioprinters, such as the integrated tissue-organ printer (ITOP) at the Wake Forest Institute for RM [160]. The ITOP used clinical imaging data to print simple-to-complex human-scale tissue constructs using biomaterials, cell-laden hydrogels (bioinks), and a multinozzle extrusion system. Examples of tissues printed and implanted in vivo include bone, cartilage, skeletal muscle, cardiac tissue, skin, liver, kidney, bladder, lungs, and trachea. Another advancement was printing of micro-channels within tissue constructs that supported the diffusion of oxygen and nutrients to cells within the construct. Although many challenges still remain for 3D bioprinting of complex human organs, the ability to print using multiple materials and cells simultaneously and create human-sized constructs represents a significant progress in realizing the goal of TE. Another example of an advanced 3D bioprinting system is the one described by Liu et al. [164]. By combining seven capillaries in a single print head, each of which is connected to a different bioink reservoir, this bioprinter can extrude multiple bioinks in a continuous manner. In addition, each capillary can be individually actuated and controlled and fabrication of complex constructs is made possible by fast and smooth switching among different reservoirs. This 3D bioprinter addresses the limitations associated with conventional multihead printers where multimaterial printing can compromise fabrication speed, complexity, or both. Although this system requires further optimizations and validations, it is a good example of the type of disruptive technology needed to advance in the field of TE.

For creating human size tissues, extrusion-based 3D bioprinting is the most suitable technique. The printing material forms an important component of this strategy, where they primarily provide cells with the right environment to proliferate, differentiate, and form tissues. Therefore a rational bioink design approach for specific applications will be crucial to the success of the bioprinting strategy. New trends in bioinks for 3D bioprinting include self-healing and shear-thinning hydrogels that are based on supramolecular assembly of nanoparticles, small molecules, or macromolecules. These materials have unique rheology and gelation properties, which can be tailored according to need and also the printing processes [165]. Such materials have been used before as injectable cell carriers and for cell encapsulation [166], but their use to formulate bioinks is a recent development.

Examples include a study by Li et al. who have described a shear-thinning hydrogel based on a polypeptide−DNA derivative [167]. Loo et al. have developed a peptide bioink using hexapeptides that self-assemble into stable nanofibrous hydrogels [168], while Schacht et al. developed a shear-thinning bioink hydrogels using recombinant spider silk proteins [169]. To produce 3D-printed cell-laden constructs, this spider silk proteins-based bioink does not require any additional components, while at the same time, it shows a good printing fidelity and cell compatibility. A hyaluronic acid (HA) bioink that crosslinks through supramolecular assembly is described by Burdick et al. [170]. This hydrogel displays shear-thinning and self-healing properties, where the hydrogel flows due to the shearing stress applied during the extrusion process, while after printing it rapidly solidifies without any further trigger. Further stability of these hydrogels can be increased by introducing methacrylates into the HA macromers, thereby allowing for printing of complex 3D structures or perfusable channel patterns without using any scaffolding materials. Further iterations to this HA bioink include a dual-crosslinking hydrogel system, where guest−host bonding was followed by photopolymerization [171]. This new bioink formulation was also use to print stable 3D structures without using any scaffolding materials.

Use of polymeric hydrogels for 3D bioprinting has attracted substantial attention in recent years due to their tunable properties and structural similarities to native ECM. Some of the polymers used to make hydrogels include PEG, polyesters, poly(*N*-isopropyl acrylamide), and polyphosphazenes [172]. The advantage of using synthetic polymers for making bioinks is that their physicochemical properties are more controllable compared to naturally derived polymers. Examples include bisilylated PEG-based hydrogels that can crosslink through Si−O−Si bond formation without need for any crosslinking agents [173]; a photocrosslinkable acrylated PEG-fibrinogen based bioink that can form hydrogel networks through calcium-mediated ionotropic interactions and then photo-crosslinked [174]. Similarly, Lorson et al. have developed thermos-reversible supramolecular hydrogels and used them as bioinks [175]. Hybrid bioinks are a new trend in 3D bioprinting, where a biocompatible polymer is combined with a material that imparts unique properties to the bioink for a specific application. An example is a hybrid bioink made from PU and graphene oxide (GO), where the GO specifically supported the formation of neural tissues [176].

Recently, researchers have been developing decellularized ECM (dECM) as bioinks for 3D printing of tissue and organ structures. Similar to the decellularized tissues, the dECM-based bioinks can more accurately recapitulate the biochemical microenvironments of the native tissue ECM compared to just using biomaterials [177]. Studies have shown that 3D-printed tissue made using dECM-based bioink support better cell proliferation, differentiation, maturation, and overall therapeutic effects in vivo after transplantation [178]. Examples of use of dECM-based bioinks for TE include fabrication of stem-cell-laden cardiac tissue patches for the treatment of myocardial infarction models [179] and hepatic tissue for liver regeneration [180]. Research and development of dECM-based bioinks are work in progress and it would be interesting to see how further developments in this direction can help create structurally and functionally relevant tissues and organs.

Nanotechnology has been making its way into several RM applications during the past decade [181]. Some of these nanotechnologies have been used in the field of biofabrication [182,183], such as in the nanocomposite bioinks (nanoinks) with tailored properties for specific applications. Examples include a bioactive DNA/HA-coated single-wall carbon nanotube (CNT)-based nanoink for printing two-dimensional (2D) and 3D flexible electronics [184]. Using a two-step process, 3D structures with conductive patterns were printed on several supports, including within hydrogels. Another example is the study by Lind et al., who 3D printed "cardiac organs-on-chip" using a combination of thermoplastic PU filled with carbon black nanoparticles (conductive inks) with other inks [185]. The printed structures within then chip conferred various properties such as biocompatibility, high conductance, and piezoresistivity. Jakus et al. used nanoinks composed of poly(lactide-*co*-glycolide) (PLGA) and graphene for printing 3D neuronal conduits that promote neural regeneration [186]. In addition to biocompatibility, neurogenic differentiation of the seeded human mesenchymal stem cells (hMSCs) was demonstrated on these materials along with formation of axons and presynaptic-like terminals.

Spheroids and organoids

It is now well-known that 2D cell culture environment can make it difficult to control cell−cell and cell substrate interactions in natural tissue, thereby presenting limitations in recreating biological and physiological features of human tissues and organs. To address this, researchers have developed different types of 3D scaffolds using natural and synthetic polymers. Hydrogels have been one of the most commonly used 3D scaffolds for cell culture and TE due to their high water content, ECM like microstructure and biocompatibility [187,188]. However, use of simple hydrogels could not fully recreate the complex microenvironment of many higher order tissues and organs. One of the basic question being asked today in TE is how precisely the physical, chemical, and biological

properties (if applicable) of a 3D scaffold can support or regulate cell function.

The regulation of the hydrogel environment is a promising method for controlling cellular behavior in three dimensions. One example of such an approach is a study by Caballero et al., who used a pattern with microgrooves to engineer anisotropic fibroblast-derived matrices [189]. Fibroblasts seeded into this matrix showed in vivo−like phenotype such as alignment, spreading, and migration. In another study, Trappmann et al. devised a way to control the swelling of a dextran hydrogel by attaching a methacrylate (a hydrophobic pendant group) to dextran (the hydrophilic polymer chain in then hydrogel) and found that the swelling of these hydrogels could be reduced from 55% to 0% (no swelling) [190]. In addition, insertion of a di-cysteine peptide sequence allowed for a partial degradation of the hydrogel through cleavage by MMP that also supported endothelial cell migration and angiogenesis. Success of such approaches provides support to more innovations in 3D cell culture and tissue biofabrication, all of which will be advancing then field of TE in the coming years.

Among 3D culture systems, cellular spheroids have been attracting more attention lately. These are 3D complexes composed only of cells, where the spheroid is formed based on the self-assembling tendencies of these cells [191]. Cell spheroids offer several advantages over 2D cell cultures, including better cell−cell interactions and diffusive mass transport. Therefore they can not only be used for investigations of physiological and developmental processes but also as building blocks for TE (Fig. 1.5). For TE, spheroids of multiple cellular origins can be combined or multiple cell types can be incorporated in a single spheroid using coculture. They are produced using a variety of devices such as microwell or hanging drop plates. However, spheroids made this way have features that are somewhat different from the structure of the native tissues. To address this, new ways of spheroid generation are being explored. One example is using phosphoproteins and glycoproteins to generate supramolecular nanofibrils and then induce self-assembly of fibroblasts [193]. Spheroids produced this way had a more tissue-like form. In another study, fragmented nanofibers as a physical artificial support were injected into the spheroids to control cell function [194]. In addition, using this approach, the researchers could create larger spheroids (~800-mm diameter) compared to the spheroids that were made only of cells. Another example of spheroids application is for studying the physical stimuli that may occur within tissues. Dolega et al. measured mechanical stress within spheroids by injecting an ultrafine polyacrylamide microbeads as a pressure sensor [195]; while Cho et al. made multicellular spheroids composed of human brain vascular pericytes, primary human astrocytes, and human brain microvascular endothelial cells in agarose gel and used it for blood−brain barrier studies [196].

Applications of cellular spheroids include cancer research, disease modeling, and in vitro platforms for drug/toxicity testing. Although spheroids have been around for more than 10 years, their application for TE has not been common. One reason is that they are primarily used for mimicking microniches, plus the control of spheroids during culturing has been an issue. Also, if a spheroid is larger than a certain size, necrosis occurs in the core, thereby reducing their usefulness for mimicking structurally complex and multicellular tissues. However, the regenerative potential and fusion capacity of these spheroids can be improved by in vitro preconditioning or by incorporation of biomaterial components. Fusing them

together can generate scaffold-free macro-tissues, while seeding them on scaffolds can generate in vivo–like engineered tissues.

A more complex spheroid type are 3D tissue organoids. An organoid is an extended cellular spheroid that has a physicochemical environment very similar to the tissue it is representing. The generation of organoids can be considered as one of the major technological breakthroughs of the past decade. Organoids can be generated using different cell sources (such as autologous cells, ES cells, iPSCs) and self-organization or fabrication methods (hanging drop plates, ultralow attachment plates, agarose-coated plates, or ECM surface culture) (Fig. 1.6A and B). Organoids can display various biological features seen in vivo, such as tissue organization, regeneration, responses to drugs, or damage. Examples of some of the tissue-specific organoids that have been developed include liver [200,201], lung [202], pancreas [203], prostrate [204], intestine [205], heart [206], brain [199]. The development organoids representing the nervous system had been a challenge so far. However, recently, Birey et al. successfully fabricated human subpallium and human cortical spheroids [207]. They showed that γ-aminobutyric-acid-releasing (GABAergic) neurons could migrate from the ventral to the dorsal forebrain and integrate into cortical circuits. Success of such efforts provide confidence that it is possible to create micro-tissues that can more closely mimic structure and physiological aspects of complex tissues.

3D bioprinting has become a popular way of creating engineered tissues to be used both for studying the basic tissue biology or pathology and for repair or regeneration in vivo. A recent application of 3D bioprinted tissue is for toxicity testing, drug screening, and development with the aim of reducing or eliminating the use of animals for these purposes. Many types of tissues are being 3D bioprinted for in vitro use. One interesting example is a multicellular 3D hepatic tissue by Chen et al., who used methacrylated gelatin (GelMA) and glycidyl methacrylated HA, with human iPSCs, adipose-derived stem cells (ADSCs), and human umbilical vein endothelial cells (HUVECs) as the bioink to print microscale hexagonal architectures that mimicked the native hepatic microenvironment [208]. In addition to better morphological

organization, this 3D-printed liver also showed increased metabolic secretion, enhanced cytochrome-P450 induction, and higher liver-specific gene expression.

Imaging technologies

Multiscale digital imaging data is becoming a critical part of many TE strategies that are aiming to recreate complex tissues and organs. These digital data act as blueprints upon which design and fabrication strategies of neotissues and neo-organs are based. A great deal of anatomical data already exists, for example, in the many medical computed tomography (CT) and MRI images, which can be harnessed for generating 3D computer-aided design (CAD) models of implants and tissues for biofabrication. Recent advances in bioimaging are also allowing for collection of data to create high-resolution designs for TE. For example, CLARITY is a technique by which the lipid content of tissues are removed, leaving behind a transparent, porous hydrogels−like tissue which maintains the original intact structures [209,210]. This technique can be used to visualize a tissue's structure and molecular composition at very high resolutions (as high as 70 nm) [211]. In addition, the ever increasing repertoire of MRI, contrast-enhanced nanotomography (nano-CT), histological data (including immunohistochemistry), and molecular imaging are providing large-scale structural information as well as fine molecular-level information (such as distribution and interaction of cells through a tissue or organ). Such information can be used to design multiphasic structures that have both structural and biochemical heterogeneity and in vivo−like organization.

Tissue neovascularization

Vasculogenesis and angiogenesis are two basic and critical processes by which vasculature forms during development. For tissue and organ bioengineering, attempts are now being made to recreate these processes to generate vascular networks [212]. In bioengineered tissues, the diffusion limit of oxygen is typically 100−200 μm and thicker tissue without an intact vasculature for oxygen and nutrient transport will face necrosis. In addition to creating structural vessels, vascular engineering designs will also have to ensure normal cellular metabolism within these structures, be permeable to allow extravasation of cells, maintain an open-vessel lumen during remodeling, and also promote integration with the host vasculature [213]. Efforts are underway in this direction, which include a study by Lewis et al., who 3D printed a cell-laden, thick (>1 cm), vascularized connective tissues that could be perfused and sustained in culture for >6 weeks [214]. The 3D vascular networks were created using a pluronic fugitive ink and the vessels were lined with HUVECs and MSCs. To demonstrate the functionality of then vasculature, osteogenic differentiation of hMSCs within the construct was induced by osteogenic media delivered through the vasculature. In addition to highlighting the importance of a functional vasculature for engineering thick tissues, this study also provides a design platform to build other tissues with functional vasculature.

Jia et al. demonstrated an alternative method to 3D print vascular networks, one that does not use sacrificial inks [215]. Here, a newly designed multilayered coaxial nozzle device was used to 3D bioprint perfusable vascular channels using a specially designed cell-responsive bioink. Printing was carried out using a trilayered coaxial nozzle, while the bioink contained sodium alginate, gelatin methacryloyl, and four-arm poly(ethylene glycol)-tetra-acrylate. A multistep crosslinking process, followed by removal of the alginate using Ca^{2+} resulted in creation of a layered, perfusable hollow tubes. Although long-term perfusability of this construct was an issue, this approach represents an advancement over the conventional strategies to engineer vasculature in tissue constructs. Anastomosis of prevascularized 3D tissues with host vasculature are also being investigated. Examples include studies by Zhu et al., who 3D printed tissues where GelMA polymer was used along with mesenchymal cells and HUVECs to form hydrogel networks representing vasculature by photo-crosslinking [118]. On in vivo implantation, anastomosis between the host circulation and the prevascular tissues construct was observed where blood vessel growth were seen into the construct having red blood cells. For bone TE, prevascularized bone scaffolds were generated using bioactive bioinks, as described by Kuss et al. [216]. To from then vascular networks, GelMA and acrylated HA with HUVECs and human adipose-derived MSCs were used. In vitro studies showed that the prevascularized construct generated more capillary-like structures when compared to nonprevascularized tissue, and when implantation in vivo in mice, anastomosis with host vasculature was observed along with microvessel and lumen formation.

Bioreactors

Bioreactors are critical for engineering new tissues. They are used to recapitulate physiological environments in which cells exist in vivo: expand cells for potential clinical use, to test potential new treatments in an in vivo−like environments, and to establish new therapeutic targets. Significant improvements in design and construction of bioreactors have been made over the past decade. Some of these systems can support growth of whole tissues of 3D bioengineered constructs, coculture of cells of different phenotypes, generate dynamic culture

conditions which facilitates mass transfer, and have advanced sensors and imaging capabilities allowing for real-time monitoring of physiological parameters. Whilst more sophisticated bioreactor can more accurately recreate the complex cell/tissue microenvironments, they are challenging to create and operate. In contrast, simpler bioreactor designs can recreate only selected conditions but are more operationally robust. Therefore a compromise between complexities versus essential functionality needs to be determined based on the application and the desired end-product. Perfusion bioreactors are being used to closely simulate the in vivo environments for TE. In a perfusion bioreactor, the media flow is either cross, downwards, or in a specific pattern that generated some kind of microgravity environment. Fluidized bed bioreactors and ones with rotating wall can achieves greater mass transfers, which are beneficial to the tissue or organ being conditioned. In one study, using a rotatory cell culture system, Crabbe et al. [217] improve reseeding of decellularized lung tissue. However, if the flow in the bioreactor is not optimized, it can have negative effects. Other factors that can have important impact on tissues being cultures in bioreactors include the scaffold's architecture, oxygenation, mechanical stimuli, and sheer stress. The design of the scaffold used for making the tissue construct will impact mass transfer during culture. The scaffold pore size not only affects the cell seeding but also distribution of nutrients and gas exchange during culture. Therefore the original scaffold design should take into consideration the thickness, pore size, and interconnectivity. In general, decellularized tissues are supposed to offer an ideal scaffold environment for TE, because they are derived from the same tissue they will be replacing.

As for assisting cell seeding within scaffolds, some physical methods such as electromagnetism or acoustics have also been used [218,219]. In bioreactors where the culture media is the only nutrient source, the presence of a suitable oxygen tension is critical. Hence, balancing the oxygen environment should be an integral part of bioreactor design. Use of oxygen delivery agents such as perfluorocarbons [220] or artificial red blood cells can help create a balanced oxygen environment, while use of fluorescent oxygen sensors can help control this environment. Use of mechanical stimuli to condition cells and tissues in artificial environments has been done since a long time. The types of mechanical stimuli can include shear stress, compression, stretch, or pressure loads. With advances in bioreactor engineering, it is now possible to engineer such capabilities into the bioreactors. At the cellular level, these stimuli activate mechano-transduction cellular signaling pathways and causes changes such as focal adhesions, cell-to-cell contacts, and changes in gene expression. Cultured tissues such as blood vessels, muscles, and ligaments would need such stimuli to develop into in vivo–like tissues before implantation. For example, in cardiac tissues, mechanical stretch and/or electrical stimuli lead to synchronized contractions [221], while application of cyclic stretch in muscles enhances ECM protein content, among other things [222]. Shear stress in a dynamic environment may not represent the physiological state for some tissues and may impact their performance. An example is liver, where the hepatocytes are shielded from shear even though the blood flow through the portal vein at a rate of 1200 mL/min.

Organ-on-a-chip and body-on-a-chip

The continuous rise in drug development cost and increase in the number of drug candidates failing in clinical trials, despite promising results from traditional preclinical model systems, have prompted development of better physiologically relevant and predictive in vitro/ex vivo systems. Therefore better and physiologically relevant in vitro models are needed that better predict drug efficacy and safety in humans and which can be used in a high-throughput way. More recently, the engineering of complex tissues in vitro has been supported by two integrated approaches: (a) organoids and (b) microfluidics-based organ systems known as "organs-on-a-chip" or "body-on-a-chip" [223]. 3D organoids have been developed to recapture the phenomenon of controlled cell growth to appropriate length scales in three dimensions, which happens in body tissues. Use of organoids is now expanding beyond basic research to disease modeling, drug discovery/ development, and personalized medicine. Also, organoids can be easily integrated with chip models via microfluidics. The organoid-based "organs-on-a-chip" systems can surpass traditional "cells-in-a-dish" models with regards to recapitulating in vivo structural and physiological microenvironments [224]. Furthermore, different tissue-specific organoids can be connected in an integrated circuit format using microfluidics to create a "body-on-a-chip."

New technologies that are permitting development of complex biological systems with control over the physical and chemical microenvironment include microfluidics. Microfluidics can allow us to create 3D microphysiological systems, such as organs-on-a-chip or body-on-a-chip. These systems can allow us to study living tissues and organs in a more complex way. Microfluidics-based 3D multifunctional systems can also support cell and organoid cultures, where control of parameters such as nutrient low, oxygen gradients, and drug/biologics distribution can be used for accurate high-throughput testing and environment sampling applications. Microfluidic-based systems have contributed significant to the in vitro modeling of tissues such as heart [225], kidney [226], and blood–brain barrier [227]. Here, well-defined cellular

environments closely mimic a physiological niche for better understanding of the biological mechanisms operating within that particular tissue.

Recreating the highly complex structures of organs is a tremendous engineering challenge. A better way for studying the physiology, drug response, or chemical toxicity in a single organ or an organ system is to create miniaturized version of these organs that capture their functions. Organ-on-chip systems represent an effort in that direction. Using these systems, cell function can be quantitatively studied in response to precisely controlled physicochemical cues. A higher version of this is body-on-chip, where multiple tissues representing different organs are placed on a single-chip format and interconnected by microfluidic channels representing vasculature. In case of drugs, it is well-known that its metabolic products can sometimes have adverse effects on body systems other than the target [228]. By only studying an isolated organs in vitro, the vital information that can emerges from synergistic effects on the entire organ systems can be lost. Use of body-on-chip can help capture that information, not only with reference to drug interactions, but also for disease etiologies or basic biological processes [229,230]. The use of 3D bioprinting technologies are helping to print complex tissues with diverse types of matrix, cells, growth factors, etc. The tissues in the organ-on-chip and body-on-chip can now be 3D printed at high resolutions and in a highly replicative manner. This has supported advancement of the organ-on-chip and body-on-chip systems from investigative stage to use as a reliable diagnostic tool.

Integration of nanotechnology

Nanotechnology is the understanding and control of matter at the nanoscale, at dimensions between approximately 1 and 100 nm, where unique phenomena enable novel applications (https://www.nano.gov/nanotech-101). Based on the application, nanotechnology can involve either measuring, modeling, imaging, or manipulating matter at then nanoscale. In the field of TE, use of nanoparticles has been shown to significantly enhance the physical and biological properties of scaffolds and also serve various functions based on the application [231]. Examples of nanoparticles used in TE include titanium oxide (TiO_2) nanoparticles, silver nanoparticles (AgNPs), gold nanoparticles (GNPs), CNTs, magnetic nanoparticles (MNPs), and GO nanoparticles. Titanium oxide nanoparticles have been primarily been used to improve the mechanical properties of TE scaffolds but have also been observed to enhance cell proliferation. Nanocomposite polymers with TiO_2 have shown superior mechanical properties compared to plain polymers for TE applications [232,233], including a biodegradable patch that was used to reinforce scars after myocardial infarction [234]. When 3D-printed scaffolds made from PLGA were used to culture human ES cell−derived cardiomyocytes, incorporation of TiO_2 nanoparticles within the scaffolds resulted in enhanced proliferation of these cells. GNPs are widely used in TE. Electrical properties of scaffolds have been enhanced using GNPs, particularly for cardiac TE [235]. Examples of such studies include better striation and enhancements in electrical coupling of cardiac cells when decellularized matrices incorporating GNPs were used [236]. In other studies, use of electrospun scaffolds containing GNP improved the treatment outcomes of infarcted heart [237].

For bone TE, GNPs have been shown to enhance osteoclast formation from hematopoietic cells [238], promote osteogenic differentiation in cells such as MSCs, and MC3T3-E1 (osteoblast precursor cells) [239]. Since, bone morphogenetic proteins (BMPs) is the primary biological factor that can modulate these biological response, GNPs can be viewed as replacements for BMPs in certain situation and can also be good candidates for inclusion in bone TE applications. Another example where GNPs have substituted the use of growth factors is for direct stem-cell differentiation. In a study, scaffolds incorporating gold nanowires and GNPs could direct stem-cell differentiation, without using growth factors [235]. This is another example that shows that certain nanoparticles can be used to substitute use of biological factors, which are known to have various side effects when applied in the body. Nanoparticles could be a new tool for controlling TE outcomes. Infection of a surgical site is a wide spread problem in clinical medicine even after availability of many ways to prevent and treat it. For tissue-engineered constructs, most of which would be surgically implanted at the target site, one way to prevent or treat the possibility of postsurgical infection is to incorporate an antimicrobial agent within the construct itself, mostly within the scaffold. Metal oxides such as iron-oxide nanoparticles, AgNPs, and selenium nanoparticles are widely being used for this purpose. Silver nanoparticles are more popular as antimicrobial agent and have been used in TE of skin [240], bone [241], and vascular grafts [242]. In addition to antimicrobial effects, AgNPs have shown to have wound healing capabilities [243].

Recently, the application of MNPs has been explored as a versatile tool for TE. For this, the MNPs are either direct incorporation into a scaffold matrix or the cells being seeded on the scaffolds are prelabeled with MNPs by internalization [244]. Using an external magnetic field, these MNPs can now be tracked or used for guiding cells, thereby making the resulting tissue magnetically responsive. This is an economical and attractive way to monitor and stimulate cells in vitro. In one study, Gomes et al. have used magnetic scaffolds where magnetic stimulation was used to differentiate human ADSCs for tendon

regeneration [244]. On implantation into an ectopic rat model, these scaffolds also showed good biocompatibility and integration within the surrounding tissues. Cezar et al. created biphasic iron-containing scaffolds (ferrogels) for use in muscle TE [245]. On implantation into a mouse muscle injury model and remote magnetic actuation, uniform cyclic compressions were observed in the engineered muscle. Consequently, there was also a reduction in inflammation, reduction in fibrosis, better regeneration, and around three-fold increase in the maximum contractile force of the target muscle. This was a significant outcome because use of a biphasic ferrogel to stimulate and regenerate injured muscle can mean avoiding use of growth factors or cells for muscle regeneration.

In another study, Antman-Passig and Shefi [246] used collagen hydrogels with MNPs for neuronal TE. These collagens in the injectable hydrogels could be aligned in vivo by the application of an external magnetic field and the alignment could be actively controlled postimplantation. This magnetically controlled patterning supported elongation and directional growth of primary neurons, which also exhibited normal electrical activity. Another interesting application of MNPs can be seen in magnetic field–guided cell targeting. Swaminathan et al. used superparamagnetic nanoparticles (SPION) to label smooth muscle cells (derived from bone marrow mesenchymal stem cell) and deliver them to abdominal aortic aneurysms (AAA) wall [247]. The use of SPIONs also did not have any adverse effects on cells and then authors believe that this could be a new approach for in situ AAA repair.

Integration of sensors in biological and tissue-engineered systems for real-time monitoring and data acquisition is a latest trend. Millimeter-sized living tissues fabricated in a microphysiological devices format are known as organs-on-a-chip. Integrating sensors in organs-on-a-chip platforms can allow real-time tracking and monitoring of selected physiological response without interfering with the tissue/ organ function. Examples of such an approach include development of a cardiac tissue patch that integrated an electronic network within the engineered tissue [248]. The network collects information from the tissue microenvironment and can be used for electrical stimulation, synchronizing cell contraction, or drug release on demand. Similarly, Lieber et al. developed a flexible scaffold mimicking 3D nanoelectronic array for engineering a cardiac tissue for a transient arrhythmia disease model [249]. This unique scaffold was used for mapping the action potential propagation in then developing cardiac tissues as well as using controlled electric stimulation to manipulate the tissue electrophysiology. Use of such nanoelectronics containing scaffolds can not only allow for spatiotemporal monitoring and control of developing cardiac tissues, but the data collected can reveal important parameters for better engineering of cardiac tissues. In a different application, Bavli et al. integrated sensors into liver-on-chip device for monitoring mitochondrial dysfunction in native liver microenvironments [250]. In chemically caused toxicity, mitochondrial damage and dysfunction happens that can often go undetected. This sensor containing liver-on-chip device was able to monitor real-time mitochondrial respiration and stress.

Current challenges

TE as a new field was introduced more than 20 years ago; however, the current technology for engineering complex tissues for clinical use is still far from ideal. Conventional scaffold fabrication methods such as soft lithography, electrospinning, and freeze–drying usually generate reduced reproducibility between scaffolds [251] and cell deposition accuracy during the scaffold fabrication is relatively low. Development of better biofabrication technologies such as SLA, 3D bioprinting, and laser bioprinting have resulted in better scaffolds and resulting tissues, but they are still insufficient to recreate the complex structural, cellular, and functional organization of higher order tissues and organs. This will be critical not only for successful clinical translation of TE products but also acceptance of TE as a mainstream field of medicine. Many challenges to the field of TE are specific to a particular technology or process. For example, when using electrospun grafts in clinical applications, the precise and reproducible control over fiber formation, their morphology, and composition is a big challenge. The manufacturing scale-up of the electrospinning process is also a concern because of the relatively slow rate of collection of electrospun fibers. In addition, homogenous cell distributions within such scaffolds are difficult to achieve. New methods that have been developed to address this issue include multilayered electrospinning, use of low fiber packing density, cell electrospraying, and dynamic cell culture in bioreactors.

3D bioprinting is an advanced biofabrication technology that is aiding in generation of complex scaffolds and tissues for RM. Compared to conventional manufacturing methods, 3D bioprinting can be used to generate predesigned scaffolds and cell arrangement that can mimic higher order tissues within the body. Therefore this technology is highly desirable for creating products for tissue/ organ repair and regeneration. In addition, bioprinted tissues would be highly reproducible, which is a requirement for commercial production. The development of suitable bioinks is currently the bottleneck of bioprinting technology. Since the ECM as well as cellular compositions of different tissue are highly diverse, the development of a universal bioink for ubiquitous application

proves highly difficult. For successful TE using 3D bioprinting, the bioinks have to be nontoxic, immune-compatible, biodegradable, and the degradation products should be harmless to the host and should ideally support the cells in their desired organization and function. Therefore development of novel, versatile, and tunable bioinks that meet many of the above criteria would be pivotal for the success of bioprinting as a robust tissue fabrication technology. Standardization of 3D bioprinters, the bioprinting process, bioinks, product and process scale-up, testing and quality control etc. are all challenges that will have to be addresses sooner than later.

Finding a suitable cell sources and obtaining sufficient quantities of cells has always been a challenge. In addition, for clinical applications, autologous cell source are preferable, which are difficult to get in many cases. Engineering of complex tissues will also require multiple cell types in sufficient qualities, unless stem cells are being used to derive these cell types. Creating suitable bioactive scaffolds where all these different cell types can grow, interact, build their own ECM, and perform in vivo–like function is another major challenge in TE. Reducing the immunogenicity of TE scaffold is one of the most critical requirements of the decellularization strategy. This aspect might have been critical in preventing the widespread use of decellularized ECM as scaffolds in clinical applications. This is particularly true for xenogenic scaffolds. If their immunogenicity is not sufficiently reduced, they can be rejected in vivo, leading to functional failure of the engineered scaffold of tissue. Use of detergents such as SDS and Triton X-100 can significantly reduce the presence of protein-based immunogenic components [252], while the use of endonucleases such as DNAse and RNAse has been shown to remove the nucleic acid components significantly. Use of mechanical decellularization approaches such as freeze–thaw and high hydrostatic pressure (HHP) can leave behind DNA remnants, which are immunogenic. Use of more extensive wash procedures and a combination of different enzymatic methods can completely clear these scaffolds of immunogenic components.

Engineering vascular tissues continue to remain a major challenge in TE. Without proper vascularization, the lack of nutrition or buildup of waste will inevitably lead to necrosis or cell death in the engineered tissues and organs [253]. This will invariably restrict their size and complexity, and their regeneration applications. To address this, many attempts are being made to engineering vascular structures. Current strategies include generating a hollow tubular network using sacrificial filaments followed by perfusion of vascular cells into the network [254], use of a modified thermal inkjet printer to printing microvascular networks [255], use of 3D printing to generate a sacrificial filament and then embed the filament network into hydrogel with encapsulated cells [254], or use 3D bioprint vascularized structure using multiple cell types and ECM substrates [214]. Even when a tissue-engineered construct can be made with vascularization support, its integration within the host (anastomosis) is a big challenge. Immune complications can also arise during this process, resulting in rejection of the implant. Although several studies have shown that vascularized small constructs, when transplanted into immune-compromised host mice can successfully integrate with the host blood supply, the implants used were usually small (maximum) 6-mm diameter and 1-mm thick [256]. As the dimensions of the tissue exceeds beyond this number, its vascularization and integration with the host vasculature is increasingly difficult. This is indeed a bottleneck for TE and a challenge that is being addressed.

When a technology is considered suitable for clinical use, there still can be major regulatory hurdles that need to be overcome before this translation is realized. These hurdles can be associated with commercialization, clinical trials, or both. Most of the regulations are designed to ensure safety of the patients who will be recipients of these products. Regulatory assessment considers the risk profile of the technology, the materials and processes used in manufacturing, storage, transport to the bedside, etc. Furthermore, the process scale-up and approvals for clinical applications are some of the aspects that can be complex and time consuming. Another important, but often overlooked, challenge for TE is the social acceptance of this technology. Finally, the willingness of patients to accept this technology and its products will determine its success (or failure). Hence, robust ethical discussions will also be required for realistic consideration and promotion of TE for successful clinical applications.

For TE, each individual tissue or organ poses its own engineering challenge. This is due to the fact that among other things, spatial constraints, physical forces, biochemical cues, individual cell types, and their growth programs can vary widely between each tissue type. Organs are even more complex in terms of these parameters. For this reason, most of the current tissue/organ models still cannot fully replicate in vivo biology. Being mostly a single tissue/organ model, they largely miss the dynamic effects of an organism's physiological status. As for the cell sources, ES cells, adult stem cells, and iPSCs require distinct environments to effectively induce their differentiation and tissue formation. Therefore designs of engineered tissues/organs will not only require expertise in bioengineering but also progressing biological knowledge that would drive such biodesigns. Another challenge in the field of TE is the lack of knowledge about the degree of self-assembly and remodeling that the engineered tissue will undergo after fabrication or in vivo implantation. This is an area that will need further research and knowledge generation, not only for the

engineering aspect, but also from the clinical and regulatory point of view.

While use of nanoparticles in TE has shown many benefits, such as enhancement of mechanical, biological, and electrical properties, and aid in gene delivery, antimicrobial effects, and molecular imaging, many challenges still lie ahead for using them in widespread clinical applications. Concerns that need to be addressed related to use of nanoparticles include nanoparticle toxicity, carcinogenicity, teratogenicity, and their bioaccumulation inside the body over a long period of time. A compelling need exists for developing better tools and methods to assess nanoparticle toxicity, carcinogenicity, and teratogenicity because most nanoparticles used in the human body have the potential to accumulate over a long period of time. This will allow them to reach a concentration that can cause toxicity to cells, resulting in cancers or harmful effects on physiological systems such as brain and reproductive systems and possibly also on the fetuses before their birth.

During the past 10 years, the basic and applied science base of TE has made great progressed in many areas. However, the clinical and commercial successes that were initially predicted have been slow to come. The slow clinical and commercial progress of TE can be attributed more to issues other than the science and technology. Scale-up issues in biomanufacturing, few than expected clinical trials, regulatory processes and health economics are some of the reasons for this. However, many of these hurdles are being overcome and the progress is encouraging. The coming decade is expected to more advancements, including incorporation of more new technologies, evolution of smart biomaterials, widespread use of stem cells, fabrication of more complex tissues and whole organs, use of bioengineered tissue as replacement for animal testing, personalized medicine, and clinical translation of way more tissue-engineered products. Development of complex tissues and organs involves the intricate process of coordinated cell growth, differentiation, morphogenesis, and maturation of diverse populations of cells. Although the ability to engineer complex tissues and whole organs is attractive and has the potential to impact translational medicine, it is still a major challenge. To meet this challenge, knowledge from multiple disciplines such as development, anatomy, physiology, and cell biology will have to be combined with enabling technologies such as biomaterials, biofabrication (including 3D bioprinting), advanced bioreactors, 3D modeling, high-content imaging, and nanotechnology.

Future directions

Through a greater understanding of biology, technological advancement, multidisciplinary approach, and clinical studies, the fields of TE and RM have been steadily advancing. Since TE is both a multi- and interdisciplinary science, joint efforts of different specialties will be needed for the commercial and clinical success of TE products. At least for commercial applications, TE and RM should be viewed from a systems engineering perspective. Successful translation of more TE technologies will be needed for long-term success of this field and also to establish confidence in TE and RM as viable solutions to many unmet medical needs. The clinical feasibility of TE and RM products has already been demonstrated for several applications. Now the challenge is for showing their efficacy in real-world patients. To benefit a larger patient population, manufacturing of these products will have to be scaled-up, produced reproducibly with high-quality control, and made broadly available in an economical way. From a business perspective, the challenges for TE and RM will be more than just the technology. A viable business model will have to be developed that takes into consideration the technology, regulatory aspects, cost considerations, and the healthcare landscape. From the science and technology perspective, some of the most promising aspects that will drive the field of TE in the future are discussed next:

Smart biomaterials

A better understanding of the interactions of biomaterials with cells and tissue in vivo will help develop the next-generation of biocompatible materials for TE and RM applications. For example, using computational models of material surface chemistries and studying their interactions with cells can be very helpful. Clinical translation of life science-based technologies is always challenging. Same is the case with TE technologies, particularly smart biomaterials. However, considering some critical factors during the research and development phase can help ensure a better translation to clinical studies and finally to the patients. These include biocompatibility of these materials over longer time (months or years), material performance consistency, and standardization of manufacturing parameters (process scalability, batch to batch reproducibility etc.). The use of computational and machine learning technologies can also have positive benefits for design of biomaterials and improve predictions during manufacturing and their performance in vivo.

It is now known that many ECM components have natural immunomodulatory domains that bind to receptors found on immune cells, enabling their adhesion and regulating their function [257]. This is facilitated by bioactive amino acid sequences that encode specific cellular cues. Therefore it is possible to use ECM proteins and/or ECM-modeled peptides in biomaterial scaffolds to mimic the natural regulatory role of the ECM on the host immune

system. This strategy to modulate favorable immune response to can ensure functionality and longevity of TE implants. Proteins-based smart biomaterials (including composite hydrogels) can have unique applications in TE and RM and need further exploration. It is also possible to make composite hydrogels with proteins and synthetic polymers. Burdick et al. have developed a self-assembly mechanism to make such hydrogels [258,259]. These hydrogels can also be further strengthened by reinforcing with photo-reactive groups (such as methacrylate groups), so that the hydrogel crosslinking can be carried out by UV radiation [259].

Biomaterials that can respond to electrical and stimulus are also interesting for many applications. It is well known that electrical stimulation positively affects cardiac cells in culture [260] and other electrically sensitive cells such as neurons have displayed improved growth and function when cultured on conductive scaffolds [261]. Electrically conductive polymers have also been combined with proteins [262] and represent an interesting class of biomaterials that need further exploration. Since some proteins can undergo structural changes in response to mechanical environmental triggers [263], combining such proteins with other biomaterials can result in mechanically responsive smart biomaterials. Growing electrically or mechanically responsive tissues for in vitro use or for in vivo for tissue regeneration would represent another advancement in the field of TE.

Cell sources

Stem cells may have their own drawback and pose certain common challenges that must be overcome to achieve clinical utility of TE. Full commitment to each germ layer in culture will be an important achievement in the development of tissue-engineered products containing stem cells. This can be achieved by optimizing growth factor combinations and use of advanced bioreactors, such as the one exemplified by scaled-up production of definitive endoderm in recent years [264]. Recent efforts to derive a wide variety of specialized cells from human ES and iPS cells are becoming successful. Examples include cardiomyocytes and endothelial cells, hepatocytes, insulin-producing beta-like cells, neuronal and other cells of the nervous system, including oligodendrocytes and subsets of astrocytes.

Embryonic stem cells

More efforts are needed for ensuring success of pluripotent stem cells (such as ES cells) as a source for cell therapy and tissue-engineered products. Purity of differentiated cell populations and exclusion of potentially tumorigenic undifferentiated stem cells must be confirmed for every application. In addition, the maturity of differentiated cells is still an issue, where some of the differentiated cells can retain embryonic phenotypes. For examples, detailed studies of various differentiated cell lineages (such as hepatocytes and pancreatic β cells) have highlighted the difficulty of achieving fully adult phenotypes from ES cells [265]. The completion of development may actually require additional maturation for several months in vivo, as shown for endocrine pancreatic progenitors of insulin-producing β-like cells. Therefore while serving as useful models for human development, the immature cells derived from pluripotent stem cells may have significant limitations as components of safe and effective tissue-engineered therapies.

In the future, a selection of small molecules could replace growth factors and hormones in driving key steps in the differentiation sequence and should facilitate development of cost-effective therapeutic products [266]. The production of ES cells and differentiation to pancreatic progenitors have been recently scaled-up under conditions compatible with GMP to support clinical testing [266]. It is anticipated that the grafted cells will be susceptible to acute immune attack, both by alloreactive T cells and by the autoimmune T cells that initially caused the patients' type 1 diabetes. One strategy to avoid this would be to deliver a tissue-engineered product with the therapeutic cells encapsulated in a semipermeable device designed to protect them from the immune system, while allowing exchange of nutrients and release of insulin to the circulation.

The need to protect grafts from the recipient's immune system is a fundamental problem for cell therapy and TE [267]. Due to the genetic mismatch between donors and recipients, the risk of immune rejection must be considered for any cell therapy or tissue-engineered products based on ES cells. One potential way to ensure successful allotransplantation of these cells would be to modify ES cells genetically to knock out MHC Class I, and possibly Class II, expression [267]. This might be the reason why differentiated ES cell derivatives show lower immunogenicity than do corresponding adult human cells [268]. There are some methods that can be used to induce immunological tolerance in recipients of allogeneic stem-cell-derived grafts [269,270]. One such method is nonablative treatment of the host with monoclonal antibodies to the T-cell antigens CD4 and CD8 [271] successful; this approach would not only allow for off-the-shelf also tissue therapies but also lower the safety and economic barriers to widespread adoption of ES cell-based therapies in medical practice. Another approach in this direction rests on cell banking strategies. The simple process of deriving clinically relevant ES cells from blood group O donors eliminates the issues of ABO type compatibility [267]. In addition, establishment of GMP-grade ES cell line banks

of relatively modest size (say 50−200 lines from appropriately selected donors) would enable complete and efficient matching at the most important MHC loci (HLA-A, -B, and -DR) for the large majority of the population. The derivation of ES cells from parthenogenetic embryos (that are homozygous for HLA loci) or selection of rare HLA-homozygous donors from the general population for obtaining pluripotent stem-cell lines can also significantly decrease the size of bank required to ensure matching of most potential recipients [272]. Stem-cell line banking on a global scale seems an idealistic but potentially feasible goal for future development of cell and tissue-engineered therapies [273].

Induced pluripotent stem cells

iPSCs are strong candidate cells for the future of TE. Already the next generation of reprograming methods are evolving where drug-like compounds can substitute for some of the transcription factors [274,275]. Indeed, recent studies have shown that efficient generation of iPSCs can be achieved using a single transcription factor *OCT4* and a cocktail of small molecules [276]. Another recent method utilizes a microRNA (miR-302) that regulates chromatin demethylation and other factors involved in global reprograming [277]. For future clinical application, it will be necessary that reprograming to generate iPSCs be carried out under GMP-compliant conditions. This has been accomplished to some extent [278]. Scale-up to yield clinical grade cell therapy and tissue-engineered constructs from iPSCs also raises the same essential manufacturing and regulatory concerns that have been discussed for the ES cells.

In spite of all the progress, questions still remain about whether iPSCs are completely equivalent to ES cells in their genetic makeup and in their potential to yield a full range of differentiated cell types. Critical issues that must be addressed for future therapeutic applications would center on the epigenetic mechanisms underlying the resetting of pluripotency [279,280]. Also to be addressed would be genetic and epigenetic variations that might persist through the reprograming process into the mature, specialized cells that will be used for therapy [281]. On the manufacturing side, it is possible that best practices from other cell therapy development will be applied to iPSCs and standards will be established to meet high level of uniformity and quality needed for such therapies. On the regulatory side, assurance of long-term performance and safety will be necessary, similar to what is required for any cell and tissue-engineered therapies.

Another future direction for iPSCs would be to use blood cells, such as the peripheral blood mononuclear cells, as preferred starting material for the production of clinical grade iPS cell lines [282]. The epigenetic and gene expression signatures of peripheral blood mononuclear cells have been shown to more closely resemble those of pluripotent stem cells, than for the fibroblasts. As for the cellular reprograming factors, the addition of Zscan4 (a zinc finger protein that is expressed selectively in 2-cell embryos) to the "Yamanaka" set of transcription factors decreased the DNA damage response during reprograming of mouse somatic cells and improved the yield of pluripotent cells [283]. This will be an interesting direction to explore for future use of iPSCs.

Adult stem cells

A relatively new cell source canned amniotic fluid-derived stem (AFS) cells that possibly represent a primitive precursors of MSC, have recently gaining a lot of attention. AFS cells are isolated from amniotic fluid or chorionic villi and share some properties with adult MSC but are capable of more extensive proliferation in cultures [284]. Since they also express some markers in common with ES cells, their precise lineage and physiological plasticity are still not certain. However, such as MSCs, AFS cells also possess immunomodulatory properties that could benefit their clinical utility [285]. A clear advantage over MSCs is their abundance (in amniotic fluid) and ease of isolation. For the treatment of neurodegenerative conditions and for neural TE, the brain-derived neural stem cells (such as HuCNS-SC) look promising. Future clinical trials based on HpSC may use cells sourced from neonatal livers that can be obtained through organ donation. Hepatic stem and progenitor cells are known to survive relatively long under ischemic conditions as compared to other stem cells [286]. Plus the development of cryopreservation and large-scale culture conditions for these cells will further make them popular for cell and tissue-engineered therapies in the future.

For liver TE, using HpSC in combination with endothelial progenitors such as the liver-derived angioblasts on whole-organ decellularized scaffolds can be a practical strategy [95,287]. Also delivering HpSC in a liver-specific matrix components (hydrogel) along with growth factors might help promote a more rapid, robust differentiation to hepatocytes [95]. In vivo studies in mice have confirmed that human biliary tree stem cells are multipotent for liver and pancreas lineages [288]. More studies will be needed with higher animal models and humans before these cells are declared useful for clinical applications. The biliary tree stem cells can easily be harvested from tissue that is frequently discarded after certain surgical procedures. Their easy availability and isolation (even through a simple procedure such as laparoscopy) represents a great value as a potential cell source for TE of islet-like structures for treating insulin-dependent diabetes.

Whole organ engineering

Use of decellularized organs is a practical approach of bioengineering whole organs for possible clinical use in transplantation. Studies of decellularized tissues and organs are advancing in scope, and some are already used in clinical studies. Since the ECM is much more than just a scaffold for cells and can also control cell organization, communication, and tissue functions, properties of the decellularized tissues can be a primary determinant and dictate reconstruction outcomes. New approaches in this area are focusing on developing decellularized tissues and organs with added benefits, such as retention of intact vasculatures, functionalization via biomaterials, and bioactive factors. When using decellularized tissues and organs for bioengineering new ones for transplantation, a complete assessment of decellularization is important. To prevent immune rejection, native antigens must be removed from the decellularized scaffolds. Also, of particular concern is the hyperacute immune rejection of a decellularized scaffold, which can occur anytime during the days or weeks after implantation [289]. This is caused by circulating antibodies to scaffold antigens within the host. Examples of decellularized scaffold that can trigger a hyperacute immune response include alpha-gal epitopes [289], structural proteins such as collagen VI of the ECM [290]. Even though structural proteins such as collagen VI are necessary for the mechanical stability of the scaffold, it is possible to limit their immunogenic effect. This will be necessary to prevent rejection after implantation into a host.

Every decellularization strategy can produce different effects on structural proteins within a scaffold. Therefore suitable method(s) must be chosen taking into consideration the target tissue type, tissue biomechanics, recellularization method, etc. Some commonly used chemical and mechanical decellularization methods have been known to damage ECM proteins [291]. Since it may be difficult to have a universal decellularization method for all tissue types, reagents and methods can be optimized based on tissue type, size, recellularization method being used, etc. The recellularization of the decellularized scaffold must also be optimized to produce a functional tissue or organ. The recellularization process has its own challenges. Primary among them is even distributions of the cells throughout the scaffold. Perfusion of cells through the vasculature of the construct is a common method used. Other methods include directly injecting cells into the tissue, using sonication to facilitate cell seeding and reendothelializing the vasculature of decellularized scaffold to improve seeding and organization of the cells [292]. Use of bioreactors has vastly improved the seeding and support of cells within decellularized scaffold for TE. For example, use of rotating wall vessel bioreactor has been shown to facilitated greater cell proliferation and viability [217]. Although great advancements have been made in whole organ bioengineering using decellularization, further efforts are needed to optimize reagents, methods, and equipment to achieve reproducible results. Use of a combined strategy that includes chemicals, mechanicals, and enzymes in a dynamic system may improve the decellularization efficiency and still retain components that will support efficient recellularization. For example, cells can be lysed using supercritical CO_2, followed by treatment with a low concentration of surfactants. Remaining cellular and genetic materials can be removed using wash with an enzymatic mixture, followed by buffers to remove all debris. Another area that needs further improvement is the scale-up of these decellularization and recellularization methods, so that enough scaffolds are available for making neo-tissues and organs to bridge the gap between donors and needy patients. Cell sourcing is also a bottleneck for whole organ bioengineering. With exploration of more adult stem-cell sources and human iPSCs, it would be possible to manufacture off-the-shelf tissues and organs in the future. This will help reduce or possibly eliminate the ever-increasing wait list and time for transplants.

Biofabrication technologies

Many TE applications have benefitted from the use of electrospun scaffolds. The high tunability of this technology can help both mechanical and bioactivity properties of the scaffolds. Recent advances in elecrospinning methods are further advancing these potentials by creating additional tools to guide cellular response and achieve enhanced tissue regeneration by generating aligned fibers, enhanced porosity, gradients of functional moieties, etc. New electrospinning methods such as coaxial electrospinning, fiber blending, emulsion electrospinning, and edge electrospinning can enable combining of different materials properties into a single scaffold. Other new methods such as coelectrospinning, hydrospinning, and 3D electrospinning are being used for generating complex fibers and scaffold architectures, and more developments are expected in the future. Enhancing cellular infiltration within electrospun scaffolds has always been a challenge. However, new electrospinning methods such as coelectrospinning, postelectrospinning processing and coaxial electrospinning have made it possible to ensure better and more uniform distribution of cells within electrospun scaffolds. Moving forwards, there are some common challenges to be addressed before electrospun scaffolds and tissues generated using them become mainstream in clinical applications. First, fiber formation, morphology, and composition have to be controlled, so that they are precise and reproducible in a manufacturing setting. Scaffolds with clinically relevant dimensions need to be made with sufficient process control of the electrospinning scale-up.

Cellular infiltration can be enhanced by further refining techniques such as multilayered electrospinning, cell layering, cell electrospraying, and dynamic cell culture systems. Despite these challenges, electrospinning remains a versatile technology and when combined with ever increasing innovative approaches, it is sure to have a lasting impact in the field of TE

Advances in 3D bioprinting hardware and the bioprinting processes are making it possible to fabricate tissues with different levels of complexities. However, this can present additional challenges when these technologies move from lab to commercialization. Accuracy and repeatability are two basic standards of quality that should be taken into consideration during manufacturing. Limiting the intrinsic variability during production can help reduce the extrinsic variability of such complex engineered tissue and organs when placed in in vivo environments [293]. Interestingly, 3D bioprinting, just like other additive manufacturing processes, can allow for in-process inspection of the product being produced, which is a positive attribute for quality control.

To increase the printing speed of multimaterial and multicell constructs, new 3D printing devices and strategies are being proposed. Also, development of perfusable vascular networks within biofabricated structures is also gaining importance from a clinical perspective. 3D cell culture techniques are also a recent trend and have contributed to significant progress in development of tissue-specific organoids, which is one of the scientific breakthroughs of recent years. Taken together, advances in 3D bioprinting, new bioink hydrogels, and 3D cell culturing are providing new opportunities for successful translation of tissue regeneration technologies and also gaining a better understanding of mechanisms involved in disease pathogenesis and progression. A future area of development in TE being made possible due to nanotechnology is referred to as "4D bioprinting." Here "time" is included as a fourth dimension in 3D bioprinting constructs, which can change their shapes or functionalities with time in response to external stimuli [118]. All these examples demonstrate the value of using nanotechnology in RM, which can add unique functionalities and broaden the portfolio of tools available for TE. Looking ahead, 3D bioprinting will benefit from advances in CAD/computer-aided manufacturing, standardization of materials, cells, and procedures to 1 day offer patient-specific tissue and organ repair therapies. There is no doubt that 3D bioprinting is transforming from an emerging trend to a main stream biomedical technology.

Tissue neovasculatization

3D bioprinting of vascular networks represents the best approach for creating vascular networks in engineered tissue and organs. Future efforts in this direction should also include design considerations, such as ability to withstand burst pressure and suitability for direct surgical anastomosis to host vasculature. The fabrication process can become even more complex when vasculature becomes part of the design. However, in vivo success of thick tissues and organs cannot be guaranteed without this.

Bioreactors

The type and complexity of the tissue being cultured in the bioreactor will affect the process design. Viscosity of the medium can also impose a mechanical load and affect cell morphology through cellular signaling [294]. It's been also observed that stem cells, when subjected to mechanical stimuli, can undergo what is known as mechano-differentiation [295,296]. All these topics are focus of intense research, which are going to influence future bioreactor designs. It is clear that to mimic in vivo organ function, there is considerable complexity required in bioreactor design. Use of computational modeling (also referred to as in silico analysis) using parameters from normal tissue/organ physiology and incorporating it into bioreactor construction can definitely improve TE outcomes. An example of this approach is a study where necessary parameters for vascular TE were derived by using a computer model to analyze fluid-structure interaction [297]. Results from this modeling matched results from an analytical model where predictions were made for pressures on the tubular scaffolds, wall shear stress, and circumferential deformation. Hence, use of in silico analysis can provide critical information that can enhance the development of the right bioreactor and culture conditions for complex tissues and organs.

Integration of nanotechnology

Current methods of cell patterning includes creation of physical patterns (using techniques such as ablation, etching, lithography, and printing), chemically modifying surface, or producing substrates with inherent topographies (fibers, hydrogels, etc.). All these methods have limitations of their own. Use of MNPs for cell control and patterning provides a new tool for fabricating tissue architecture that can match in vivo conditions. Examples of this approach include a study where a heterotypic coculture of mouse myoblast and human keratinocyte (HaCaT) cells was generated and capillary-like structures were formed with HUVEC cells [298]. Thus using nanoparticles, the biological properties of scaffolds and the resulting constructs can be significantly altered; thereby helping to engineering tissues with better overall function. Further integration and use of sensors and other electronic

elements in TE systems can support long-term studies and provide insights into the function, pathophysiological conditions, and also response to treatments. In a clinical setting, such system can monitor implanted tissues and organs in patients and provide important information on time if an intervention, drug adjustment, or other type of care is needed for the success of the implant. When translating nano-specific technologies to clinical applications, there are many challenges to overcome. For example, in applications where the chronic bioaccumulation of nanoparticles is a possibility, more long-term studies will be needed to determine safety. In products the notification of chemicals, criteria for classification, and labeling requirements are not widely available and will have to be revised. In addition to the technology itself, regulatory aspects will have to be addressed. Currently, there are no specific standards for nano-specific risk assessments within biological systems, nor clear regulatory guidelines for biological products containing nanoparticles. All these are challenges that need to be addressed for integration of nanotechnology in tissue-engineered clinical products.

Conclusions and future challenges

With advances in TE, technological advances such as use of stem cell, gene editing, 3D bioprinting, and nanotechnology, are enabling fabrication of tissue/organ with increasing complexities, resolution, and functionality, thereby supporting regenerative therapies that are tailored to specific patients and their needs. Use of electronic components or magnetic responsive elements within TE products can enable such features, where sensing and actuation can be controlled remotely and host response can be actively modulated postimplantation of the TE product. This has a potential to revolutionize not only patient follow-up but also regenerative therapies for human patients. Based on the requirements of individual patients, drug dosages, cells delivery, or treatment outcomes can be controlled which can significantly broaden the therapeutic efficacy of current TE systems. In addition, use of use of real-time monitoring and control systems in TE can advance our knowledge of disease mechanisms and homeostasis. One more area that can immensely help personalization of TE is use of artificial intelligence (AI) and large-scale data analysis. AI and data analytics can significantly accelerate design, fabrication, and testing of TE systems in future based on feedbacks from current products and processes. In all, use of personalized TE therapies can not only benefit patient outcomes but can also result in huge savings of social and healthcare costs, as inefficient and failed therapies are associated with huge costs at the healthcare and personal levels.

One of the future challenges in TE will be to develop technologies for faster biofabrication of complex, hierarchical tissue architectures, and human-scale dimensions for accurately recapitulating living tissues and organs. For successful TE, a smart biomaterial should not only mimic the structural components of the ECM but also be able to interact with cells in a dynamic way to promote adhesion, proliferation, differentiation, and tissue morphogenesis. However, the design of smart materials combines several of these properties is still a challenge. For example, it can be challenging to develop a smart material with optimal chemical and mechanical properties without negatively affecting its biological properties or vice versa. Of course, understanding the fundamental biology of tissue formation, growth, and maturation will be critical for developing bio-inspired materials, but deriving ideally fabricated structures out of them can further be challenging. This is due to the fact that TE by itself is a multistep, multicomponent approach, and finding the perfect solution at every step can be more difficult than easy.

Many novel synthetic and smart biomaterials have been developed in the last decade, and this trend is expected to continue. For biomaterials to be used for fabricating medical devices and tissue-engineered constructs, the development of efficient and safe sterilization, packaging, and storage methods, with minimal impact on the properties and performance of the material components will be necessary. Unfortunately, not much efforts are being places in this direction, which has to change if commercialization and clinical use of tissue-engineered products will have to be accelerated. Significant challenges for translation of biomaterial technology to the clinic still remain. A major limitation toward designing biomaterials for different TE applications is the limited fundamental understanding of the interactions between material and cells within tissues. Even though biomaterial engineering is producing materials with the ability to control cellular behavior to some extent, many challenges still remain in creating smart biomaterials that can respond to cells and their environments after implantation in vivo. Another challenge for the future would be the real-time monitoring and/or remote manipulation of tissue-engineered systems. Success in this direction will help establish a new paradigm for RM broadly.

Introduction

Tissue engineering aims to understand the principles of in vivo tissue growth and development and applies this understanding to the engineering of functional replacement tissue ex vivo for clinical use subsequent to disease or injury. However, tissue formation is an inherently complex process—involving multiple biological, chemical, and physical processes that interact on a variety of length scales and timescales—and deciphering general principles of tissue development is a challenging task [1]. Nevertheless, a deep understanding of these principles is necessary to efficiently engineer functional tissue in vitro. For this reason, tissue engineering approaches commonly coordinate techniques from a variety of different disciplines, including molecular, cell and developmental biology, chemical engineering, and biophysics, to dissect this complexity. Recent years have seen an increasing interest in applying tools from the mathematical and computational sciences to the design, development, and implementation of tissue engineering protocols [2,3].

Mathematical and computational models are routinely used to help understand complex systems and optimize industrial processes in the engineering and physical sciences. There are many remarkable examples of the long-standing use of quantitative methods in the cell and molecular biosciences [4]. Recent rapid advances in both available computational power and high-throughput experimental procedures have stimulated an extraordinary cross-fertilization of ideas from the mathematical, statistical, physical, and life sciences, particularly within the areas of systems biology and bioinformatics [5]. Concurrently, much progress has also been made in recent years toward understanding general principles of tissue growth and development. In this chapter, we will explore how mathematical models, in collaboration with experimental studies and machine learning, can help further understanding of these principles. Given the breadth and rapid growth of this field, we will necessarily only focus on a few key areas, particularly: understanding molecular basis of stem and progenitor cell fate commitment; spatiotemporal regulation of cellular differentiation; and general principles of tissue morphogenesis.

Modeling stem cell dynamics

Stem cells are present during all stages of the development and are uniquely characterized by their capacity to maintain their numbers by self-renewing, as well as differentiate along distinct lineages. Embryonic stem (ES) cells have the capacity to produce all somatic tissues, a property known as pluripotency, and there is much interest in elucidating the molecular mechanisms of pluripotency [6]. Following the seminal work of the Yamanaka group in demonstrating that adult fibroblasts could be reprogramed to ES cell-like state by the forced expression of just four pluripotency-associated transcription factors (Klf4, c-Myc, Oct-3/4, and Sox2), there is a hope of using adult somatic cell−derived induced pluripotent stem (iPS) cells as patient specific, and less controversial, alternatives to human ES cells [7−9].

In contrast to ES and iPS cells, adult stem cells are typically lineage restricted and thereby constrained in their therapeutic potential (they are generally only multi- or unipotent) [10]. Nevertheless, due to their regenerative

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00001-0

capacities and the relative ease, with which they may be obtained, there is also considerable interest in understanding the processes, by which adult stem cells orchestrate tissue growth and development and applying this understanding to engineering functional replacement tissue in the laboratory [1]. A standard tissue engineering approach to this problem is to harvest appropriate stem cell populations and, using defined culture conditions (which include regulating the chemical, physical/mechanical, and geometric properties of the growth environment), recapitulate in vivo regenerative processes to produce functional tissue in vitro. The ultimate success of this strategy relies on a clear understanding of the molecular mechanisms of stem cell self-renewal and differentiation and the spatiotemporal control of these processes.

Stem cell fate is critically dependent upon interactions with neighboring cells—including differentiated progeny [11] and other stem/progenitor cells [12]—and extracellular components that constitute the stem cell niche [13]. Stem cell interactions with the niche are mediated through intracellular molecular regulatory networks that include transcriptional, signaling, and epigenetic regulatory components [14]. These networks are highly complex, containing multiple feedback loops and feed forward loops that allow the cell to respond dynamically to changes in its environment. These types of feedback-based mechanisms are reminiscent of control systems in engineering, and recent years have seen considerable interest in viewing cell fate decisions from a dynamical systems perspective [14]. In the field of synthetic biology field, for instance, switches and oscillators have been implemented experimentally in synthetic model systems using rational designs based upon mathematical reasoning [15–17]. A general principle that emerges from this viewpoint is that the molecular switches that underpin stem cell fate decisions are ultimately dependent upon positive feedback loops in the cells' underlying intracellular molecular regulatory circuitry [18].

Positive feedback–based molecular switches

Positive feedback–based switches play a central role during the development by initiating all-or-none commitment events in response to external stimuli and commonly underpin stem and progenitor cell fate decisions, including during hematopoiesis [19]; neural development [20]; and human embryonic and mesenchymal and stem cell fate commitment [21,22]. In order to illustrate the general principle of a feedback-based switch, consider as an example the following dimensionless equations, which describe a simple "toggle switch" consisting two cross-inhibitory transcription factors, X and Y [15]:

$$\frac{dx}{dt} = \frac{\alpha_1}{1 + y^{\beta_1}} - x \tag{2.1}$$

$$\frac{dy}{dt} = \frac{\alpha_2}{1 + x^{\beta_2}} - y \tag{2.2}$$

where x and y denote the intracellular concentration of X and Y. Eqs. (2.1) and (2.2) describe the rate of change in expression of X and Y over time and state that X and Y are synthesized with effective rates α_1 and α_2, respectively (first terms on the RHS) and decay with constant half-lives (second terms on RHS). The parameters β_1 and β_2 capture cooperativity in repression, allowing for repression by multiprotein complexes and/or binding of multiple regulatory sites on the respective promoters, for instance. Note that although this system is characterized by repressive interactions, it nevertheless represents a simple positive feedback loop since both factors indirectly activate their own expression via inhibiting expression of the other. This kind of switch has been engineered in both *Escherichia coli* [15] and mammalian cells [23] and behaves as a genetic "memory unit" [15] (indeed it behaves similarly to an SR flip-flop for memory storage in electronic systems).

The dynamics of this system may be explored by plotting changes in expression of X and Y against each other to form the system's *phase plane*. The phase plane for this system is shown in Fig. 2.1A–C for different parameter values. For appropriate regimes, this system supports stable expression of *either X or Y*, but not coexpression of both, as one might expect (Fig. 2.1A and C). For instance, if the effective rate of synthesis of Y is higher than that of X, then Y is expressed, while X is repressed (Fig. 2.1A); by contrast, if the effective rate of synthesis of X is higher than that of Y, then X is expressed, while Y is repressed (Fig. 2.1C). In these cases, since only one stable equilibrium point is present, the system is said to be *monostable*. In general, monostability occurs in the absence of cooperativity ($\beta_1 = \beta_2 = 1$) or if the effective rates of synthesis of the two repressors are unbalanced ($\alpha_1 \gg \alpha_2$ or $\alpha_1 \ll \alpha_2$). However, if the effective rates of synthesis of the two repressors are balanced ($\alpha_1 \approx \alpha_2$) and transcriptional repression is cooperative ($\beta_1, \beta_2 > 1$), then these two alternate states may stably coexist (Fig. 2.1B). In this case the system is said to be *bistable* and it is the capacity of this system to possess different equilibrium patterns of expression depending on parameter values that allow it to act as a switch. Particularly, this system is a *toggle* switch, since expression of either of the repressors may be toggled "on" and "off" by transiently inducing changes in expression by varying the effective rates of synthesis α_1 and α_2 [15].

Ultimately, the toggle switch described earlier works, since each factor directly represses transcription of the other while indirectly activating its own transcription.

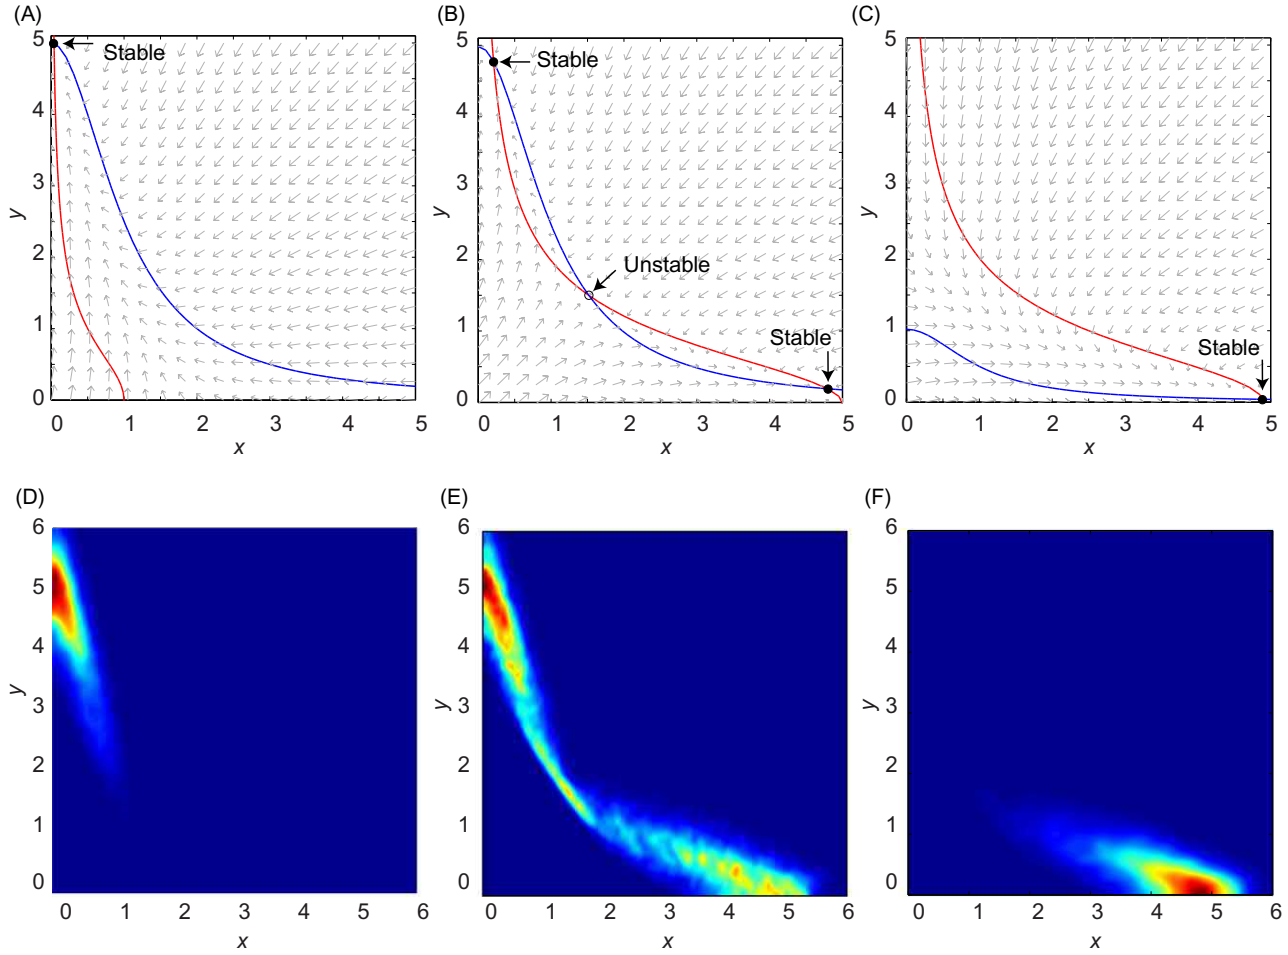

FIGURE 2.1 **Bistability and monostability in a genetic toggle switch.** (A–C) Phase planes for Eqs. (2.1) and (2.2) for different model parameters showing that this simple molecular switch supports both monostability (A and C) and bistability (B). Arrows show the direction field illustrating the flow toward the stable equilibria from different initial conditions. (D–F) Corresponding probability density functions show that expression variability can arise within a cellular population in the presence of molecular noise. Red shows regions of high probability of finding a cell; blue shows regions of low probability. Here stochasticity in expression of the two genes has been modeled as white noise process with amplitudes $\sigma_1 = 0.55$ (noise in expression of x) and $\sigma_2 = 0.75$ (noise in expression of y). Parameter values: (panels A and D) $\alpha_1 = 1$, $\alpha_2 = 5$; (panels B and E) $\alpha_1 = 5$, $\alpha_2 = 5$; (panels C and F) $\alpha_1 = 5$, $\alpha_2 = 1$. In all cases, $\beta_1 = \beta_2 = 2$.

However, mutual cross-repression is by no means the only positive feedback motif that can give rise to molecular switches of this kind. For instance, direct autoregulation, which is also common in eukaryotic genetic regulatory networks [16,24], can give rise to multistability and switching, either on its own [16] or in concert with other mechanisms. For example, if in addition to mutual cross-repression, each of the transcription factors in the toggle switch also directly regulates its own expression positively then a third "primed" state, in which both factors are promiscuously coexpressed within individual cells, may also be supported resulting in a potentially *tristable* system. This occurs, for instance, during hematopoiesis: the lineage-specifying master transcription factors, GATA1 and PU.1, each enhance their own expression while repressing that of the other [25]. Since both GATA1 and PU.1 also regulate multiple downstream targets (GATA1 specifies the erythroid/megakaryocyte lineages, while PU.1 specifies the myelomonocytic lineage), the state of this motif affects widespread genetic programs and effectively defines a lineage choice. By differentially regulating multiple downstream targets, positive feedback–based switches, such as this, can act as input/output (I/O) devices within larger genetic regulatory networks [26]. In the context of development, positive feedback–based I/O devices are important, since they provide a mechanism by which the cell populations can convert spatial information (for instance, an extracellular morphogen gradient) into a defined commitment responses, resulting in spatial localization of widespread gene or protein expression patterns [16,27]. We will discuss further how spatial localization of intracellular feedback mechanisms

can give rise to complex spatiotemporal patterns of expression in the section "Pattern formation."

Variability in stem cell populations

Although useful, the toggle-switch model given in Eqs. (2.1) and (2.2) is deterministic, and it does not account for environmental fluctuations or variability in gene expression, which are inevitably present. Gene and protein expression are intrinsically stochastic processes [28,29] and cell−cell variability may arise in isogenic cell populations either due to gene expression "noise," or due to stochastic partitioning errors or asymmetry during cell division [30−32] (Fig. 2.2). For instance, if such expression noise is accounted for in the toggle-switch model, then cell−cell variability in expression patterns can naturally arise within a population of genetically identical cells (Fig. 2.1D−F). This variability is particularly evident in the bistable regime, when expression fluctuations can induce transitions between the coexisting stable states (Fig. 2.1E). This kind of cell division−independent, nongenetic population heterogeneity is remarkably robust and appears to be a relatively widespread feature of both prokaryotic and eukaryotic cell populations [33−35].

It has long been postulated that stochasticity may have an important role in stem cell fate commitment [36−39]. In the 1960s Till et al. assessed the colony-forming ability of adult mouse bone marrow cells in the spleens of irradiated mice [36]. Using a serial transplantation assay, they found that the number of colony-forming units (CFUs) per colony varied considerably beyond that expected from sampling errors alone, in a manner consistent with a "birth-and-death" process (a simple Markov process, well studied in the statistical physics literature [40]), in which CFU self-renewal and differentiation occur stochastically with defined probabilities [36]. They confirmed this conclusion by numerically simulating colony formation using the birth-and-death model, providing a good early example of the use of computational simulations in stem cell biology. Similarly, Ogawa et al. came to related conclusions concerning the stochastic nature of stem cell fate commitment, in their studies of paired hematopoietic progenitor cells in the 1980s [37−39].

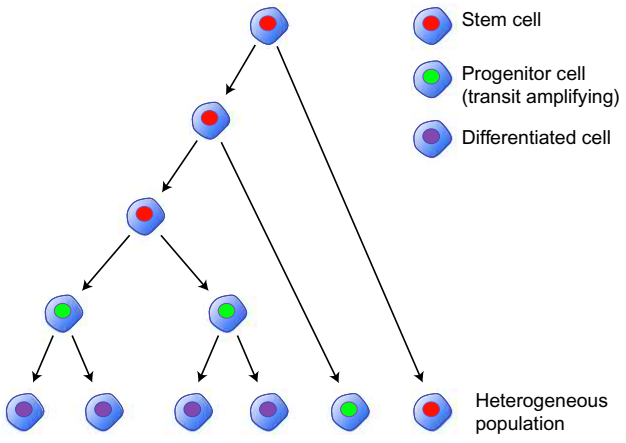

FIGURE 2.2 Heterogeneity in a hierarchically structured population of stem, progenitor, and terminally differentiated cells. Stem cells maintain their numbers by symmetric and asymmetric divisions and give rise to transit amplifying progenitor cells, which in turn produce terminally differentiated progeny. This hierarchy of divisions naturally produces a mixed population containing stem, progenitor, and terminally differentiated cell types in proportions that vary with environment, age, and disease or insult.

Within the last few years, studies have confirmed substantial variability in both equilibrium expression patterns in a variety of mammalian stem and progenitor cell populations [33,41−45] and the dynamics of cellular differentiation and reprograming [21,46,47]. In our own recent work, we have investigated variability in colony-forming ability of primary human bone marrow stromal cell (HBMSC) populations using a two-stage colony-forming assay [48]. We found considerable variability in both the sizes of primary (P0) colonies, seeded from single HBMSCs, and secondary (P1) colonies, formed by detaching cells from P0 colonies and reseeding at clonal density, with apparently little correlation between primary and secondary colony sizes (dependent on the primary colony, transplanted cells produced either small secondary colonies or a wide range of disparate colony sizes). We also observed distinct spatial heterogeneities in expression of mesenchymal and niche-associated markers (including CD146, alpha smooth muscle actin, and alkaline phosphatase, see Fig. 2.3A−C) indicating spatial regulation of cell behavior within the colonies. Computational analysis, using a cellular automaton model that accounted for proliferation and migration of individual cells, showed that this behavior is consistent with tissue growth within a structured cellular hierarchy (consisting stem, transit amplifying, and differentiated cell types, see Fig. 2.2), regulated by cell−cell interactions.

Taken together these results indicate that cell−cell variability in expression patterns and stochasticity in stem cell commitment may be closely related, with stochastic mechanisms allowing dynamic "priming" of subpopulations of stem cells for different lineages prior to commitment [49]. These observations suggest that cell fate commitment events are regulated at the population, rather than individual cell, level. Thus intracellular molecular regulatory networks may not control individual stem cell fate commitment per se, but rather control the overall structure of the cellular population [36], possibly by modulating molecular noise [50]. In this regard a more probabilistic view of stem cell fate may be appropriate, in which statistical properties of ensembles of cells,

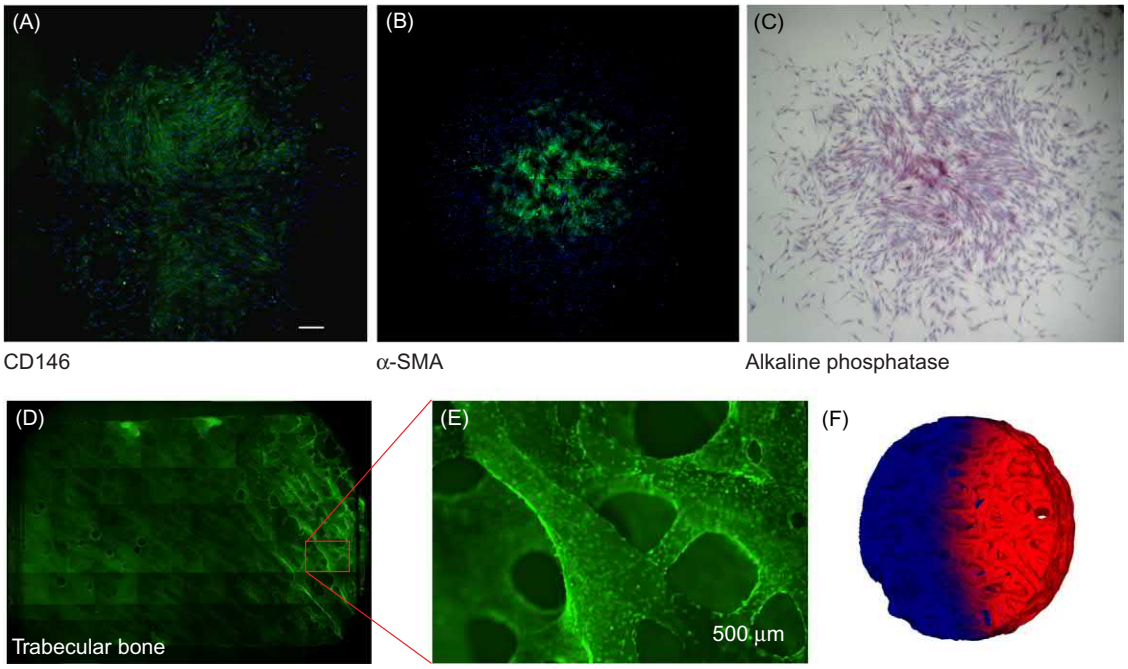

FIGURE 2.3 **Tissue growth in monolayer and 3D culture.** Panels (A–C) show intracolony variability of differentiation and niche markers within primary human bone marrow stromal cell samples seeded at clonal density to form single cell–derived colonies. P0 colonies were fixed and assessed for the following mesenchymal markers. (A) CD146 (melanoma cell adhesion molecule) expression measured using mouse monoclonal antibody, in combination with fluorescein isothiocyanate (FITC)-conjugated antimouse IgG secondary antibody. (B) Alpha smooth muscle actin expression measured using mouse monoclonal antibody in conjunction with FITC-conjugated antimouse IgG secondary antibody. (C) Alkaline phosphatase activity in red, stained with naphthol AS-MX phosphate and fast violet B salts. Staining of all three markers is strongest toward the center of the colony. Panels (D–F) show cell colonization of complex 3D geometries. (D) Slice of human trabecular bone used in a 3D colonization assay. (E) Primary human bone marrow stromal cells were seeded onto the trabecular bone sample and cell colonization was visualized over time using CellTracker Green labeling (bright green). (F) Typical simulation of corresponding mathematical model of cell proliferation and colonization of trabecular bone sample. Domain geometry was obtained from a μCT scan of the trabecular bone sample. Regions of high cell number density are in red; regions of low cell number density are in blue. *3D*, Three-dimensional; *IgG*, immunoglobulin G; *μCT*, microcomputerized tomography.

rather than characteristics of individual cells (or averaged properties of populations of cells) are considered. An enhanced quantitative understanding of the intrinsic variability of stem cell populations will require developments in both high-throughput single-cell profiling procedures and the mathematical and statistical techniques needed to decipher the complex datasets that result from these experimental advances. Such advances will enable a better understanding of how variability can be controlled to produce more defined stem cell populations, which will ultimately lead to the development of more robust stem cell isolation and expansion protocols for tissue engineering and regenerative medicine applications.

Modeling tissue growth and development

Any success in engineering functional tissue ex vivo must rely not only on deciphering individual stem cell behavior but also on developing an enhanced understanding of the mechanisms of morphogenesis in vivo, including the environmental, chemical, mechanical, genetic, and epigenetic processes, involved in spatial regulation of cellular differentiation. There have been a number of remarkable recent successes in engineering complex, spatially structured, and *functional* three-dimensional (3D) tissues in the lab, including the optic cup [51]; the anterior pituitary (adenohypophysis) [52]; the trachea [53]; articular cartilage [54,55]; vascularized bone [56]; and, recently, allogeneic veins [57].

The formation of structure either during in vivo development or ex vivo tissue formation is dependent upon cells translating spatial information concerning their relative location within the developing organism or tissue into different patterns of gene and protein expression based upon their current genetic state and developmental history [58]. The extraordinary reproducibility of development requires not only that positional information is precisely and robustly defined (i.e., insensitive to environmental fluctuations) but also that cellular sensing of such information is correspondingly sensitive and appropriately coordinated. Spatial gradients have long been known to provide positional information for spatial patterning during development (for instance, see the work of Wolpert and coworkers [59–61]). Since spatial patterns emerge on relatively

short length scales, Crick suggested that spatial information may be supplied by diffusion gradients [62], although local mechanisms, such as cell−cell communication, are also important [63]. Consequently, mathematical models of reaction−diffusion processes—which take into account both chemical diffusion and cellular responses to evolving chemical gradients—have been widely used to study tissue growth and development.

Monolayer tissue growth in vitro

One of the simplest reaction−diffusion models is Fisher's equation, which was originally used to study the spread of a favored gene through a population [64] but serves as a good model for expansion of an in vitro monolayer cell colony due to proliferation and cellular migration. Denoting the cell number density (the number of cells/m^2 for monolayer culture) at position $\boldsymbol{x}$ and time t by $n(\boldsymbol{x}, t)$, Fisher's equation reads the following:

$$\frac{\partial n}{\partial t} = rn(N - n) + D\nabla^2 n \tag{2.3}$$

This equation describes the rate of change of cell number density in space and time. The first term on the RHS of Eq. (2.3) describes cellular proliferation. At low cell number densities proliferation is approximately exponential, with linear growth rate rn; however, as the cell number density reaches N, the maximum at confluence, the proliferation rate tends to zero accounting for inhibition of cell division due to cellular crowding. This model is known as logistic growth and is a good first approximation to two-dimensional expansion of an unstructured population of identical cells. Hierarchically, structured populations that contain subpopulations of stem, progenitor, or transit amplifying cells may exhibit more complex patterns of proliferation not captured by the logistic model (Fig. 2.2). Mathematical models of growth kinetics in such heterogeneous populations have been considered by a number of authors [48,65−67]. The second term on the RHS of Eq. (2.3) describes cell motility and states that cells move in a random manner with motility coefficient D, similar to a diffusion coefficient. More complex forms of motility, including chemotaxis or haptotaxis, may be included by adapting this migration term [68]. In one spatial dimension, assuming appropriate initial conditions, Fisher's equation predicts that the colony advances as a "traveling wave" (meaning that the invasion front maintains a constant shape, moving at a constant speed) with wave speed $v = 2\sqrt{rND}$ [64]. In the case that growth is spherical and axisymmetric (for instance, a radially expanding colony), the wave speed approaches this constant asymptotically for large radius [64]. Since the wave speed depends upon both the diffusion coefficient and the linear growth rate, reaction−diffusion fronts may advance much faster than by diffusion alone, and in a precisely quantifiable way. Consequently, Fisher's equation provides an illustrative example of how a simple mathematical model may be used to investigate the relationship between proliferative and migratory parameters and colony growth rate. If the linear growth rate is known (for instance, from an independent proliferation assay), then cellular motility coefficients may be estimated using this relationship. For instance, Maini et al. have used this model to analyze an invasion front in a wound-healing assay for human peritoneal mesothelial cells [69,70] and we have previously used this relationship to estimate the migration rate of primary HBMSCs [71]. We found that for slowly proliferating migratory cell types, such as HBMSC populations, Fisher's equation provides a good model for colony growth; however, for highly proliferative populations, such as the MG63 human osteosarcoma cell line, a sharp-front variation of Fisher's model is more appropriate [71].

Tissue growth on complex surfaces in vitro

Fisher's equation as outlined earlier describes monolayer growth. However, tissue engineering strategies commonly rely on seeding appropriate cell populations onto complex 3D porous biomimetic scaffolds in order to provide geometric support for tissue development [1,72]. In this situation, while good peripheral tissue growth is usually observed, poor growth or necrotic cell death is often seen in the central regions of such constructs (though this is not always acknowledged). Spatial heterogeneity of this kind is usually related to inadequate nutrient supply and/or accumulation of toxic waste products at the scaffold interior, problems that we shall discuss in the following section. However, spatial tissue inhomogeneity may also arise from poor cellular ingrowth due to uneven initial seeding of cells and/or locally adverse scaffold geometries. Numerous groups have investigated the effects of seeding strategies, scaffold geometry, and nutrient supply on subsequent tissue growth, using both experimental and computational methods [73−75]. For instance, we have investigated HBMSC population ingrowth in a complex geometry using an experimental−computational approach, which simulated Fisher's equation over a surface obtained from microcomputerized tomography scanning of trabecular bone [75] and compared simulations with experimentally derived invasion fronts. We observed that despite the complex geometry, Fisher's equation described tissue ingrowth over the trabecular bone surface surprisingly well, with the average migration front advancing at an approximately constant speed dependent upon geometric properties of the bone surface, such as porosity and tortuosity [75] (see Fig. 2.3D−F). Applications of simple models of this kind are useful, since they allow quantitative

assessment of how scaffold architecture affects key proliferation and migratory parameters that govern the efficacy of tissue ingrowth.

Three-dimensional tissue growth in vitro

Nutrient-limited growth has been observed for a wide variety of engineered tissues, including articular cartilage, intervertebral fibrocartilage, and cardiac tissue [74,76,77]. In the absence of enhanced transport of nutrients and cellular waste products, spatial heterogeneities in cell numbers rapidly develop: peripheral cells have access to ample nutrient that they consume, leaving those on the interior nutrient starved. Consequently, diffusion-limited viable scaffold-based tissue growth is typically restricted to a few hundred micrometers (approximately the intercapillary distance in vivo). Spatial variability in cell numbers can also lead to variability in deposited extracellular matrix components that can severely inhibit the formation of mechanically competent tissue (see Fig. 2.4). The problem of nutrient-limited growth and resultant tissue integrity has been examined from a computational perspective by numerous groups in both the context of tissue engineering [74,78–80] and avascular solid tumor growth [81].

For example, we used the following mathematical model to investigate the relationship between evolving oxygen concentration profiles and nutrient-limited tissue formation in the early stages of growth in developing engineered cartilage tissue [74]:

$$\frac{\partial c}{\partial t} = D\nabla^2 c - \alpha\beta cn \tag{2.4}$$

$$\frac{\partial n}{\partial t} = \beta cn \tag{2.5}$$

where $c(\boldsymbol{x}, t)$ and $n(\boldsymbol{x}, t)$ represent oxygen concentration (mol/m^3) and chondrocyte cell number density (number of cells/m^3 for 3D culture) at position $\boldsymbol{x}$ and time t, respectively. These equations describe the rate of change of oxygen concentration and cell numbers in both space and time. The first one describes the evolution of the oxygen concentration in the developing tissue: the first term on the RHS of this equation accounts for transport of oxygen, which is assumed to occur by diffusion with constant diffusion coefficient D; the second term accounts for oxygen depletion and states that oxygen is consumed at a rate proportional to the local cell number density. The second equation describes changes in cell number density: the term on the RHS accounts for cellular proliferation at a rate proportional to the oxygen concentration (cell death and migration are assumed to be negligible during the initial phase of tissue growth, which these models consider). The parameters α and β control the relative rates of cellular proliferation and oxygen consumption. Note that the cell number density and the oxygen concentration are intrinsically coupled to each other: changes in oxygen

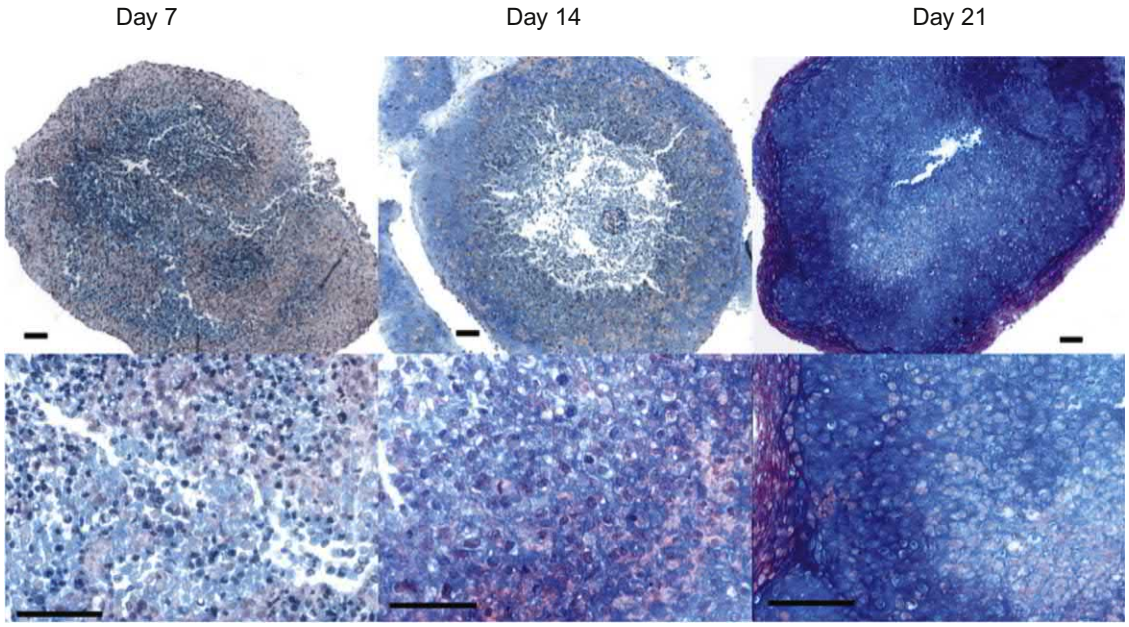

FIGURE 2.4 21-Day pellet culture time course of murine chondrocytic ATDC5 cells. Pellets were stained with alcian blue and sirius red to demonstrate the presence of proteoglycans and collagenous ECM, respectively. Spatial variability in cell numbers is apparent after 7 days and extends throughout the culture period. Cell number variability also leads to variability in deposited ECM components, which affects the structural properties of the engineered tissue. Scale bar: 100 μm. *ECM*, Extracellular matrix.

concentration affect cellular proliferation, which in turn effect changes in oxygen levels. To close the system, we assume that oxygen levels are initially constant and the scaffold is uniformly seeded with chondrocytes and take a no-flux boundary condition at the scaffold center and a continuity condition on the scaffold surface for the oxygen concentration. Although this model is somewhat simplified, it was nevertheless found to provide a good fit to experimentally derived evolving oxygen and cell number density profiles, indicating that oxygen availability is a rate-limiting process during the early stages of in vitro cartilaginous tissue formation. Furthermore, this analysis indicated that in the absence of enhanced transport processes or regulation of cellular proliferation, spatial heterogeneities are inevitable: nutrient supply by diffusion alone will always result in proliferation-dominated peripheral regions that severely restrict viable tissue growth, and therefore potential for clinical scale-up. This problem has been tackled both by enhancing nutrient transport, for instance using bioreactors, in which transport is enhanced by advection or perfusion [82,83], or using printed scaffolds that possess an artificial "vasculature," which can channel nutrients to the tissue center [84]; and by coculture with endothelial cells in order to encourage the concomitant formation of de novo vasculature within the developing tissue [85].

Pattern formation

During development, extraordinarily complex spatiotemporal structures emerge spontaneously, and it is these intricate "patterns" that ultimately provide tissues and organs with the microscopic and macroscopic structure necessary to their function. Reproducing such pattern-forming processes in vitro is a major goal of tissue engineering, and a quantitative understanding of these self-organizing processes will be needed to reproducibly and reliably engineer macroscopically structured functional tissues ex vivo. Remarkable progress has been made toward understanding the biochemical and biophysical basis of morphogenesis from both experimental and theoretical perspectives (see Ref. [86] and references therein for some examples).

In the 1950s Turing presented a simple chemical mechanism, by which spatial patterns may arise spontaneously in biological systems [87], which has become acknowledged as a milestone in our understanding of development [88]. Turing's mechanism relies upon diffusion of a chemical "morphogen" destabilizing a spatially homogeneous state, and driving evolution toward a stable spatially heterogeneous, or patterned, state. This mechanism is both simple and remarkable, since diffusion usually has a homogenizing, or stabilizing, role. However, it can give rise to an extraordinary range of complex patterns. Consequently, it has received much attention in the mathematical biology literature [89]. The biochemical and biophysical basis of morphogenesis has developed considerably, since Turing's initial work and his concepts have been used to help understand a range of mammalian developmental systems, including vertebrate limb bud development, angiogenesis, and wound healing [64,89,90]. Recent developments have also begun to take into account both chemical mechanisms and biomechanical forces (which are known to play a critical part in the development of tissues, such as bone [63]) in morphogenesis [91,92].

An archetypical model of pattern formation is the *activator–inhibitor* model of Gierer and Meinhardt [93]. The generalized Gierer–Meinhardt (GM) model consists of the following coupled equations, which describe reactions between an *activator* with concentration $u(\boldsymbol{x},t)$ (mol/m^3) and an antagonist, or *inhibitor*, with concentration $v(\boldsymbol{x},t)$ (mol/m^3) at position $\boldsymbol{x}$ and time t:

$$\frac{\partial u}{\partial t} = D_u\nabla^2 u + \rho_u + \frac{\rho u^2}{(1+\kappa u^2)v} - \mu_u u \tag{2.6}$$

$$\frac{\partial v}{\partial t} = D_v\nabla^2 v + \rho_v + \rho u^2 - \mu_v v \tag{2.7}$$

These equations describe the rate of change of activator and inhibitor concentrations in space and time. Here $D_u, D_v, \rho_u, \rho_v, \rho, \mu_u$, and μ_v are positive constants, which characterize the rates of diffusion, production, and decay of the two species. The first terms on the RHS of Eqs. (2.6) and (2.7) account for diffusion; the second and third terms account for production: the activator enhances its own production (forming an autocatalytic positive feedback loop) and that of the inhibitor, while the inhibitor represses production of the activator; the fourth terms account for the decay of both species with constant half-lives. If the inhibitor diffuses more quickly than the activator, then this model can give rise to a variety of different spatially inhomogeneous patterns (including various types of spots and strips, see Fig. 2.5 for some examples). The essential mechanism, by which these patterns arise, depends on spatial control of positive feedback: small fluctuations away from the spatially homogeneous state are initially strongly locally amplified by the positive feedback present in the system due to activator autocatalysis; however, this amplification does not continue uninhibited but rather is spatially confined due to fast diffusion of the inhibitor away from regions of local activation. This type of *short-range* activation and *long-range* inhibition underpins many examples of biological pattern formation. For instance, using a joint experimental–computational approach, Garfinkel et al. have recently shown that this mechanism can account for complex patterns formed by adult vascular mesenchymal

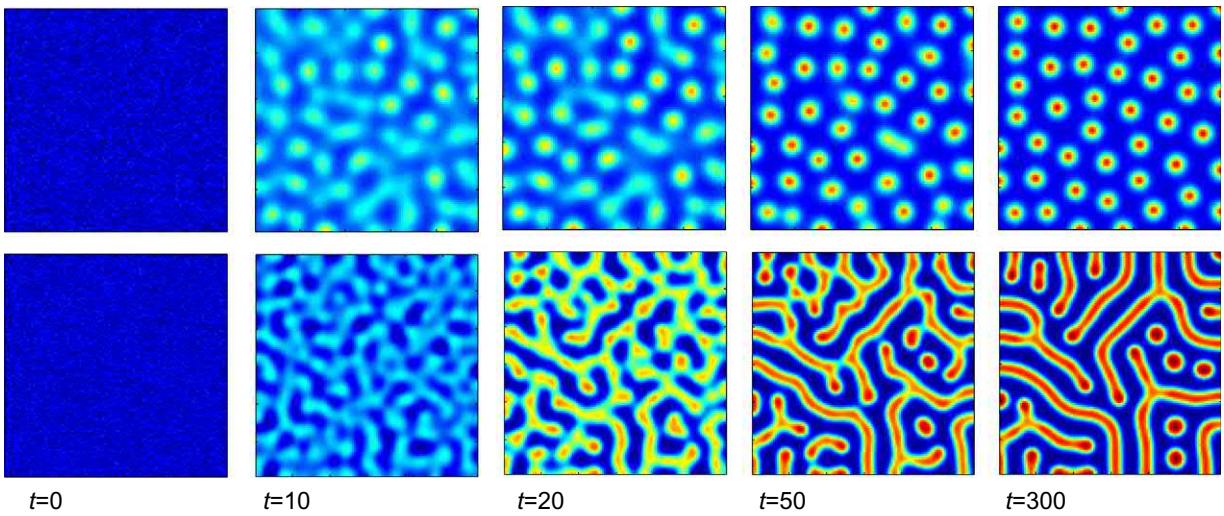

FIGURE 2.5 Spontaneous pattern formation in a simple reaction–diffusion model. Simulations of the generalized Gierer–Meinhardt model [93], a classic activator–inhibitor reaction–diffusion process given in Eqs. (2.6) and (2.7), show how different kinds of spatial patterns can emerge spontaneously from the same model equations with different parameters. This model has been used to explain experimentally observed patterns formed by adult vascular mesenchymal cells in culture [94]: (top row) emergence of regular spots and (bottom row) emergence of stripes.

cells (VMCs) in monolayer culture in vitro [94]. VMCs differentiate and self-organize into variety of complex spatial patterns, similar to those seen in the GM model, during development, disease progression, as well as in vitro culture. Garfinkel et al. reasoned that bone morphogenetic protein 2 (BMP-2), which is expressed by VMCs and positively regulates its own transcription, may act as a local activator; while matrix gamma-carboxyglutamic acid protein (MGP), a relatively small molecule that inhibits BMP-2 induced differentiation, may play the part of a fast diffusing long-range inhibitor (see Ref. [94] and references therein). They found that experimental culture of VMCs demonstrated good qualitative agreement with the patterns formed in a generalized GM model based on spatiotemporal interactions between BMP-2 and MGP. In addition, their analysis predicted that different patterns would emerge from the same underlying mechanism if the kinetics of BMP-2 activation and MGP inhibition were perturbed. To test this, they showed experimentally that addition of MGP to the media preparation shifted the observed pattern from labyrinthine stripes to spots, while addition of warfarin (which blocks MGP inhibition of BMP-2, see Ref. [94] and references therein) resulted in "stripe-doubling," two changes that were predicted by their mathematical model.

Despite the relative success of activator–inhibitor models, such as this, Turing-type patterns are difficult to engineer synthetically, since they are sensitive to parameter changes and rely on particular disparities in kinetic and transport parameters. Consequently, the importance of these mechanisms in development has been long debated [95]. However, Turing did not intend his model to be an accurate description of any particular morphogenetic process, nor did he intend it to make hard biological predictions. Rather, the power of his work was that it initiated a new way of thinking about how complex self-organizing patterns may arise when feedback is spatially controlled. Perhaps, the greatest advantage to the tissue engineer of mathematical models of this kind is that they provide examples of how simple chemical, biological, and physical processes can interact spontaneously to produce complex spatial patterns in ways that are hard to explore using experiment and intuition alone. In the long term, better understanding of the complex self-organizing mechanisms of tissue and organ morphogenesis from such a mathematical perspective may allow more efficient and reproducible engineering of macroscopically structured tissue.

Machine learning in tissue engineering

Recent years have seen significant advances in the development of sensitive biochemical assays that reveal previously inaccessible aspects of cell and tissue biology. A representative example of these advances is single-cell sequencing technologies, which now enables the (parallel) genome-wide quantification of transcript abundance, gene accessibility, epigenetic modifications, 3D genome organization at single-cell resolution, providing information on thousands of features from different intracellular information levels [96].

While mathematical models have been tremendously successful in understanding, in detail, the interactions of a limited number of genes and their products (see Refs. [97–99]

for some recent examples), obtaining and dissecting a full mathematical representation of large numbers of genes and proteins remains challenging, since mathematical models quickly become analytically intractable due to the large number of interacting parameters. Therefore rather than modeling data directly, tools from statistics and computer science are needed to extract predictive patterns from complex datasets, which may then be used to inform the development of mathematical models. The modeling task is thus partitioned into complementary phases consisting a statistical analyses or machine learning to reveal the structure in the data and to provide a simplified phenomenological description, followed by the generation of hypotheses of how observed structures may have emerged. The latter can subsequently be validated experimentally or translated into mathematical models to probe the basic biological principles that give rise to the observed phenomena, as described, for instance, in the previous sections of this chapter.

Supervised methods

Finding (or recognizing) patterns in high-dimensional data is a common problem in data analytics. *Supervised* machine learning methods address this task by "learning" how combinations of measured input features (e.g., gene expression levels) combine to elicit a given response (e.g., a desired cell function) that can be discrete (for classification) or continuous (for regression). If response variables are known (at least for a representative subset of observations, known as the training set), then the mapping from input features to responses can be learnt by comparing the discrepancy between true and predicted responses and choosing the mapping that minimizes this discrepancy. Once such an optimal mapping has been established, it can be used to predict responses for unseen data. The key challenge is therefore in finding such an optimal mapping. There are a number of different supervised methods that are widely used to address this task.

Support vector machines (SVMs) learn a (high-dimensional) decision boundary for binary classification tasks [100]. SVMs have been used in tissue engineering, for example, to correctly predict the toxicity of drugs on tissue-engineered brain organoids in vitro [101]. As another example, SVMs were able to positively identify mesodermal cells (expressing the protein *Brachyury*) using cell density and *myosin light chain* phosphorylation levels (as a proxy of local tissue tension) as input features [102].

Random forests (RFs) are ensembles of decision trees, which can be used for classification or regression [103]. RFs have been used to successfully explore a number of single-cell expression datasets, including to predict muscle stem cell quiescence from expression profiles [104]; interrogate the effect of thrombopoietin on megakaryocyte commitment in hematopoietic stem cells [105]; and identify the physical interactions between stem and niche cells in the bone marrow [106].

Increasingly, artificial neural networks (ANNs), particularly deep neural networks, are being used to address problems in regenerative medicine. In particular, in the field of image classification and object detection, a variant of ANNs called deep convolutional neural networks (CNNs) have achieved expert-level performance, for instance, matching the classification accuracy of dermatologists in detecting skin cancer [107]. The superior performance of deep CNNs stems from their ability to learn representations directly from data that independently extract important features, such as color, shape, and regularity, and encode specific structures, such as abnormal skin patterns, as a combination of learnt features. However, the complexity of deep ANNs (which can have several thousand to millions of free parameters that must all be learnt from the training data) necessitates much larger training datasets, typically containing >1 million labeled examples, which may be impractical for many applications.

Transfer learning presents a common solution to this problem. Here, a set of well-annotated but unrelated training data is used to learn generic features that are commonly associated with the input data type(s) yet not specific to the particular problem at hand. Once established, it has been shown that such pretrained models may be subsequently retrained on a much smaller number of labeled examples that are specific to the problem of interest. In the case of skin cancer detection, a model, trained to recognize 1000 completely unrelated object categories (e.g., cars and animals) using 1.28 million annotated example images, was retrained on 127,000 images of different types of skin disease associated with 757 skin different disease classes [107], thus significantly reducing the amount of data and time required for training. We predict that such approaches will increasingly become implemented in standard analysis pipelines—for instance, in image analysis of cells and tissues—and will significantly aid the development of new biological insights.

Unsupervised methods

In the case where responses are not known a priori, methods from *unsupervised* learning can help find structures in data by optimizing a loss function that relies entirely on intrinsic properties of the data itself. Clustering is an example of such an unsupervised method. For instance, in K-means clustering [108], data are split into a prespecified number of clusters (K), which are determined using a loss function that aims to assign cluster membership in a way that minimizes the intracluster variability while maximizing the intercluster variability. The simplicity of this

approach has led to its widespread application to complex data, such as single-cell transcriptomic data [109]. There exist a wide range of similar clustering methods, some of which are specifically tailored to the datasets that arise from high-throughput assays. For instance, a range of graph-based approaches, developed to cluster high-throughput data [110,111], have been applied to single-cell expression data in an effort to eliminate some of the effects of outliers and take account of the intrinsic complexity and high levels of noise inherent to these data [112,113].

Machine learning of cellular dynamics

In parallel to the increase in single-cell data, a variety of computational methods have been developed to better understand stem cell differentiation dynamics. Single-cell omics methods are destructive and permit only a single measurement to be taken at one point in time. However, these static snapshots can be used to reconstruct the likely sequence of phenotypic changes that a typical cell will undergo during development, and such trajectory inference techniques are therefore increasingly being used to decipher the dynamics of stem cell commitment [114–117]. Although successful, a major difficulty with trajectory inference is that different trajectories can give rise to the same distribution of cell states and hence inferred trajectories may represent one of many possibilities [118]. In some circumstances, this limitation can be overcome using (even scant) prior knowledge about the interrogated system (such as knowledge of characteristic end points) to derive better approximations of the developmental trajectories, which can then be used to make predictions for further experimental validation, or as the basis for further mechanistic mathematical models [109].

Regulatory network inference

In the absence of prior knowledge on the (causal) relationships between genes and their products (i.e., knowledge of the structure of the underlying gene regulatory network), mathematical models may not appear to be immediately practical. However, knowledge of the causal interactions between features needed to establish a mathematical model can sometimes be learned directly from data using machine learning approaches. There are a number of methods for such "structure learning," the most widely used being Bayesian networks [119]. Bayesian networks have proven useful for the prediction of regulatory interactions in a variety of biomedical contexts [120,121]. Bayesian networks seek to infer a graphical structure—essentially a network wiring diagram, in which each node represents a regulatory species (e.g., a gene or protein) and edges linking two nodes indicate conditional dependence (some of which may be causal), while the absence of edges indicates conditional independence [119]—which is most compatible with the coexpression patterns observed in the data collected. For example, Sachs et al. [121] used a Bayesian network approach to infer a signaling network in human immune cells, in which nodes represent phosphorylated proteins and phospholipids, while edges between nodes indicate conditional dependence, interpreted as a functional regulatory relationship (e.g., activation, inhibition, or coregulation).

The use of Bayesian networks allows for prediction of true functional relationships between genes and proteins of interest. However, due to technical limitations, they are not capable of inferring feedback structures and may contain both true and false negatives and positives. To improve their ability to detect the true underlying dependence structure, interventional data may also be used, in which the expression levels of specific nodes are altered through knockdown or application of small molecule kinase inhibitors to test which interactions are truly functional [121].

Recently, alternative network inference approaches have been developed to overcome some of the limitations intrinsic to the Bayesian approach, such as their inability to detect feedback loops, a network motif commonly observed in stem cell gene regulatory networks [122]. Among these, alternative approaches are methods based on information theory [123], and, increasingly, methods tailored to single-cell transcriptomic data [124]. Notably, aggregate methods that construct consensus regulatory networks from an ensemble of different methods frequently achieve the highest comparable prediction accuracy when benchmarked against known networks [125,126].

In summary, network inference methods can be used to obtain insights from large-scale biological data and the hypotheses generated through network inference can guide further in vitro and in silico experiments to identify the molecular regulatory mechanisms that underpin stem cell differentiation.

From mathematical models to clinical reality

Mathematical methods are routinely used in engineering to optimize complex processes for industrial implementation. Mathematical models can be tremendously powerful yet rely on prior knowledge to enable the formulation of hypotheses in form of a set of equations. In the absence of such prior knowledge, or where data complexity is overwhelming, machine learning can be used to first learn structure in data, categorize observations, and help generate hypotheses for subsequent testing by experiment or formulation of mathematical models. We anticipate that as tissue engineering protocols make their way from

development in the lab to routine use in the clinic, mathematical and machine learning methods will play an increasingly central role in their optimization and scale-up. Mathematical optimization approaches are already being used to design custom scaffolds for tissue regeneration [72,127–129]. For example, Hollister et al. have outlined a strategy for the rational design of porous scaffolds with defined architectural properties that balance conflicting mechanical and transport requirements (reviewed in Ref. [72]). This strategy uses a set of mathematical tools from homogenization theory—which allow macroscopic material and transport properties to be inferred from scaffold microstructure—to aid scaffold design in silico for practical implementation using novel solid free-form fabrication techniques. Such custom approaches have been successfully used to design optimized scaffolds for bone tissue engineering in craniofacial reconstruction, for instance [128]. As another example, Unadkat et al. have recently outlined an algorithm-based strategy to design biomaterial surface micro-topographies that optimally regulate cell function [130]. It is likely that advanced multidisciplinary protocols, such as these, which coordinate mathematical, computational, chemical, and materials engineering techniques, will lead to further advances in scaffold design in the near future. Indeed, design optimization is perhaps the area, in which there is the most potential for genuinely productive application of mathematical and computational principles to tissue engineering and regenerative medicine. Such sophisticated design strategies are likely to become essential to the future of tissue engineering and ultimately will help to take tissue engineering from experimental concept to clinical reality.

Chapter 3

Moving into the clinic

Chi Lo, Darren Hickerson, James J. Yoo, Anthony Atala and Julie Allickson
Wake Forest Institute for Regenerative Medicine, Wake Forest University, Winston-Salem, NC, United States

Introduction

A high demand for organs needed for transplantation exists in the United States. The staggering number is more than 100,000 on the organ transplant list with approximately 18 people dying daily while waiting for an organ [1]. In contrast, a patient requiring an organ donor is added to the transplant list every 10 minutes [2]. This urgent demand and limited supply of donor organs requires a significant change in the way we address the need for organ transplants. The field of tissue engineering and regenerative medicine has been identified as a promising, innovative path for fulfilling this need. The goal of tissue engineering is to produce constructs that mimic a native organ or structure for replacement or to function as a bridge to encourage the body to regenerate the native structure in vivo. The constructs may include a scaffold component, a cellular component, and biochemical factors/molecules or a combination of these parts (see Fig. 3.1). These therapies have the capacity to replace, repair, or regenerate cells, tissues, and organs to restore normal function in the body. This new era of health care is a paradigm shift from treatment-based to cure-based therapies.

This chapter covers the status of tissue engineering in clinical translation; where we are and where we are going with research and development. It will also provide information on products that are currently in clinical studies as well as those in the market. In this chapter, overview of an academic model with a pathway from proof of concept to final product for implant will be discussed. This translational process includes process and product development (PD), which then transitions to clinical manufacturing along with quality control (QC) testing and quality assurance (QA) oversight in clinical trials. When a project has both an integrated PD approach and a solid design for product manufacturing, a shorter pathway to the clinic may be facilitated. The regulatory considerations for translation, including the relevant FDA regulations and guidance documents that govern tissue-engineered products, and testing in a clinical trial, will also be discussed. Careful review and understanding of the FDA regulations and guidance documents can help accelerate the development process and streamline the pathway to treating patients.

Current state of tissue engineering

Tissue engineering is a term that can be traced back to the 1980s when Fung, a scientist in the field of bioengineering, submitted a proposal to National Science Foundation for engineering a living tissue [3]. This important proposal planted the seed that led to several other organizations and individuals to further develop the field. Drs. Robert Langer and Joseph Vacanti brought clarity and definition to tissue engineering in their article in *Science* (May 1993) where they referenced the

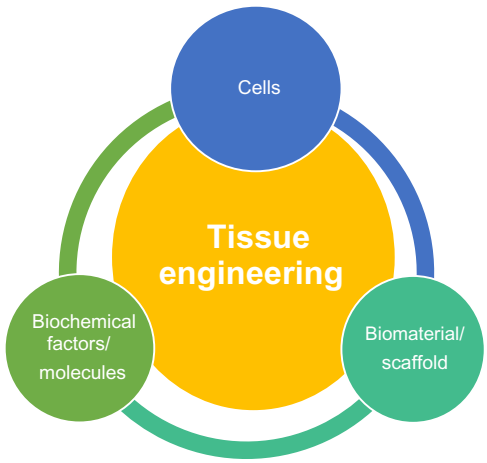

FIGURE 3.1 Components of a tissue engineered construct required to mimic a native organ or structure or to function as a bridge to encourage the body to regenerate the native structure.

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00003-4

proceedings of the Granlibakken workshop and the discussions on tissue engineering as an interdisciplinary field bringing together engineering and life sciences to produce biologically relevant constructs. Interestingly, in 1994 when searching the term "tissue engineering," only approximately 10 references could be found [3]. From then on, the field grew rapidly. With the field expanding, scientists wondered whether tissue engineering would result in a functional structure that could be implanted in the body. In 2001 another symposium was provided by BECON (National Institutes of Health Bioengineering Consortium), which further provided clarity on tissue engineering, which was described as one area of reparative medicine. Haseltine coined the term "regenerative medicine" to define the in vitro construction of tissues and organs for implant using natural human components and high-technology nonliving materials [4]. In 1999 Dr. Atala, a leader in the field of tissue engineering, discussed the arrangement of tissue-engineered bladder replacement clinical studies in a future perspective article [5]. These were the first published communications of tissue-engineered products moving into the clinic. A later publication suggested the translational pathway of in vitro construction of an organ or tissue on the lab bench to manufacturing a clinically relevant construct for implantation [6]. In 2006 Atala et al. published in Lancet the stunning results of engineered bladders that were implanted in patients requiring cystoplasty [7]. The meetings, publications, and milestones highlighted here represent only some of the work that drove the field to where it is today.

Regenerative medicine as a field has matured into a new era with regulations evolving to ensure safety of these complex products. There has been significant progress in the last few years in moving promising treatments to the clinic where numerous replacement tissues can now be generated de novo. Clinical studies in regenerative medicine include orthobiologics, musculoskeletal, urology, and wound healing. Some of the first examples of commercialized tissue engineering products are dermal substitutes such as Dermagraft (Organogenesis) and Apligraft (Organogenesis) [8,9]. Dermagraft (a skin substitute consisting of cells, an extracellular matrix, and a scaffold) was used for the treatment of diabetic foot ulcers and chronic wounds. Apligraft (a bilayered skin substitute) is approved for both diabetic foot ulcers and venous leg ulcers. After FDA clearance of these products' premarket approval applications, both were released for public use. GINTUIT (Organogenesis and XVIVO, a cellular-based product with bovine collagen) is a sheet applied topically for mucogingival conditions [10]. This product was the first FDA-approved combination product by Center for Biologics Evaluation and Research (CBER) arm of the FDA and the first for use in dental application.

When searching for the term "tissue engineering," the growing field currently has about 113,000 publications in PubMed and close to 84 clinical trials posted on *clinicaltrials.gov*. The Alliance for Regenerative Medicine stated in their 2018 Q3 report that there are 41 clinical trials worldwide in tissue engineering (distinguished from cell or gene therapy) with around a third of those in Phase 3 trials [11]. There are currently a handful of marketed FDA-approved products. The field is starting to mature as more and more products reach market and technologies can accelerate following safety and efficacy demonstration in early clinical studies in patients.

Pathway for clinical translation

One of the most important aspects in the acceleration of clinical translation for regenerative medicine technology is to have a comprehensive understanding of the regulations that are required to move a product to market. Without knowledge of the regulatory requirements, one could spend excessive time and resources on the path to clinic. The clinical translational pathway starts with the end in mind: the patient, the condition to be treated, and the form and function of the final clinical product. So first and foremost, it is critical to have the clinician involved as the treatment and study model is being conceptualized. Clinicians have a deep understanding of what is required at the bedside; what current treatments are lacking and how the proposed product can be more efficient; what the cost considerations are; and what approach will provide a better quality of life for their patients. The clinicians also have the best understanding in terms of patient access and urgency for treatment. For example, if a physician is treating a stroke patient post episode and the treatment is most effective when administered immediately, culturing autologous cells from the patient for weeks would not be a viable option; however, having an off-the-shelf allogeneic cellular product could be a possibility.

The general translational pathway is illustrated in Fig. 3.2. Transfer of technology from the lab bench to PD and then on to manufacturing requires an enormous amount of time and efforts to move products through the translation pathway, especially if these units are located at different sites. Methods often have to be observed and performed multiple times during technology transfer for all aspects to translate successfully. For example, if tissue-derived biomaterial is used to produce an engineered muscle product, harvesting a specific region of tissue from an organ is required before decellularization (cell removal). In order to harvest the tissue, it is important to understand the anatomy for identifying the tissue layers, proper orientation of the tissue as well as methods to dissect and separate the layers to obtain target segments. It is also crucial to understand what the ideal target

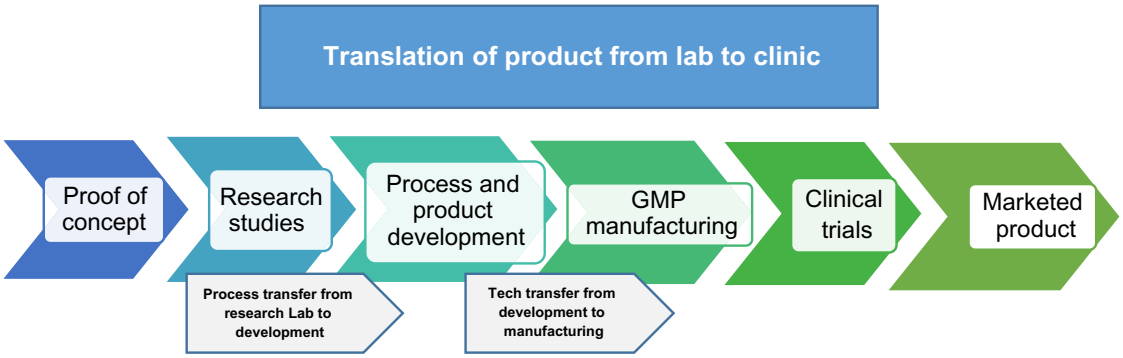

FIGURE 3.2 General pathway for clinical translation.

tissue should look like after separation, the amount of force required to separate the layers without damaging the tissue, and what a normal biomaterial source organ should look like and whether organs should be discarded due to disease or damage. The technology transfer of just this one step may take several training sessions with multiple batches of incoming organs in order to encounter different scenarios that require troubleshooting. Since this is the first step to manufacturing the biomaterial, all subsequent steps in the process could not be worked on until this step is ironed out. Therefore having all teams at a single site to answer questions and address any issues that emerge can accelerate the translation process.

One important academic model developed for clinical translation is an all-inclusive model where the research, preclinical studies, PD, manufacturing, quality testing, and QA oversight for the technology are retained in-house, and projects move from proof of concept all the way to early phase clinical trials in one location. Benefits of this model include a multidisciplinary team that can meet regularly and tackle issues quickly as they arise. The site is equipped with the academic power to develop innovative technology by established researchers funded to solve specific issues in health care. The researcher can perform the in vitro studies and preclinical studies providing pilot data that support the technology. Definitive preclinical research studies can be performed under FDA Good Laboratory Practices (GLP) to test for efficacy, toxicity, tumorigenicity, and biodistribution. A research core facility provides equipment and expertise to facilitate data collection and translation. The in-house translational core or clinical translational unit includes PD, manufacturing, QC, QA, and a regulatory affairs team. The regulatory team prepares briefing documents and communicates with regulators. These embedded services can provide acceleration of PD and intellectual property (IP). An in-house legal team provides guidance on IP and licensing to investigators. Having all stages of the translational pathway under one umbrella can save time and resources, allowing for development of multiple clinical products simultaneously to be incorporated early on and throughout the process.

When definitive preclinical research studies are performed under the all-inclusive academic model, they can be performed with the knowledge of the data that will be used to support an FDA IND (Investigational New Drug) submission, which means that studies will be conducted under GLP documentation standards. Often, if research is conducted in an academic setting, the investigator and any collaborators plan the animal studies with only the goal of publication in mind. When the project shows promise for translation after the study, the results can be included in FDA IND submissions. Under the all-inclusive academic model, the study model and experiment plan can be discussed with the FDA during pre-IND (PIND) discussions to confirm the animal model, and the study fully supports the translation of the product to the clinic.

A clinical translational unit in an academic environment can benefit moving technology to early phase clinical trials by submitting IND filings, transferring technology, producing clinical products, testing clinical products, and coordinating and training clinicians with product responsibilities. The scope of each project will be dependent on the phase of translation the project is in when introduced to the translational unit, thereby dictating the amount of involvement required by the team. The clinical translational unit has the goal of facilitating translation of scientific discoveries into clinical therapies, while meeting the requirements of the US FDA to ensure safety and compliance. The clinical translational unit develops and manufactures products and provides regulatory support to navigate the pathway to early phase clinical trials. An overview of this process is presented in Fig. 3.3.

Following proof of concept and benchtop research activities, PD occurs with the aim of preparing the product for human clinical use. During this stage the laboratory investigator will transfer the technology to the PD team. The PD team then develops and refines the test

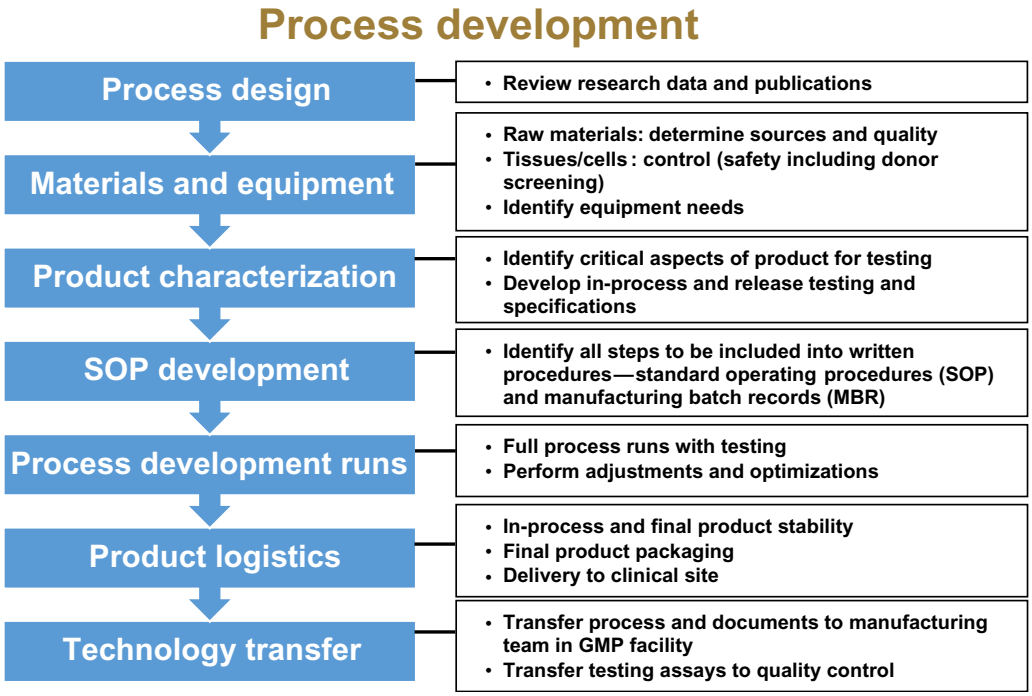

FIGURE 3.3 Components of the process development phase of clinical translation.

article for definitive preclinical GLP studies. Along with preclinical management staff, they assist with coordination and/or execution of GLP studies that meet FDA requirements. PD develops processes and sources materials suitable for human clinical trials, ensuring compliance with regulations. All materials in direct contact with the manufactured product need to be biocompatible and bioreactors, if applicable, should be constructed using USP Class VI materials. The transition of the technology from treating an animal to human requires most of the PD focus. When large animal models such as pigs or sheep are used, often the size of the construct and the number of cells required for the product are not significantly different than the human construct. However, if animal models used smaller constructs, then there can be significant effort in developing new bioreactors to support construct maturation, and new cell culturing techniques and media optimization to support expansion of cells to larger numbers. PD develops tests and assays to characterize the product going into manufacturing. To ensure the product is made consistently, the assays should have precise specification criteria. The testing should be performed in-process and at the time of final product. A large number of technical studies are performed during the development process. For instance, certain reagents or instruments used to manufacture the product during the development phase may not be suitable for a clinical grade product. If possible, appropriate clinical grade reagents and surgical grade instruments should be selected. The technical study would then compare producing the product with the traditional reagents and instruments and the newly identified materials. Other technical studies may focus on shifting the process to closed systems to reduce contamination risks or handling risks, which may harm the operator or the product. PD also gathers data required to support the *I*N*i*tial *T*argeted *E*ngagement for *R*egulatory *A*dvice on *C*BER Produc*T*s (INTERACT), or a PIND application, to the FDA. They perform PD process runs with testing to optimize and improve on the workflow. PD will identify product stability at all hold points throughout the process. Product packaging and logistics related to final transport to the clinical site is also developed. Once a process is refined and can be performed following written standard operating procedures (SOPs), the PD team works with manufacturing to transition development processes into formal SOPs and manufacturing batch records (MBRs). The PD team works closely with the manufacturing and QC teams to transition the projects into the good manufacturing practices/good tissue practices (GMP/GTPs) facility. An overview of this late translation process is shown in Fig. 3.4.

The role of manufacturing is to perform activities to produce cell and tissue products for clinical trials in accordance with GMP/GTP requirements or to manufacture FDA-registered products in accordance with GTP. The manufacturing team works with the PD team to transition processes into SOPs and MBRs for the GMP/GTP environment. They perform manufacturing engineering

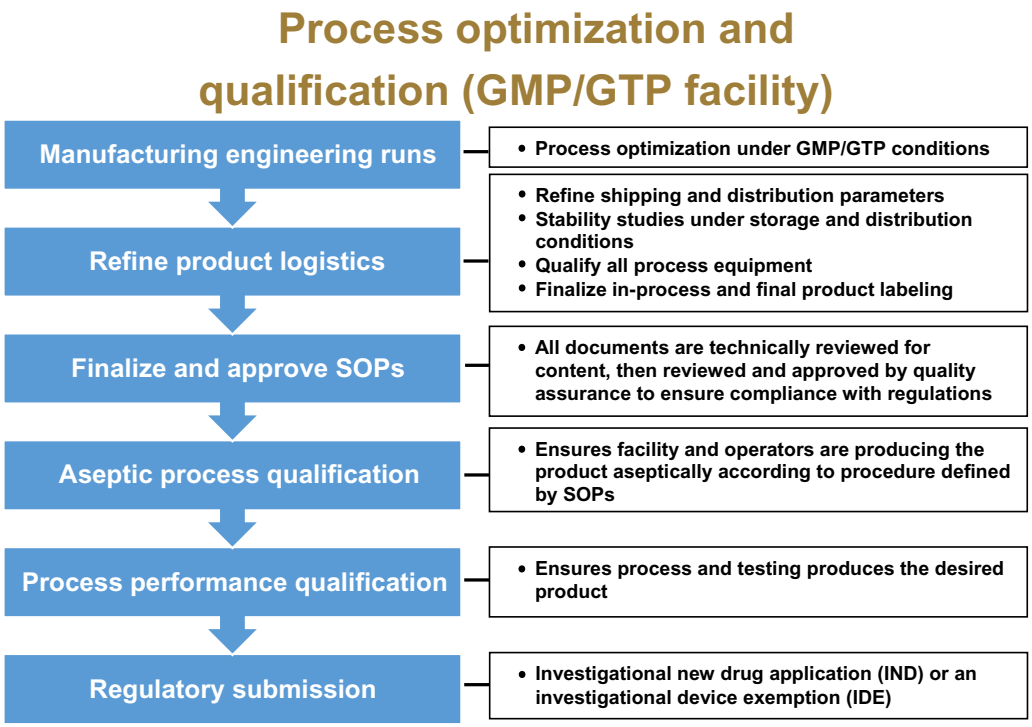

FIGURE 3.4 Components of late translation: process optimization and qualification for manufacturing and regulatory filing.

runs within the GMP/GTP facility and optimize the process if necessary. The product logistics are further refined and all processing equipment must be qualified for installation and operation (IOQ). Preventative maintenance and calibration services must be performed on equipment regularly to ensure proper function. SOP and MBR documents are finalized with technical review, then reviewed and approved by QA. All manufacturing personnel must be trained to manufacture the desired product safely, effectively, and efficiently. The training should be clearly documented, and no operator will perform processing without documented training. Clinical processing includes a primary operator and secondary operator that assists and verifies that each critical step is performed properly. For certain processes, multiple primary operators may be required. To ensure sufficient materials inventory, control, and documentation in advance of each process, a materials kit is made with separate bins for different storage temperatures, such as room temperature, refrigerator, −20°C or −80°C freezer. Tracking numbers and expiration dates of all materials in the kits are recorded to ensure traceability. Before clinical processing can occur, two important qualifications to be completed are the aseptic process qualification (APQ) and the process performance qualification (PPQ). The APQ, or process simulation, uses a growth promoting media in place of all reagents and ensures the GMP/GTP facility maintains environmental control during processing to produce an aseptic product while performing the procedure per SOPs. The APQ may not always be necessary if the product is terminally sterilized prior to administration to a patient, but the production area must be otherwise evaluated and monitored to ensure it is appropriately free of particulates and adventitious agents during production. The PPQ ensures that the finalized SOPs, MBRs, environment, and trained personnel can produce the desired product and pass all in-process and final release testing. The PPQ run (s) are also carried out as if producing the final clinical product; by doing so, any issues to the process can be identified and resolved prior to manufacturing the product for first in human application. An IND application or an investigational device exemption can be submitted at this point. The submissions are built on data from PD, QC testing, and manufacturing, which includes all technical studies and engineering runs. One notable caveat is that the PPQ may be performed (or may need to be repeated) after the FDA approves the application; thus, any changes required by the FDA are be included in the final PPQ.

Once approval is granted from the regulatory agencies, manufacturing can begin, and patients can be recruited for the study. The manufacturing process for early phase clinical trials or registered products may include tissue receipt, cell isolation and expansion, scaffold preparation, cell seeding onto scaffold, packaging, and shipment to the clinical site. Samples are collected throughout the process and submitted to QC for in-process testing to characterize

the clinical product at various stages of production and then ultimately final release testing prior to delivery to the patient. During clinical manufacturing and QC testing, all activities require documentation to ensure concurrent recording of processes/testing and traceability of all in-process chemicals, materials, and equipment. All written records must follow good documentation practices. Manufacturing and QC testing is monitored by QA to ensure procedures are followed to ensure patient safety.

QA establishes policies and procedures and QC performs testing to ensure compliance with regulatory and internal requirements. QA has responsibility of ensuring documentation is reviewed and meets regulatory requirements after manufacturing has produced the product. QA is also responsible for a document management system and ensuring appropriate record archiving takes place. They also govern and control incoming materials, reagents, and consumables to ensure only released items meeting specifications are used in the GMP/GTP facility for the manufacturing of a clinical product. They are responsible for facility oversight, ensuring that PD and manufacturing activities take place in a controlled environment with equipment that is calibrated and validated to meet GMP and GTP requirements. QA is responsible for the master validation plan of the facility and will perform regular in-house audits of the process and facility. QA certifies the final product at time of release to clinical site by reviewing all documentation and testing results to ensure all procedures were properly followed and the product has met all specifications. QA maintains all relevant documents that support the GMP/GTP facility or any clinical product in order to be ready for FDA inspections that can occur at any time.

A critical piece of translation is regulatory affairs, which manages and directs strategic and operational aspects of regulatory matters for technologies in regenerative medicine including cell and gene therapy, tissue engineering, biomaterials, and devices. This team maintains regulatory and compliance processes. It prepares, reviews, and evaluates documents for submission to regulatory authorities. The required expertise of this team is to provide focused regulatory drivers for accelerated pathways to control time and cost of translation.

Project management (PM) is an important link to facilitate organization, communication and information processing within the translational unit for both preclinical and clinical effort. PM coordinates individual team member's efforts and tracks outstanding items to prevent project delays. They promote efficient purchasing of reagents, materials, supplies equipment, and service agreements. Administrative tasks for the project are also performed by the PM.

The overall head or director of the translation unit should have extensive experience in preclinical, PD, manufacturing, QC, QA, and regulatory affairs, but with a strong emphasis on the production of a clinical product. The head of translation oversees strategic and operational aspects of global regulatory matters for all products moving to commercialization under FDA jurisdiction and research and development projects, including the regulatory and compliance processes, team management, milestone achievement, as well as the preparation, review and evaluation of documents for submission to regulatory authorities. Responsibilities for the head of translation includes setting priorities, providing strategic input, identifying and assessing regulatory risks, understanding global imperatives including market-related drivers, interfacing with regulatory authorities, keeping up with US and global regulatory requirements and guidance, and providing oversight and review of key regulatory documents. Under the direction of the head of translation, the teams work alongside researchers and clinicians to facilitate the translational process in a safe and timely manner that supports an overall mission of facilitating translation of the research from the bench to the bedside.

Regulatory considerations for tissue engineering

Regulatory requirements for biologics used in tissue engineering follows GMP and GTP regulations. GMP were initially developed for pharmaceuticals or drug production, which are easier processes and straight forward when dealing with defined products such as small molecule drugs as opposed to viable organisms or cells. Oversight of therapeutics derived from biological sources under the US FDA has provided clarity in regulations through guidance documentation and communication (written and presentations) to facilitate understanding of requirements to move a technology to the market. The FDA provides more guidance for investigators now than at any prior point in its history. This strengthened relationship with regulators provides an opportunity to transfer the science to the bedside in an efficient, safe, and cost-conscious manner.

Growth in the field of regenerative medicine and tissue engineering has led to an elevated use of novel therapies to repair or replace tissues and organs and further requirements to provide safety in clinical products. Global regulatory standards were established with the goal of reducing the risk of communicable transmissible disease. As regulators are caretakers of the health-care structure, they need to be able to balance risks and benefits when assessing technology that may have lifesaving capabilities. In 2011 the US FDA issued a final rule requiring human cell, tissue, and cellular and tissue-based product (HCT/P) Establishments to be compliant with current

GTPs covering collection, donor screening, donor testing, processing, labeling, packaging, storage, and distribution of HCT/Ps [12]. The regulations for GTPs are found in 21 CFR 1271 Subpart D [13] and cover facilities, environmental controls, equipment, supplies and reagents, recovery, processing and processing controls, labeling controls, storage, and distribution of products. The regulation was drafted for products under the CBER. The GTP regulation covers human cells, tissues, and tissue-based products in addition to any cell product procured from a donor and implanted or transplanted into a recipient.

FDA provides two tiers of regulation for HCT/Ps according to a risk-based approach. HCT/Ps under 21 CFR 1271 [13,14] and Section 361 of the Public Health Service Act (PHSA) are regulated solely as 361 products when they meet criteria listed in 21 CFR 1271.10(a) [13]:

- minimally manipulated;
- intended for a homologous use only as reflected by the labeling, advertising, or other indications of the manufacturer's objective intent; and
- not combined with another article.

HCT/Ps not covered by Section 361 of the PHSA are covered under Section 351 of the PHSA (351), which is also regulated by CBER. This tier includes products that do not meet all the criteria in 21 CFR 1271.10(a) and are regulated as drugs and/or biological products. These products under Section 351 of the PHSA require premarket approval by FDA. Minimal manipulation and homologous use are further defined in a guidance document published by FDA in 2017 [14], which provides a resource for clarity on regulations required for the HCT/Ps. In summary, HCT/Ps regulated as a 361 do not require premarket approval and are covered under 21 CFR 1271 for GTPs. HCT/Ps regulated as a 351 product requires premarket approval and are covered under both 21 CFR 210 and 211 for GMP and 21 CFR 1271 for GTP [13]. The 351 products are regulated as an IND, while 361 products do not require an IND since they are geared toward the prevention of communicable diseases and infection, but they still include donor eligibility requirements. Tissue-engineered constructs are generally combination products that include cells and a scaffold and are regulated as a 351, thereby requiring an IND. The scaffold is considered a device and regulated by the Center for Devices and Radiological Health and device regulations under the general review of CBER according to the primary mode of action of the product.

A tissue-engineered construct requires an IND and compliance with GMP and GTP. GTP controls all steps in recovery, donor screening, donor testing, processing, storage, labeling, packing, and distribution according to 21 CFR 1271.150(a). Core requirements as referenced in 21 CFR 1271.150(b) include

- facilities;
- environmental controls;
- equipment;
- supplies and reagents;
- recovery;
- processing and process controls;
- labeling controls;
- storage;
- receipt, predistribution shipment, and distribution of an HCT; and
- donor eligibility determinations, donor screening, and donor testing.

For a 351 HCT/P, GMP requirements cover areas such as documentation, validation, facilities, equipment, personnel, training, controlled documentation, manufacturing, process control, labeling, packaging, storage, and distribution. These are covered under 21 CFR Part 210

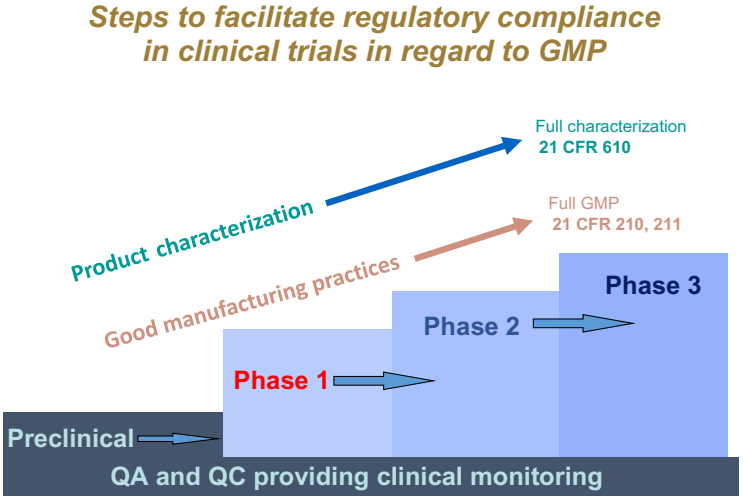

FIGURE 3.5 Steps to facilitate regulatory compliance in clinical trials for tissue engineered products.

GMP for manufacturing, processing, packaging, and storage of drug products and 21 CFR Part 211 GMP for finished pharmaceutical products (Fig. 3.5).

In September 2004 the US Department of Health and Human Services, FDA, Center for Drug Evaluation and Research, CBER, and Office of Regulatory Affairs released a Guidance for Industry: Sterile Drug Products Produced by Aseptic Processing—Current Good Manufacturing Practice to assist manufacturers in complying with the GMP regulations for pharmaceutical manufacture [12]. Then, in July 2008, the FDA issued a specific guidance for industry: current good manufacturing practice (CGMP) for Phase 1 Investigational Drugs to replace the original Phase 1 CGMP guidance issued in 1991 (20 and 21). The goal of this 2008 guidance is to further clarify the requirements for CGMP compliance, set forth more broadly in the 2004 and 1991 guidance documents, but for the manufacture of investigational new drugs used in Phase 1 clinical trials. It explains these drugs are exempt from complying with 21 CFR part 211 under 21 CFR 210.2(c) (Phase 1 investigational drugs); the original guidance was directed mostly at large, repetitive, commercial batch manufacturing of products. The 1991 guidance is still relevant for Phase 2 and 3 products, which means that once products reach this stage, they will be required to fully comply with 21 CFR 210 and 211. By Phase 3, products will also comply with 21 CFR 610, which outlines testing criteria to fully characterize the product. For example, potency tests should be fully developed prior to commercialization [15]. The progression of increasing compliance and regulatory oversight is graphically presented in Fig. 3.5. As the tissue engineering field is still considered up and coming, regulatory bodies are adapting traditional regulations and creating new regulations to accommodate the field. After feedback from translational teams, additional adjustments may be made by regulatory agencies; hence, throughout translation, regulatory considerations should be monitored closely to ensure compliance.

Conclusion

With an aging population in the United States and globally, and with demand for organ transplants exceeding availability, regenerative medicine becomes a critical goal of health care for sustainability as it will provide a significant improvement in quality of health care for the future. One important aspect of regenerative medicine is tissue engineering where the cellular material along with extracellular components and a scaffold are used in the construction of an organ or tissue. In this chapter the translational process was discussed from proof of concept to clinical trials. To reduce the total time for the translation process, regulatory considerations should be monitored throughout the process to efficiently translate treatments to patients to improve their quality of life.

Part One

The basis of growth and differentiation

Chapter 4

Molecular biology of the cell

J.M.W. Slack
Department of Biology and Biochemistry, University of Bath, Bath, United Kingdom

To a naive observer the term "tissue engineering" might seem a contradiction in terms. The word "engineering" tends to conjure up a vision of making objects from hard components, such as metals, plastics, concrete, or silicon, which are mechanically robust and will withstand a range of environmental conditions. The components themselves are often relatively simple, and the complexity of a system emerges from the number and connectivity of the parts. By contrast, the cells of living organisms are themselves highly delicate and highly complex. Despite our knowledge of a vast amount of molecular biology detail concerning cell structure and function, their properties are still understood only in qualitative terms, and so any application using cells requires a lot of craft skill as well as rational design. What follows is a very brief account of cell properties, intended for newcomers to tissue engineering who have an engineering or physical science background. It is intended to alert the readers about some of the issues involved in working with cells and to pave the way for an understanding of how cells form tissues and organs, topics dealt with in more detail in the later chapters. As it comprises very general material, it is not specifically referenced, although some further reading is provided at the end.

Cells are the basic building blocks of living organisms in the sense that they can survive in isolation. Some organisms, such as bacteria, protozoa or many algae, actually consist of single free-living cells. But most cells are constituents of multicellular organisms, and although they can survive in isolation, they need very carefully controlled conditions in order to do so. A typical animal cell suspended in liquid is a sphere of the order of about 20 μm diameter (Fig. 4.1). Most cells will not grow well in suspension, and so they are usually grown attached to a substrate, where they flatten and may be quite large in horizontal dimensions but only a few microns in vertical dimension. All eukaryotic cells contain a nucleus in which is located the genetic material that ultimately controls everything that the cell is composed of and all the activities it carries out. This is surrounded by cytoplasm, which has a very complex structure and contains substructures called organelles which are devoted to specific biochemical functions. The outer surface of the cell is the plasma membrane, which is of crucial importance as it forms the frontier across which all materials must pass on their way in or out. The complexity of a single cell is awesome since it contains thousands of different types of protein molecules, arranged in many very complex multimolecular aggregates comprising both hydrophobic and aqueous phases and also many thousands of low molecular weight metabolites, including sugars, amino acids, nucleotides, fatty acids, and phospholipids. Although some individual steps of metabolism may be near to thermodynamic equilibrium, the cell as a whole is very far from equilibrium and is maintained in this condition by a continuous interchange of substances with the environment. Nutrients are chemically transformed with release of energy which is used to maintain the structure of the cell and to synthesize the tens of thousands of different macromolecules on which its continued existence depends. Maintaining cells in a healthy state means providing them with all the substances they need, in the right overall environment of temperature, solute concentration, and substratum, and also continuously removing all potentially toxic waste products which the cells continuously produce.

The cell nucleus

The nucleus contains the genes that control the life of the cell. A gene is a sequence of DNA that codes for a protein, or for a nontranslated RNA, and it is usually considered also to include the associated regulatory sequences as well as the coding region itself. The vast majority of eukaryotic genes are located in the nuclear chromosomes, although there are also a few genes carried in the DNA of

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00005-8

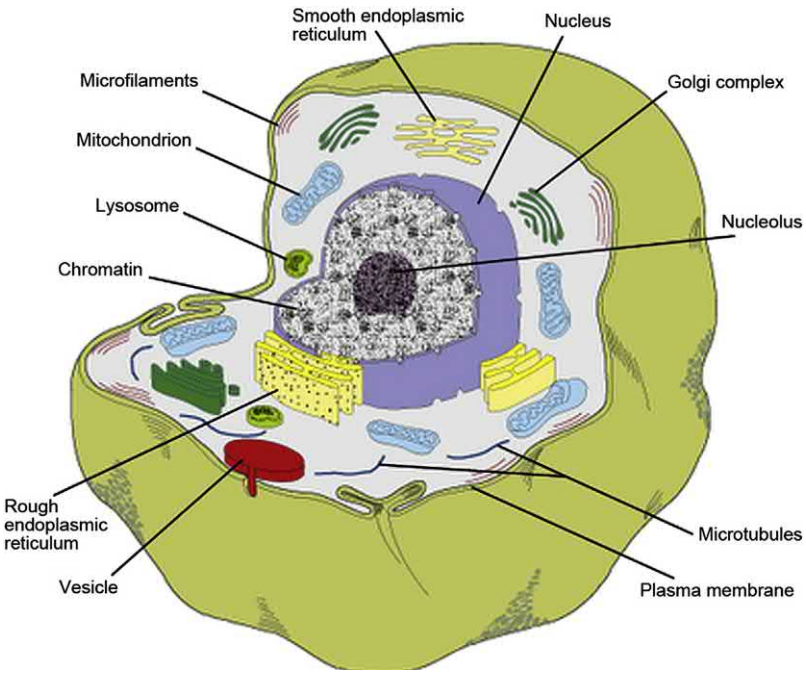

FIGURE 4.1 Structure of a generalized animal cell. (http://scienceblogs.com/clock/2006/11/09/cell-structure/ accessed 15.05.13).

mitochondria and chloroplasts. The genes encoding nontranslated RNAs include those for ribosomal or transfer RNAs and also for a large number of microRNAs and long noncoding RNAs that can modulate the expression of protein coding genes. The total number of protein coding genes in vertebrate animals is about 25,000. The idea that every cell nucleus carries an identical set of genes derived from the parents is generally true, but there are some irreversible DNA modifications. The B and T lymphocytes of the immune system undergo irreversible rearrangements in the genes encoding antibodies and T-cell receptors, respectively. There are many transposable elements within the genome that may move to other locations during development. In addition all cells, both in vivo and in cell culture, continuously accumulate somatic mutations.

The nuclear DNA is complexed into a higher order structure called chromatin by the binding of basic proteins called histones. Protein coding genes are transcribed into messenger RNA (mRNA) by the enzyme RNA polymerase II. Transcription commences at a transcription start sequence and finishes at a transcription termination sequence. Genes are usually divided into several exons, each of which codes for a part of the mature mRNA. The primary RNA transcript is extensively processed before it moves from the nucleus to the cytoplasm. It acquires a "cap" of methyl guanosine at the 5′ end, and a polyA tail at the 3′ end, both of which stabilize the message by protecting it from attack by exonucleases. The DNA sequences in between the exons are called introns and the portions of the initial transcript complementary to the introns are removed by splicing reactions catalyzed by "snRNPs" (small nuclear ribonucleoprotein particles). It is possible for the same gene to produce several different mRNAs as a result of alternative splicing, whereby different combinations of exons are spliced together from the primary transcript. In the cytoplasm, the mature mRNA is translated into a polypeptide by the ribosomes. The mRNA still contains a 5′ leader sequence and a 3′ untranslated sequence, flanking the protein coding region, and these untranslated regions may contain specific sequences responsible for translational control or intracellular localization.

Control of gene expression

There are many genes whose products are required in all tissues at all times, for example, those concerned with basic cell structure, protein synthesis, or metabolism. These are referred to as "housekeeping" genes. But there are many others whose products are specific to particular cell types and indeed the various cell types differ from each other, because they contain different repertoires of proteins. This means that the control of gene expression is central to tissue engineering. Control may be exerted at several points. Most common is control of transcription, and we often speak of genes being "on" or "off" in particular situations, meaning that they are or are not being transcribed. There are also many examples of translational regulation, where the mRNA exists in the cytoplasm but

is not translated into protein until some condition is satisfied. Control may also be exerted at the stage of nuclear RNA processing or indirectly via the stability of individual mRNAs or proteins.

Control of transcription depends on regulatory sequences within the DNA and on proteins called transcription factors that interact with these sequences. The promoter region of a gene is the region to which the RNA polymerase binds, just upstream from the transcription start site. The RNA polymerase is accompanied by a set of general transcription factors, which together make up a transcription complex. In addition to the general factors required for the assembly of the complex, there are numerous specific transcription factors that bind to specific regulatory sequences that may be either adjacent to or at some distance from the promoter (Fig. 4.2). These are responsible for controlling the differences in gene expression between different types of cell.

Transcription factors

Transcription factors are the proteins that regulate transcription. They usually contain a DNA-binding domain and a regulatory domain, which will either upregulate or repress transcription. Looping of the DNA may bring these regulatory domains into contact with the transcription complex with resulting promotion or inhibition of transcription. There are many families of transcription factors, classified by the type of DNA-binding domain they contain, such as the homeodomain or zinc-finger domain. Most are nuclear proteins, although some exist in the cytoplasm until they are activated and then enter the nucleus. Activation often occurs in response to intercellular signaling (see later). One type of transcription factor, the nuclear receptor family, is directly activated by lipid-soluble signaling molecules such as retinoic acid or glucocorticoids, which can penetrate cell membranes easily.

Each type of DNA-binding domain in a protein has a corresponding type of target sequence in the DNA, usually 20 nucleotides or less. The activation domains of transcription factors often contain many acidic amino acids making up an "acid blob," which accelerates the formation of the general transcription complex. Transcription factors often recruit histone acetylases which open up the chromatin by neutralizing amino groups on the histones by acetylation and allow access of other proteins to the DNA. Although it is normal to classify transcription factors as activators or repressors of transcription, their action is also sensitive to context, and the presence of other factors may on occasion cause an activator to function as a repressor, or vice versa.

Other controls of gene activity

The chromosomal DNA is complexed with histones into nucleosomes and is coiled into a 30 nm diameter filament, which is in turn arranged into higher order structures. This complex of DNA and proteins is referred to as chromatin, and the structure of chromatin is very important for gene regulation. In much of the genome the nucleosomes are to some extent mobile, allowing access of transcription factors to the DNA. This type of chromatin is called euchromatin. In other regions the chromatin is highly condensed and inactive, then being called

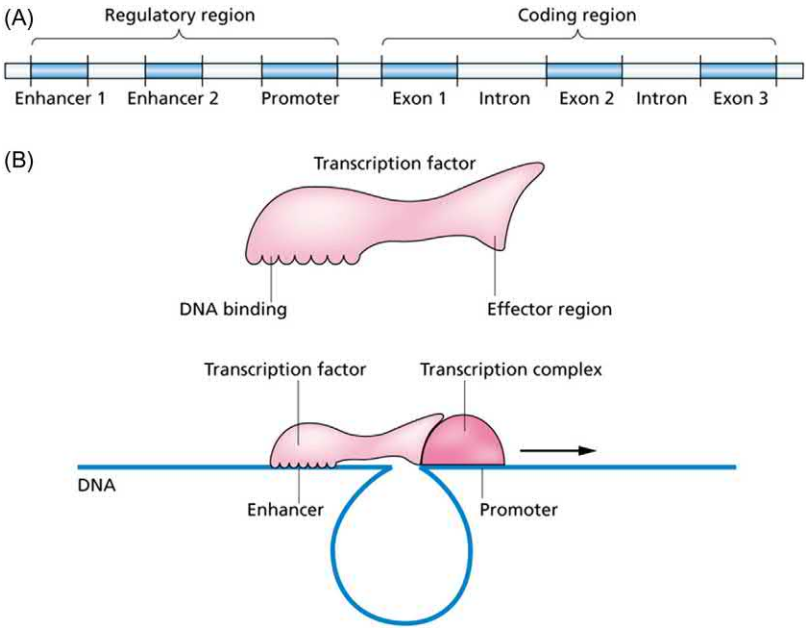

FIGURE 4.2 (A) Structure of a typical gene. (B) Operation of a transcription factor. *From Slack JMW. Essential developmental biology. 3rd ed. Oxford: Wiley-Blackwell; 2012 [1].*

heterochromatin. In the extreme case of the nucleated red blood cells of nonmammalian vertebrates, the entire genome is heterochromatic and inactive. Chromatin structure is regulated to some degree by protein complexes (such as the polycomb and trithorax groups), which affects the expression of many genes but are not themselves transcription factors. An important element of the chromatin remodeling is the control through acetylation of lysines on the exposed N-termini of histones. This partially neutralizes the binding of the histones to the negatively charged phosphodiester chains of DNA, so opens up the chromatin structure and enables transcription complexes to assemble on the DNA. The degree of histone acetylation is controlled, at least partly, by DNA methylation, because histone deacetylases are recruited to methylated regions and will tend to inhibit gene activity in these regions.

DNA methylation occurs on cytosine residues in CG sequences of DNA. Because CG on one strand will pair with GC on the other, antiparallel, strand, potential methylation sites always lie opposite one another on the two strands. There are several DNA methyl transferase enzymes, including de novo methylases that methylate previously unmethylated CGs, and maintenance methylases that methylate the other CG of sites bearing a methyl group on only one strand. Once a site is methylated, it will be preserved through subsequent rounds of DNA replication, because the hemimethylated site resulting from replication will be a substrate for the maintenance methylase. There are many other chemical modifications of the histones in addition to acetylation, including methylation of sites within the histone polypeptides, and these modifications can also be retained on chromosomes when the DNA is replicated. So both DNA methylation and histone modifications provide means for maintaining the state of activity of genes in differentiated cells even after the original signals for activation or repression have disappeared.

The cytoplasm

The cytoplasm consists partly of proteins in free solution, although it also possesses a good deal of structure that can be visualized as the cytoskeleton (see later). Often considered to be in free solution, although more likely in macromolecular aggregates, are the enzymes that carry out the central metabolic pathways. In particular the pathway called glycolysis leads to the degradation of glucose to pyruvate. Glucose is an important metabolic fuel for most cells. Mammalian blood glucose is tightly regulated at around 5−6 mM, and glucose is a component of most tissue culture media. Glycolysis leads to the production of two molecules of adenosine triphosphate (ATP) per molecule of glucose, with a further 36 molecules of ATP produced by oxidative phosphorylation of the pyruvate. This ATP is needed for a very wide variety of synthetic and biochemical maintenance activities. Apart from the central metabolic pathways, the cell is also engaged in the continuous synthesis and degradation of a wide variety of lipids, amino acids, and nucleotides.

The cytoplasm contains many types of organelle that are structures composed of phospholipid bilayers. Phospholipids are molecules with a polar head group and a hydrophobic tail. They tend to aggregate to form structures in which all the head groups are exposed on the surface and the hydrophobic tails associate with each other in the center. Most cell organelles are composed of membranes comprising two sheets of phospholipid molecules with their hydrophobic faces joined. The mitochondria are the organelles responsible for oxidative metabolism, as well as other metabolic processes such as the synthesis of urea. They are composed of an outer and an inner phospholipid bilayer. The oxidative degradation of sugars, amino acids, and fatty acids is accompanied by the production of ATP. Pyruvate produced by glycolysis is converted to acetyl CoA, also formed by the degradation of fatty acids and amino acids, and this is oxidized to two molecules of CO_2 by the citric acid cycle, with associated production of ATP in the electron transport chain of the mitochondria. Because of the importance of oxidative metabolism for ATP generation, cells need oxygen to support themselves. Tissue culture cells are usually grown in atmospheric oxygen concentration (about 20% by volume), although the optimum concentration may be somewhat lower than this since the oxygen level within an animal body is normally lower than the external atmosphere. Too much oxygen can be deleterious, because it leads to the formation of free radicals that cause damage to cells. Tissue culture systems are therefore often run at lower oxygen levels, such as 5%. The oxidation of pyruvate and acetyl CoA also results in the continuous production of CO_2 which needs to be removed to avoid acidification of the culture medium.

Among the organelles in the cytoplasm is the endoplasmic reticulum, which is a ramifying system of phospholipid membranes. The interior of the endoplasmic reticulum can communicate with the exterior medium through the exchange of membrane vesicles with the plasma membrane. Proteins that are secreted from cells, or that come to lie within the plasma membrane, are synthesized by ribosomes that lie on the cytoplasmic surface of the endoplasmic reticulum, and the products are passed through pores into the endoplasmic reticulum lumen. From here they move to the Golgi apparatus, which is another collection of internal membranes, in which carbohydrate chains are added. From there they move to the cell surface or the exterior medium. Secretion of materials is a very important function of all cells, and it needs to be

remembered that their environment in tissue culture depends not only on the composition of the medium that is provided but also on what the cells themselves have been making and secreting.

Intracellular proteins are synthesized by ribosomes in the soluble cytoplasm. There is a continuous production of new protein molecules, the composition depending on the repertoire of gene expression of the cell. There is also a continuous degradation of old protein molecules, mostly in a specialized structure called the proteasome. This continuous turnover of protein requires a lot of ATP.

The cytoskeleton

The cytoskeleton is important for three distinct reasons. First, the orientation of cell division may be important. Second, animal cells move around a lot, either as individuals or as part of moving cell sheets. Third, the shape of cells is an essential part of their ability to carry out their functions. All of these activities are functions of the cytoskeleton. The main components of the cytoskeleton are microfilaments, microtubules, and intermediate filaments. Microtubules and microfilaments are universal constituents of eukaryotic cells, while intermediate filaments are found only in animals. Microfilaments are made of actin, microtubule of tubulin, and intermediate filaments are composed of different proteins in different cell types: cytokeratins in epithelial cells, vimentin in mesenchymal cells, neurofilament proteins in neurons, and glial fibrilliary acidic protein in glial cells.

Microtubules

Microtubules (Fig. 4.3) are hollow tubes of 25 nm diameter composed of tubulin. Tubulin is a generic name for a family of globular proteins that exist in solution as heterodimers of α- and β-type subunits and is one of the more abundant cytoplasmic proteins. The microtubules are polarized structures with a minus end anchored to the centrosome and a free plus end at which tubulin monomers are added or removed. Microtubules are not contractile but exert their effects through length changes based on polymerization and depolymerization. They are very dynamic, either growing by addition of tubulin monomers, or retracting by loss of monomers, and individual tubules can grow and shrink over a few minutes. The monomers contain guanosine triphosphate (GTP) bound to the b subunit, and in a growing plus end, this stabilizes the tubule. But if the rate of growth slows down, hydrolysis of GTP to guanosine diphosphate (GDP) will catch up with the addition of monomers. The conversion of bound GTP to GDP renders the plus end of the tubule unstable, and it will then start to depolymerize. The drugs colchicine and colcemid bind to monomeric tubulin and prevent polymerization and among other effects this causes the disassembly of the mitotic spindle. Because these drugs cause cells to become arrested in mitosis, they are often used in studies of cell division kinetics.

The shape and polarity of cells can be controlled by locating capping proteins in particular parts of the cell cortex, which bind the free plus ends of the microtubules and stabilize them. The positioning of structures within the cell also depends largely on microtubules. There exist special motor proteins that can move along the tubules, powered by hydrolysis of ATP, and thereby transport other molecules to particular locations within the cell. The kinesins move toward the plus ends of the tubules while the dyneins move toward the minus ends. Microtubules are prominent during cell division. The minus ends of the tubules originate in the centrosome, which is a microtubule-organizing center able to initiate the assembly of new tubules. In mitotic prophase the centrosome divides, and each of the radiating sets of microtubules becomes known as an aster. The two asters move to the opposite sides of the nucleus to become the two poles of the mitotic spindle. The spindle contains two types of microtubules. The polar microtubules meet each other near the center and become linked by plus-directed motor proteins. These tend to drive the poles apart. Each chromosome has a special site called a kinetochore that binds another group of microtubules called kinetochore microtubules. At anaphase the kinetochores of homologous chromosomes separate. The polar microtubules continue to elongate while the kinetochore microtubules shorten by loss of tubulin from both ends and draw the chromosome sets into the opposite poles of the spindle.

Microfilaments

Microfilaments (Fig. 4.4) are polymers of actin, which is the most abundant protein in most animal cells. In vertebrates, there are several different gene products of which α actin is found in muscle and β/γ actins in the cytoskeleton of nonmuscle cells. For all actin types the monomeric soluble form is called G-actin. Actin filaments have an inert minus end and a growing plus end to which new monomers are added. G-actin contains ATP, and this becomes hydrolyzed to ADP shortly after addition to the filament. As with tubules, a rapidly growing filament will bear an ATP cap that stabilizes the plus end. Microfilaments are often found to undergo "treadmilling" such that monomers are continuously added to the plus end and removed from the minus end while leaving the filament at the same overall length. Microfilament polymerization is prevented by a group of drugs called cytochalasins, and existing filaments are stabilized by another group called phalloidins. Like microtubules, microfilaments have associated motor proteins that will actively migrate along the fiber. The most abundant of these is

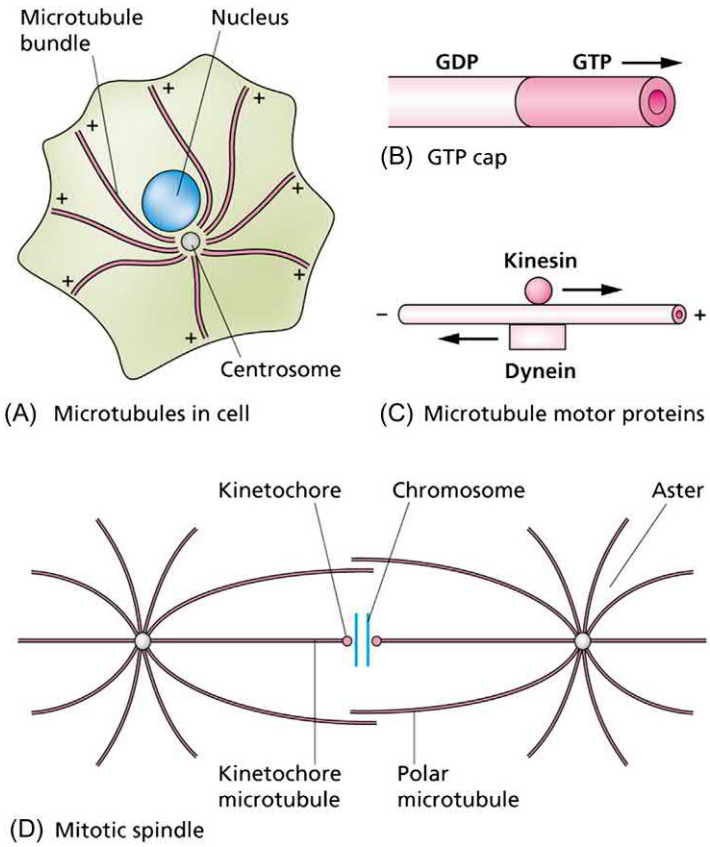

FIGURE 4.3 Microtubules: (A) arrangement in cell, (B) the GTP cap, (C) motor proteins move along the tubules, and (D) structure of the cell division spindle. *From Slack JMW. Essential developmental biology. 3rd ed. Oxford: Wiley-Blackwell; 2012.*

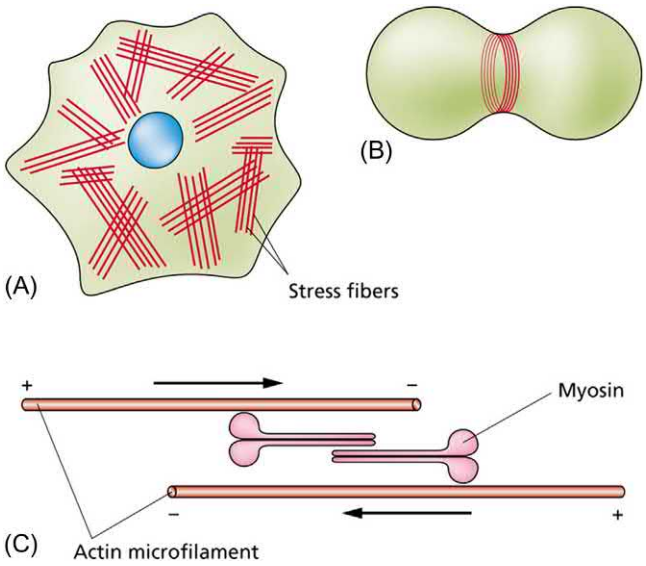

FIGURE 4.4 Microfilaments: (A) arrangement in cell, (B) role in cell division, and (C) contraction achieved by movement of myosin along microfilament. *From Slack JMW. Essential developmental biology. 3rd ed. Oxford: Wiley-Blackwell; 2012.*

myosin II, which moves toward the plus end of microfilaments, the process being driven by the hydrolysis of ATP. To bring about contraction of a filament bundle the myosin is assembled as short bipolar filaments with motile centers at both ends. If neighboring actin filaments are arranged with opposite orientation then the motor activity of the myosin will draw the filaments past each other leading to a contraction of the filament bundle.

Microfilaments can be arranged in various different ways depending on the nature of the accessory proteins with which they are associated. Contractile assemblies contain microfilaments in antiparallel orientation associated with myosin. These are found in the contractile ring that is responsible for cell division and in the stress fibers by which fibroblasts exert traction on their substratum. Parallel bundles are found in filopodia and other projections from the cell. Gels composed of short randomly orientated filaments are found in the cortical region of the cell.

Small GTPases

There are three well-known GTPases that activate cell movement in response to extracellular signals: RHO,

RAC, and CDC42. They are activated by numerous tyrosine kinase-, G-coupled-, and cytokine-type receptors. Activation involves exchange of GDP for GTP and many downstream proteins can interact with the activated forms. RHO normally activates the assembly of stress fibers. RAC activates the formation of lamellipodia and ruffles. CDC42 activates formation of filopodia. In addition all three promote the formation of focal adhesions, which are integrin-containing junctions to the extracellular matrix (ECM). These proteins can also affect gene activity through the kinase cascade signal transduction pathways.

The cell surface

The plasma membrane is the frontier between the cell and its surroundings. It is a phospholipid bilayer incorporating many specialized proteins. Very few substances are able to enter and leave cells by simple diffusion; in fact, this method is really only available to low molecular weight hydrophobic molecules such as retinoic acid, steroids, or thyroid hormones. The movement of inorganic ions across the membrane is very tightly controlled. The main control is exerted by a sodium−potassium exchanger known as the NaKATPase that expels sodium (Na) and imports potassium (K) ions. Because three sodium ions are expelled for every two potassium ions imported, this process generates an electric potential difference across the membrane, which is intensified by differential back diffusion of the ions. The final membrane potential is negative inside the cell and ranges from about 10 mV in red blood cells to about 70 mV in excitable cells such as neurons. This maintenance of membrane potential by the NaKATPase accounts for a high fraction of total cellular ATP consumption. Calcium (Ca) ions are very biologically active within the cell and are normally kept at a very low intracellular concentration, about 10^{-7} M. This is about 10^4 times lower than the typical exterior concentration, which means that any damage to the plasma membrane is likely to let in a large amount of calcium which will damage the cell beyond repair. The proteins of the plasma membrane are sometimes very hydrophobic molecules entirely contained within the lipid phase, but more usually they have hydrophilic regions projecting to the cell exterior or to the interior cytoplasm or both. These proteins have a huge range of essential functions. Some are responsible for anchoring cells to the substrate or to other cells through adhesion molecules and junctional complexes. Others, including ion transporters and carriers for a large range of nutrients, are responsible for transporting molecules across the plasma membrane. Then there are the receptors for extracellular signaling molecules (hormones, neurotransmitters, and growth factors) which are critical for controlling cellular properties and behavior. Some types of receptor serve as ion channels, for example, admitting a small amount of calcium when stimulated by their specific ligand. Other types of receptor are enzymes and initiate a metabolic cascade of intracellular reactions when stimulated. These reaction pathways often involve protein phosphorylation and frequently result in the activation of a transcription factor and thereby the expression of specific target genes. The repertoire of responses that a cell can show depends on which receptors it possesses, how these are coupled to signal transduction pathways, and how these pathways are coupled to gene regulation. It is sometimes called the "competence" of the cell. The serum that is usually included in tissue culture media contains a wide range of hormones and growth factors and is itself likely to stimulate many of the cell surface receptors.

Cell adhesion molecules

Organisms are not just bags of cells, rather each tissue has a definite cellular composition and microarchitecture. This is determined partly by the cell surface molecules by which cells interact with each other and partly by the components of the ECM. Virtually all proteins on the cell surface or in the ECM are glycoproteins, containing oligosaccharide groups added before secretion from the cell. These carbohydrate groups often have rather little effect on the biological activity of the protein, but they may affect its physical properties and stability.

Cells are attached to each other by adhesion molecules (Fig. 4.5). Among these are the cadherins that stick cells together in the presence of Ca, the cell adhesion molecules (CAMs) that do not require Ca, and the integrins that attach cells to the ECM. When cells come together, they often form gap junctions at the region of contact. These consist of small pores joining the cytosol of the two cells. The pores, or connexons, are assembled from proteins called connexins and can pass molecules up to about 1000 molecular weight by passive diffusion.

Cadherins are a family of single-pass transmembrane glycoproteins that can adhere tightly to similar molecules on other cells in the presence of calcium. They are the main factors attaching embryonic cells together, which is why embryonic tissues can often be caused to disaggregate simply by removal of calcium. The cytoplasmic tail of cadherins is anchored to actin bundles in the cytoskeleton by a complex including proteins called catenins. One of these, β-catenin, is also a component of the important WNT signaling pathway, providing a link between cell signaling and cell association. Cadherins were first named for the tissues in which they were originally found, so E-cadherin occurs mainly in epithelia and N-cadherin occurs mainly in neural tissue.

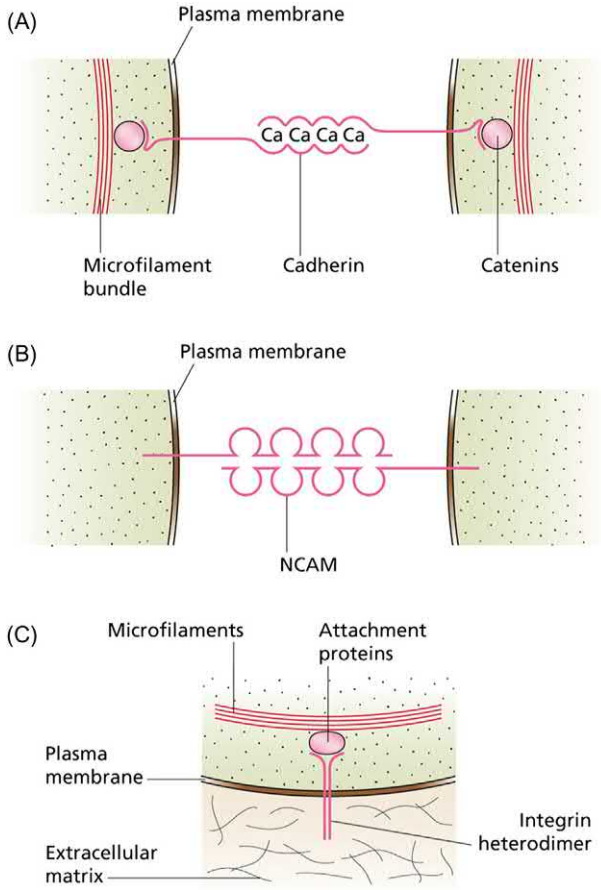

FIGURE 4.5 Cell adhesion molecules: (A) calcium-dependent system, (B) calcium-independent system, and (C) adhesion to the extracellular matrix. *From Slack JMW. Essential developmental biology. 3rd ed. Oxford: Wiley-Blackwell; 2012.*

The immunoglobulin superfamily is made up from single-pass transmembrane glycoproteins with a number of disulfide-bonded loops on the extracellular region, similar to the loops found in antibody molecules. They also bind to similar molecules on other cells, but unlike the cadherins, they do not need calcium ions to do so. The neural CAM is composed of a large family of different proteins formed by alternative splicing. It is most prevalent in the nervous system but also occurs elsewhere. It may carry a large amount of polysialic acid on the extracellular domain, and this can inhibit cell attachment because of the repulsion between the concentrations of negative charge on the two cells.

The integrins are cell surface glycoproteins that interact mainly with components of the ECM. They are heterodimers of α and β subunits and require either magnesium or calcium ions for binding. There are numerous different α and β chain types, and so there is a very large number of potential heterodimers. Integrins are attached by their cytoplasmic domains to microfilament bundles, so, such as cadherins, they provide a link between the outside world and the cytoskeleton. They are also thought on occasion to be responsible for the activation of signal transduction pathways and new gene transcription following exposure to particular ECM components.

Extracellular matrix

Glycosaminoglycans (GAGs) are unbranched polysaccharides composed of repeating disaccharides of an amino sugar and a uronic acid, usually substituted with some sulfate groups. GAGs are constituents of proteoglycans, which have a protein core to which the GAG chains are added in the Golgi apparatus before secretion. One molecule of a proteoglycan may carry more than one type of GAG chain. GAGs have a high negative charge, and a small amount can immobilize a large amount of water into a gel. Important GAGs, each of which has different component disaccharides, are heparan sulfate, chondroitin sulfate, and keratan sulfate. Heparan sulfate, closely related to the anticoagulant heparin, is particularly important for cell signaling as it is required to present various growth factors, such as the fibroblast growth factors, to their receptors. Hyaluronic acid differs from other GAGs because it occurs free and not as a constituent of a proteoglycan. It consists of repeating disaccharides of glucuronic acid and N-acetyl glucosamine and is not sulfated. It is synthesized by enzymes at the cell surface and is abundant in early embryos.

Collagens are the most abundant proteins by weight in most animals. The polypeptides, called α chains, are rich in proline and glycine. Before secretion, three α chains become twisted around each other to form a stiff triple helical structure. In the ECM the triple helices become aggregated together to form the collagen fibrils often visible in the electron microscope. There are many types of collagen, which may be composed of similar or of different α chains in the triple helix. Type I collagen is the most abundant and is a major constituent of most extracellular material. Type II collagen is found in cartilage and in the notochord of vertebrate embryos. Type IV collagen is a major constituent of the basal lamina underlying epithelial tissues. Collagen helices may become covalently crosslinked through their lysine residues, and this contributes to the changing mechanical properties of tissues with age. Elastin is another extracellular protein with extensive intermolecular cross-linking. It confers the elasticity on tissues in which it is abundant and also has some cell-signaling functions.

Fibronectin is composed of a large disulfide-bonded dimer. The polypeptides contain regions responsible for binding to collagen, to heparan sulfate, and to integrins on the cell surface. These latter, cell-binding, domains are

characterized by the presence of the amino acid sequence Arg-Gly-Asp. There are many different forms of fibronectin produced by alternative splicing. Laminin is a large extracellular glycoprotein found particularly in basal laminae. It is composed of three disulfide-bonded polypeptides joined in a cross shape. It carries domains for binding to type IV collagen, heparan sulfate, and another matrix glycoprotein, entactin.

Signal transduction

Lipid soluble molecules such as steroid hormones can enter cells by simple diffusion. Their receptors, called nuclear hormone receptors, are multidomain molecules that also function as transcription factors. Binding of the ligand activates the factor, in many cases also causing translocation to the nucleus where the receptor–ligand complex can upregulate its target genes (Fig. 4.6A). Most signaling molecules are proteins which cannot diffuse across the plasma membrane and so work by binding to specific cell surface receptors. There are three main classes of these: enzyme-linked receptors, G-protein-linked receptors, and ion channel receptors. Enzyme-linked receptors are often tyrosine kinases or Ser/Thr kinases (Fig. 4.6B). All have a ligand-binding domain on the exterior of the cell, a single transmembrane domain, and the enzyme active site on the cytoplasmic domain. For receptor tyrosine kinases, the ligand binding brings about dimerization of the receptor, and this results in an autophosphorylation, whereby each receptor molecule phosphorylates and activates the other. The phosphorylated receptors can then activate a variety of targets. Many of these are transcription factors that are activated by phosphorylation and move to the nucleus where they upregulate their target genes. In other cases there is a cascade of kinases that activate each other down the chain, culminating in the activation of a transcription factor. Roughly speaking, each class of signaling molecules has its own associated receptors and a specific signal transduction pathway; however, different receptors may be linked to the same signal transduction pathway, or one receptor may feed into more than one pathway. The effect of one pathway upon the others is often called "cross talk." The significance of cross talk can be hard to assess from biochemical analysis alone but is easier using genetic experiments in which individual components are mutated to inactivity and the overall effect on the cellular behavior can be assessed.

There are several classes of G-protein-linked receptor (Fig. 4.6C). The best known are seven-pass membrane proteins, meaning that they are composed of a single polypeptide chain crossing the membrane seven times. These are associated with trimeric G proteins composed of α, β, and γ subunits. When the ligand binds, the activated receptor causes exchange of GDP bound to the α subunit for GTP, then the activated α subunit is released and can interact with other membrane components. The most common target is adenylyl cyclase that converts ATP to cyclic adenosine monophosphate

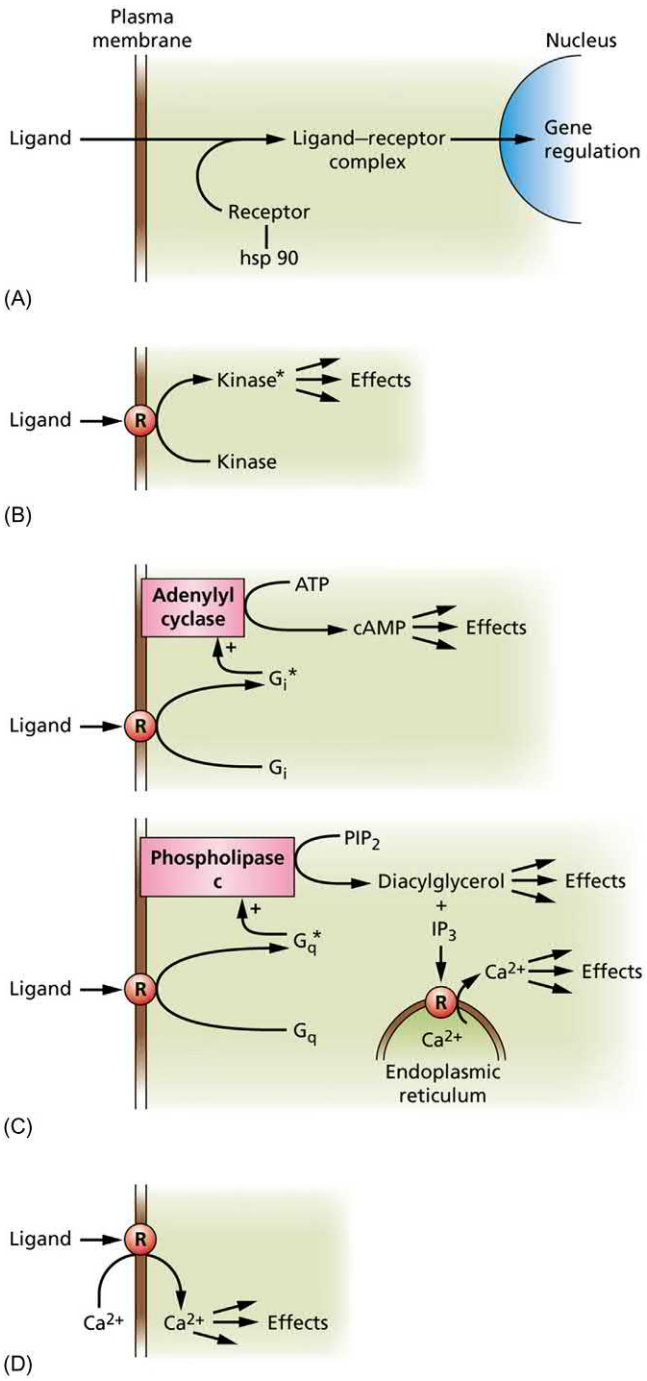

FIGURE 4.6 Different types of signal transduction: (A) nuclear receptor, (B) enzyme-linked receptor, (C) G protein–linked receptor, and (D) ion channel receptor. *From Slack JMW. Essential developmental biology. 3rd ed. Oxford: Wiley-Blackwell; 2012.*

(cAMP). cAMP activates protein kinase A (PKA) that phosphorylates various further target molecules affecting both intracellular metabolism and gene expression. Another large group of G-protein-linked receptors use a different trimeric G protein to activate the inositol phospholipid pathway (Fig. 4.6C). Here the G protein activates phospholipase C which breaks down phosphatidylinositol bisphosphate (PIP_2) to diacylglycerol (DAG) and inositol trisphosphate (IP_3). The DAG activates an important membrane-bound kinase, protein kinase C. Like PKA, this has a large variety of possible targets in different contexts and can cause both metabolic responses and changes in gene expression. The IP_3 binds to an IP_3 receptor (IP_3R) in the endoplasmic reticulum and opens Ca channels which admit Ca ions into the cytoplasm. Normally cytoplasmic calcium is kept at a very low concentration of around 10^{-7} M. An increase caused either by opening of an ion channel in the plasma membrane, or as a result of IP_3 action, can have a wide range of effects on diverse target molecules. Ion channel receptors (Fig. 4.6D) are also very important. They open on stimulation to allow passage of Na, K, Cl, or Ca ions. As mentioned above, Na and K ions are critical to the electrical excitability of nerve or muscle, and Ca ions are very potent, having a variety of effects on cell structure and function at low concentration.

Growth and death

Tissue engineering inevitably involves the growth of cells in culture, so the essentials of cell multiplication need to be understood. A typical animal cell cycle is shown in Fig. 4.7 and some typical patterns of cell division in Fig. 4.8. The cell cycle is conventionally described as consisting of four phases. M indicates the phase of mitosis (cell division), S indicates the phase of DNA replication, and G1 and G2 are the intervening growth phases. For growing cells, the increase in mass is continuous around the cycle and so is the synthesis of most of the cell's proteins. Normally the cell cycle is coordinated with the growth of mass. If it were not, cells would increase or decrease in size with each division. There are various internal controls built into the cycle, for example to ensure that mitosis does not start before DNA replication is completed. These controls operate at checkpoints around the cycle at which the process stops unless the appropriate conditions are fulfilled. Control of the cell cycle depends on a metabolic oscillator comprising a number of proteins called cyclins and a number of cyclin-dependent protein kinases (Cdks). In order to pass the M checkpoint and enter mitosis, a complex of cyclin and Cdk (called M-phase promoting factor, MPF) has to be activated. This phosphorylates and thereby activates the various components required for mitosis (nuclear breakdown, spindle formation, chromosome condensation). Exit from M phase requires the inactivation of MPF, via the destruction of cyclin. Passage of the G1 checkpoint depends on a similar process operated by a different set of cyclins and Cdks, whose active complexes phosphorylate and activate the enzymes of DNA replication. This is also the point at which the cell size is assessed. The cell cycle of G1, S, G2, and M phases is universal, although there are some modifications in special circumstances. The rapid cleavage cycles of early development have short or absent G1 and G2 phases, and there is no size check, the cells halving in volume with each division. The meiotic cycles that generate sperm and eggs for reproduction require the same active MPF complex to get through the two nuclear divisions, but there is no S phase in between. In the mature organism most cells are quiescent unless, they are stimulated by growth factors. In the absence of growth factors, cells enter a state called G0, in which the Cdks and cyclins are absent. Restitution of growth factors induces the resynthesis of these proteins and the resumption of the cycle starting from the G1 checkpoint. One factor maintaining the G0 state is a protein called Rb (retinoblastoma protein). This becomes phosphorylated, and hence deactivated, in the presence of growth factors. In the absence of Rb a transcription factor called E2F becomes active and initiates a cascade of gene expression culminating in the resynthesis of cyclins, Cdks, and other components needed to initiate S phase. Cells often have the capability for exponential growth in tissue culture (Fig. 4.8C), but this is very rarely found in animals. Although some differentiated cell types can go on dividing, there is a general tendency for differentiation to be accompanied by a slow down or cessation of division. In postembryonic life, most cell division is found among stem cells and their immediate progeny called transit amplifying cells. Stem cells are cells that can both reproduce themselves and generate differentiated progeny for their particular tissue type (Fig. 4.8D). This does not necessarily mean that every division of a stem cell has to be an asymmetrical one, but over a period of time, half the progeny will go to renewal and half to differentiation. The term "stem cell" is also used for embryonic stem cells of early mammalian embryos. These are early embryo-type cells that can be grown in culture and are capable of repopulating embryos and contributing to all tissue types.

Asymmetric cell divisions necessarily involve the segregation of different cytoplasmic determinants to the two daughter cells, evoking different patterns of gene activity in their nuclei and thus bringing about different pathways of development. The asymmetry often arises from autosegregation of a self-organizing protein complex called the PAR complex. This is active both for asymmetric division in early embryos and for those in various tissues in postnatal life.

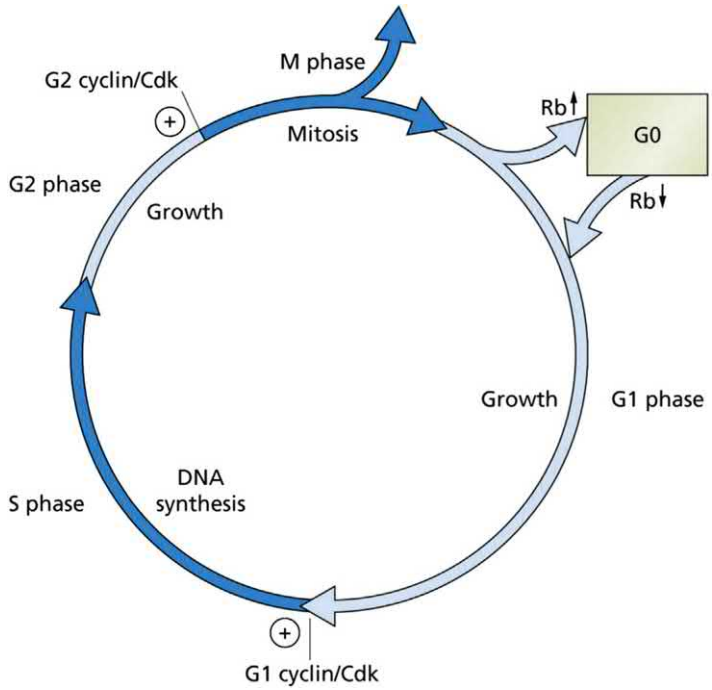

FIGURE 4.7 The cell cycle, with phases of growth, DNA replication and division. *From Slack JMW. Essential developmental biology. 3rd ed. Oxford: Wiley-Blackwell; 2012.*

Culture media

Tissue engineering is heavily focused on the growth of cells, tissues, and even organs in vitro, so it is very important to understand the principles of cell culture (Fig. 4.9).

On a laboratory scale, cells are usually grown in small containers made of polystyrene, which is optically clear and easily sterilized by irradiation. To enable attachment of cells the plastic needs to be specially treated. For specific application a layer of fibronectin or collagen or polylysine may be added to further improve cell attachment. Some cell types can be grown in suspension culture often in bottles incorporating a rotating stirrer arm. Since such bottles may be nearly filled with medium, they allow for large amounts of cell production relative to similar-sized surface culture methods. But for visual observation a sample must be taken out of the vessel for examination. For really large-scale cell production a bioreactor must be used. This is a temperature controlled vessel with controlled flows of medium and gases and continuous monitoring of conditions. Massive bioreactors are used in the pharmaceutical industry for the production of antibodies or recombinant proteins from mammalian cell cultures.

Mammalian cells will only remain in good condition very close to the normal body temperature, so good temperature control is essential during culture. Because water can pass across the plasma membranes of animal cells, the medium must match the osmolarity of the cell interior; otherwise cells will swell or shrink due to osmotic pressure difference. Mammalian cell media generally have a total osmolarity about 350 mOsm. The pH needs to be tightly controlled, 7.4 being normal. The pH control is usually achieved with bicarbonate-CO_2 buffers (2.2 g/L bicarbonate and 5% CO_2 being a common combination). These give better results with most animal cells than other buffers, perhaps because bicarbonate is also a type of nutrient. Most media contain phenol red indicator. This has a red color at neutral pH and goes purple at alkaline pH and yellow at acid pH. The medium must contain a variety of components: salts, amino acids, sugars, plus low levels of specific hormones, and growth factors required for the particular cell type in question. Because of the complexity of tissue culture media, they are rarely optimized for a given purpose by varying every one of the components systematically. Usually changes are incremental and the result of a "gardening" type of approach rather than a systematic one. The requirement for hormones and growth factors is usually met by including some animal serum, often 10% fetal calf serum. This is long-standing practice but has two substantial disadvantages. Serum can never be completely characterized, and there are often differences between batches of serum that can be critical for experimental results. Also animal serum cannot now be used for the preparation of cells that are intended for implantation into human patients. This is because of the perceived possibility of transmitting animal diseases to patients. The various problems with serum have led to an increased formulation of serum-free media, which are often completely "defined" meaning that all the macromolecular hormones, growth factors, and other components in the medium are chemically pure.

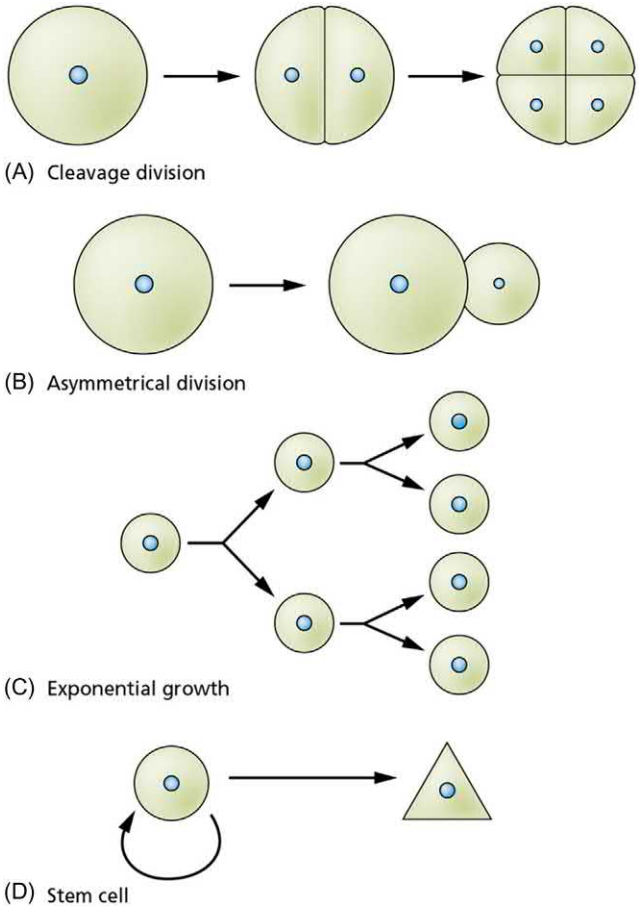

FIGURE 4.8 Types of cell division: (A) cleavage as found in early embryos, (B) asymmetrical division also found in some early embryos, (C) exponential growth found in tissue culture, and (D) stem-cell division found in renewal tissues in animals. *From Slack JMW. Essential developmental biology. 3rd ed. Oxford: Wiley-Blackwell; 2012.*

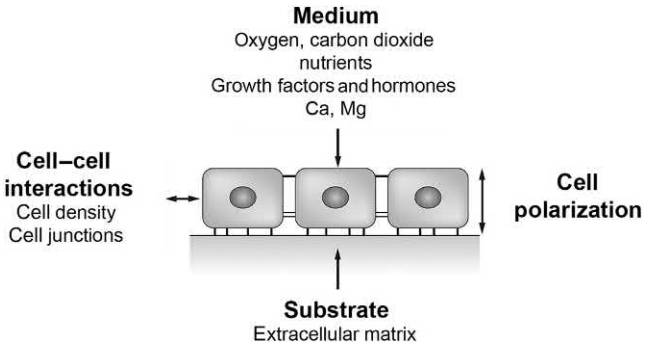

FIGURE 4.9 Multiple factors control the cellular environment for cells in culture.

Assuming cells are kept in near optimal conditions, they can in principle grow exponentially, with a constant doubling time. Indeed, it is possible to grow many types of tissue culture cell in exponential cultures rather like microorganisms. In order to keep them growing at maximal rate, they need to have their medium renewed regularly and to be subcultured and replated at lower density whenever they approach confluence, that is, approach a density at which they cover all the available surface. Subculturing is usually carried out by treatment with the enzyme trypsin, which degrades much of the extracellular and cell surface protein and makes the cells drop off the substrate and become roughly spherical bodies in suspension. The trypsin is diluted out, and the cells are transferred at lower density into new flasks. The cells take an hour or two to resynthesize their surface molecules and can then adhere to the new substrate and carry on growing.

Cells in tissues and organs

Cell types

On the basis of light microscopy, it is estimated that there are about 210 different types of differentiated cell in the mammalian body. This number is certainly an underestimate since there are many subtypes of cells that cannot be seen via the light microscope, particularly the different types of neuron in the nervous system and different types of lymphocyte in the immune system. Cells types are different from one another because they are expressing different subsets of genes and hence contain different proteins. The products of a relatively small number of genes may dominate the appearance of a differentiated cell, for example, the proteins of the contractile apparatus of skeletal muscle are very abundant. However, a typical cell will express many thousands of genes, and its character will also depend on the genes expressed at low levels and, by exclusion, on the genes that are not expressed. It is possible to control cell differentiation to some extent. There are special culture media that are favorable for differentiation of particular cell types, such as adipocytes, muscle, or bone. In some cases differentiated cells can continue to grow in pure culture, but in many cases, differentiation causes slowing or cessation of cell division.

From a morphological point of view, most cells can be regarded as epithelial or mesenchymal (Fig. 4.10). These terms relate to cell shape and behavior rather than to embryonic origin. An epithelium is a sheet of cells, arranged on a basement membrane, each cell joined to its neighbors by specialized junctions, and showing a distinct apical-basal polarity. Mesenchyme is a descriptive term for scattered stellate-shaped cells embedded in loose ECM. It fills up much of the space within the embryo and later forms fibroblasts, adipose tissue, smooth muscle, and skeletal tissues.

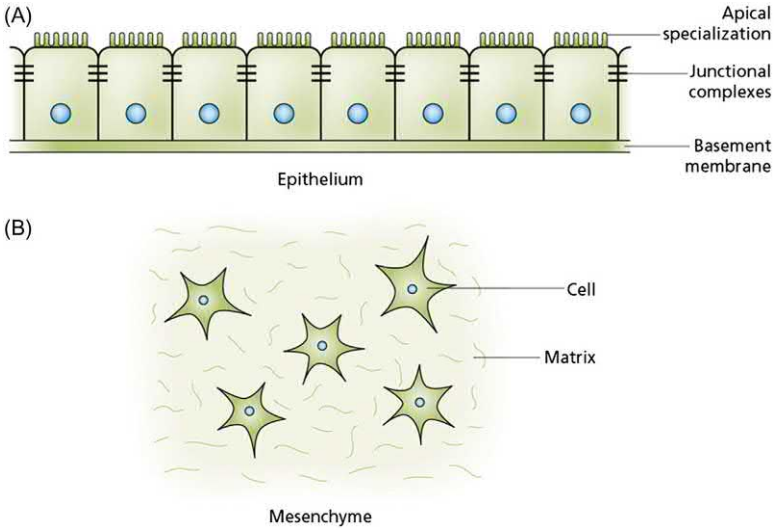

FIGURE 4.10 Most tissues are composed of epithelial (A) and mesenchymal (B) components. *From Slack JMW. Essential developmental biology. 3rd ed. Oxford: Wiley-Blackwell; 2012.*

Tissues

From a developmental biology standpoint, a tissue is the set of cell types arising from one sort of progenitor or stem cell. For example, the intestinal epithelium is a tissue. It is structured into crypts, containing undifferentiated cells, and villi covered with differentiated cells. There are four principal mature cell types: absorptive, goblet, Paneth, and enteroendocrine cells. The stem cells are located at the crypt base and produce progenitor cells, called transit amplifying cells, which divide a few times before differentiating into one of the four mature cell types. The tissue comprises the stem cells, the transit amplifying cells, and the differentiated cells. This is an example of a renewal tissue, in which there is continuous production and replacement of differentiated cells. Not all tissues are renewal tissues, although most display a small degree of renewal or the ability to replace the constituent cell types following damage. For example, the central nervous system arises from the neuroepithelium of the early embryo and contains a variety of types of neuron together with glial cells, especially astrocytes and oligodendrocytes. There is only replacement of neurons in two regions of the brain and turnover of glial populations is slow. But because it arises from a clearly identified progenitor cell population, the central nervous system can be regarded as one tissue.

In cases where differentiated cells are derived from different stem or progenitor cell populations, they cannot be considered as a single tissue. For example, the thyroid gland contains many follicles of thyroglobulin-producing epithelial cells. It also contains endocrine cells producing the hormone calcitonin. However, the latter do not arise from the same endodermal bud as the rest of the thyroid. Instead they arise from the neural crest of the embryo. Likewise, many tissues contain macrophages (histiocytes) derived from the hematopoietic stem cells of the bone marrow. These cells are properly considered to belong to the blood/immune tissue rather than the epithelia or connective tissues in which they reside.

Organs

Organs are the familiar structures in the body, which are each associated with a particular function. They are typically composed of several tissue layers and arise from multiple developmental origins. For example, the stomach has the function of preliminary food digestion. The lining of the stomach is one tissue, the gastric epithelium, derived from gastric stem cells. The outer layers consist of smooth muscle and connective tissues, blood vessels, nerve fibers, and cells of the blood and immune system. Together, these make up a discrete and integrated body part: an organ.

Likewise, a single named muscle is one organ, composed of several tissues, each consisting of more than one cell type. A muscle contains many muscle fibers that are postmitotic multinucleate cells. It also contains muscle satellite cells that are stem cells that can regenerate fibers. The fibers and the satellite cells are one tissue, arising from the myotome of the somites of the embryo. Surrounding the bundles of fibers are connective tissue sheaths composed of fibroblasts and ECM derived from lateral plate mesoderm, together with blood vessels, nerve fibers, and cells of the blood and immune system.

Organs often have an epithelial and mesenchymal component. The epithelium is usually the functional part, for example, the epithelial lining of the various segments of the gut have specific properties of protection, absorption or secretion, while the underlying mesenchyme (often called “stroma” in adult organs) provides mechanical

support, growth factors, and physiological response in terms of muscular movements.

With the exception of the kidney, all other organs draw their epithelium and mesenchyme from different germ layers of the embryo. The implication of this for tissue engineering is that it will probably be necessary to assemble structures from separate epithelial and mesenchymal cells, designed such that each population can support the other by secretion of appropriate factors. A further consideration for the creation of organs in vitro is that cells need a continuous supply of nutrients and oxygen and continuous removal of waste products. In vivo this is achieved by means of the blood vascular system that culminates in capillary beds of enormous density such that all cells are within a few cell diameters of the blood. For tissue engineering the lesson is clear: it is possible to grow large avascular structures only so long as they are two dimensional: for example, large sheets of epidermis a few cells thick can be grown in vitro and used successfully for skin grafting. But any tissue more than a fraction of a millimeter thickness needs to be provided with some sort of vascular system.

Tissue engineering needs not attempt to copy everything that is found in the normal body. However, it is necessary to be aware of the constraints provided by the molecular biology of the cell. Factors to be considered include the following:

- How to keep cells in the desired state by providing the correct substrate and medium?
- How to create engineered structures containing two or more cell types of different origins which can sustain one another?
- How to provide a vascular system capable of delivering nutrients and removing waste products?
- How to control cell division to achieve homeostasis rather than uncontrolled growth or regression?

Chapter 5

Molecular organization of cells

Jon D. Ahlstrom
PolarityTE, Salt Lake City, UT, United States

Introduction

Multicellular tissues exist in one of two types of cellular arrangements, epithelial or mesenchymal. Epithelial cells adhere tightly to each other at their lateral surfaces and to an organized extracellular matrix (ECM) at their basal domain, thereby producing a sheet of cells resting on a basal lamina with an apical surface. Mesenchymal cells, in contrast, are individual cells with a bipolar morphology that are held together as a tissue within a three-dimensional (3D) ECM (Fig. 5.1). The conversion of epithelial cells into mesenchymal cells, an "epithelial−mesenchymal transition" (EMT), is central to many aspects of embryonic morphogenesis and adult tissue repair, as well as a number of disease states [1−3]. The reverse process whereby mesenchymal cells coalesce into an epithelium is a "mesenchymal−epithelial transition" (MET). Understanding the molecules that regulate this transition between epithelial and mesenchymal states offers important insights into how cells and tissues are organized.

The early embryo is structured as one or more epithelia. An EMTallows the rearrangements of cells to create additional morphological features. Well-studied examples of EMTs during embryonic development include gastrulation in *Drosophila* [3], the emigration of primary mesenchyme cells (PMCs) in sea urchin embryos [4], and gastrulation in amniotes (reptiles, birds, and mammals) at the primitive streak [2]. EMTs also occur later in vertebrate development, such as during the emigration of neural crest cells from the neural tube [5], the formation of the sclerotome from epithelial somites, and palate fusion [2]. The reverse process of MET is likewise crucial to development; examples include the condensation of mesenchymal cells to form the notochord and somites [6], kidney tubule formation from nephrogenic mesenchyme [7], and the creation of heart valves from cardiac mesenchyme [8]. In the adult organism, EMTs and METs occur during wound healing and tissue remodeling [9]. The conversion of neoplastic epithelial cells into invasive cancer cells has long been considered an EMT process [1,10]. However, there are also examples of tumor cells that have functional cell−cell adhesion junctions yet are still migratory and invasive as a group [11]. This "collective migration" also occurs during development [11]. Hence, there is debate whether an EMT model accurately describes all epithelial metastatic cancers. Similarly, the fibrosis of cardiac, kidney, lens, and liver epithelial tissue has also long been categorized as an EMT event [6,12]. However, research in the kidney in vivo shows that the myofibroblasts induced after kidney injury are derived from mesenchymal pericytes rather than the proximal epithelial cells [13]. Therefore, defining the origin of the cells that contribute to fibrotic tissue scarring (epithelial or otherwise) will require further investigation.

The focus of this chapter is on the molecules that regulate the organization of cells into epithelium or mesenchyme. We will first discuss the cellular changes that occur during an EMT, including changes in cell−cell and cell−ECM adhesions, changes in cell polarity, and the stimulation of invasive cell motility. Then we will consider the molecules and mechanisms that control the EMT or MET, including the structural molecules, transcription factors, and signaling pathways that regulate EMTs.

Molecules that organize cells

The conversion of an epithelial sheet into individual migratory cells and back again requires the coordinated changes of many distinct families of molecules.

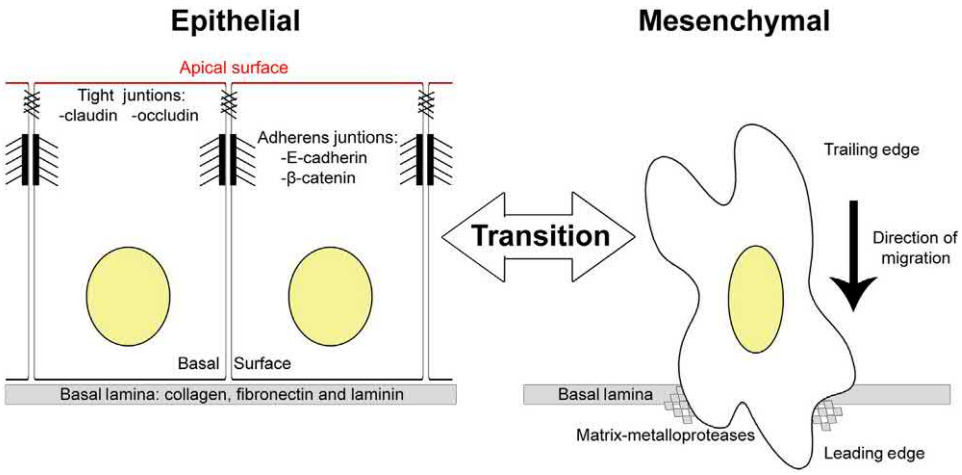

FIGURE 5.1 **Epithelial versus mesenchymal.** Epithelial cells adhere tightly together by tight junctions and adherens junctions localized near the apical surface. Epithelial cells also have a basal surface that rests on a basal lamina. In contrast, mesenchymal cells do not have well-defined cell−cell adhesion complexes; they have front-end/back-end polarity instead of apicobasal polarity, and mesenchymal cells are characterized by their ability to invade the basal lamina.

Changes in cell−cell adhesion

Epithelial cells are held together by specialized cell−cell junctions, including adherens junctions, desmosomes, and tight junctions [14]. These junctions are localized in the lateral domain near the apical surface and establish the apical polarity of the epithelium. For an epithelial sheet to produce individual mesenchymal cells, cell−cell adhesions must be disrupted. The principal transmembrane proteins that mediate cell−cell adhesions are members of the cadherin superfamily [15]. E-cadherin and N-cadherin are classical cadherins that interact homotypically through their extracellular immunoglobulin G domains with like-cadherins on adjacent cells. Cadherins are important mediators of cell−cell adhesion. For example, misexpression of E-cadherin is sufficient to promote cell−cell adhesion and assembly of adherens junctions in fibroblasts [16]. In epithelial cancers (carcinomas), E-cadherin acts as a tumor suppressor [10]. In a mouse model for β-cell pancreatic cancer, the loss of E-cadherin is the rate-limiting step for transformed epithelial cells to become invasive [17]. Although the loss of cadherin-mediated cell−cell adhesion is necessary for an EMT, the loss of cadherins is not always sufficient to generate a complete EMT in vivo. For example, the neural tube epithelium in mice expresses N-cadherin, but in the N-cadherin knockout mouse an EMT is not induced in the neural tube [18]. Hence, cadherins are essential for maintaining epithelial integrity, and the loss of cell−cell adhesion caused by the reduction of cadherin function is an important step for an EMT.

One characteristic of an EMT is "cadherin switching." Often, epithelia that express E-cadherin will downregulate E-cadherin expression at the time of the EMT and express different cadherins such as N-cadherin [19]. Cadherin switching may promote motility. For instance, in mammary epithelial cell lines, the misexpression of N-cadherin is sufficient for increased cell motility. However, blocking N-cadherin expression does not result in motility even though the adherens junctions are reduced. Hence, cadherin switching may be necessary for cell motility, but cadherin switching alone is not sufficient to bring about a complete EMT [20].

There are several ways in which cadherin expression and function are regulated. Transcription factors that are central to most EMTs, such as Snail-1, Snail-2, Zinc finger E-box-binding (Zeb)1, Zeb2, Twist, and E2A, all bind to E-boxes on the *E-cadherin* promoter and repress the transcription of *E-cadherin* [21]. Posttranscriptionally, the E-cadherin protein is ubiquitinated by the E3-ligase, Hakai, which targets E-cadherin to the proteasome [22]. E-cadherin turnover at the membrane is regulated by either caveolae-dependent endocytosis or clathrin-dependent endocytosis [23], and p120-catenin prevents endocytosis of E-cadherin at the membrane [24]. E-cadherin function can also be disrupted by matrix metalloproteases, which degrade the extracellular domain of E-cadherin [25]. Some or all of these mechanisms may occur during an EMT to disrupt cell−cell adhesion.

Cell−cell adhesion is maintained principally by cadherins, and changes in cadherin expression are typical of an EMT.

Changes in celleextracellular matrix adhesion

Altering the way in which a cell interacts with the ECM is also important in EMTs. For example, at the time that sea urchin PMCs ingress, the cells have increased

adhesiveness for ECM [4]. CelleECM adhesion is mediated principally by integrins. Integrins are transmembrane proteins composed of two noncovalently linked subunits, α and β, that bind to ECM components such as fibronectin, laminin, and collagen. The cytoplasmic domain of integrins links to the cytoskeleton and interacts with signaling molecules. Changes in integrin function are required for many EMTs, including neural crest emigration [26], mouse primitive streak formation [2], and cancer metastasis [27]. However, the misexpression of integrin subunits is not sufficient to bring about a full EMT in vitro [28] or in vivo [29].

The presence and function of integrins are modulated in several ways. For example, the promoter of the *integrin β6* gene is activated by the transcription factor Ets-1 during colon carcinoma metastasis [30]. Most integrins can also cycle between "on" (high-affinity) or "off" (low-affinity) states. This "inside-out" regulation of integrin adhesion occurs at the integrin cytoplasmic tail [31]. In addition to integrin activation, the "clustering" of integrins on the cell surface affects the overall strength of integrineECM interactions. The increased adhesiveness of integrins caused by clustering, known as avidity, can be activated by chemokines and depends on RhoA and phosphatidylinositol 3° kinase (PI3K) activity [31].

Changes in ECM adhesion are required for an EMT. Cell−ECM adhesions are maintained by integrins, which have varying degrees of adhesiveness depending on the presence, activity, or avidity of the integrin subunits.

Changes in cell polarity and stimulation of cell motility

Cellular polarity is defined by the distinct arrangement of cytoskeletal elements and organelles in epithelial versus mesenchymal cells. Epithelial polarity is characterized by cell−cell junctions found near the apicolateral domain (nonadhesive surface), and a basal lamina opposite of the apical surface (adhesive surface). Mesenchymal cells, in contrast, do not have apicobasal polarity, but rather front-end/back-end polarity, with actin-rich lamellipodia and Golgi localized at the leading edge [2]. Molecules that establish cell polarity include Cdc42, PAK1, PI3K, PTEN, Rac, Rho, and the PAR proteins [32,33]. Changes in cell polarity help to promote an EMT. In mammary epithelial cells, the activated transforming growth factor-β (TGF-β) receptor II causes Par6 to activate the E3 ubiquitin ligase Smurf1, which then targets RhoA to the proteasome. The loss of RhoA activity results in the loss of cell−cell adhesion and epithelial cell polarity [34].

For mesenchymal cells to leave the epithelium, they must become motile. Many of the same polarity (Crumbs, PAR, and Scribble complexes), structural (actin and microtubules), and regulatory molecules (Cdc42, Rac1, and RhoA) that govern epithelial polarity are also central to cell motility [35]. Cell motility mechanisms also vary depending on whether the environment is two-dimensional or 3D [36]. Many mesenchymal cells express the intermediate filament vimentin, which may be responsible for several aspects of the EMT phenotype [37].

In short, a wide variety of structural, polarity, and regulatory molecules must be reassigned as cells transition between epithelial polarity and mesenchymal migration.

Invasion of the basal lamina

In most EMTs, the emerging mesenchymal cells must penetrate a basal lamina, which consists of ECM components such as collagen type IV, fibronectin, and laminin. The basal lamina functions to stabilize the epithelium and is a barrier to migratory cells [38]. One mechanism that mesenchymal cells use to breach the basal lamina is to produce enzymes that degrade it. Plasminogen activator is one protease associated with a number of EMTs, including neural crest emigration [38] and the formation of cardiac cushion cells during heart morphogenesis [39]. The type II serine protease TMPRSS4 also promotes an EMT and metastasis when overexpressed in vitro and in vivo [40]. Matrix-metalloprotease (MMPs) are also important for many EMTs. When MMP-2 activity is blocked in the neural crest EMT, neural crest emigration is inhibited, but not neural crest motility [41]. In mouse mammary cells, MMP-3 overexpression is sufficient to induce an EMT in vitro and in vivo [42]. Misexpressing MMP-3 in cultured cells induces an alternatively spliced form of Rac1 (Rac1b), which then causes an increase in reactive oxygen species (ROS) intracellularly, and Snail-1 expression. Either Rac1b activity or ROS is necessary and sufficient for an MMP-3einduced EMT [43]. Hence, a number of extracellular proteases are important to bring about an EMT.

Although epithelial cells undergoing an EMT eventually lose cell−cell adhesion and apicobasal polarity and gain invasive motility, the EMT program is not necessarily ordered or linear. For example, in a study in which neural crest cells were labeled with cell adhesion or polarity markers and individual live cells were observed to undergo the EMT in slice culture, neural crest cells changed epithelial polarity either before or after the complete loss of cell−cell adhesion, or lost cell−cell adhesion either before or after cell migration commenced [44]. Therefore, whereas an EMTconsists of several distinct phases, these steps may occur in different orders or combinations, some of which (e.g., the complete loss of cell-cell adhesion) may not always be necessary.

Changes in a wide range of molecules are needed for an EMT because epithelial cells lose cell–cell adhesion, change cellular polarity, and gain invasive cell motility.

The epithelial–mesenchymal transition transcriptional program

At the foundation of every EMT or MET program are the transcription factors that regulate the gene expression required for these cellular transitions. Whereas many of the transcription factors that regulate EMTs have been identified, the complex regulatory networks are still incomplete. Here we review the transcription factors that are known to promote the various phases of an EMT. Then we examine how these EMT transcription factors themselves are regulated at the promoter and posttranscriptional levels.

Transcription factors that regulate epithelial–mesenchymal transition

The Snail family of zinc-finger transcription factors, including Snail-1 and Snail-2 (formerly Snail and Slug), are direct regulators of cell–cell adhesion and motility during EMTs [21,45]. The knockout of *Snail-1* in mice is lethal early in gestation, and the presumptive primitive streak cells that normally undergo an EMT retain apicobasal polarity and adherens junctions, and express *E-cadherin* messenger RNA [46]. Snail-1 misexpression is sufficient for breast cancer recurrence in a mouse model in vivo, and high levels of *Snail-1* predict the relapse of human breast cancer [47]. Snail-2 is necessary for the chicken primitive streak and neural crest EMTs [48]. One way in which Snail-1 or Snail-2 causes decreases in cell–cell adhesion is by repressing the *E-cadherin* promoter [21]. This repression requires the mSin3A corepressor complex, histone deacetylases, and components of the Polycomb 2 complex [49]. Snail-1 is also a transcriptional repressor of the tight junction genes *Claudin* and *Occludin* [21] and the polarity gene *Crumbs3* [50]. The misexpression of Snail-1 and Snail-2 further leads to the transcription of proteins important for cell motility, such as fibronectin, vimentin [51], and RhoB [52]. Moreover, Snail-1 promotes invasion across the basal lamina. In Madin–Darby Canine Kidney (MDCK) cells, the misexpression of Snail-1 represses laminin (basement membrane) production [53] and indirectly upregulates *mmp-9* transcription [54]. Snail and Twist also make cancer cells more resistant to senescence, chemotherapy, and apoptosis, and endow cancer cells with "stem cell" properties [6]. Hence, Snail-1 or Snail-2 is necessary and sufficient for bringing about many of the steps of an EMT, including loss of cell–cell adhesion, changes in cell polarity, gain of cell motility, invasion of the basal lamina, and increased proliferation and survival.

Other zinc finger transcription factors important for EMTs are Zeb homeobox 1 (Zeb1; also known as δEF1), and Zeb2 (also known as Smad-interacting protein-1; Sip1). Both Zeb1 and Zeb2 bind to the *E-cadherin* promoter and repress transcription [21]. Zeb1 can also bind to and repress the transcription of the polarity proteins Crumbs3, Pals1-associated tight junction proteins, and Lethal giant larvae 2 [55]. Zeb2 is structurally similar to Zeb1, and Zeb2 overexpression is sufficient to downregulate E-cadherin, dissociate adherens junctions, and increase motility in MDCK cells [56].

The lymphoid enhancer-binding factor/T-cell factor (LEF/TCF) transcription factors also have an important role in EMTs. For instance, the misexpression of Lef-1 in cultured colon cancer cells reversibly causes the loss of cell–cell adhesion [57]. LEF/TCF transcription factors directly activate genes that regulate cell motility, such as the L1 adhesion molecule [58], and the *fibronectin* gene [59]. LEF/TCF transcription factors also upregulate genes required for basal lamina invasion, including *mmp-3* and *mmp-7* [60].

Other transcription factors that have a role in promoting EMTs are the class I basic helix-loop-helix factors E2-2A and E2-2B [61], the forkhead box transcription factor FOXC2 [62], the homeobox protein Goosecoid [63], and the homeoprotein Six1 [64,65].

Transcription factors that regulate an EMT often do so by directly repressing cell adhesion and epithelial polarity molecules and by upregulating genes required for cell motility and basal lamina invasion.

Regulation at the promoter level

Given the importance of the Snail, Zeb, and LEF/TCF transcription factors in orchestrating the various phases of an EMT, it is essential to understand the upstream events that regulate these EMT-promoting transcription factors. The activation of *Snail-1* transcription in *Drosophila* requires the transcription factors Dorsal [nuclear factor κB (NF-κB)] and Twist [21]. The human *Snail-1* promoter also has functional NF-κB sites [66], and blocking NF-κB reduces *Snail-1* transcription [67]. In addition, a region of the *Snail-1* promoter is responsive to integrin-linked kinase (ILK) [21], and ILK can activate Snail-1 expression via poly-adenosine phosphate-ribose polymerase [68]. In mouse mammary epithelial cells, high-mobility group protein A2 and Smads activate *Snail-1* expression and subsequently *Snail-2*, *Twist*, and *Id2* transcription [69]. For *Snail-2* expression, myocardin-related transcription factors (MRTFs) interact with Smads to

induce *Snail-2* [70] and MRTFs may have a role in metastasis [71] and fibrosis [72]. There are also several *Snail-1* transcriptional repressors. In breast cancer cell lines, metastasis-associated protein 3 binds directly to and represses the transcription of *Snail-1* in combination with the Mi-2/nucleosome remodeling deacetylase complex [73], as does lysine-specific demethylase [74]. The Ajuba LIM proteins (Ajuba, LIMD1, and WTIP) are additional transcriptional corepressors of the Snail family [75].

The transcription of LEF/TCF genes such as *Lef-1* are activated by Smads [76]. The misexpression of Snail-1 results in the transcription of *δEF-1* and *Lef-1* through a yet unknown mechanism [21].

Posttranscriptional regulation of epithelial–mesenchymal transition transcription factors

The activity of EMT transcription factors is also regulated at the protein level, including translational control, protein stability (targeting to the proteasome), and nuclear localization. Noncoding RNAs are emerging as important regulator EMTs. In a breast cancer model, Myc activates the expression of microRNA-9 (miR-9), and miR-9 directly binds to and represses the *E-cadherin* promoter [77]. Members of the miR-200 family repress the translation of *Zeb1*, and the expression of these miR-200 family members is repressed by Snail-1. In addition, *Zeb2* transcription can be activated by naturally occurring RNA antisense transcripts [78]. It is not yet known whether there are noncoding RNAs that regulate Snail family members. However, the Y-box binding protein-1 is important for the selective activation of *Snail-1* translation [79].

Protein stability is another layer of EMT control. Snail-1 is phosphorylated by glycogen synthase kinase 3β (GSK-3β) and targeted for destruction [80]. Therefore, the inhibition of GSK-3β activity by Wnt signaling may have multiple roles in an EMT, leading to the stabilization of both β-catenin and Snail-1. Some proteins that prevent GSK 3β-mediated phosphorylation (and thus promote Snail-1 activation) are lysyl oxidase–like proteins (LOXL)2, LOXL3 [81], and ILK [82]. A Snail 1especific phosphatase (Snail-1 activator) is C-terminal domain phosphatase [83]. Snail-2 is targeted for degradation by the direct action of p53 and the ubiquitin ligase Mdm2 [84].

In addition to protein translation and stability, the function of Snail-1 depends on nuclear localization mediated by Snail-1's nuclear localization sequence. The phosphorylation of human Snail-1 by p21-activated kinase 1 promotes the nuclear localization of Snail-1 (and therefore Snail-1 activation) in breast cancer cells [85]. In zebrafish, LIV-1 promotes the translocation of Snail-1 into the nucleus [86]. Snail-1 also contains a nuclear export sequence (NES) that depends on the calreticulin nuclear export pathway [87]. This NES sequence is activated by the phosphorylation of the same lysine residues targeted by GSK-3β, which suggests a mechanism whereby phosphorylation of Snail-1 by GSK-3β results in the export of Snail-1 from the nucleus and subsequent degradation.

LEF/TCF activity is also regulated by other proteins. β-Catenin is required as a cofactor for LEF/TCF-mediated activation of transcription, and Lef-1 can also associate with cofactor Smads to activate the transcription of additional EMT genes [88]. In colon cancer cells, thymosin β4 stabilizes ILK activity [89].

EMT transcription factors such as Snail-1, Zeb1, and Lef-1 are regulated by a variety of mechanisms at both the transcriptional and posttranscriptional levels by noncoding RNA translation control, protein degradation, nuclear localization, and cofactors such as β-catenin.

Molecular control of the epithelial–mesenchymal transition

The initiation of an EMT or MET is a tightly regulated event during development and tissue repair because deregulation of cellular organization is disastrous to the organism. A variety of external and internal signaling mechanisms coordinate the complex events of the EMT, and these same signaling pathways are often disrupted or reactivated during disease. EMTs or METs can be induced by either diffusible signaling molecules or ECM components. We next discuss the role of signaling molecules and ECM in triggering an EMT, and then present a summary model for EMT induction.

Ligand-receptor signaling

During development, five main ligand-receptor signaling pathways are employed: TGF-β, Wnt, receptor tyrosine kinase (RTK), Notch, and Hedgehog. These pathways, among others, have a role in triggering EMTs. Although the activation of a single signaling pathway can be sufficient for an EMT, in most cases an EMT or MET is initiated by multiple signaling pathways acting in concert.

Growth factor-β pathway

The TGF-β superfamily includes the TGF-β, activin, and bone morphogenetic protein (BMP) families. These ligands operate through receptor serine/threonine kinases to activate a variety of signaling molecules including Smads, mitogen-activated protein kinase (MAPK), PI3K, and ILK. Most EMTs studied to date are induced in part, or solely, by TGF-β superfamily members [90]. During

embryonic heart development, TGF-β2 and TGF-β3 have sequential and necessary roles in activating the endocardium to invade the cardiac jelly and from the endocardial cushions [91]. In the avian neural crest, BMP4 induces *Snail-2* expression [92]. In the EMT that transforms epithelial tissue into metastatic cancer cells, TGF-β acts as a tumor suppressor during early stages of tumor development, but as a tumor/EMT inducer at later stages [90,93]. TGF-β signaling may combine with other signaling pathways to induce an EMT. For example, in cultured breast cancer cells, activated Ras and TGF-β induce an irreversible EMT [94], and in pig thyroid epithelial cells, TGF-β and epidermal growth factor (EGF) synergistically stimulate the EMT [95].

One outcome of TGF-β signaling is to change epithelial cell polarity immediately. In a TGF β−induced EMT of mammary epithelial cells, TGF-βRII directly phosphorylates the polarity protein, Par6, leading to the dissolution of tight junctions [34]. TGF-β signaling also regulates gene expression through the phosphorylation and activation of Smads. Smads are important cofactors in the stimulation of an EMT. For example, Smad3 is necessary for a TGF β−induced EMT in lens and kidney tissue in vivo [96]. The Smad3/4 also complex with Snail-1 and corepress the promoters of cell−cell adhesion molecules [97]. Furthermore, TGF-βRI directly binds to and activates PI3K [98], which in turn activates ILK and downstream pathways.

ILK is emerging as an important positive regulator of EMTs [99]. ILK interacts directly with growth factor receptors (TGF-β, Wnt, or RTK), integrins, the actin skeleton, PI3K, and focal adhesion complexes. ILK directly phosphorylates Akt and GSK-3β, and results in the subsequent activation of transcription factors such as AP-1, NF-κB, and Lef-1. Overexpression of ILK in cultured cells causes the suppression of GSK-3β activity [82], translocation of β-catenin to the nucleus, activation of Lef-1/β-catenin transcription factors, and the downregulation of E-cadherin [100]. Inhibition of ILK in cultured colon cancer cells leads to the stabilization of GSK-3β activity, decreased nuclear β-catenin localization, the suppression of *Lef-1* and *Snail-1* transcription, and reduced invasive behavior of colon cancer cells [101]. ILK activity also results in Lef 1−mediated transcriptional upregulation of MMPs [60]. Hence, ILK (inducible by TGF-β signaling) is capable of orchestrating most of the major events in an EMT, including the loss of cell−cell adhesion and invasion across the basal lamina.

Wnt pathway

Many EMTs or METs are also regulated by Wnt signaling. Wnts signal through seven-pass transmembrane proteins of the Frizzled family, which activates G-proteins and PI3K, inhibits GSK-3β, and promotes nuclear β-catenin signaling. For example, during zebrafish gastrulation, Wnt11 activates the GTPase Rab5c, which results in the endocytosis of E-cadherin [102]. Wnt6 signaling is sufficient for increased transcription of *Snail-2* in the avian neural crest [103]. Snail-1 expression increases Wnt signaling [104], which suggests a positive feedback loop.

One of the downstream signaling molecules activated by Wnt signaling is β-catenin. β-Catenin is a structural component of adherens junctions. Nuclear β-catenin is also a limiting factor for the activation of LEF/TCF transcription factors. β-Catenin is pivotal for regulating most EMTs. Interfering with nuclear β-catenin signaling blocks the ingression of sea urchin PMCs [105], and in β-catenin mouse knockouts, the primitive streak EMT does not occur and no mesoderm is formed [106]. β-Catenin is also necessary for the EMT that occurs during cardiac cushion development [107]. In breast cancer, β-catenin expression is highly correlated with metastasis and poor survival [108], and blocking β-catenin function in tumor cells inhibits invasion in vitro [109]. It is unclear whether β-catenin overexpression alone is sufficient for all EMTs. If β-catenin is misexpressed in cultured cells, it causes apoptosis [110]. However, the misexpression of a stabilized from of β-catenin in mouse epithelial cells in vivo results in metastatic skin tumors [111].

Signaling by receptor tyrosine kinase ligands

The RTK family of receptors and the growth factors that activate them also regulate EMTs or METs. Ligand binding promotes RTK dimerization and activation of the intracellular kinase domains by autophosphorylation of tyrosine residues. These phosphotyrosines act as docking sites for intracellular signaling molecules, which can activate signaling cascades such as Ras/MAPK, PI3K/Akt, JAK/STAT, or ILK. We will cite a few examples of RTK signaling in EMTs and METs.

Hepatocyte growth factor (HGF; also known as scatter factor) acts through the RTK c-met. HGF is important for the MET in the developing kidney [112]. HGF signaling is required for the EMT that produces myoblasts (limb muscle precursors) from somite tissue in the mouse [10]. In epithelial cells, HGF causes an EMT through MAPK and early growth response factor-1 signaling [113].

Fibroblast growth factor (FGF) signaling regulates mouse primitive streak formation [114]. FGF signaling also stimulates cell motility and activates MMPs [115,116].

EGF promotes the endocytosis of E-cadherin [117]. EGF can also increase Snail-1 activity via the inactivation

of GSK3-β [118], and EGF promotes increased *Twist* expression through a JAK/STAT3 pathway [119].

Insulin growth factor (IGF) signaling induces an EMT in breast cancer cell lines by activating Akt2 and suppressing Akt1 [120]. In prostate cancer cells, IGF-1 promotes Zeb-1 expression [121]. In fibroblast cells, constitutively activated IGF-IR increases NF-κB activity and Snail-1 levels [122]. In several cultured epithelial cell lines, IGFR1 is associated with the complex of E-cadherin and β-catenin, and the ligand IGF-II causes the redistribution of β-catenin from the membrane to the nucleus, activation of the transcription factor TCF-3, and a subsequent EMT [123].

Another RTK known for its role in EMTs is the ErbB2/HER-2/Neu receptor, whose ligand is heregulin/neuregulin. Overexpression of HER-2 occurs in 25% of human breast cancers, and the misexpression of HER-2 in mouse mammary tissue in vivo is sufficient to cause metastatic breast cancer [124]. Herceptin (antibody against the HER-2 receptor) treatment is effective in reducing the recurrence of HER 2−positive metastatic breast cancers. HER-2 signaling activates *Snail-1* expression in breast cancer through an unknown mechanism [47]. The RTK Axl is also required for breast cancer carcinoma invasiveness [125].

Vascular endothelial growth factor (VEGF) signaling promotes Snail-1 activity by suppressing GSK3-β [126] and results in increased levels of *Snail-1*, *Snail-2*, and *Twist* [127]. Snail-1 can also activate the expression of VEGF [128]. RTK signaling is important for many EMTs.

Notch pathway

The Notch signaling family also regulates EMTs. When the Notch receptor is activated by its ligand Delta, an intracellular portion of the Notch receptor ligand is cleaved and transported to the nucleus, where it regulates target genes. Notch1 is required for cardiac endothelial cells to undergo an EMT to make cardiac cushions, and the role of Notch may be to make cells competent to respond to TGF-β2 [129]. In the avian neural crest EMT, Notch signaling is required for the induction and/or maintenance of *BMP4* expression [130]. Similarly, Notch signaling is required for the TGF β−induced EMT of epithelial cell lines [131], and Notch promotes *Snail-2* expression in cardiac cushion cells [132] and cultured cells [133].

Hedgehog pathway

The hedgehog pathway is also involved in EMTs. Metastatic prostate cancer cells express high levels of hedgehog and *Snail-1*. If prostate cancer cell lines are treated with the hedgehog-pathway inhibitor, cyclopamine, levels of *Snail-1* are decreased. If the hedgehog-activated transcription factor, Gli, is misexpressed, *Snail-1* expression increases [134].

Additional signaling pathways

Other signaling pathways that activate EMTs include inflammatory signaling molecules, lipid hormones, ROS species, and hypoxia. Interleukin-6 (inflammatory and immune response) can promote Snail-1 expression in breast cancer cells [135], and Snail-1, in turn, can activate interleukin-6 expression [136], providing a link between inflammation and EMTs [137]. The lipid hormone prostaglandin E2 (PGE2) induces Zeb1 and Snail activity in lung cancer cells [138], and Snail-1 can also induce PGE2 expression [139]. ROS species can also activate EMTs by PKC and MAPK signaling [140]. Hypoxia is important for initiating EMTs during development [141] and disease [137], often through hypoxia-inducible factor-1, which directly activates *Twist* expression [142]. Hypoxia also activates lysyl oxidases, which stabilize Snail-1 expression [143] by inhibiting GSK-3β activity [144].

In addition to diffusible signaling molecules, ECM molecules regulate EMTs or METs. This was first dramatically demonstrated when lens or thyroid epithelium was embedded in collagen gels, and then promptly underwent an EMT [2]. Integrin signaling appears to be important in this process [145] and involves ILK-mediated activation of NF-κB, Snail-1, and Lef-1 [146]. Other ECM components that regulate EMTs include hyaluronan [147], the γ-2 chain of laminin 5 [148], periostin [149], and podoplanin [150,151]. Avariety of diffusible signals and ECM components can stimulate EMTs or METs.

A model for epithelial−mesenchymal transition induction

Many experimental studies on EMT mechanisms are piecework, and although great progress has been made in discovering EMT pathways, the entire signaling network is still incomplete. Fig. 5.2 shows many of the various signaling mechanisms, although in actuality only a few of the inductive pathways will be used for individual EMTs. From experimental evidence, it appears that many EMT signaling pathways converge on ILK, the inhibition of GSK-3β, and stimulation of nuclear β-catenin signaling to activate Snail and LEF/TCF transcription factors. Snail, Zeb, and LEF/TCF transcription factors then act on a variety of targets to suppress cell−cell adhesion, induce changes in cell polarity, stimulate cell motility, and promote invasion of the basal lamina.

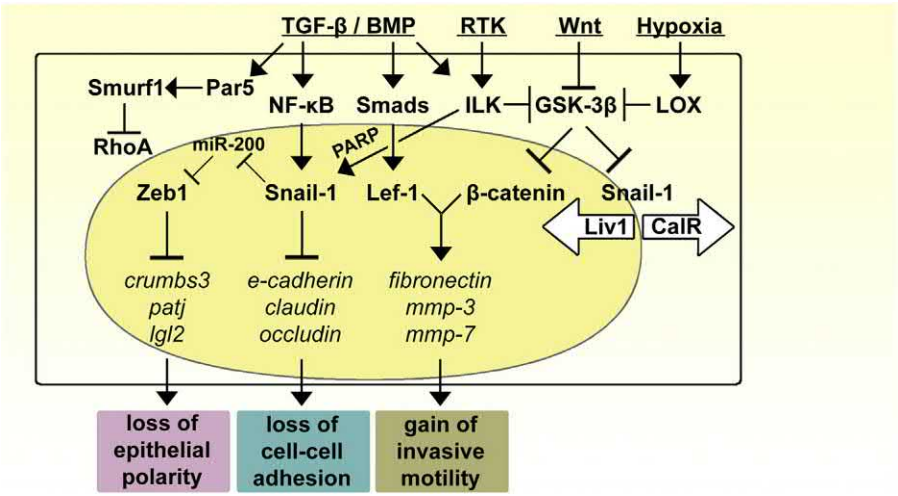

FIGURE 5.2 **Induction of an EMT.*EMT*, epithelial−mesenchymal transition;** This figure summarizes some of the important molecular pathways that bring about an EMT. Many of the signaling pathways converge on the activation of Snail-1 and nuclear β-catenin signaling to change gene expression, which results in the loss of epithelial cell polarity, the loss of cell−cell adhesion, and increased invasive cell motility. *BMP*, bone morphogenetic protein; *CalR*, calreticulin; *GSK-3β*, glycogen synthase kinase 3β; *Igl2*, immunoglobulin 2; *ILK*, integrin-linked kinase; *LOX*, lysyl oxidase; *miR-200*, microRNA-200; *mmp*, matrix-metalloprotease; *NF-κB*, nuclear factor κB; *RhoA*, Ras homolog gene family, member A; *RTK*, receptor tyrosine kinase; *TGF-β*, transforming growth factor-β; *Zeb1*, zinc finger E-box-binding homeobox 1.

Conclusion

Since the term "EMT" was coined [10], important insights have been made in this rapidly expanding field of research. EMT and MET events occur during development, tissue repair, and disease, and many molecules that regulate the various EMTs or METs have been characterized, thanks in large part to the advent of cell culture models. However, the EMT regulatory network as a whole is still incomplete. An improved understanding of EMT and MET pathways will lead to more effective strategies for tissue engineering and novel therapeutic targets for the treatment of disease.

List of acronyms and abbreviations

BMP	bone morphogenetic protein
ECM	extracellular matrix
EGF	epidermal growth factor
EMT	epithelial−mesenchymal transition
FGF	fibroblast growth factor
GSK-3β	glycogen synthase kinase 3β
HGF	hepatocyte growth factor
IGF	insulin growth factor
ILK	integrin-linked kinase
LEF/TCF	lymphoid enhancer-binding factor/T-cell factor
LOXL proteins	lysyl oxidase−like proteins
MDCK cells	Madin−Darby canine kidney cells
MET	mesenchymal-epithelial transition
MMPs	matrix-metalloproteases
MRTFs	myocardin-related transcription factors
NES	nuclear export sequence
PGE2	prostaglandin E2
PI3K	phosphatidylinositol 3 kinase
PMC	primary mesenchyme cells
ROS	reactive oxygen species
RTK	receptor tyrosine kinase
TGF-β	transforming growth factor-β
VEGF	vascular endothelial growth factor
Zeb	zinc finger E-box-binding

Glossary

Apical	surface of the epithelial layer where adherens junctions and tight junctions are located. This is opposite the basal surface
Basal	surface of the epithelial layer where the basal lamina is found. This is opposite the apical surface
Basal lamina	consists of extracellular matrix components such as collagen type IV, fibronectin, and laminin. The basal lamina functions to stabilize the epithelium and is a barrier against migratory cells
Epithelial	epithelial cells adhere tightly to each other at their lateral surfaces and to an organized extracellular matrix at their basal domain, thereby producing a sheet of cells resting on a basal lamina with an apical surface

Epithelial–mesenchymal transition	The conversion of epithelial cells into mesenchymal cells
Mesenchymal	mesenchymal cells are individual cells with a bipolar morphology that are held together as a tissue within a three-dimensional extracellular matrix
Mesenchymal–epithelial transition	The conversion of mesenchymal cells into epithelial cells

Introduction

Historical background

For many years the extracellular matrix (ECM) was thought to serve only as a structural support for tissues. This began to change as multiple research groups observed differences in cell structure and organization, as well as changes in gene expression, when cells were cultured in the presence or absence of ECM components. For example, mammary gland epithelial cells cultured on Engelbreth–Holm–Swarm (EHS), a specialized matrix synthesized by EHS tumors with many of the properties of basement membranes, synthesized milk molecules and underwent the branching morphogenesis characteristic of mammary glands [1]. These and other findings implicating matrix molecules in myotube formation and morphogenesis of multiple tissues and organs suggested that cells express receptors for matrix molecules that, when bound to their respective matrix molecule(s), are critical for embryonic development [2]. This led to the development of the model called dynamic reciprocity, in which ECM molecules interact with specific cell-surface receptors and initiate intracellular signal transduction cascades, promoting expression of specific genes whose products, in turn, affect the ECM [2]. This set the stage for further investigations into the mechanisms by which ECM molecules influence cell behavior. These mechanisms regulated by matrix molecules include changes in cell adhesion, migration, growth, differentiation, and apoptosis, modulation of cytokine and growth factor signaling, and stimulation of intracellular signaling.

Evidence for the mechanisms underlying the roles of cell–matrix interactions in the regulation of cell signaling events and cell behaviors come from a combination of in vitro cell cultures with matrix molecules and in vivo experiments in animals lacking specific matrix molecules or their receptors. After describing some of the most prominent ECM molecules and their receptors later, we discuss the importance of selected cell–matrix interactions and their associated signal transduction in development and wound healing. We then end with a discussion of the relevance of cell–matrix interactions in designing engineered tissues.

Extracellular matrix composition

The extracellular microenvironment contains both traditional structural matrix components, such as fibronectin, hyaluronic acid, proteoglycans, collagens, glycosaminoglycans, and elastins, and nonstructural matricellular proteins, including secreted protein acidic and rich in cysteine (SPARC), tenascin, osteopontin, and thrombospondins. The distribution and organization of these molecules is not static, but varies from tissue to tissue and, during development, from stage to stage, which has significant implications for tissue functions [3]. For example, mesenchymal cells are immersed in an interstitial matrix that confers specific biomechanical and functional properties to connective tissue, whereas epithelial and endothelial cells contact a specialized matrix, the basement membrane, via their basal surfaces only, conferring mechanical strength and specific physiological properties to the epithelia [4]. Alterations in the temporal and spatial composition, organization, and

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00007-1

distribution of ECM during development and tissue repair results not only from differential gene expression of certain matrix proteins in specific tissues, but also from changes in their alternative splicing and posttranslational modifications, as alternative splicing may change their binding potential to other matrix molecules and/or receptors. Furthermore, variations in glycosylation can alter cell adhesion and migration, and proteolytic cleavage can generate fragments with diverse biological functions [5–7].

In addition to the direct effects exerted by matrix molecules on tissue development and function, the ECM indirectly affects tissue function through its interactions with nonmatrix proteins such as growth factors and cytokines. Therefore tissue-specific and developmental stage–specific variations in ECM composition may thereby regulate the ability of these associated molecules to initiate intracellular signaling and influence cell behavior by limiting their diffusion, protecting them from degradation, presenting them more efficiently to their receptors, and/or sequestering them away from their receptors [3,8]. For example, while vascular endothelial growth factor (VEGF) binding to heparan sulfate proteoglycans (HSPGs) enhances its binding to and activation of VEGF receptors, proteoglycan binding to heparin-binding epidermal growth factor (EGF) (HB-EGF) interferes with the activation of EGF receptors HB-EGF until its release by proteoglycan degradation [9,10]. Beyond proteoglycan facilitation of growth factor and cytokine signaling, specific domains of some ECM molecules or fragments derived from their proteolysis, referred to as matricryptins, can directly bind growth factor receptors and influence their downstream signaling. Either within the context of intact matrix molecules or following protease-mediated matricryptin release, the EGF-like repeats of laminin or tenascin-C can bind and activate the EGF receptor (EGFR), while the proteoglycan decorin inhibits several growth factor receptors, including EGFR and VEGFR2 [8,11]. Regulation of growth factor receptors by intact ECM molecules may facilitate a stable signaling environment for the associated cells because the ligands are unable to diffuse or be internalized, creating persistent signaling through the growth factor receptors [12,13]. In contrast, following proteolytic cleavage of matrix components, released matricryptins that bind and inhibit VEGFR2, such as endorepellin and endostatin, are more likely to diffuse away from their generation sites and can be internalized, suggesting more transient impacts on cell function [5,8,10]. Taken together, matrix molecules, growth factors, and growth factor receptors form a complex network of interactions, with similarly complex effects on cell survival and function.

Receptors for extracellular matrix molecules

Many cell-surface receptors mediate cell–matrix interactions that connect extracellular binding events to intracellular signaling pathways. Integrins, a family of heterodimeric transmembrane proteins composed of α and β subunits, were the first ECM receptors to be identified. The 18 α and 8 β subunits pair in various combinations to yield 24 separate heterodimers, many of which recognize specific sequences on their respective ligands, including the well-characterized RGD motif present in fibronectin, vitronectin, thrombospondin, and fibrinogen (Fig. 6.1; [14]). Some integrin heterodimers exhibit a high degree of ligand specificity, while others interact with multiple possible ligands (Fig. 6.1), facilitating plasticity and redundancy in specific systems [14]. Apart from integrin β_4, the integrins have large extracellular domains and very small intracellular domains. Despite the small size of their cytoplasmic domains, integrins bind a variety of intracellular proteins, facilitating their intracellular connections with the cytoskeleton and activation of signal transduction pathways [15,16]. Complicating our understanding of integrin-mediated, matrix-induced signaling is the ability of multiple integrins to directly bind nonmatrix molecules, including the adhesion molecules ICAM1-3, VCAM1, and RGD-containing cadherins, thereby mediating cell–cell adhesions, and the interactions and coordinated signaling of fibroblast growth factor (FGF) receptor (FGFR) and VEGFR2 with integrin $\alpha_v\beta_3$ [17,18]. Despite this complexity, integrin knockout and inhibition experiments have elucidated many of the matrix-induced integrin signaling events described later in more detail.

In addition to integrins, several transmembrane proteoglycans, including syndecans, RHAMM (receptor for hyaluronan-mediated motility), and CD44, can also serve as receptors for ECM molecules, including collagen, fibronectin, laminin, and hyaluronan [7]. Syndecans 1–4 mediate cell–ECM interactions via chondroitin- and heparan-sulfate glycosaminoglycans, whose composition varies based upon the type of syndecan and the tissue in which it is expressed. These differential glycosaminoglycan modifications alter the binding capacity of ligands such as fibronectin and tenascin [19]. The short cytoplasmic domains of syndecans can interact with signaling proteins and the cytoskeleton and thereby induce signal transduction upon binding to their ECM ligands, resulting in changes in cell adhesion and migration [20]. Although syndecan activation by its matrix ligands can directly activate downstream signaling, syndecan also mediates the formation of larger signaling complexes that activate signaling in an indirect manner. In these complexes the protein core of syndecan directly binds some integrins, while the heparan sulfate moieties of syndecan bind several growth factors and matrix molecules, ultimately facilitating ligand-mediated activation of growth factor receptors and integrins [20].

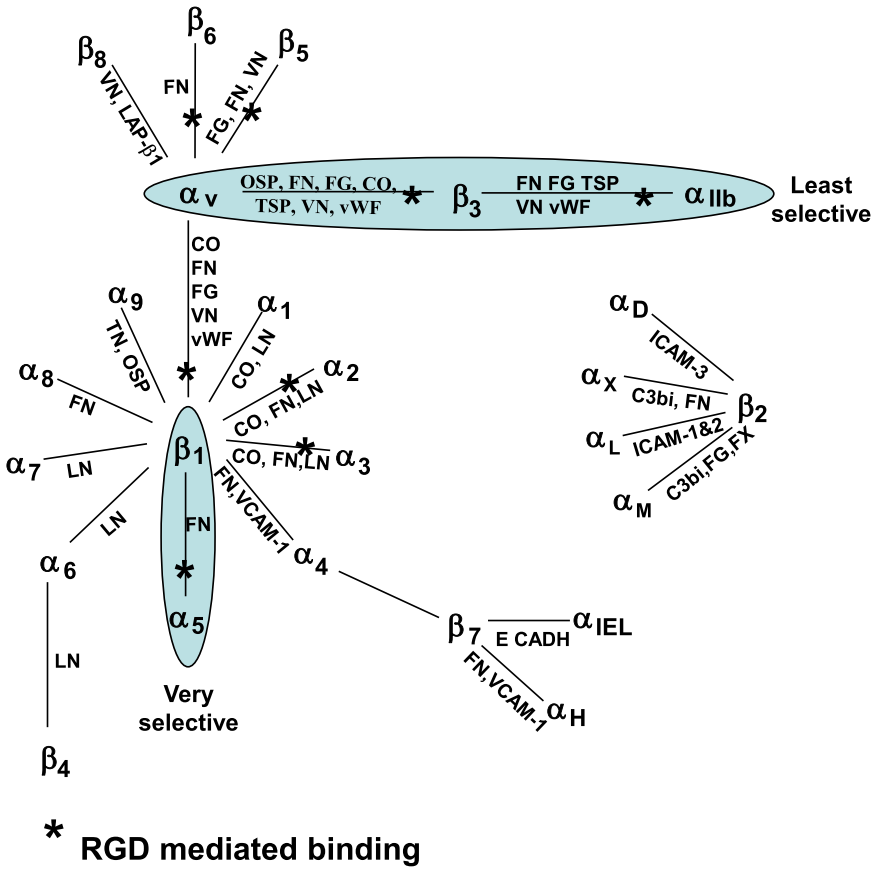

FIGURE 6.1 Members of the integrin family of ECM receptors and their respective ligands. These heterodimeric receptors are composed of one a and one b subunit, and are capable of binding a variety of ligands, including Ig superfamily cell adhesion molecules, complement factors, and clotting factors in addition to ECM molecules. Cell–cell adhesion is largely mediated through integrin heterodimers containing the b_2 subunits, while cell–matrix adhesion is mediated primarily via integrin heterodimers containing the b_1 and b_3 subunits. In general, the b_1 integrins interact with ligands found in the connective tissue matrix, including laminin, fibronectin, and collagen, whereas the b_3 integrins interact with vascular ligands, including thrombospondin, vitronectin, fibrinogen, and von Willebrand factor. *CO*, Collagens; *C3bi*, complement component; *ECM*, extracellular matrix; *FG*, fibrinogen; *FN*, fibronectin; *FX*, Factor X; *ICAM-1*, intercellular adhesion molecule-1; *ICAM-2*, intercellular adhesion molecule-2; *ICAM-3*, intercellular adhesion molecule-3; *LN*, laminin; *OSP*, osteopontin; *TN*, tenascin; *TSP*, thrombospondin; *VCAM-1*, vascular cell adhesion molecule-1; *VN*, vitronectin; *vWF*, von Willebrand factor.

Similar to syndecans, the proteoglycan receptor CD44 interacts with multiple matrix ligands, including collagen IV, collagen XIV, fibronectin, osteopontin, and laminin, in addition to its primary ligand, hyaluronan [21]. Binding to these ligands is regulated, at least in part, by the tissue-specific splicing and glycosylation that yield multiple CD44 isoforms [22]. CD44 can also interact with another hyaluronan receptor, RHAMM, a peripheral membrane receptor that must bind transmembrane protein(s) like CD44, integrins, and/or receptor tyrosine kinases in order to transmit the signal from hyaluronan to intracellular signaling proteins [23]. Hyaluronan is present in most tissues in a high molecular weight, native form, but hyaluronidases and reactive oxygen or nitrogen species can generate lower molecular weight fragments following tissue injury and during tissue inflammation and repair [24]. The native and cleaved forms of hyaluronan elicit different cellular responses, likely due to differential receptor selectivity. CD44 binds more stably to high molecular weight hyaluronan than low molecular weight hyaluronan fragments, whereas hyaluronan fragments, but not the native high molecular weight form, bind and activate toll-like receptors (TLRs), strongly suggesting that the fragments function as "danger signals" that sense tissue damage and induce inflammatory responses [21,23].

Beyond proteoglycans and integrins, the elastin–receptor complex (ERC), TLRs, CD36, and receptor tyrosine kinases can also serve as matrix receptors. The ERC is a complex of three proteins: neuraminidase 1, cathepsin A, and the elastin-binding protein (EBP). EBP binds specifically to VGVAPG-repeating peptides and the GxxPG sequence found in elastin, fibrillin, laminin, and fragments derived from these matrix molecules, and this EBP binding initiates signal transduction through the neuraminidase-1

that is important in both mechanotransduction and elastin deposition [25,26]. Following tissue injury, active proteases generate elastin-derived peptides that then promote proliferation and/or migration of fibroblasts, epithelial/endothelial cells, and monocytes downstream of the ERC [26]. These effects suggest that elastin-derived peptides are able to promote wound healing, an idea supported by evidence that these peptides enhance the healing of burn wounds when used in conjunction with more conventional treatments [27].

In addition to the ERC, TLRs and CD36 can function as matrix receptors and thereby affect cell function. Fibronectin and low molecular weight fragments of hyaluronan bind and activate TLRs that are also activated by microbial molecules, suggesting that fragments of matrix molecules may function as "danger signals" that induce inflammation following tissue damage and the matrix degradation that accompanies the healing process [5,23]. The scavenger receptor CD36 interacts with thrombospondin, collagen I, and collagen V, and, in endothelial cells, thrombospondin binding to CD36 induces apoptosis and is thus antiangiogenic in vivo [28,29]. Interestingly, both CD36 and TLR 4 interact with and are modified by the neuraminiase-1 subunit of the ERC, suggesting that ERC-binding elastin-derived peptides can regulate the course of wound inflammation and angiogenesis by altering the ligand binding and/or signaling downstream of these receptors [30].

Receptor tyrosine kinases can also function as matrix receptors. The receptor tyrosine kinase category of matrix receptors includes EGFR and VEGFR2, which interact with matrix molecules and proteolytically released matricryptins as described before, and the discoidin domain receptors DDR1 and DDR2 are activated by fibrillar collagens [31,32]. Unlike most other receptor tyrosine kinases, which are activated by dimerization, DDR1 and DDR2 exist as constitutive homodimers, suggesting an alternative mechanism of activation. Upon ligand binding, the discoid domain receptors (DDRs) undergo autophosphorylation and induce multiple downstream signaling pathways that remain active over long time periods, likely reflecting the long-lived nature of their collagen ligands [33]. DDR2 participates in the fibroblast recruitment and myofibroblast differentiation critical for wound healing, as both processes are reduced during wound healing in DDR2-deficient mice [33]. This function of DDR2, coupled with its prolonged signaling following ligand binding, suggests that collagen-DDR signaling may provide a stable signal for fibroblast recruitment and myofibroblast proliferation throughout the healing process.

Next, we will first discuss selected examples that illustrate the dynamics of cell–ECM interactions during development and wound healing, as well as the potential mechanisms involved in the signal transduction pathways initiated by these interactions. At the end, we will discuss the implications of cell–ECM interactions in tissue engineering.

Cell–extracellular matrix interactions

Multiple biological processes, including those relevant to development and wound healing, require interactions between cells and their environment and the regulated modulation of such interactions. During development, the cellular cross talk with the surrounding ECM promotes the formation of patterns, the development of form (morphogenesis), and the acquisition and maintenance of differentiated phenotypes during embryogenesis. Similarly, during wound healing these interactions contribute to the processes of clot formation, inflammation, granulation tissue development, and remodeling. As outlined next, the current body of research in the fields of both embryogenesis and wound healing implicates multiple cellular behaviors, including cell adhesion/deadhesion, migration, proliferation, differentiation, and apoptosis (programed cell death), in these critical events.

Development

Adhesion and migration

Today, there is a vast body of experimental evidence that demonstrates the direct participation of ECM in cell adhesion and migration, but some of the most compelling experiments came from early studies in gastrulation, migration of neural crest cells (NCCs), angiogenesis, and epithelial organ formation. Cell interactions with fibronectin are important during gastrulation. Inhibition of fibronectin–integrin interactions in amphibian embryos by the introduction of blocking antibodies or RGD-containing peptides, which compete with integrins for ECM binding, into their blastocoel cavities disrupts normal cell movement and leads to abnormal development, while introduction of recombinant fibronectin lacking the RGD motif perturbs amphibian gastrulation [34,35]. These effects are not unique to fibronectin, as they can also be introduced by manipulation of other molecules, such as hyaluronan and HSPGs. Inhibition of hyaluronan synthesis in zebra fish embryos interferes with cell movements in gastrulation, potentially due to a defect in Rac1 activation, as expression of constitutively active Rac rescued the observed migratory defects [36]. HSPGs are also critical for gastrulation, likely resulting from their regulation of fibronectin and laminin expression as well as their ability to regulate growth factor signaling. A mutation of glypican-4, a HSPG, both increases fibronectin and laminin expression and inhibits polarized cell migration during somite formation, likely due to Rac1 redistribution across the entire membrane rather than

localization at a leading edge [37]. This change in Rac1 localization may result from the change in fibronectin or laminin signaling through integrins, a change in HSPG regulation of growth factor signaling, or both. Binding of fibronectin to HSPG causes a conformational change in fibronectin, exposing growth factor binding sites that then bind platelet-derived growth factor (PDGF)-AA, generating a stable PDGF gradient that promotes the directional cell migration critical for gastrulation [38]. HSPGs are also necessary for FGF signaling during gastrulation, as inhibition of HSPG synthesis alters FGF localization, inhibits FGF signaling, and arrests mouse embryonic development at gastrulation [39].

In addition to their roles in gastrulation, cell−matrix interactions are also important for the migration of NCCs, which develop in the dorsal portion of the neural tube just after closure of the tube, deadhering from each other and then migrating extensively throughout the embryo in ECM-filled spaces, giving rise to a variety of phenotypes. The importance of cell−ECM interactions in NCC migration is supported by studies performed in the white mutant of Mexican axolotl embryos. The NCC that give rise to pigment cells fail to emigrate from the neural tube in these embryos, but when microcarriers containing subepidermal ECM from normal embryos are implanted into the appropriate area in these mutants, the NCC pigment cell precursors emigrate normally [40]. Laminin and fibronectin, the latter of which appears between chick NCC just prior to their emigration from the neural tube, play particularly critical roles in this process [41]. Inhibition of fibronectin, laminin-111 (laminin-1), laminin-411 (laminin-8), or their integrin receptors, using function-blocking antibodies, competing peptides, or antisense RNA, prevents NCC migration, while exogenous laminin or fibronectin is sufficient to induce premature NCC migration [40,42]. More recent studies have identified different subsets of NCC, which may exhibit different responses to specific matrix molecules. For example, cranial NCC does not migrate in response to fibronectin but do migrate on laminin [43]. Matrix remodeling also contributes to NCC migration and the initial epidermal-to-mesenchymal transition that allows NCC deadhesion from its site of origin, as several matrix metalloproteinases (MMPs) are required for deadhesion and/or migration events. MMP-9, for example, is necessary for NCC deadhesion and migration during avian development. The role of MMP-9 in deadhesion may be related to its ability to cleave the cell−cell adhesion molecule N-cadherin, while its role in migration may involve laminin degradation [44]. Proteoglycans also participate in the NCC migration process. Aggrecan and versican, proteoglycans that predominate in tissues surrounding the migrating NCC, inhibit NCC migration and are thought to form nonadhesive boundaries that delimit NCC migration pathways [40,45]. In contrast, syndecan-4 facilitates directional migration of NCC. In conjunction with a noncanonical Wnt pathway, syndecan-4 inhibits Rac1 at the rear of the cell, restricting Rac activity to the leading edge of the migrating cell and facilitating directional migration [46].

Cell−matrix interactions are also critical for the endothelial cell adhesion and migration events necessary for angiogenesis, a process in which new blood vessels form from preexisting vessels. Early indications of the role of ECM in angiogenesis were observed when human umbilical vein endothelial cells (HUVEC) were cultured on EHS tumor matrix (Matrigel) that resembles the composition of basement membranes, with large amounts of laminin, collagen IV, entactin/nidogen, and proteoglycans. When HUVEC are cultured on Matrigel for 12 hours, they migrate and form tube-like structures. In contrast, when these cells are cultured with collagen I, they only form tube-like structures after they are maintained *inside* the gels for one week, at which time the cells have secreted their own basement membrane molecules [47]. The observation that tube formation occurs more rapidly on Matrigel than within collagen gels strongly suggested an important role for one or more of the matrix molecules present within the basement membrane in the development of capillary-like endothelial tubes. Indeed, laminin-111, the predominant matrix molecule in Matrigel, induces endothelial cell adhesion, migration, and tube formation in vitro, as well as angiogenesis in vivo [48]. Similarly, overexpression of laminin-411, the predominant laminin isoform in vascular basement membranes, increases endothelial cell migration in an integrin α_6- and β_1-dependent manner, while mice lacking expression of laminin α_4 exhibit defects in capillary basement membrane formation, suggesting that laminin-411 participates in angiogenesis and vascular maturation, respectively [49,50]. Antibody-mediated inhibition and shRNA-mediated knockdown of integrin α_6, the α subunit of laminin receptors $\alpha_6\,\beta_1$ and $\alpha_6\,\beta_4$, reduced endothelial tube formation and endothelial cell migration on and adhesion to basement membrane extracts, and decreased FGF-induced angiogenesis in the chick chorioallantoic membrane (CAM) assay [51]. Taken together, these data implicate laminin/integrin interactions in blood vessel development and stabilization.

Along with laminin, several other matrix molecules are critical for developmental blood vessel formation and maturation, including collagen IV, the HSPG perlecan, and nidogen [50]. Mice deficient in any of these three proteins have defective basement membrane formation, and collagen IV is also critical in the ability of the vasculature to withstand mechanical stress [50]. Nidogen and perlecan each interact simultaneously with collagen IV and laminins to organize and stabilize the basement membrane, while perlecan, an HSPG, can bind proangiogenic

growth factors and promote receptor binding, thereby facilitating angiogenesis induced by these factors [50]. VEGF and PDGF interaction with HSPG can sequester these factors until their release by proteases, limit their diffusion, and/or function as coreceptors to promote receptor binding and activation [50]. Binding of VEGF to HSPG appears to be important in its localization and function during development. In mouse embryos, sole expression of a VEGF isoform that lacks the heparin-binding domain, VEGF121, increases diffusion of VEGF from the site of secretion and decreases blood vessel branching. This altered vascular patterning appears to result from impaired endothelial cell migration, as shown by decreased filopodia formation in the migrating "tip cell" of nascent sprouts [52]. In embryos solely expressing the HSPG-binding VEGF isoform, VEGF188, branching of the blood vessels and filopodia formation by endothelial tip cells were increased when compared with wild type [52]. HSPG are also important for vessel stability and maturation, as HSPG are required for PDGF-BB-induced signaling, which, in turn, is important for pericyte migration and interaction with nascent blood vessels [50].

In contrast to the proangiogenic activities of many matrix molecules, matricryptins released by their proteolysis can exert antiangiogenic effects. Many soluble integrin ligands released through proteolytic activity are antiangiogenic, such as tumstatin and arresten (derived from collagen IV), endostatin (derived from collagen XVIII), and endorepellin (derived from perlecan) [5]. These matricryptins could inhibit angiogenesis by interacting with different receptors, activating alternative signaling pathways downstream of the same receptors, and/or compete with the intact matrix molecules for receptor binding. In the last case the displacement of the intact matrix molecules by soluble matricryptins would alter the presentation of the ligands to their receptors, resulting in changes in mechanical resistance that alter signaling events downstream of the receptor and yielding different cellular responses [53]. Although the ways in which matricryptins and intact matrix molecules induce different cellular outcomes are not completely understood, the fact that soluble and intact ECM receptor ligands may, at times, lead to alternative outcomes is likely of importance in vivo following matrix degradation. During angiogenesis, endothelial cell migration and invasion into surrounding tissues are accompanied by the activation of matrix-degrading enzymes, which then cleave the matrix and release both matrix-bound growth factors and generate ECM fragments, providing additional angiogenic or antiangiogenic cues to further influence the process [3]. Therefore matrix molecules that initially facilitate angiogenesis may be proteolytically cleaved to create antiangiogenic matrix fragments, preventing additional blood vessel formation and/or resulting in vessel maturation. Thus the temporal and spatial production and cleavage of matrix molecules may have important consequences for tissue homeostasis. However, the contribution of matricryptins to developmental angiogenesis and vessel maturation remains unclear due to difficulty in distinguishing between cleaved and uncleaved matrix molecules in tissue sections and an inability to delete the matricryptin without also mutating the parent matrix molecule.

Proliferation

Many cell–ECM interactions directly modulate cell proliferation, with some matrix molecules inducing and others inhibiting proliferation. Fibronectin and tenascin-C stimulate cell proliferation in vitro via their EGF-like repeats, which bind and activate the EGFR [8,54,55]. In contrast, laminin inhibits cell proliferation in vitro. Normal human breast cells cultured on plastic continue to divide but stop dividing if grown in a basement membrane matrix, likely due to the laminin-111 present in this matrix mixture [56,57]. Similarly, laminin inhibits endothelial cell proliferation through integrin $\alpha_3\beta_1$, providing a potential mechanism whereby the vascular basement membrane maintains vessel quiescence in the absence of angiogenic stimuli [58].

Some of the ECM effects on cell proliferation are indirect, requiring matrix cooperation with growth factors. As mentioned before under migration/adhesion, binding of growth factors to matrix molecules can affect their interactions with their receptors, limit their diffusion, and/or sequester them until protease-mediated release. Several matrix-associated growth factors, including HB-EGF and TGFβ, can regulate cell proliferation during development.

The importance of HB-EGF in cell proliferation during development is exemplified by its role in the proliferation of vascular smooth muscle cells (VSMCs). Mice expressing Heparin Sulphate (HS)-deficient perlecan exhibit increased VSMC proliferation in vivo following vascular injury and enhanced growth factor-induced VSMC proliferation in vitro [59]. This suggests that the perlecan core protein promotes VSMC proliferation and/or that the HS-modified perlecan inhibits VSMC proliferation. While there is some evidence for the former, many more studies have elucidated the ability of heparan sulfate on HSPG to bind growth factors and regulate their receptor binding and downstream signaling. Expression of perlecan without the growth factor–binding HS moieties leaves proproliferative growth factors free to interact with their receptors and induce proliferation. One such growth factor is HB-EGF, an HSPG-binding growth factor whose protease-mediated release from HSPG enables receptor activation and, in VSMC, ultimately induces proliferation [9]. A mouse embryo expressing a mutant

HB-EGF that could not be cleaved and released from HSPG showed defects resembling the HB-EGF knockout, with abnormal heart development and spontaneous fibrosis, suggesting that HB-EGF release is necessary for its function [60]. In contrast, embryos expressing a soluble version of HB-EGF that could not bind HSPG showed excessive proliferation of keratinocytes, suggesting the importance of HSPG binding in the regulation of HB-EGF-induced keratinocyte proliferation during development [60].

As with proteoglycan binding to HB-EGF, binding of the proteoglycans biglycan and decorin to TGFβ inhibits its receptor binding and downstream signaling until proteolytic cleavage of these proteoglycans releases TGFβ [61]. The proteoglycan betaglycan forms a complex with TGFβ and its receptor to effectively present the ligand to the receptor and induce signaling [62]. Because TGFβ-induced signaling in VSMC can either induce or repress their proliferation, dependent upon the concentration of TGFβ present, the relative abundance of decorin, biglycan, and betaglycan may be critical in determining the amount of TGFβ that can activate its receptors, which may then determine whether the VSMC proliferate in response to TGFβ [63].

TGFβ-binding proteoglycans may also regulate its signaling during early stages of mammary gland development occurring in puberty [64]. During this period, inductive events mediated by the basement membrane take place between the epithelium and the surrounding mesenchyme, which play an important role in epithelial proliferation during gland branching. Endogenous TGFβ produced by the ductal epithelium and surrounding mesenchyme forms complexes with mature periductal ECM but is absent from the nascent ECM in proliferating regions of newly forming ducts [65]. This TGFβ, after its activation from a latent to an active form, may participate in stabilizing the epithelium by stimulating expression of matrix molecules, inhibiting cell proliferation, and/or inhibiting matrix-degrading enzymes. In support of this possibility the mammary gland cells in transgenic mice expressing a kinase-deficient TGFβ receptor showed excessive proliferation, whereas application of exogeneous TGFβ or TGFβ overexpression in mammary epithelial cells decreased cell proliferation [64]. Although it is unclear how the interactions between TGFβ and proteoglycans can influence its function in this context, mice whose mammary epithelial cells are deficient in Ext1, an enzyme needed to synthesize heparan sulfate, undergo reduced mammary gland branching and duct formation, suggesting that HSPG do participate in this process [66]. It remains to be seen whether the heparan sulfate–associated betaglycan, which binds TGFβ and facilitates its downstream signaling, participates in TGFβ-repressed proliferation.

Differentiation

Matrix molecules are critical in regulating the differentiation of multiple cell types during development. Here, we focus on two types of developmental differentiation: mammary gland epithelial cells and keratinocytes.

In the mouse mammary gland the basement membrane and its individual components, in conjunction with lactogenic hormones, are responsible for the induction of the differentiated phenotype of the epithelial cells. When mid-pregnant mammary epithelial cells are cultured on plastic, they do not express mammary-specific genes. However, when the same cells are plated and maintained on basement membrane components (Matrigel), they form alveolar-like structures and exhibit the fully differentiated phenotype with expression of genes encoding milk proteins, such as β-casein [1]. Function-blocking antibodies and conditional knockouts identified laminin-111 as the ECM molecule present in Matrigel ultimately responsible for the observed differentiation, and that integrins β_1 and α_6 are critical in maintaining the differentiated state [1]. One role of laminin-111 in this process is in establishing mammary epithelial cell polarity, which redistributes the prolactin receptor to the apical surface of the epithelium and facilitates ligand binding, receptor activation, and signaling needed to induce expression of β-casein [67]. ECM molecules also regulate expression of another milk protein, the whey acidic protein (WAP). Matrigel decreases the production of TGFα by mammary gland epithelial cells, thereby increasing expression of WAP, which is otherwise inhibited by TGFα [68]. WAP may then participate in the maintenance of mammary epithelial differentiation by inhibiting the activity of laminin-degrading enzymes [69].

Like mammary epithelial cells, keratinocytes are epithelial cells that terminally differentiate. Keratinocytes form the stratified epidermal layers of the skin, in which the basal layer is highly proliferative, does not express the markers for terminal differentiation, and is the only cell layer in contact with the basement membrane. As these cells divide, the daughter cells lose contact with the basement membrane, move up to the suprabasal layers, and begin to express differentiation markers [70]. This suggests that physical interaction with the basement membrane may repress basal keratinocyte differentiation. Indeed, the basement membrane component fibronectin inhibits differentiation of the basal cells, as does activation of β1 integrin, while the keratinocytes in a conditional integrin β1 skin knockout mouse exhibit reduced proliferation and increased differentiation [70,71]. This suggests that fibronectin–integrin interactions prevent keratinocyte terminal differentiation in the basal keratinocyte layer, which is important in maintaining the proliferative capacity of these cells. Other basement membrane

components, including collagen IV and laminin-511, facilitate keratinocyte proliferation in culture, suggesting that these molecules may promote proliferation of the basal keratinocyte layer in vivo [72,73]. As such, multiple basement membrane components may work together to regulate proliferation of these cells by promoting cell proliferation and by preventing terminal differentiation.

Apoptosis

Programed cell death occurs during embryogenesis of higher vertebrates in areas undergoing remodeling, as in the development of the digits, palate, nervous system, in the selection of thymocytes in the thymus, during mammary gland involution, and during angiogenesis. In the mammary gland, for example, intact basement membrane molecules promote proliferation, differentiation, and survival of mammary epithelial cells, whereas matrix fragments induce apoptosis during the involution of the mammary gland [74]. The numerous alveoli that produce milk during lactation regress and are resorbed during involution due to enzymatic degradation of alveolar basement membrane and apoptosis [64,75]. During this involution, apoptosis appears to proceed in two distinct phases, an early phase characterized by increased levels of proinflammatory and apoptosis-associated proteins, including several members of the tumor necrosis factor (TNF) and TNF receptor superfamilies as well as the proapoptotic Bcl family member Bax [75]. This is then followed by a later apoptotic phase in which cell−ECM interactions are altered due to matrix degradation and reduced expression of matrix-binding integrins, preventing prosurvival integrin signaling and resulting in apoptosis [75]. This later phase of matrix degradation and apoptosis may be regulated, at least in part, by decreased production of WAP, a milk protein that can inhibit the activity of proteases that cleave laminin [69]. Decreased production of WAP by dying or dedifferentiated cells could relieve WAP-mediated protease inhibition, promoting protease activation and matrix degradation. This, in turn, would decrease the interaction of intact matrix molecules with integrins, decreasing prosurvival signaling. Furthermore, it is possible that integrins then interact with soluble matrix fragments, which is known to induce apoptosis in endothelial cells (see later) [53].

In endothelial cells, binding to intact matrix molecules in the basement membrane promotes survival and inhibits apoptosis, whereas binding to matrix fragments induces apoptosis [76]. For example, $\alpha_v\beta_3$ integrin interactions with intact matrix molecules play a crucial role in endothelial cell survival during embryonic angiogenesis. Indeed, disruption of these interactions with an antibody to $\alpha_v\beta_3$ inhibits the development of new blood vessels in the CAM by inducing endothelial cell apoptosis [77]. In contrast, $\alpha_v\beta_3$ binding to tumstatin, a proteolytic fragment of collagen IV, induces endothelial cell apoptosis, preventing angiogenesis and/or promoting vessel regression [78]. This interaction may promote apoptosis by interfering with normal integrin−ECM binding, thereby removing a critical survival signal. However, tumstatin may also promote apoptosis through a separate mechanism, such as via the recruitment and activation of caspase 8, as has been suggested previously for such soluble ligands [53]. Taken together, these findings suggest that disruption of cell−ECM interactions may lead to an increase in the expression or activation of proapoptotic molecules and may also lead to the removal of prosurvival signals, which then directly or indirectly cause apoptosis in endothelial cells.

Wound healing

Adhesion and migration

Early in the wound healing process, blood components and tissue factors are released into the wounded area in response to tissue damage, promoting both the coagulation cascade and platelet adhesion and activation, resulting in the formation of a clot consisting of platelets, cross-linked fibrin, fibronectin, and vitronectin, with lesser amounts of SPARC, tenascin, and thrombospondin [79]. Activated platelets, along with degranulating mast cells, release a number of cytokines and growth factors important in in regulating the wound healing process and initiating the next phase of wound healing, the inflammatory response. The fibrin-fibronectin clot has functions in addition to hemostasis, sequestering cytokines and growth factors while providing a temporary ECM that facilitates the adhesion and migration of multiple cell types, particularly leukocytes, into the wounded area [79].

Leukocyte adhesion, migration, and secretion of inflammatory mediators are regulated by their interactions with multiple molecules, some of which are ECM molecules [80]. After initial interactions between neutrophil and macrophage integrins with nonmatrix cell adhesion molecules ICAM and VCAM, these leukocytes interact with chemoattractant cytokines, or chemokines, associated with HSPG on the endothelial surface, in the endothelial basement membrane, and within the fibrin-based provisional matrix [80]. This chemokine binding to HSPG creates and maintains stable chemokine gradients critical for appropriate leukocyte recruitment, as shown by their defective recruitment by mutant chemokines lacking the ability to bind glycosaminoglycans, in mice deficient in heparan sulfate biosynthesis, and in mice overexpressing heparanase [80,81]. Leukocyte adhesion to and migration through the basement membrane and provisional matrix are also mediated by matrix interactions with matrix

receptors. Neutrophils bind several matrix molecules in the basement membrane, including fibronectin, vitronectin, laminin-511, laminin-411, and the proteoglycan lumican, and also bind fibrin and fibronectin in the provisional matrix [82]. Laminin-511 stabilizes the endothelium by binding endothelial integrin $\alpha_6\beta_4$ at hemidesmosomes and limits neutrophil movement through the endothelium to regions with low levels of laminin-511 [70,83]. In contrast, both laminin-411 and lumican are necessary for neutrophil extravasation, the former likely through integrin $\alpha_6\beta_1$ and the latter via β_2 integrin(s) [84,85].

After leukocytes leave the vasculature, they encounter the provisional matrix, which then regulates their adhesion, migration, and behavior. Integrin $\alpha_M\beta_2$ expressed by various inflammatory cells interacts with fibrin, urokinase plasminogen activator (uPA), and thrombospondin 4, inducing inflammatory cell adhesion and migration [86]. Binding of $\alpha_M\beta_2$ to uPA also promotes plasmin activation and thus fibrin degradation and removal of the provisional matrix [86]. In addition to the impact of integrin $\alpha_M\beta_2$ activation on matrix degradation, integrin $\alpha_M\beta_2$–ligand binding promotes proinflammatory cytokine production. In monocytes, fibrin binding induces expression of proinflammatory cytokines and chemokines, including IL-1β, IL-6, TNF-α, and several CC chemokines, and neutrophil binding to thrombospondin-4 induces secretion of the chemokine CXCL8 and the respiratory burst [86,87]. Many of these cytokines and chemokines can interact with matrix components, particularly HSPGs, to form a stable gradient that guides extravasated leukocytes to the injured area [80]. The presence of many matrix-degrading enzyme during this process ensures the generation of matrix fragments that also affect inflammation [5]. Hyaluronidases and reactive oxygen and nitrogen species can generate low molecular weight hyaluronan fragments, for example, which then activate TLRs like TLR4 in tissue macrophages and induce their release of proinflammatory cytokines, promoting adhesion and migration of additional inflammatory cells to the injured area [24]. As such, the types of ECM molecules and matrix fragments present in the injured area may greatly affect the inflammatory phase of wound healing.

This inflammatory phase overlaps with the next phase of wound healing, a proliferative phase that involves proliferation and migration of epithelial keratinocytes during reepithelialization as well as endothelial cells and fibroblasts during granulation tissue formation. In the reepithelialization phase of cutaneous wound healing, keratinocytes migrate beneath the fibrin-rich provisional matrix, likely due, at least in part, to the fact that these cells do not express the fibrin-interacting integrin $\alpha_V\beta_3$ [79,88]. The keratinocytes do express multiple receptors for fibronectin, collagen, tenascin, and vitronectin, including the integrins $\alpha_2\beta_1$, $\alpha_3\beta_1$, $\alpha_5\beta_1$, $\alpha_6\beta_1$, and $\alpha_6\beta_4$, and these receptor–matrix interactions, along with the activity of matrix-degrading MMPs and plasmin, promote keratinocyte migration and subsequent wound closure [70,79]. Keratinocyte migration requires the synthesis and deposition of laminin-332 and cellular fibronectin, as well as their interactions with multiple integrins [79]. Interactions between epithelial cells and ECM are also critical in the closure of other types of epithelial wounds. After wounding, retinal pigment epithelial cells exhibit a sequential pattern of ECM molecule deposition that is critical in the epithelial cell adhesion and migration associated with wound closure. Within 24 hours of wounding, these epithelial cells secrete fibronectin, followed shortly by laminin and collagen IV. If cell adhesion to these ECM molecules is blocked with either cyclic peptides or specific antibodies, the epithelial cells fail to migrate and close the wound, underscoring the importance of such interactions in wound closure [89,90].

Along with the deposition of new matrix molecules that facilitate cell adhesion and migration, proteases such as MMPs and plasmin are important in keratinocyte migration, facilitating migration by cleaving matrix molecules and cell–cell adhesion molecules that otherwise promote cell adhesion and prevent migration [9]. MMP-10, for example, may cleave laminin-332 and the α_6 subunit of integrin $\alpha_6\beta_4$ to allow deadhesion of keratinocytes from laminin-332, facilitating migration [91,92]. MMP-7 appears to cleave E-cadherin to allow cells to detach from each other and facilitate their migration, as keratinocytes in MMP-7-deficient mice exhibit both a lack of E-cadherin cleavage and migration defects [91]. In addition to direct cleavage of adhesion molecules or receptors by MMPs, proteases can also mediate the release of HB-EGF from HSPG, which then induces keratinocyte migration through the EGFR [9]. Therefore proteases can facilitate cell adhesion/deadhesion and migration using multiple mechanisms during reepithelialization.

During later stages of wound healing, macrophages and fibroblasts in the injured area deposit cellular fibronectin, tenascin-C, SPARC, proteoglycans, and collagens, which are important in the generation of the granulation tissue, a temporary connective tissue consisting of multiple types of ECM molecules and newly formed blood vessels [79]. These matrix molecules provide substrates for the migration of endothelial cells into the granulation tissue to form the wound vasculature, while also facilitating the recruitment of fibroblasts, myofibroblasts, and lymphocytes whose migration is stimulated by a variety of chemokines produced by tissue fibroblasts and macrophages [93]. Many chemokines have been characterized in multiple species, including humans, other mammals, and even birds, and have been grouped into a large superfamily which is further subdivided based upon the

position of the N-terminal cysteine residues. These chemokines, along with cell−ECM interactions, are critical in the adhesion and chemotaxis/migration of the cells that ultimately enter the wounded area and generate the granulation tissue [93]. One prototypical chemokine, CXCL8 (IL-8), has several functions that are important in wound healing. Many of these functions have been elucidated in studies performed in the chick model system using the chicken version of CXCL8, chCXCLi2 (cCAF/cIL-8) [94]. After wounding, fibroblasts in the injured area produce large quantities of chCXCLi2, most likely resulting from their stimulation by thrombin, a coagulation enzyme activated upon wounding that is known to induce fibroblasts to express and secrete chCXCLi2. The initial rapid increase in chCXCLi2 generates a gradient that chemoattracts neutrophils, a finding that has since been replicated with human neutrophils and CXCL8 [80,95]. CXCL8 derived from tissue fibroblasts and macrophages, along with the additional CXCL8 secreted from the endothelial cells of the wound vasculature and bound to various matrix components of the granulation tissue, participates in granulation tissue formation by stimulating angiogenesis and matrix deposition [96,97]. Therefore CXCL8 not only functions in the inflammatory phase of wound healing by serving as a leukocyte chemoattractant but also plays an important role in granulation tissue formation.

Angiogenesis is a critical part of granulation tissue formation and relies heavily upon cell−ECM interactions. The localization of the matrix molecules and the proteases that degrade them have critical roles in this process. In some cases, interaction of an angiogenic factor or its receptor with a matrix molecule is important in ligand−receptor interactions and/or downstream signaling, whereas in others, matrix fragments signal differently from the parent matrix molecule [5,14]. As mentioned earlier, many extracellular signaling molecules, including CXCL8, VEGF, and FGF, bind HSPG, which can alter their diffusion and interaction with their receptors [8,50]. In addition to HSPG, however, FGF and VEGF signaling is heavily influenced by the presence of specific matrix molecules and integrins. Integrin $\alpha_v\beta_3$ is important in VEGFR2 and FGFR activation and angiogenesis induced by VEGF and FGF, respectively, and integrin $\alpha_v\beta_5$ is also involved in VEGF-induced angiogenesis [14]. In the case of VEGF/VEGFR2 signaling, an integrin $\alpha_v\beta_3$ ligand, vitronectin, promotes the interaction of this integrin with VEGFR2, enhances VEGF-induced VEGFR2 signaling, and promotes endothelial cell migration [98,99]. Similarly, fibronectin simultaneously binds VEGF and integrin $\alpha_5\beta_1$, promoting VEGF-induced endothelial cell migration, whereas collagen I binding to β_1 integrins instead inhibits signaling downstream of VEGFR2 [98,100]. VEGF can also bind integrin $\alpha_9\beta_1$ directly, promoting VEGFR2-mediated signaling and ultimately endothelial cell adhesion and migration [100,101]. Similarly, FGF2 can bind directly to integrin $\alpha_v\beta_3$, which is necessary for endothelial cell migration and angiogenesis induced by FGF2. FGF2 mutants defective in integrin binding were unable to promote endothelial cell migration, tube formation on Matrigel, and angiogenesis in vivo [102]. Taken together, these results underscore the importance of the microenvironment in regulation of angiogenesis induced by VEGF and FGF2.

Along with the matrix proteins in the microenvironment, protease activity is needed for the endothelial cells to degrade and then migrate through the basement membrane and surrounding connective tissue during angiogenesis [5,103]. These proteases can regulate endothelial cell adhesion and migration during angiogenesis by releasing matrix-bound factors, as mentioned earlier, and also by generating functional matrix fragments and exposing previously concealed matricryptic sites [5]. Some of these "matricryptins" promote cell migration and angiogenesis. For example, a matricryptic site in collagen IV exposed by MMP-9-mediated proteolysis changes integrin binding from $\alpha_1\beta_1$ to $\alpha_v\beta_3$, and blocking this site with an antibody or inhibiting integrin $\alpha_v\beta_3$ prevents endothelial cell adhesion and migration in vitro and angiogenesis in vivo [100]. Similarly, a fragment of collagen 1 that is released by MMP-mediated cleavage promotes angiogenesis [5]. However, the contribution of matricryptins in the regulation of angiogenesis is complicated by the fact that although some matricryptins promote angiogenesis, many others inhibit angiogenesis, including fragments derived from collagen XVIII (endostatin) and collagen IV (canstatin, tumstatin, and arresten). Endostatin, canstatin, and arresten inhibit endothelial cell migration and tube formation [78]. These matricryptins may exert their inhibitory effects by binding VEGFR2 (endostatin) and/or integrin $\alpha_v\beta_3$ (endostatin, canstatin, and tumstatin), both of which are essential for VEGF-induced cell migration and angiogenesis, thereby blocking signaling downstream of the individual receptor(s) and the substantial cross talk that occurs between them [5,78].

Proliferation

After cutaneous wounding, keratinocytes alter their proliferation and migration in order to close the wound, a process known as reepithelialization. As this process occurs, the cells at the edge of the wound migrate, whereas the cells away from the wound proliferate to provide the cells needed to cover the wounded area. The proliferative state of the keratinocytes may be sustained by interactions with the ECM of the remaining or nascent basement membrane. ECM derived from the basal lamina, when present in a dermal wound model, can maintain keratinocytes in a

proliferative state for several days. As mentioned before, the proliferation of the basal layer of keratinocytes needed to replace the upper keratinocyte layers in uninjured skin requires components of the epithelial basal lamina, including fibronectin, with potential contributions of collagen IV and laminin-511, which promote proliferation in vitro, and the laminin receptor $\alpha_6\beta_4$ is necessary for keratinocyte proliferation [72,73]. In addition, integrins appear to regulate keratinocyte proliferation. For example, fibronectin-binding integrins $\alpha_5\beta_1$ and $\alpha_v\beta_6$ are upregulated in keratinocytes after wounding, suggesting a potential mechanism whereby fibronectin may prevent terminal differentiation and/or promote proliferation of keratinocytes during reepithelialization [93]. Furthermore, expression of integrin α_9 is increased upon wounding, and keratinocytes in mice lacking epithelial integrin α_9 or β_1 exhibit reduced proliferation [14,104]. These results suggest a role for integrin $\alpha_9\beta_1$, a receptor for several matrix molecules, including laminin, tenascin-C, and emilin, in keratinocyte proliferation [104]. Complicating our understanding of integrin $\alpha_9\beta_1$-mediated adhesion in this process, emilin-1-deficient keratinocytes exhibit excessive proliferation during reepithelialization in vivo and in cultured cells in vitro, the latter of which is dependent upon α_9 and α_4 integrins [105]. As such, the specific integrins and their specific ligands present at different stages of the reepithelialization process may either promote keratinocyte proliferation or limit such proliferation.

While reepithelialization progresses, the granulation tissue begins to form, a process involving many ECM molecules, including cellular fibronectin, collagen III, collagen I, and hyaluronic acid, and multiple proliferating cell types, notably the endothelial cells of the wound vasculature and fibroblasts. Fibronectin, fibronectin fragments, laminins, collagen VI, SPARC, tenascin-C, and hyaluronan provide a context that facilitates fibroblast and endothelial cell proliferation [106]. Fibroblasts lacking the collagen receptor DDR2 exhibit reduced proliferation in vitro, and the granulation tissue of $DDR2^{-/-}$ wounds contain fewer fibroblasts, likely due to decreases in their proliferation and/or migration, suggesting that some matrix molecules provide cues necessary for cell proliferation [33]. Matrix molecules can also promote proliferation directly, as shown by the ability of the EGF-like domains of tenascin-C to promote fibroblast proliferation in an EGFR-dependent manner [54]. Growth factors themselves can require specific ECM molecules to induce proliferation, as is seen in the fibronectin requirement for TGFβ1-mediated fibroblast proliferation [107]. In addition to fibroblast proliferation in the granulation tissue, endothelial cells proliferate during angiogenesis of this tissue, a process that is dependent upon growth factors, such as FGFs and VEGFs, and their interactions with matrix molecules. Signaling induced by both FGFs and VEGFs is enhanced by HSPG, as discussed earlier, while VEGF binding to fibronectin or vitronectin enhances its effect on endothelial cell proliferation [50,99]. In contrast, certain ECM molecules and/or proteolytic fragments can inhibit proliferation. The matricellular proteins SPARC inhibits VEGF- and FGF2-induced proliferation, indicating that interactions between growth factors and ECM can also be inhibitory [8]. Furthermore, SPARC and decorin, as well as peptides derived from SPARC, decorin, collagen IV (tumstatin), and collagen XVIII (endostatin) are antiangiogenic due to their inhibitory effects on endothelial cell proliferation [29,103].

Differentiation

As the granulation tissue forms, some of the fibroblasts within the wounded area differentiate into myofibroblasts, contractile cells that express the protein α-smooth muscle actin and secrete a number of matrix molecules, including fibronectin and collagens I and III [93]. Myofibroblast differentiation is regulated by cytokines and growth factors, mechanical tension, and interactions with multiple matrix molecules, including proteoglycans, cellular fibronectin, interstitial collagen, and hyaluronan. One of the best characterized growth factors that induces myofibroblast differentiation is TGFβ1, which is initially secreted in an inactive, latent state and must be activated either through a change in conformation or proteolytic cleavage to an active form able to bind its receptor [14]. Release of active TGFβ1 is insufficient for receptor activation, however, as several proteoglycans, including decorin, can bind active TGFβ1 and prevent it from binding its receptor [8]. For TGFβ1 to bind and activate its receptor thus also requires proteolytic degradation of these sequestering proteoglycans. In contrast, binding of the proteoglycan betaglycan to TGFβ1 has different effects on downstream signaling depending upon whether betaglycan is membrane-associated or soluble. Membrane-bound betaglycan presents TGFβ1 to its receptor and facilitates downstream signaling, whereas soluble betaglycan competes with membrane betaglycan for TGFβ1 binding and therefore prevents downstream signaling [62]. Changes in the presence or abundance of proteoglycans and enzymes that degrade them can thus influence the availability of active TGFβ1 in the healing wound, impacting its ability to induce myofibroblast differentiation and contraction of the granulation tissue.

Matrix molecules other than proteoglycans are also important in myofibroblast differentiation. TGFβ1-induced differentiation requires the Fibronectin Extra Domain A (EDA)-containing form of cellular fibronectin and the binding of this EDA domain to integrins $\alpha_5\beta_1$ and $\alpha_v\beta_3$ [93]. Interstitial collagens, in conjunction with mechanical tension exerted by integrin-mediated adhesion to

collagens, also participate in the differentiation process. Fibroblasts cultured on relaxed collagen gels fail to differentiate, whereas fibroblasts grown on stiffened collagen matrices exhibit myofibroblast characteristics [108]. This finding, coupled with data demonstrating increased myofibroblast differentiation when splints are used to increase mechanical tension in wounds, suggest a role for mechanical tension in myofibroblast differentiation in vivo [109]. Tensile stress may regulate cell signaling and cell−matrix interactions by revealing cryptic sites in intact matrix molecules, by changing the conformation of latent TGFβ1 to facilitate receptor binding, and by altering signaling downstream of matrix receptors [93,108]. For example, mechanical stress could expose the EDA domain of fibronectin needed for TGFβ-induced myofibroblast differentiation, and several RGD-binding integrins can interact with the RGD motif of the latency-associated peptide of TGFβ1 and either induce the appropriate change in conformation needed to bind the receptor or present the latent complex to MMPs to facilitate proteolytic cleavage and release of active TGFβ1 from the latent complex [108]. Tensile stress exerted on the cell by the matrix may also induce the formation of stress fibers that exert intracellular tension on integrins interacting with these matrix molecules, promoting the formation of strong adhesions needed for wound contraction and closure [108]. Mechanical strain may further alter myofibroblast differentiation and function by altering signaling downstream of integrins subjected to increased mechanical tension while adhering to their matrix ligands [108].

Apoptosis

Late in the wound healing process, the granulation tissue undergoes remodeling to form scar tissue. This remodeling phase is characterized by decreased tissue cellularity due to the disappearance of multiple cell types, including fibroblasts, myofibroblasts, endothelial cells, and pericytes, and by the accumulation of ECM molecules, particularly interstitial collagens. The observed reduction in cell numbers during the remodeling phase occurs largely via apoptosis, and many of these apoptotic cells are endothelial cells and myofibroblasts, as shown by studies using in situ DNA fragment end-labeling in conjunction with transmission electron microscopy [110]. Apoptosis of fibroblasts and myofibroblasts may be important in preventing excessive scarring and facilitating the resolution of wound healing. Indeed, reduced fibroblast and myofibroblast apoptosis in keloids and hypertrophic scars is associated with increased matrix deposition and scarring, whereas inducing myofibroblast apoptosis in a mouse scleroderma model reduced fibrosis [109,111]. Myofibroblast apoptosis is regulated by mechanical tension and occurs after the myofibroblasts contract to close the wound, as the tension of the tissue decreases. Using a splint to maintain tension in a healing wound inhibits myofibroblast apoptosis, whereas the release of tension in this model promotes apoptosis, implicating mechanotransduction in apoptosis regulation [109]. This may be mediated by changes in signaling through the collagen receptor DDR2 after release of tension. Though more work must be done to understand the relationship between DDR2, collagens, and mechanotransduction, a recent study found that $DDR2^{-/-}$ myofibroblasts undergo more apoptosis in a lung fibrosis model than wild-type myofibroblasts, coinciding with reduced fibrosis [112]. Taken together, cell/matrix interactions and associated mechanotransduction regulate myofibroblast apoptosis after wound contraction.

Signal transduction events during cell−extracellular matrix interactions

As discussed before, ECM molecules are capable of interacting with a variety of receptors. Such interactions activate signal transduction pathways within the cell, altering levels of both gene expression and protein activation, ultimately changing cellular outcomes in cell adhesion, migration, proliferation, differentiation, and death. The signaling pathways linked to these specific outcomes have been studied for many of the ligand−receptor interactions, particularly those involving integrins [14]. In the case of integrins, it is important to remember that these receptors can participate in both “outside-in” and “inside-out” signaling [113,114]. Outside-in signaling occurs when an extracellular ligand binds the receptor and initiates intracellular signaling, and in inside-out signaling, intracellular signaling increases the affinity of the receptor for its ligand. Binding of the receptor to the ligand then initiates outside-in signaling. Unless otherwise indicated, the signaling events discussed next refer to outside-in signaling.

Based upon the many studies that investigate matrix-induced signaling, we postulate the existence of three categories of cell−ECM interactions, namely, type I interactions that are involved in adhesion and migration, type II interactions involved in proliferation, differentiation, and survival, and type III interactions involved in apoptosis (Fig. 6.2). Although these three categories of cell signaling in cell−ECM interactions may not be exhaustive of the general types of adhesions that occur during development and wound healing, they encapsulate some of the best understood interactions and their associated signaling events. Each category has its place in many developmental and repair events, and they may operate in sequence to promote the cell survival, adhesion, migration, differentiation, and apoptosis needed to generate tissues and organs, and to promote their repair and regeneration following injury.

Type I interactions are generally mediated by integrin and proteoglycan receptors and are important in the

adhesion/deadhesion processes that accompany cell migration (Fig. 6.2A). Integrins interact with ligands outside the cell, and this triggers intracellular signaling through proteins associated with integrins in integrin adhesion complexes [115]. These integrin adhesion complexes include proteins that connect the integrins indirectly with the actin microfilaments, those involved in signal transduction, and others involved in mechanotransduction. For example, the microfilaments interact with the cytoplasmic domain of integrin β subunits through the structural proteins talin and α-actinin, transduce mechanical signals through vinculin and talin, facilitate signaling through focal adhesion kinase (FAK) and paxillin, and regulate the actin cytoskeleton via vasodilator-stimulated phosphoprotein and zyxin [115,116]. However, many of these proteins have overlapping roles and ultimately work together to control cell adhesion and migration. Binding of an integrin to its ligand triggers autophosphorylation of FAK on tyrosine 397 (PY397), which then serves as the binding site for the SH2 domain of the c-Src tyrosine kinase [117]. This kinase subsequently phosphorylates FAK itself at position 925, increasing its activity while facilitating FAK binding to downstream signaling molecules, including Grb2/Sos, PI3K, and $p130^{Cas}$ [104]. This autophosphorylation and activation of FAK is enhanced when cells adhere to stiff matrices when compared with adhesion to softer matrices, and the phosphorylation of $p130^{Cas}$ downstream of FAK/Src signaling only occurs on stiff matrices, suggesting the importance of mechanosensation in FAK/Src signal transduction [118,119].

After FAK phosphorylation at Y925, it interacts with the Grb2/Sos complex, promoting the downstream activation of Ras and the MAP kinase cascade, which may be involved in cell adhesion/deadhesion and migration events [117,120]. Beyond Ras and the MAPK cascade, the FAK/Src complex activates a number of downstream signaling molecules necessary for adhesion and migration, including paxillin, $p130^{Cas}$, tensin, and vinculin. Paxillin regulation

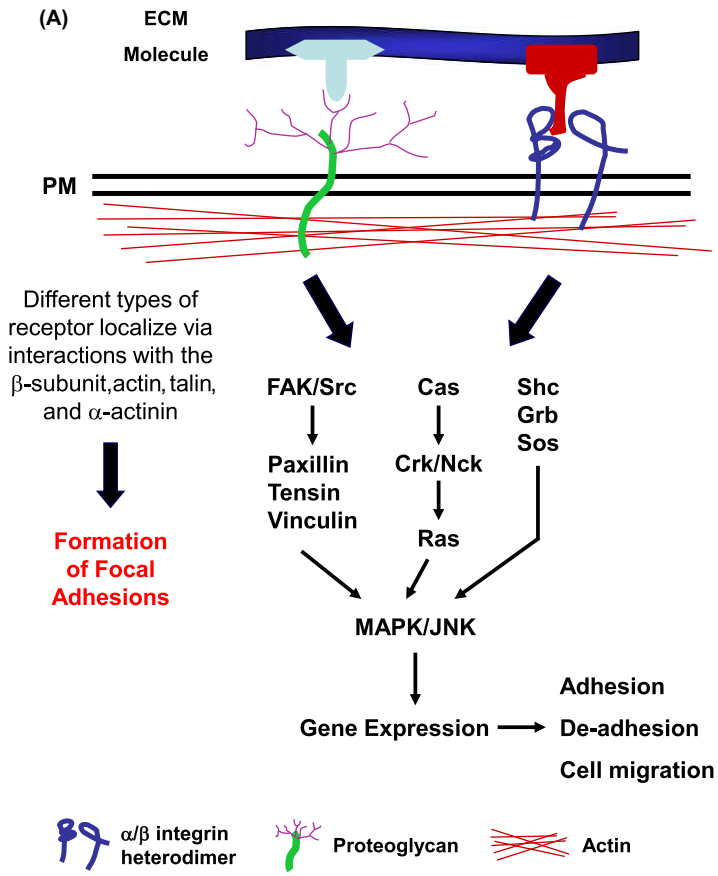

FIGURE 6.2 Schematic diagram of cell–ECM interactions present during healing and regenerative responses. Type I (A), Type II (B) and Type III (C). Such interactions between the ECM receptors and their respective ligands initiate signal transduction cascades culminating in a variety of cellular events important in repair and regeneration, including changes in cellular adhesion and migration and altered rates of proliferation and apoptosis. The presence and/or extent of such changes may influence the balance of repair and regenerative responses to favor one outcome over another; thus interventions that alter ECM signaling events may shift this balance to favor tissue regeneration and thus decrease scarring. *ECM*, Extracellular matrix.

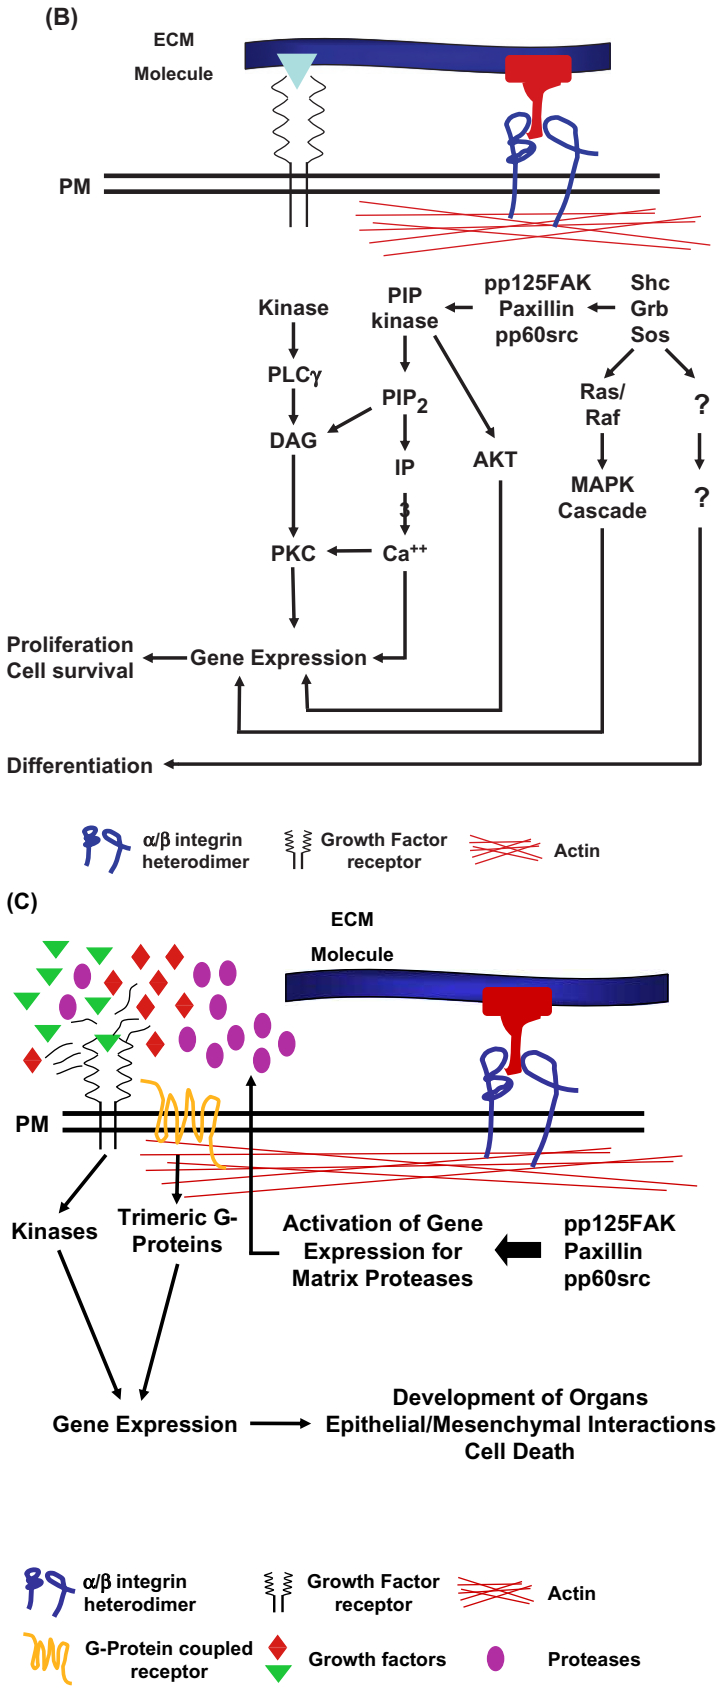

FIGURE 6.2 (Continued)

by FAK/Src is necessary for integrin-mediated signaling and motility, as shown by the reduced migration and decreased phosphorylation/activation of multiple signaling molecules in paxillin-deficient fibroblasts, coupled with the impaired migration seen in cells overexpressing a paxillin mutant that could not be phosphorylated by FAK/Src [121]. Both phosphorylated paxillin and $p130^{Cas}$ bind the Crk/DOCK180/ELMO complex, activating DOCK180, a guanine nucleotide exchange factor (GEF) that activates Rac1, while paxillin recruits another Rac1/Cdc42 GEF, β-PIX, thereby inducing lamellipodia formation and cell migration [117,122,123]. Src-mediated signaling also activates another Rac GEF, Vav2, along with a Rho GTPase-activating protein (GAP) that inhibits RhoA [123]. Similarly, members of the tensin family, which bind both actin microfilaments and integrins and are phosphorylated downstream of FAK/Src signaling, interact with and activate DLC1, a GAP inhibiting RhoA, and Dock5, a GEF-activating Rac1 [124]. Collectively, this signaling increases the activity of Rac1, promoting the formation of lamellipodia at the leading edge of migrating cells, while decreasing activity of RhoA and thereby causing deadhesion, ultimately facilitating directional migration.

To this point, we have discussed the roles of FAK and Src in outside-in, traditional receptor-mediated signal transduction. However, these kinases can participate in inside-out signaling as well. FAK/Src signaling stimulates integrin activation, cell adhesion to matrix molecules, and focal adhesion strengthening [125]. This integrin activation is mediated by members of the talin and kindlin families, which are recruited to the integrins at nascent adhesions in a FAK-dependent manner [114]. Indeed, integrin activation and integrin-mediated adhesions are inhibited in cells lacking talin or kindlin and in cells whose talin cannot bind integrins [126,127]. Integrin activation and matrix binding then initiates outside-in signaling, promoting FAK/Src activity and leading to Rac1 activation and RhoA inhibition. Like tensin, kindlin may participate in this outside-in signaling after integrin activation by interacting with and activating DLC1, leading to deadhesion downstream of RhoA inactivation [114]. Taken together, these findings suggest a continuous cycle of outside-in and inside-out signaling, with outside-in signaling triggering protrusion formation and deadhesion and inside-out signaling increasing adhesion formation, which may function in sequence to promote cell migration.

Integrins can also cooperate with growth factor receptors to promote downstream signaling, as described earlier. c-Src activated downstream of VEGFR2 phosphorylates β_3 integrin and increases adhesion of integrin $\alpha_v\beta_3$ to vitronectin. Vitronectin-induced integrin activation promotes its interaction with VEGFR2 in a Src-manner, ultimately increasing endothelial cell migration downstream of VEGFR2 signaling [98,99,128]. This VEGF-induced endothelial cell migration is also dependent upon FAK, suggesting that signaling downstream of VEGFR2 and integrin $\alpha_v\beta_3$ work together to regulate and coordinate cell migration during angiogenesis [129].

Matrix receptors other than integrins, such as proteoglycans, CD44, the ERC, RHAMM, and DDR1/2, are also important in cell adhesion and migration. Syndecans are proteoglycans that can function as coreceptors, associating with matrix molecules and integrins to promote cell adhesion and migration [20]. Syndecan-4, for example, can bind the heparin-binding domain of fibronectin and the fibronectin receptor integrin $\alpha_5\beta_1$, activating PKC and Rac activation and RhoA inactivation downstream of PKC [130]. This promigratory regulation of Rho GTPases is coupled with a loss of integrin-mediated adhesions, as syndecan-4-induced PKC and RhoG promote integrin $\alpha_5\beta_1$ internalization and degradation after fibronectin binding, thus promoting the deadhesion needed for cells to migrate [113]. In addition to interacting with matrix molecules and integrins to facilitate or alter downstream signaling, syndecans are also present in complexes including integrins, matrix molecules, growth factors, and growth factor receptors. In these complexes, syndecans can promote growth factor binding and activation of its receptor, as is the case for FGF2 and VEGF, prevent receptor binding until proteolytic release of the ligand, as in the case for HB-EGF, and may contribute to cell migration downstream of these growth factors [20].

Receptors other than syndecans and integrins can also promote cell migration, including the hyaluronan-binding receptors CD44, RHAMM, and TLRs. As described in more detail before, native hyaluronan has a high molecular weight that interacts with CD44 and RHAMM but not TLRs, whereas smaller hyaluronan fragments generated by hyaluronidases or reactive oxygen or nitrogen species interact with TLRs [21,23,24]. High molecular weight hyaluronan binding to CD44 induces phosphorylation of its intracellular domain and activation of c-Src, resulting in fibroblast migration [131]. RHAMM, another hyaluronan receptor, cooperates with CD44 to facilitate fibroblast migration by regulating ERK1/2 activation downstream of CD44, and in smooth muscle cells, hyaluronan induces cell migration downstream of RHAMM via PI3K and Rac [132]. In contrast to high molecular weight hyaluronan, low molecular weight hyaluronan induces inflammation, largely through its activation of TLRs and downstream activation of NFκB and induction of cytokine expression [23,131]. As such, low molecular weight hyaluronan induces inflammatory cell migration in an indirect manner via increasing levels of proinflammatory cytokines.

In addition to hyaluronan fragments, fragments of other matrix molecules can induce cell adhesion and migration through their interactions with the ERC and growth factor receptors. Fragments of elastin, laminin,

and fibrillin bind the ERC, which promotes matrix deposition and thereby increases cell adhesion, while also inducing cell migration, likely through activation of MAP kinase cascades [25]. Similarly, several matrix molecules with EGF-like domains bind and activate the EGFR, either as part of the intact matrix molecule, or, more likely, following release of the EGF-like domains after proteolytic degradation, and promote cell migration downstream of the EGFR [133].

Signaling downstream of the collagen receptors DDR1 and DDR2 can induce migration in some cell types, while decreasing cell migration in others. Therefore the signaling and cellular outcome is dependent upon the cellular context. DDR1 activation by collagen inhibits epithelial cell adhesion and migration induced by integrin $\alpha_2\beta_1$ ligation, likely through recruitment of the phosphatase SHP-2 but promotes migration of smooth muscle cells and T cells in response to collagen [134]. Inhibition or knockdown of DDR1 inhibited migration of Th17 cells through a collagen matrix, and inhibition of DDR1 inhibited Th17 cell recruitment to the chemokine CCL20 in vivo, suggesting the importance of this collagen receptor in T-cell migration [134]. DDR1-mediated Th17 migration in vitro requires activation of RhoA and its effector ROCK, as well as the activation of ERK downstream of Rho/ROCK signaling [135]. Collagen-induced fibroblast migration is instead mediated by DDR2, as shown by the reduced migration of DDR2$^{-/-}$ fibroblasts through Matrigel, which was rescued by reexpression of DDR2 in these cells [33,134].

DDR2-mediated migration in this context requires MMP2, presumably to promote invasion through the Matrigel [33]. In contrast, DDR2-mediated fibroblast migration was dependent upon JAK2 and ERK [33]. Complicating our understanding of DDR1 and DDR2 signaling is the cross talk linking these receptors to collagen-binding integrins, which are expressed in the same cells and bind the same ligands, and DDR1/2 signaling promotes integrin binding to collagens [134]. As such, these receptors likely work together to mediate cell adhesion and migration.

Type II interactions involve processes in which the matrix−receptor interactions, in conjunction with growth factor or cytokine receptors, affect proliferation, survival, differentiation, and/or maintenance of the differentiated phenotype (Fig. 6.2B). These cooperative effects may occur in a direct manner, for example, by the direct interaction of EGF-like repeats present in certain ECM molecules with the EGF receptor, thereby promoting cell proliferation [12]. However, more current evidence supports the importance of indirect cooperative effects, particularly with regards to the anchorage dependence of cell growth. S-phase entry, even when growth factors are present, requires the interaction of cells with a substrate, while detachment of cells from matrix promotes a type of apoptosis called anoikis, underscoring the critical role of cell−ECM adhesion in cell survival and proliferation [136].

The prosurvival function of matrix interactions is largely mediated by integrins and their downstream activation of FAK. In epithelial cells, FAK/Src complexes promote cell survival through PI3K-induced Akt activation [137,138]. Signaling downstream of Akt then increases levels of antiapoptotic Bcl family members while decreasing levels of proapoptotic Bcl family members, inhibiting apoptosis and resulting in cell survival [138]. A similar mechanism may promote cell survival following CD44 binding to hyaluronan, which also activates PI3K and Akt [139].

While cell survival signaling induced by matrix binding to receptors like integrins and CD44 is necessary but not sufficient to induce proliferation, integrin signaling can promote cell proliferation either alone or in conjunction with growth factor signaling. Integrin-induced activation of the Rac/JNK pathway can induce cell proliferation by stimulating expression of cyclin D and by promoting the degradation of p21, a cell cycle inhibitor [140]. In fibroblasts, FAK/Src signaling induces Rac activation downstream of p130CAS, which then promotes cell survival and proliferation via the JNK pathway [117]. ERK1/2, which are, like JNK, MAP kinases, can be activated by integrin ligation. However, when activating ERK1/2, integrin ligation activates the Src kinase Fyn, which binds the Shc adaptor protein, leading to the recruitment of Grb2/Sos and downstream activation of the Ras/ERK pathway [136]. This ultimately induces phosphorylation of the transcription factor Elk-1, which then activates genes important in cell cycle progression [136,141].

Beyond the direct impact of integrin signaling on cell proliferation, integrins can facilitate cell survival and proliferation in conjunction with growth factors, their receptors, and their associated signaling [14]. Matrix molecules and matrix receptors can directly interact with growth factors to affect downstream signaling. Fibronectin and collagen both interact with VEGF. Binding of VEGF to fibronectin increases VEGFR activation and endothelial cell proliferation, whereas binding to collagen activates a phosphatase and thus decreases VEGFR activity [98]. HSPG can interact with many growth factors, including FGF and VEGF, limiting their diffusion, sequestering them until enzyme-mediated release, or promoting their receptor binding [50]. FGF and VEGF binding to HSPG promote their interactions with their respective receptors and activate mitogenic signaling [8]. Matrix molecules can also bind growth factor receptors and activate them directly, as in the binding and activation of the EGFR by the EGF-like domains of laminin and tenascin-C, which may promote cell proliferation [133]. In contrast, decorin binding to the EGFR promotes EGFR internalization and thus inhibits mitogenic signaling downstream of this receptor [11].

Integrins may interact directly with growth factors and/or their receptors to regulate downstream signaling. Multiple VEGF isoforms bind and activate integrin $\alpha_9\beta_1$, which, along with VEGFR2, is necessary for VEGF-induced paxillin and Erk phosphorylation and angiogenesis [18]. Similarly, integrin $\alpha_V\beta_3$ interacts with both IGF-1 and FGF2 and is required for proliferation induced by both growth factors [136]. Integrins can also interact with growth factor receptors to regulate downstream signaling, as suggested by data showing that cell–ECM interactions are critical for the efficient and prolonged activation of MAP kinases by growth factors, likely participating in MAPK-induced proliferation [142]. Indeed, several growth factor receptors interact with integrins, including VEGFR2 and EGFR, and integrin-mediated adhesion can regulate growth factor-induced proliferation [136]. Angiogenesis induced by the growth factors FGF2 and VEGF requires the presence and activation of integrin $\alpha_V\beta_3$ and, in the case of VEGF, integrin $\alpha_V\beta_5$ [14]. Integrin signaling and FAK are necessary for activation of Erk1/2 by both FGF2 and VEGF, though Erk1/2 activation by FGF2/$\alpha_v\beta_3$ is dependent upon Pak-1-induced Raf phosphorylation but not Ras, while Erk1/2 activation by VEGF/$\alpha_v\beta_5$ requires Ras [143]. As it induces cell proliferation, FGF2-induced Pak-1 also inhibits apoptosis and thereby increases cell survival through its downstream regulation of apoptosis signal-regulating kinase 1 [14]. Once growth factor signaling is initiated, this signaling can, in turn, activate associated integrins and promote matrix adhesion. For example, VEGFR2 signaling induces phosphorylation of integrin β_3, leading to activation of FAK and p38 as well as VEGFR2-integrin binding and enhanced VEGFR2 signaling [98].

Interactions among growth factors, matrix molecules, and their receptors are not limited to integrins, however. Activation of several nonintegrin matrix receptors, including the ERC, CD44, TLRs, and discoidin domain receptors, are associated with cell survival and proliferation. Activation of the ERC by elastin fragments induces smooth muscle cell proliferation through activation of the MAPK cascade [144]. However, signaling through the ERC can inhibit proliferative signaling if the ERC neuraminidase subunit desialylates growth factor receptors, which interferes with ligand binding and downstream signaling [145]. These different effects of the ERC on cell proliferation, coupled with the ability of elastin-derived peptides to bind integrins $\alpha_v\beta_3$ and $\alpha_v\beta_5$ as well as the ERC, complicates our understanding of elastin-derived peptides on cell proliferation [25]. Hyaluronan, which, like the ERC, binds multiple receptors, leads to Erk activation and endothelial cell proliferation through CD44, though high molecular weight hyaluronan more commonly inhibits cell division [23,132]. Low molecular weight hyaluronan fragments can activate CD44, inducing Erk activation, cyclin expression, and smooth muscle cell proliferation, although these hyaluronan fragments can also induce epithelial cell survival downstream of TLRs-induced NFκB [23,146]. Another nonintegrin receptor, DDR2, is important in cell proliferation, as $DDR2^{-/-}$ fibroblasts and chondrocytes proliferate less than wild-type fibroblasts, which could be explained, at least in part, by the ability of DDR2 to induce fibroblast survival through activation of the PDK1/Akt pathway [33,112]. Taken together, these examples suggest roles for nonintegrin matrix receptors in cell survival and proliferation, though the associated signaling pathways are not completely defined.

Like cell survival and proliferation, differentiation of many cell types, including keratinocytes, endothelial cells, and fibroblasts, is regulated by cell interactions with ECM molecules, hormones, and growth factors. For example, hyaluronan induces keratinocyte differentiation in vitro in a CD44-dependent manner, and CD44 deficiency inhibits keratinocyte differentiation in vivo, suggesting a role for epidermal hyaluronan in this process [147]. Complicating the picture of hyaluronan function in this differentiation process, hyaluronidase treatment increases the rate of keratinocyte differentiation, potentially due to the low molecular weight hyaluronan generated by hyaluronidase treatment, which has different receptor-binding properties than intact, high molecular weight hyaluronan [148]. Binding to components of the basement membrane negatively regulates keratinocyte differentiation in the basal layer of the epidermis, likely due, at least in part, to fibronectin interactions with the β_1 integrins also needed to repress differentiation [70,71].

During angiogenesis, endothelial cells undergo a differentiation process to generate the mature vasculature. Although in vitro models of this complex process are incomplete, they provide clues regarding the ability of the matrix to regulate this process. One early model involved the growth of endothelial cells on a basement membrane-like matrix mixture, Matrigel, which then formed capillary-like tubes, suggesting that one or more of the matrix molecules in this mixture could induce differentiation [47]. As mentioned before, laminins are present in large amount both in Matrigel and in basement membranes of blood vessels in vivo, though laminin-111 predominates in Matrigel and laminin-411 in basement membranes [149]. Whereas the binding of fibronectin to integrin $\alpha_5\beta_1$ in endothelial cells leads to cell proliferation, laminin binding to integrin $\alpha_2\beta_1$ in these cells promotes the formation of capillary-like structures, underscoring the importance of laminin-mediated adhesions in the formation of these structures in vitro [48,136]. Downstream molecules needed to generate the capillary-like tubes include integrin-linked kinase (ILK), which, when overexpressed, rescues capillary-like tube formation in the absence of ECM molecules, while expression of a dominant negative version of ILK blocks tube formation even when ECM and VEGF are present

[150,151]. More recent experiments found that ILK is necessary for the development of capillary-like structures in embryoid bodies derived from $ILK^{-/-}$ embryonic stem cells, further implicating ILK in this process [152]. Once nascent vessels are formed, contractile smooth muscle cells called pericytes are recruited to stabilize the endothelium and promote synthesis of the basement membrane [93]. Pericyte differentiation relies upon growth factors, including TGFβ and PDGF-BB, in conjunction with cell−matrix interactions. Some of these required matrix interactions are needed to activate TGFβ from its latent form, as described before [63]. However, pericytes in a mural cell-specific integrin β_1 knockout exhibited impaired differentiation, resulting in defective vessel stabilization and maturation [153]. Because various integrins are important for TGFβ activation, the role of integrin-mediated matrix adhesion in pericyte differentiation remains unclear.

Like pericytes, myofibroblasts are contractile cells differentiating from precursor cells, in this case, fibroblasts, in response to TGFβ signaling. TGFβ-induced myofibroblast differentiation requires activation of TGFβ from its latent form, adhesion of cells to the EDA domain of fibronectin, and the presence of mechanical tension, which may facilitate activation of TGFβ and/or reveal cryptic sites in matrix molecules to promote receptor binding [93,108]. The specific integrins involved in TGFβ activation include integrins $\alpha_v\beta_5$, $\alpha_v\beta_6$, and β_1 subunit-containing integrins [154,155]. Integrin $\alpha_4\beta_7$ may also participate in the differentiation process by binding to the EDA domain of fibronectin, leading to downstream activation of FAK, PI3K, and associated signaling pathways [6]. FAK may also be activated by mechanotransduction from matrices under tension, which is also important in myofibroblast differentiation [6,106]. Evidence demonstrating the need for ILK and Akt in TGFβ-induced myofibroblast differentiation further suggests a role for signaling downstream of integrin activation in this process [156]. Interestingly, a nonintegrin, EDA fibronectin-binding receptor may also facilitate myofibroblast differentiation, as TGFβ-induced myofibroblast differentiation in vitro requires the TLR TLR4 [157].

Type III interactions primarily involve processes leading to apoptosis (Fig. 6.2C). Typically, cell−matrix adhesions promote cell survival, whereas normally adherent cells that fail to interact with matrix molecules undergo anoikis, a form of cell death. Anoikis results from a lack of prosurvival FAK/Src-induced PI3K/Akt or Erk signaling, coupled with proapoptotic signaling that inhibits antiapoptotic Bcl family members, increases expression/activity of proapoptotic Bcl family members, and recruits and activates caspases [158]. Therefore inhibition of these prosurvival, antiapoptotic signaling pathways downstream of cell deadhesion leads to apoptosis. This does not, however, explain why the presence of unligated integrins can promote apoptosis even when other integrins adhere to their matrix ligands. Interestingly, these unligated integrins recruit procaspase-8, which subsequently becomes activated to generate caspase 8 and thereby promotes apoptosis [159]. Caspase 3 activated downstream of caspase 8 may also inhibit prosurvival signaling from integrins that are attached to matrix by cleaving kindlin-3 and paxillin [127,160].

Alterations in the ligand presentation by ECM can also regulate apoptosis. Integrin ligation by soluble, rather than intact, ligands can function as integrin antagonists and promote apoptosis rather than survival or proliferation [53]. Many of these soluble ligands can be created by matrix degradation during tissue remodeling. For example, endostatin, derived from collagen XVIII, as well as tumstatin, canstatin, and arresten, derived from collagen IV, all inhibit angiogenesis by promoting, among other things, endothelial cell apoptosis [78]. Endostatin binding to integrin $\alpha_5\beta_1$ decreases expression of prosurvival Bcl family members, leading to apoptosis via the intrinsic pathway [161]. Tumstatin induces endothelial cell apoptosis via integrin $\alpha_v\beta_3$, interfering with its ability to bind matrix-associated VEGF and inhibiting prosurvival FAK and PI3K/Akt signaling [162]. Similarly, arresten and canstatin, also fragments of collagen IV, bind integrins $\alpha_1\beta_1$ and $\alpha_V\beta_5$/$\alpha_V\beta_3$, respectively. In doing so, they inhibit prosurvival signaling downstream of FAK, decreasing levels of prosurvival Bcl family members (arresten) and inhibiting PI3K/Akt (canstatin) [162]. Furthermore, both arresten and canstatin activate caspases by increasing expression of Fas ligand, which activates the extrinsic apoptotic pathway [162]. Matrix fragments can promote apoptosis through nonintegrin receptors. For example, elastin fragments promote apoptosis in some cell types, likely through the ERC [25]. The proapoptotic activity of many matrix fragments suggests that these fragments disrupt normal prosurvival signaling through intact matrix molecule activation of their receptors.

While most intact matrix molecules promote prosurvival, antiapoptotic signaling, integrins that interact with specific ligands can still promote apoptosis in some cases. For example, the matricellular protein CCN1 binding to syndecan-4 and integrin $\alpha_6\beta_1$ induces expression of Bax, which promotes cytochrome C release from the mitochondria and subsequent caspase 9 activation, leading to fibroblast apoptosis [163]. In endothelial cells, thrombospondin interaction with CD36 leads to the activation of the Src kinase Fyn, inducing downstream activation of caspases 8 and 9, the former through increased expression of death domain receptors and their ligands [164]. As such, matrix fragments and specific matrix molecules may cooperate to induce apoptosis.

Relevance for tissue engineering

Designing tissue and organ replacements that closely simulate normal physiology is a challenging endeavor. One avenue to achieve this goal is to study how tissues and organs arise during embryogenesis and during normal processes of repair, and how those functions are maintained. When developing tissue replacements, one needs to consider how to avoid a strong immune response, provide the appropriate substrate for cell survival and differentiation, and provide the microenvironment needed to promote regeneration and tissue maintenance. Each of these considerations is discussed in more detail later.

Avoiding a strong immune response that can cause chronic inflammation and/or rejection

One way to avoid an immune response would involve using autologous cells, though it is time-consuming and labor-intensive to collect and expand autologous cells for use in engineered tissues, decreasing the practicality of this approach. Using autologous cells may also be detrimental in preparing engineered tissues if these cells rarely or never divide. In the case of nondividing or terminally differentiated cells, it may be beneficial to instead transplant stem cells, such as adult stem cells or induced pluripotent stem cells (iPSC) capable of differentiating into the needed cell type(s), or transplant cells differentiated from stem cells [165]. Adult stem cells, such as mesenchymal stem cells (MSC), generally do not induce an immune response after transplantation. Although they are limited in the types of cells that they can become, these cells can promote tissue repair and regeneration [166]. Unlike adult stem cells, iPSC can differentiate into every cell type and can be modified using gene editing techniques to correct any mutations that might be present in these cells [167]. Because iPSC are derived from the patient's own cells, they should not induce immune responses, at least in theory [165]. However, transplanted iPSCs and cells differentiated from them have induced immune responses, the mechanisms involved in responses against autologous cells remain unclear, and may depend upon their ex vivo manipulations prior to transplant [167]. Other drawbacks to the use of iPSC include the time-consuming nature of their preparation and subsequent differentiation and the risk of tumorigenesis from implanting undifferentiated cells [165]. Another potential strategy that avoids using cells altogether would involve the inclusion of exosomes derived from adult stem cells, such as MSC, in the engineered tissue. Exosomes are extracellular vesicles that can contain mRNA coding for specific proteins and/or the proteins themselves, including matrix-remodeling enzymes such as MMPs and ADAMs, matrix receptors such as CD44, and molecules involved in signal transduction, which can modify the matrix and matrix-mediated signaling events to alter gene expression in nearby cells [168]. Because one of the chief benefits of MSC is thought to involve their ability to modify the microenvironment, many of the benefits of MSC could be provided by MSC-derived exosomes [169]. However, exosomes still contain MHC molecules, making allogeneic exosomes susceptible to immune rejection, giving them some of the same limitations as allogeneic cells [170].

Creating the proper substrate for cell survival and differentiation

Cells transplanted directly into an injured tissue are insufficient to promote tissue regeneration, because cells need to interact with supportive ECM molecules and growth factors to survive and carry out their intended functions after transplantation [171]. To provide this supportive matrix in an engineered tissue, expanded adult cells, adult stem cells, iPSC, or heterologous cells in conjunction with immunosuppressant drugs are seeded within biocompatible implants composed of ECM molecules. Addition of growth and differentiation factors to these matrices as well as agonists or antagonists that favor cell–ECM interactions may increase the rate of successful tissue replacement. However, growth factor activity in the engineered tissue is dependent upon its stability and ability to diffuse both within the engineered tissue and in peripheral host tissue. For example, many growth factors have short half-lives in normal tissues, so it is important to increase their stability and activity to prolong their function in engineered tissues [169]. Preventing a specific type of VEGF proteolysis can increase its half-life and activity, which could be particularly important in treatment of chronic wounds, whose excessive protease levels would otherwise cleave wild-type VEGF and limit its activity. Indeed, in a mouse model of impaired healing, VEGF lacking specific proteolytic sites promoted VEGF duration and activity, leading to improved angiogenesis and healing [172]. Some of the methods used to increase the duration and activity of growth factors involve adding components of the normal ECM that stabilize these factors and/or promote their activity to the engineered tissue, covalently coupling the growth factors to a matrix molecule or biomaterial, or generating growth factors more resistant to proteolytic digestion [171]. In the case of VEGF, covalent linkage to a fibrin matrix or addition of heparin, fibronectin, and/or fibronectin fragments to the matrix promotes angiogenesis to a greater extent than addition of VEGF alone [171,173]. In addition to restricting VEGF diffusion, heparin and fibronectin fragments likely promote VEGF binding and activation of VEGFR2 [50]. In the case of fibronectin, this matrix molecule binds both VEGF and integrin $\alpha_5\beta_1$ to facilitate VEGF-induced

angiogenesis [98,100]. Based upon this example of VEGF and angiogenesis, it is clear that inclusion of matrix molecules and/or matrix fragments to an engineered tissue can promote growth factor retention and signaling in the tissue itself.

Perhaps one of the most effective substrates to use for engineering a specific tissue would be the mixture of matrix components in an acellular version of that tissue, the dermis, or tendon tissue with the cells removed, for example. Removal of the cells would decrease the likelihood of an immune response against the tissue while preserving the unique anatomy and collection of adhesive molecules that promote cell survival, proliferation, and differentiation within that tissue [174]. These acellular matrices could either provide support for endogenous cells moving into the tissue or for cells seeded within this acellular matrix. There is a limited supply of human tissues for transplant, largely from cadavers, but decellularized matrices from pigs and cows have also been used in wound therapy with positive outcomes [174]. Beyond acellular matrices, there are a number of naturally occurring matrix molecules and polysaccharides that have been used in the generation of engineered tissues. For example, fibrin, collagen, gelatin (denatured gelatin), and hyaluronan all have binding sites for multiple cell adhesion receptors that can promote cell survival, proliferation, and migration to cells within the engineered tissue and those that are recruited to the tissue [174]. These matrices can be combined with or linked to growth factors to regulate growth factor release over time. For example, growth factors placed within fibrin hydrogels can be released by fibrin proteolysis to allow growth factor delivery over time [175]. In another example, heparin-modified hyaluronan allows growth factor attachment to the associated heparin molecules, which could facilitate receptor binding and downstream signaling of some growth factors (e.g., VEGF), while retaining and sequestering other growth factors to prevent receptor binding until proteolytic release from heparin (e.g., HB-EGF) [9,176].

While the foregoing examples show that ECM molecules can be used successfully in tissue engineering, the use of natural ECM molecules and decellularized matrices in engineered tissue have several disadvantages, including the possibility of generating an immune response, variability, possible contamination, and ease of degradation [177]. Degradation of matrix molecules can alter their receptor binding, adhesive function, and downstream signaling. For example, binding of soluble, rather than intact, matrix molecule to integrins can promote apoptosis rather than cell survival, and low molecular weight fragments of hyaluronan bind to TLRs and induce inflammation [21,23,53,78,161]. Generally speaking, apoptosis and inflammation are not optimal for the success of an engineered tissue.

Likewise, artificial biocompatible materials have drawbacks in that, unlike ECM molecules, they are generally incapable of transmitting growth and differentiation cues to cells. Much attention is now devoted to the design of "semisynthetic biomaterials" in which functional regions of ECM molecules, including those that interact with receptors or growth factors or those that are cleaved by proteases, are incorporated into artificial biomaterials to impart additional functionality [171]. The inclusion of ECM-like cell-binding sites that promote cell adhesion, growth, and/or differentiation into such biomaterials may be critical in developing and maintaining functional engineered tissues by providing the appropriate cellular microenvironment. For example, because many integrins bind to the RGD motif on matrix molecules, RGD peptides can be used to make synthetic implants more biocompatible and to allow the development of tissue structure, or as antagonists to prevent or moderate unwanted cell−ECM interactions [171]. Similarly, collagen, fibrin, and vitronectin have been used to coat synthetic biomaterials to increase their biocompatibility and promote successful biological interactions [165,175,178]. However, the use of these biomaterials in engineered tissues requires additional knowledge regarding the types of cell−ECM interactions that result in the desired cellular effects within the context of the tissue of interest.

Providing the appropriate environmental conditions for tissue maintenance

To maintain tissue homeostasis, it is crucial to create a balanced environment with the appropriate cues for preservation of specific cell function(s). It is important to realize that such stasis on the level of a tissue is achieved via tissue remodeling—the dynamic equilibrium between cells and their environment. The same ECM molecule may have multiple cellular effects whose cellular outcome likely depends upon the combination of variables, such as the domain of the molecule involved in the cellular interactions, the receptor used for these interactions, and the cellular microenvironment. These variables can, in turn, be influenced by matrix remodeling, as enzymatic degradation of the ECM can release functional fragments of ECM that then alter cell−ECM interactions by removing certain binding sites while exposing others. Another important consideration is the role of mechanical tension on matrix signaling, and, depending upon the desired effect, it may be necessary to control the stiffness and pore size of the biomaterial. Hyaluronan and collagen hydrogels can be "tunable" in terms of stiffness and pore size, depending upon the concentrations of molecule, polymerization conditions, and chemical cross-linking [171,179]. One biocompatible material that is "tunable"

in terms of stiffness and pore size is starPEG, which can use heparin as a functional cross-linker. Altering the concentration or molecular weight of the starPEG changes its stiffness and pore size and can thus change the mechanical tension exerted on cells, while the use of heparin as a cross-linker yields additional functionality due to its ability to bind growth factors and enhance their signaling [171]. Combinations of this hybrid biomaterial with RGD and growth factors increased endothelial cell survival and tube formation, suggesting the potential of this approach in designing engineered tissues [180]. Interestingly, the heparin of starPEG is also able to sequester chemokines and reduce inflammation and promote healing in db/db mice, which could be particularly useful when engineering tissues for use in environments that need to reduce inflammation and promote regeneration and repair [181].

Because organ transplantation is one of the least cost-effective therapies and is not always available, tissue engineering offers hope for more consistent and rapid treatment of those in need of body part replacement, and therefore has greater potential to improve patient quality of life. The selected examples presented before illustrate that further advances in tissue engineering require additional knowledge of the basic mechanisms of cell function and of the ways they interact with the environment. The recent surge in research on ECM molecules themselves and their interactions with particular cells and cell-surface receptors has led to realization that these interactions are many and complex, allow the modulation of fundamental events during development and wound repair, and are crucial for the maintenance of the differentiated phenotype and tissue homeostasis. As such, the manipulation of specific cell–ECM interactions has the potential to modulate particular cellular functions and processes in order to maximize the effectiveness of engineered tissues.

Introduction

Tissue development and homeostasis requires cell−cell and cell−extracellular matrix (ECM) interactions. The ECM is not merely a structural scaffold for cell attachment but also directly presents biochemical and mechanical cues to cells and sequesters growth factors and other soluble cytokines to regulate cell signaling. Mechanical and biochemical cues elicited by the ECM permit the coordinated modulation of a wide spectrum of biological processes.

The broad array of ECM functions can be attributed to the extensive diversity of its constituent matrix molecules and their organizational complexity. For example, the three major ECM molecular categories, including collagens and elastic fibers, glycoproteins, and proteoglycans/glycosaminoglycans, are comprised of macromolecules that contain a plethora of structural motifs that are posttranslationally modified to dictate their function. The multidomain nature of ECM proteins plays a key role in their ability to incorporate many disparate biological activities within a single protein. ECM proteins are comprised of multiple domains, with complex posttranslational modifications that regulate their size and function. Moreover, ECM proteins are assembled as multicomponent polymers, and these multiprotein polymers also interact with other matrix proteins to generate an extensive interconnected, highly organized, insoluble protein network within tissues [1].

The ECM has been subcategorized as basement membrane and interstitial matrix based upon its geographical region within the tissue. The basement membrane is the thin ECM structure that separates epi-, meso-, and endothelial cell layers that anchors these cell layers to the underlying connective tissue. For example, basement membrane encases the endothelium of blood vessels and surrounds the epithelium of ductal tissues. The interstitial matrix fills the interstitial space between cells and is highly variable between tissue types.

Specialized tissue-resident cells orchestrate ECM assembly through the synthesis, secretion, organization, posttranslational glycosylation and cross-linking, and enzymatic degradation of ECM proteins and glycosaminoglycans (GAGs). Many ECM proteins require posttranslational proteolytic processing or chemical modification following their synthesis and/or secretion into the extracellular space prior to their incorporation into either the basement membrane or interstitial ECM. These modifications are critical for regulating matrix architecture, including fiber thickness and alignment, porosity, and hydration, and exert profound effects on the phenotype of the cellular constituents within the tissue. The relative abundance of different ECM components in combination with extracellular processing controls the phenotype of the resultant ECM. Accordingly, the biochemical and mechanical properties of the ECM are intimately linked. ECM synthesis and posttranslational modifications and assembly are tightly regulated processes. In this way, each tissue type is able to finely tune their ECM to match their differentiation and function and to orchestrate changes in the ECM that are necessary to maintain tissue homeostasis.

Not surprisingly, the complexity of native ECM has proven difficult to recapitulate in vitro. ECM components reconstituted into hydrogels do not possess all the properties and intricacies of the cell-generated in vivo matrix [2]. Clarifying the molecular intricacy of ECM assembly and structure/function are needed to provide critical insight to inform design principles for improved tissue engineering.

Collagens

Collagens are key ECM constituents in most mammalian tissues. As such, they are the most abundant proteins in mammals, making up nearly 30% of total protein mass [3]. There are at least 44 distinct α chains in humans that assemble into 28 recognized types of collagen, which gives rise to significant diversity within the collagen superfamily (Table 7.1). Collagen molecules exist as homo- or heterotrimers of three type-specific collagen α chains. The repeating amino acid sequence Gly-X-Y (X and Y can be any amino acid, but Y is often proline) in a

[a]*COL6A5 has also been designated COL29A1.*

portion of each α chain enables folding of a tight, right-handed triple helix domain, the signature structural motif of the collagens. Additional domains within the collagen molecule determine the different supramolecular assemblies formed after secretion into the extracellular space, which are used to classify collagens into the subfamilies discussed later [3].

Fibrillar collagens

Collagens that assemble to form long, rod-like bundles called fibrils are classified as the fibrillar collagens. Fibrillar collagens account for a large majority of the collagen content in humans and are comprised of collagen I, II, III, V, XI, XXIV, and XXVII, with collagens I–III as the most common [4]. Most collagen fibrils are heterotypic, containing multiple types of collagen within a single fibril. For example, collagen fibrils in the skin are often composed of collagen I and III, and cartilage is typically collagen II/IX/XI or collagen II/III. Collagen fibrils typically contain one long triple helical region and assemble into a fibrillar suprastructure that enables them to provide structural support to tissues and bear large tensile loads. Due to their mechanical strength, collagen fibrils are typically found in stromal ECM and connective tissue such as skin, tendons, ligaments, and bone.

Fibrillar collagen biosynthesis has been the most extensively studied and is illustrated in Fig. 7.1. Fibrillar collagen α chains are synthesized in the endoplasmic reticulum as pro-α chains, with long propeptide regions on either side of the triple helical domain. Prior to triple helix formation, the α chains can undergo extensive post-translational modifications, including proline and lysine hydroxylation, lysine and hydroxylysine glycosylation, and tyrosine sulfation [3,5]. Proline hydroxylation by prolyl hydroxylases is particularly critical for the stability of the ensuing triple helix. Associations between pro-α chains begin with disulfide bonding among their C-terminal propeptides and initiate the formation of the triple helix near the C-terminus [6,7]. Triple helix formation then propagates toward the N-terminus like a zipper forming a procollagen molecule. Formation of the complete triple helix quenches further posttranslational modification of the triple helical region. The procollagen molecule is shuttled to the Golgi, where it is packaged for secretion into the extracellular space.

Following their extracellular secretion, extracellular BMP1/tolloid-like proteinases and ADAMTS (a disintegrin and metalloproteinase with thrombospondin motifs) family proteinases cleave the C- and N-terminal propeptides, respectively, yielding a mature collagen molecule. Mature collagen molecules undergo entropy-driven self-assembly into small microfibrils of about 20 nm diameter and 4–12 μm in length. The collagen molecules pack together in a longitudinally staggered pattern that forms areas of high and low packing density. This causes the characteristic 67 nm periodic banding pattern observed in collagen fibrils. Immature microfibrils associate with each other and are organized into very long mature collagen fibrils that can be 20–500 nm in length [8].

The axial and radial growth of fibrils is controlled by several different molecules. Collagens V and XI play a

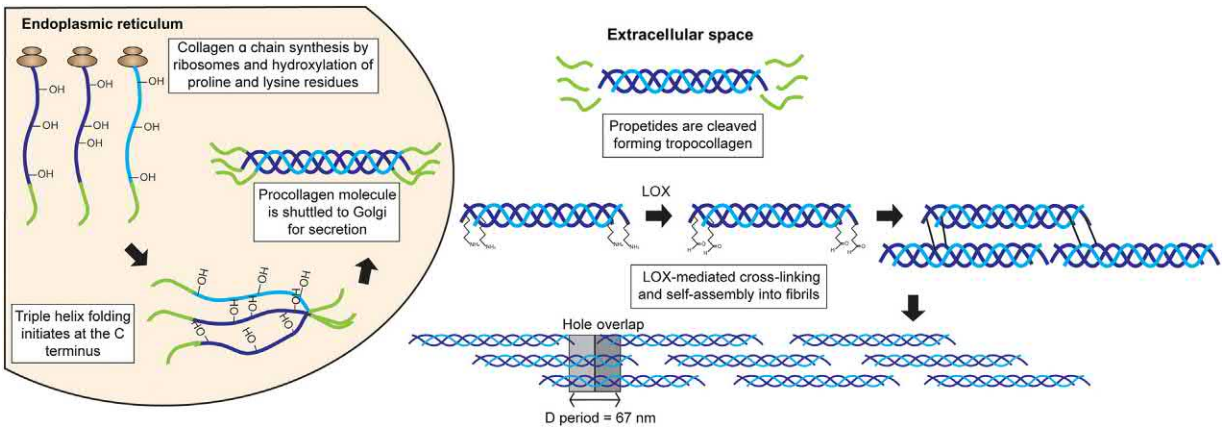

FIGURE 7.1 Collagen synthesis and fibrillogenesis.
Collagen α chains are synthesized by ribosomes and are modified by prolyl and lysyl hydroxylases in the endoplasmic reticulum. Proline hydroxylation within the helical region is required for helix stability. Lysine hydroxylation in the telopeptide region by lysyl hydroxylase 2b influences the structure of future LOX-mediated cross-links. Three α chains (depicted are the two α1 chains and one α2 chain of collagen I) associate near the C-terminus and triple helix folding propagates toward the N-terminus. The resulting procollagen molecule is transported to the Golgi and secreted into the extracellular space, where the C- and N-terminal propeptides are enzymatically cleaved. Collagen molecules self-assemble into microfibrils during which LOX catalyzes the formation of reactive aldehydes in telopeptide lysine and hydroxylysine residues that spontaneously react to form intermolecular cross-links. The packing pattern of collagen molecules within a microfibril yields its characteristic banding pattern that can be visualized by electron microscopy or atomic force microscopy. *LOX*, Lysyl oxidase.

key regulatory role in fibril assembly. Much of the N-terminal propeptide remains uncleaved in these two collagen types, which may sterically hinder incorporation of additional collagen molecules. Thus fibril size is related to the ratio of the major fibril component (type I or II) to the minor component (type V or XI), with a high V/XI content yielding thinner fibril bundles and a low V/XI content yielding thick fibrils [9]. Healthy collagen I fibrils in skin, tendon, ligaments, and bone contain 5%–10% collagen V, and collagen II fibrils in cartilage contain 5%–10% collagen XI. In addition to collagens V and XI, in vivo manipulations have revealed that collagen-binding small leucine-rich repeat proteoglycans (SLRPs) such as biglycan, decorin, lumican, and fibromodulin facilitate both fibril elongation and lateral association with other growing collagen fibrils [8]. The FACIT (fibril-associated collagens with interrupted triple helices) family of collagens also plays a critical role in fibrillar collagen structure and is discussed extensively later.

In the final step of collagen maturation, fibrils undergo varying degrees of enzymatic and nonenzymatic covalent cross-linking. The mechanical properties of fibrillar collagens are highly dependent on these modifications. The lysyl oxidase (LOX) family enzymes catalyze the oxidative deamination of peptidyl lysine and hydroxylysine residues in the telopeptide region adjacent to the triple helix in the collagen molecule. The aldehyde produced by this reaction spontaneously reacts with another LOX-derived aldehyde or with the amine group in helical lysine or hydroxylysine residues to form intra- and intermolecular cross-links. These initial divalent cross-links can mature further into multivalent cross-links through the incorporation of additional amino acids [10]. The hydroxylation of telopeptide lysines by lysyl hydroxylase 2 during collagen synthesis in the endoplasmic reticulum gives rise to cross-linking maturation products with distinct mechanical properties and are enriched in bone, ligaments, tendons, and pathologically fibrotic tissues [10,11]. Collagen in softer connective tissues such as skin or cornea contains lower levels of hydroxylated telopeptide lysine residues and therefore contains a much different profile of mature collagen cross-links. Tissues finely tune the quantity and quality of LOX-mediated collagen cross-links to meet their structural needs. Although many of the cross-linking maturation products have been identified, the precise mechanisms by which they all form and are regulated are not fully understood. Recent advances in mass spectrometry methods have allowed quantification of specific LOX-mediated cross-linking products in tissues to understand their role in tissue structure and in the progression of fibrotic disease [12,13]. LOX activity has traditionally been difficult to assay in situ because the posttranslational modifications and copper cofactor required for catalysis decouple extracellular LOX levels from its enzymatic activity. A novel imaging approach seeks to overcome this challenge using gadolinium-based sensors that detect the oxidized lysine residues in collagen that form after LOX modification [14]. This is a promising approach to noninvasively monitor the progression of fibrotic diseases and therapeutic response.

Collagen cross-linking can also be mediated via transglutaminase 2, which links collagen and fibronectin, as well as by advanced glycation end products, which are generated spontaneously as the collagen ages in tissue.

Fibril-associated collagens with interrupted triple helices (FACIT)

Collagens type IX, XII, XIV, XVI, XIX, XX, XXI, and XXII comprise the FACIT subfamily. As their name implies, these collagens contain at least two triple helical domains and associate with the surface of collagen fibrils, despite not forming fibrils themselves. Many FACIT collagens also share homologous domains with other noncollagenous ECM proteins such as fibronectin, thrombospondin-1, and von Willebrand factor. The FACIT subfamily is a more heterogenous and structurally complex group of collagens relative to the fibrillar collagens, which may be due to their roles in facilitating interactions between specific fibril types and unique tissue environments [15].

Collagen IX is the best characterized FACIT collagen and is found covalently bound to collagen II fibrils in cartilage. Collagen IX links collagen fibrils to other collagen fibrils, and collagen fibrils to ECM components, as well as collagen fibrils to cells [16]. Consistent with these functions, mutations in any of the three collagen IX α chains cause multiple epiphyseal dysplasia, a rare disorder characterized by defects in cartilage mineralization at the ends of growing bones. Compromised cartilage mineralization leads to early onset osteoarthritis and short stature and limbs.

Collagens XII and XIV are both homotrimers and associate with collagen I fibrils in connective tissues. Collagen XII helps to organize and stabilize type I collagen fibrils to maintain muscle and bone integrity. One of collagen XII's noncollagenous domains (NC3) interacts with other matrix proteins including decorin, fibromodulin, and tenascin. The NC3 domain of collagen XII can be alternatively spliced to form a smaller, minor isoform, collagen XIIb, which lacks this binding activity and resembles collagen XIV. Type XII collagen levels are elevated in fibrosis and in the desmoplastic stroma of some tumors, implying that collagen XII facilitates the aberrant organization of the interstitial ECM observed in these conditions [17,18]. However, a mechanistic understanding of these observations is not known and is an active area

of investigation. Collagen XIV regulates radial fibril growth and the integration of fibrils into fibers in collagen-dense structural tissues such as tendon [19]. It is found in skin, tendon, cornea, and articular cartilage, particularly in the area of high mechanical stress, which suggests a role for collagen XIV in regulating fibril mechanical properties [20]. Consistently, the skin of mice bearing a *Col14a1* knockout is mechanically inferior and has reduced maximum tensile loading. Developing tendons in *Col14a1*-null mice also displayed disrupted fibrillar architecture and defects in load bearing, which were not observed in mature *Col14a1*-null tendons [19]. This suggests a temporal and tissue-specific role of type XIV collagen in fibrillogenesis.

The remaining FACIT collagens have not been as well characterized. Most are tissue-restricted and are believed to play similar roles related to organizing fibrillar collagen structures and as substrates for cell adhesion [21]. A small subset such as collagen XXII can also localize in basement membrane [22].

Basement membrane–associated collagens

Collagen IV is the major collagenous component of basement membranes. Six individual genes code for collagen IV α chains, producing at least three distinct, tissue-specific heterotrimeric collagen IV molecules [23]. The trimeric molecules contain three domains: an N-terminal 7S domain, the triple helical domain, and a C-terminal NC1 domain. Four molecules come together and associate via their 7S domains, and the NC1 domain at the opposite end binds the NC1 domain of another molecular in a collagen IV tetramer [24]. Continuous NC1 end-to-end linking of tetramers along with lateral associations of molecules via their triple helical domains form the collagen IV network suprastructure [25].

Other network-forming collagens include the short-chain collagens VIII and X. These molecules share a high degree of sequence homology and form hexagonal networks. Collagen X is produced by hypertrophic chondrocytes and can only be found within the hypertrophic zone of the epiphyseal growth plate cartilage. On the other hand, collagen VIII can be found in the endothelial basement membranes of several tissues [26]. Collagen VIII is a major component in the Descemet membrane in the cornea, and mutations can cause corneal clouding [27,28]. Furthermore, collagen VIII has been shown to participate in angiogenesis, tissue remodeling, and fibrosis, and may also play a role in stabilizing atherosclerotic plaques [29].

Other collagens

Collagen VII forms anchoring fibrils that are critical for linking basement membrane to the interstitial matrix. Two collagen VII molecules join together near their C-terminal to form a U-shaped dimer, which then traps interstitial fibrillar collagens I, III, and V. The NC1 domains at the N-terminals of each molecule bind basement membrane proteins collagen IV, laminin-332, and laminin-311 with high affinity, thus stabilizing the interstitial matrix with the basement membrane [30]. Mutations in COL7A1 lead to dystrophic epidermolysis bullosa, a disorder causing blistering and scarring of the skin [31]. Circulating autoantibodies to collagen VII are also known to cause a form of epidermolysis bullosa in addition to being linked with inflammatory bowel disease and Crohn's disease [32,33].

The MACIT (membrane-associated collagens with interrupted triple helices) collagens are a subfamily of transmembrane collagens (XIII, XVII, XXIII, and XXV) that anchor cells to the basement membrane. Collagen XVII is found in hemidesmosomes and is important for epithelial adhesion to the basement membrane, particularly in areas of high mechanical stress [34].

Collagens XV and XVIII constitute the multiplexins (*multiple* triple heli*x* domains and *in*terruptions), which are a subfamily of basement membrane–associated collagens. Both of these collagens share structural homology and are proteoglycans. Collagen XV contains a variable glycosaminoglycan side chain comprised mostly of chondroitin sulfate, whereas collagen XVIII contains several heparan sulfate side chains. Mutations in collagen XVIII cause Knobloch syndrome, which leads to degeneration of the retina and vitreous, causing extreme nearsightedness and often, blindness [35]. Proteolytic cleavage of collagen XVIII can release a protein fragment called endostatin, an antiangiogenic heparin-binding peptide. Endostatin inhibits angiogenesis by reducing migration and proliferation of vascular endothelial cells [35–37]. A number of other collagenous and noncollagenous ECM proteins have since been shown to release bioactive fragments upon enzymatic cleavage, some of which are also antiangiogenic. These fragments are collectively known as matricryptins.

Major adhesive glycoproteins

Fibronectin

The glycoprotein fibronectin is a prominent and ubiquitous ECM constituent that plays a critical role in cell adhesion, migration, proliferation, and differentiation [38]. Cell binding to fibronectin modifies cell behavior that has endowed fibronectin with key features that mediate important biological processes such as wound healing and embryonic development and implicates the molecules in pathological processes including fibrosis and cancer. Fibronectin exists as a dimer of two 230–250 kDa subunits, each composed of three types of repeating modules:

FN1, FN2, and FN3 (Fig. 7.2). Interestingly, these fibronectin modules are also commonly found within domains of many other ECM and ECM-associated proteins. Cellular fibronectin is secreted by interstitial fibroblasts and other stromal cells that also act to organize fibronectin into an insoluble fibrillar network. Hepatocytes in the liver also secrete soluble fibronectin that circulates in blood plasma with a concentration near 300 μg/mL.

The fibronectin dimer forms from two nearly identical fibronectin monomers joined by a disulfide linkage near the C-terminal of each subunit. Each subunit contains 12 FN1 modules, 2 FN2 modules, and 15−17 FN3 modules. Fibronectin contains nine glycosylation sites (seven N-linked and 2 O-linked) per subunit, such that the molecule is on average 5% carbohydrate. Glycosylation regulates fibronectin stability and its affinity to some of its binding partners such as collagen [39,40]. Unlike collagen, fibronectin is produced from only one gene, and alternative splicing of the mRNA transcript causes variability within the fibronectin protein. The number of FN3 modules depends on the presence of two extra domains, extra domain A (EDA) and extra domain B, located between the 11th and 12th FN3 modules and 7th and 8th modules, respectively. In addition, a variable (V) region between ^{14}FN3 and ^{15}FN3 can be spliced to form 5 distinct variants bringing the total number of human fibronectin isoforms to 20 [41].

The diverse functional domains within the fibronectin dimer give rise to its diverse biological activity. For instance, regions within the FN1 repeats mediate its binding to collagen (^{6}FN1−^{9}FN1 with ^{1}FN2−^{2}FN2) and fibrin (^{4}FN1−^{5}FN1 and ^{10}FN1−^{12}FN1) and contain the weaker of two heparin-binding domains (^{1}FN1−^{5}FN1) [42]. A third fibrin-binding site is exposed near the collagen-binding site following chymotrypsin digestion [43]. The FN3 repeats contain the strongest heparin-binding site (^{12}FN3−^{14}FN3) and most importantly, the major integrin-binding motif, RGD, within ^{10}FN3. The RGD binds integrins α3β1, α5β1, α8β1, αvβ1, αIIbβ3, αvβ3, αvβ5, and αvβ6. Importantly, ^{9}FN3 contains a DRVPPSRN synergy sequence, which exclusively binds α5β1 and αIIbβ3 integrins. Integrin binding to the synergy site enhances

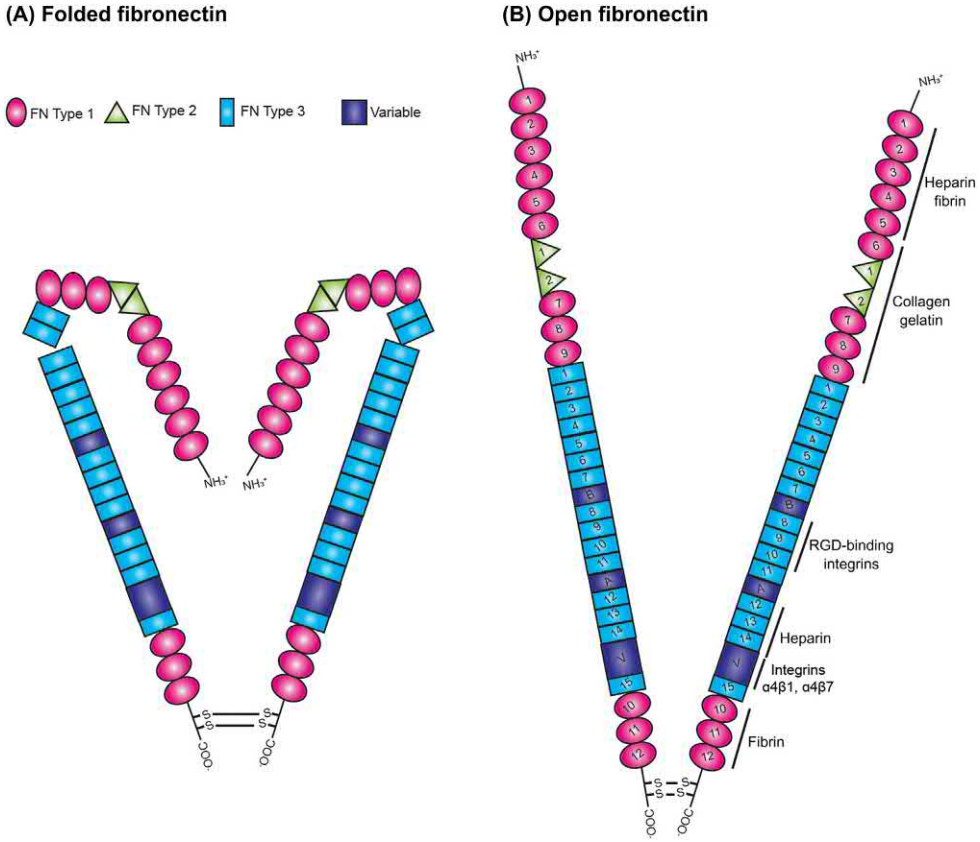

FIGURE 7.2 Fibronectin structure.
(A) Soluble fibronectin dimers adopt a folded conformation that opens upon cell binding. (B) Fibronectin contains three types of repeating domains, FN1−3, two alternatively spliced FN3 domains, FNA and FNB, and an alternatively spliced variable region. Integrin ligation of fibronectin and cell-generated tension open the fibronectin molecule exposing fibronectin-binding sites that initiates fibronectin assembly into a fibrillar matrix. Fibronectin also binds heparin, collagen, and fibrin at the sites shown.

cell spreading, fibril assembly, and can elevate cytoskeletal tension to reinforce focal adhesion signaling [44–46]. A second integrin-binding site, LDV, in the V regions is recognized by α4β1 and α4β7, and α4β1 and α9β1 integrins also recognize a site in the EDA region.

In contrast to spontaneous collagen fibrillogenesis, fibronectin's assembly into a fibrillar network is cell-mediated [38]. The first step in fibronectin fibrillogenesis is the binding of soluble fibronectin to a receptor on the cell surface. Based on cell binding and network assembly experiments with isolated fibronectin peptides and RGD mutations, the N-terminal 70 kDa region (70K; ^{1}FN1–^{9}FN1) likely contains the initial cell-binding cite that triggers subsequent fibrillar assembly [47]. The binding of soluble fibronectin by a cell force induces a conformational change in the fibronectin that exposes a cryptic site that can then interact with additional fibronectin molecules [48,49]. Cell-mediated tension through the integrin–fibronectin bond is predicted to facilitate continuous interaction with additional fibronectin molecules and elongation of the fibronectin fibril [50]. Cell adhesion to the RGD motif then mediates fibrillar elongation, with the synergy site also being implicated in fibronectin matrix assembly [45]. Consistently, mutations that prevent synergy site binding disrupt assembly, which can be rescued by enhancing integrin activation with Mn^{2+}. Integrin α5β1 binding of fibronectin and the ensuing signaling that activates cell contractility have also been implicated in fibronectin assembly [51].

As one of the major cell adhesive ECM proteins, fibronectin is crucial for a large number of biological processes. For instance, fibronectin plays a critical role in wound healing. Fibronectin associates with fibrin in blood clots to make up the provisional matrix, where it promotes the migration of fibroblasts, macrophages, and new epithelial cells into the wound site and facilitates the formation of a mature ECM [52]. In injuries that limit the production of endogenous fibronectin, such as following irradiation, topically applied fibronectin can significantly improve wound healing [53]. Moreover, biomaterials engineers showed that adsorption of fibronectin onto poly(ethyl acrylate) (PEA) exposes the assembly initiation site to stimulate spontaneous organization of fibrillar fibronectin at the material surface. This strategy fortuitously enhances integrin-binding and enables optimal growth factor presentation to cells. Not surprisingly, the application of PEA materials facilitates bone regeneration by stimulating osteoblast differentiation at remarkably low concentrations of BMP-2 [54].

Fibronectin also plays essential roles in embryonic development, and fibronectin-null mutations are embryonic lethal at day 8.5 [55]. In addition, fibronectin is especially abundant in many solid tumor types, where it potentiates protumor integrin signaling and its deposition at secondary sites helps facilitate tumor metastasis [46].

Laminin

Along with collagen IV, laminins are the other major constituents of basement membranes. However, laminin is the dominant adhesive protein in the basement membrane, and so it serves as a crucial link between cell layers and the basement membrane. Laminin is a large, 400–900 kDa heterotrimeric glycoprotein consisting of three polypeptide chains: α, β, and γ. There are 5 different α chains, 3 β chains, and 3 γ chains all encoded by different genes that combine to form at least 15 distinct laminin proteins [56]. Laminin nomenclature is based upon which chains compose the protein, such that laminin-511 is the laminin made up of α5, β1, and γ1 chains [57].

The main function of laminin is to provide sites for cell attachment and to assemble together with other proteins to generate a structurally functional basement membrane. Laminins self-polymerize into layered sheets and filaments that often contain multiple different laminin chains. Laminin polymerization facilitates the organization of the basement membrane, such that in the absence of laminin chains, basement membrane assembly is disrupted, despite the presence of other basement membrane components including collagen IV, perlecan, and nidogen. Critically, however, laminin does not directly bind collagen IV but is linked to the collagen scaffold via nidogen, emphasizing the key role of nidogen in the structural integrity of the basement membrane [58].

Several different cell surface receptors bind laminin including integrins α1β1, α2β1, α3β1, α6β1, α6β4, α7β1, α9β1, and αvβ3; syndecans 1 and 4; 67 kDa laminin receptor; and α-dystroglycan. The integrin-binding sites vary with the type of laminin. The main integrin-binding site is in the LG3 domain near the C-terminal end of the α chain [59]. Interestingly, recombinant LG3 domains do not bind integrin, and it is now known that a conserved glutamate residue in the γ chain is also required for integrin binding [60]. This Glu is absent in the γ3 chain; therefore laminin-113 and laminin-213 do not bind integrins [61].

Laminins play a critical role in tissue maintenance and cell survival. Along with fibronectin, collagen purified laminins are widely used in cell culture. In particular, laminin-111 is present in high concentrations in the commercially available reconstituted basement membrane hydrogel Matrigel. Dysfunctional laminins are the cause of multiple pathologies. For example, impaired function of laminin-211 and laminin-332 can cause congenital muscular dystrophy and junctional epidermolysis bullosa, respectively [62]. Laminins also play a role in tumor metastasis. Tumor cells that overexpress LAMA4 have a high metastatic efficiency, and exposure to integrin-binding epitopes of laminin in the premetastatic niche can awaken dormant cells to induce the formation of metastatic lesions [63,64].

Elastic fibers and microfibrils

While collagens resist tensile loads in tissues, elastic fibers impart tissues with the ability to stretch and recover from transient deformation. Not surprisingly, elastic fibers are abundant in tissues in which mechanical deformations are common and critical to their function, such as lungs, arteries, and skin. Elastic fibers exhibit extraordinary elasticity and undergo years of strain/recoil cycles without losing their mechanical properties [65]. By way of comparison, the extensibility of elastic fibers is five times greater than that of a rubber band of the same cross-sectional area. Elastic fibers are also acknowledged as providing important biochemical cues for cells such that recent advances in tissue engineering and regeneration have started utilizing these ECM fibers to improve results [48].

The highly elastic nature of elastin fibers is imparted by the structure of their main component, elastin. Elastin forms from its soluble precursor, tropoelastin, which self-associates immediately after synthesis into elastin polymers. The structure of tropoelastin monomers was only recently elucidated. It was shown that interspersed hydrophobic domains form large coils such that the shape is dominated by a condensed coil that confers elastic behavior at the level of the monomer [66]. Tropoelastin also has a separate cell-interacting domain outside the coiled structure. In a similar manner to collagen, lysine side chains of elastin can also be oxidized by the LOX family of enzymes to form reactive aldehydes that mediate cross-linking of elastin fibers and regulate elastin network architecture.

Elastic fibers consist of both elastin and other associated microfibrillar proteins such as fibrillin. Fibrillins serve as a scaffold to organize elastic fibers and are found surrounding the surface of amorphous elastin [67]. Fibrillins are also found as microfibrils in the ECM of many tissues independent of elastin. Fibrillins are important for the integrity and stability of elastic fibers and some nonelastic ECM. Not surprisingly, mutations in fibrillin-1 cause Marfan syndrome, a disease affecting the connective tissue [68]. Marfan syndrome can present with a multitude of symptoms, but the most common and serious consequences of the Marfan-associated fibrillin-1 mutations are cardiovascular, skeletal complications, and visual defects. Fibrillin mutations are also associated with a dysregulation of TGF-β activity [69]. Additional proteins associated with elastic fibers and microfibrils include fibulins, elastin microfibril interfacers, and microfibril-associated glycoproteins [70,71]. The importance of the cooperation between elastin and microfibrils in tissue function is highlighted by studies in which germline deletion of either elastin, fibrillin-1, or fibulin-1 induces mouse mortality shortly after birth.

Other adhesive glycoproteins and multifunctional matricellular proteins

Vitronectin

Vitronectin exists in the ECM of numerous tissues and circulates at high concentrations in blood. Cell adhesion to vitronectin is primarily mediated via integrin recognition of an RGD site in the molecule. Interestingly, although many integrins interact with vitronectin, one of the main fibronectin-binding integrins, $\alpha5\beta1$, cannot bind to vitronectin. Vitronectin can bind other matricellular proteins as well, including collagen, thrombin, heparin, plasminogen, and plasminogen activator-1. Vitronectin plays a role in wound healing, viral infection, and tumor growth [72,73]. However and somewhat surprisingly, the vitronectin knockout mouse apparently develops normally, and the adult mice do not exhibit any obvious pathological defects, suggesting this ECM molecule is not essential and/or that other proteins are able to compensate for its loss [74].

Thrombospondins

Thrombospondins are a five-member family of proteins composed of repeating EGF-like domains, Ca^{2+} binding domains, and TSP1 and TSP2 contain thrombospondin type-1 repeat (TSR) domains. This family forms homotrimeric (TSP1 and TSP2) and homopentameric (TSP3, TSP4, and TSP5/COMP) structures that assemble via a coiled-coil oligomerization domain near their N-terminus. Thrombospondins are cell adhesive and bind many ECM proteins such as fibronectin, collagens, laminin, and fibrinogen [75]. TSP1 can also bind latency-associated peptide to induce the release of active TGF-β [76]. The thrombospondin family has been implicated in a diverse range of activities related to their binding functions and ability to modulate cell behaviors. One important example is the antiangiogenic function of TSP1, which inhibits endothelial cell proliferation through its TSR domain [77,78]. This antiangiogenic property forms the basis of some TSP1-based therapies in a handful of contexts including eye diseases and cancer. TSR domains can be found within a plethora of other extracellular and cell surface proteins. Notably, this includes ADAMTS family of proteases responsible for processing of procollagen and von Willebrand factor as well as ECM remodeling through cleavage of lecticans [79].

Tenascins

The tenascin family includes four members, tenascins C, R, W, and X, that share structural similarities and

modulate cell adhesion and cellular biochemical signaling. The tenascins form rod-like structures containing EGF-like domains and fibronectin type 3 repeats. Tenascins assemble into hexamers via interactions between their oligomerization domains in the N-terminus. Tenascin expression is often limited and tissue-restricted with tenascin R only found in the nervous system, tenascin X primarily located in muscle connective tissue, and tenascin W in kidney and bone [80]. Tenascin C can be found in connective tissues and the nervous system but is also expressed at the site of tissue injury and during development and is often overexpressed in some cancers [81]. The effects of tenascin C are pleiotropic and context-dependent. Tenascin C can bind multiple integrins, although typically the tenascin-integrin adhesions are weak and do not stimulate cytoskeletal rearrangements consistent with focal adhesion assembly and cellular tension generation [82,83]. Interactions between tenascin C and ^{13}FN3 within fibronectin can induce cell-adhesion detachment from fibronectin to reduce integrin adhesion signaling [84]. Consistently, cleavage of tenascin C by meprin can rescue cell adhesion to fibronectin [85]. Tenascin C levels are also elevated in sites of high mechanical stress, suggesting it may be involved in adaptive ECM remodeling and/or signaling.

Proteoglycans

Proteoglycans are indispensable components of the interstitial ECM. All proteoglycans consist of a core protein that has at least one, but usually multiple, serine O-linked glycosaminoglycan chains. Glycosaminoglycans are unbranched polysaccharide chains composed of repeating disaccharide units, typically an amino sugar with an uronic sugar [86]. The highly hydrophilic glycosaminoglycan chains in proteoglycans trap large amounts of water within the matrix, which endows proteoglycans with the ability to regulate tissue turgidity and implicates these molecules as modulators of tissue biomechanical properties and viscoelasticity [1]. There are four classes of glycosaminoglycans: hyaluronan, heparin/heparan sulfate, chondroitin sulfate, and keratan sulfate.

Hyaluronan and lecticans

Hyaluronan is a large, 5−20,000 kDa (3−7 MDa average) glycosaminoglycan prevalent in tissues throughout the body, especially in the brain. The hyaluronan-binding proteoglycans are versican, aggrecan, brevican, and neurocan, known collectively as the lecticans or hyalectins. The binding of the core proteins to hyaluronan is noncovalent and stabilized by a link protein (Fig. 7.3). Hyaluronan is unique among the GAGs in that it is not sulfated, and it is synthesized at the plasma membrane rather than in the Golgi. It is synthesized by one of three hyaluronan synthases that add sugars to the cytoplasmic end of the chain while it elongates in the extracellular space. Hyaluronidases in the interstitial matrix degrade hyaluronan and are responsible for maintaining the steady turnover in the ECM with a half-life spanning from hours to weeks, depending on the tissue [87,88]. There are six known cell surface receptors for hyaluronan, and the two best characterized are CD44 and receptor for hyaluronan mediated motility (RHAMM). CD44-binding regulates hyaluronan clearance and importantly, can interact with growth factor receptors such as EGFR and TBRI to influence their activity and growth factor signaling [89,90]. As its name suggests, RHAMM-binding of hyaluronan

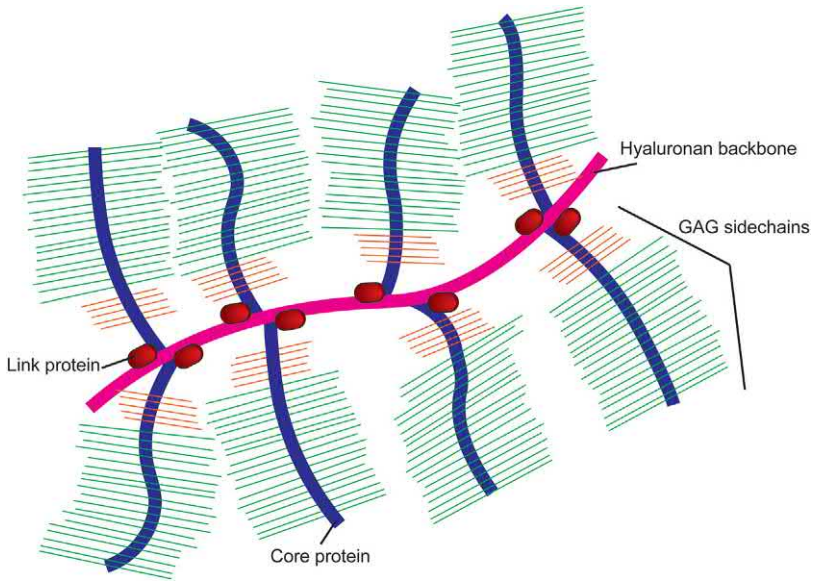

FIGURE 7.3 Hyaluronan binds proteoglycans in the ECM.
The core protein of lecticans binds numerous glycosaminoglycan chains and attaches to hyaluronan with the help of link protein. Many lecticans assemble along a hyaluronan backbone forming a massive, carbohydrate-rich ECM macromolecule. Proteoglycans regulate the hydration of tissue ECMs, which is a major determinant of overall tissue viscoelasticity and regulates interstitial pressure. *ECM*, Extracellular matrix.

modulates cell motility but also regulates cell cycle progression.

Like some other glycosaminoglycans, hyaluronan functions to resist compressive stresses. However, unlike other glycosaminoglycans, hyaluronan lowers its viscosity under sheer stress without losing its elasticity, rendering it an ideal biological lubricant. Hyaluronan is a major component of synovial fluid, which absorbs shock and lubricates joints. Hyaluronan also serves as a backbone to bind a large number of aggrecan molecules, the dominant proteoglycan in cartilage. About 90% of aggrecan mass consists of other bound glycosaminoglycans, primarily chondroitin sulfate, and this high concentration of GAGs contributes to the hydrated gel structure of cartilage that supports its large compressive loading function. Aggrecan also plays an important role in chondrocyte differentiation and facilitates chondrocyte-ECM interactions [91]. Furthermore, the gel-like phase created by hyaluronan-rich matrices can contribute to tumor pathology. Notably, high expression of hyaluronan in pancreatic tumor stroma plays a major role in generating the abnormally high interstitial pressure associated with this disease that compromises vascular integrity and impedes drug delivery, which have been attributed to the poor patient outcome associated with these cancers [92,93].

Hyaluronan with other lecticans also contribute to several other important biological processes including normal processes such as embryonic development and wound healing, as well as diseases including chronic inflammation and tumor metastasis [94–96]. The combination of hyaluronans biochemical properties in conjunction with its unique biomechanical properties endows hyaluronan with unique features that have motivated its widespread application as a facile material for tissue engineering applications [97]. Moreover, hyaluronan production can form a hydrated pericellular matrix around cells that influences the traffic of soluble factors and pericellular processes. These matrices surround gastrulating cells and are found within developing organs, associated with cells participating in wound repair, and are critical for arterial smooth muscle cell proliferation [98,99].

Perlecan

The major proteoglycan within basement membranes is the heparan sulfate proteoglycan perlecan. Perlecan is an essential ECM component, and most mice harboring a perlecan knockout exhibit embryonic lethality due to aberrant brain and skeletal development. Perlecan is particularly important in vascular basement membrane, where it helps preserve endothelial barrier function [100]. In addition to its role in basement membrane structure/function, perlecan is also present in the pericellular matrix of fibroblasts. In the interstitial ECM, heparan sulfate side chains sequester cytokines and other soluble molecules to modulate a plethora of cell and tissue behaviors critical for tissue homeostasis.

Small leucine-rich repeat proteoglycans and syndecans

Two other important proteoglycans include the SLRPs and syndecans. SLRPs are a diverse group of matricellular proteins containing leucine-rich repeat motifs that link with a variety of glycosaminoglycans. As discussed above, the SLRP decorin can modulate collagen fibrillogenesis, but the binding activity of SLRPs have also been implicated in inflammation and growth factor signaling [101]. Syndecans are a four-member group of transmembrane receptors that contain heparan sulfate and chondroitin sulfate chains. Syndecans are ECM receptors but can also facilitate cell–cell adhesion, and their extracellular GAG chains bind various growth factors.

Conclusion

Once dismissed as a biologically inert scaffold, research over the past few decades demonstrates the integral role played by the ECM in orchestrating many biological processes, including development, tissue homeostasis, wound healing, and disease. Not only do cell-ECM interactions directly modulate cell behavior, but ECM constituents also regulate the local abundance of matrix-associated signaling molecules and dictate the local and global mechanical properties of the tissue. As such, the ECM is critical for successful tissue engineering. Clarification of the role played by ECM composition, posttranslational modification, and organization and how these features direct cell differentiation and tissue-specific function will inform a more accurate design of materials to improve engineered tissues.

Chapter 8

Morphogenesis and tissue engineering

Priscilla S. Briquez and Jeffrey A. Hubbell
Pritzker School of Molecular Engineering, University of Chicago, Chicago, IL, United States

Introduction to tissue morphogenesis

The development of the human body from a zygote to its adult shape requires a tremendous feat of organization of cells. During this process, cells proliferate, migrate, differentiate, survive, or die in a highly controlled fashion, to eventually arrange themselves into tissues and organs (Fig. 8.1). All these controlled cellular mechanisms constitute the basis for *tissue morphogenesis*, literally defined as the *generation of tissue shape* [1,2].

Physiologically, the *shape* or *structure* of tissues is highly optimized to their biological functions. Indeed, many structures are unique to the organ in which they are found and fulfill highly specialized functions, such as kidney nephrons that filter blood and produce urine, or pancreatic islets that secrete the hormone insulin into a rich microvasculature to regulate blood glycemia. In contrast, some structures are shared between different organs, in which cases they perform similar or identical functions; for example, blood vessels bring nutrients to and remove waste products from most of the tissues, ensuring tissue viability. Because tissue structures have evolved to be functionally optimal, damage to the structures often results in partial or total loss of functions.

Nevertheless, it is the biological *functions* of tissues that are to be preserved in order to maintain life, acquire survival advantages, or perpetuate the species. To preserve biological functions throughout life, tissues undergo constant renewal and remodeling. At steady state the internal maintenance of tissue is called *homeostasis* and mainly includes cell renewal and metabolism control, yet without substantial structural changes. In addition to internal regulation, tissues adapt to external environmental variations. In these cases, tissue *remodeling* can result in structural modifications in the tissue, often to resist those environmental changes. For instance, bone structures remodel to reinforce areas where physical forces are applied [3]. In fact, biological tissues are highly *dynamic* systems.

Apart from the developmental stages, *morphogenesis* also occurs at an adult age, for example, upon wounding or in disease. Interestingly, some tissues possess natural abilities to regenerate when damaged, meaning that they can rebuild their initial structure and fully recover their functions. However, most tissues in the body have limited regenerative capabilities, and regeneration does not necessarily take place even though the tissues may have the potential to do so. Instead, wounded tissues are sometimes replaced by dysfunctional ones, such as scars [4], or by no tissue at all, leaving open chronic wounds [5]. Other pathologies additionally involve tissue morphogenesis, for instance, tumor formation in cancer [6].

The detailed characterization of developmental and regenerative morphogenetic processes provides a strong inspiration to the field of regenerative medicine and tissue engineering, which aims to replace or heal damaged or dysfunctional tissues for clinical applications. Currently, many tissue engineering strategies rely on the mimicry of physiological tissue morphogenesis, by delivering cells, material scaffolds, bioactive signaling molecules, a combination of those, or even more complex structured tissues, in place of defective tissues or organs [7]. In this chapter, we will give the reader an overview of key morphogenetic mechanisms that one can recapitulate when engineering tissues. Particularly, we seek to impart a good understanding of the dynamic interactions between cells and with their microenvironment within tissues, as well as between a tissue and the different physiological systems within the body, an understanding that is essential for tissue engineers.

Biology of tissue morphogenesis

As detailed in previous chapters, tissues are composed of cells and extracellular matrix (ECM). In tissues, cells constantly receive a multitude of signals, which can be from

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00009-5

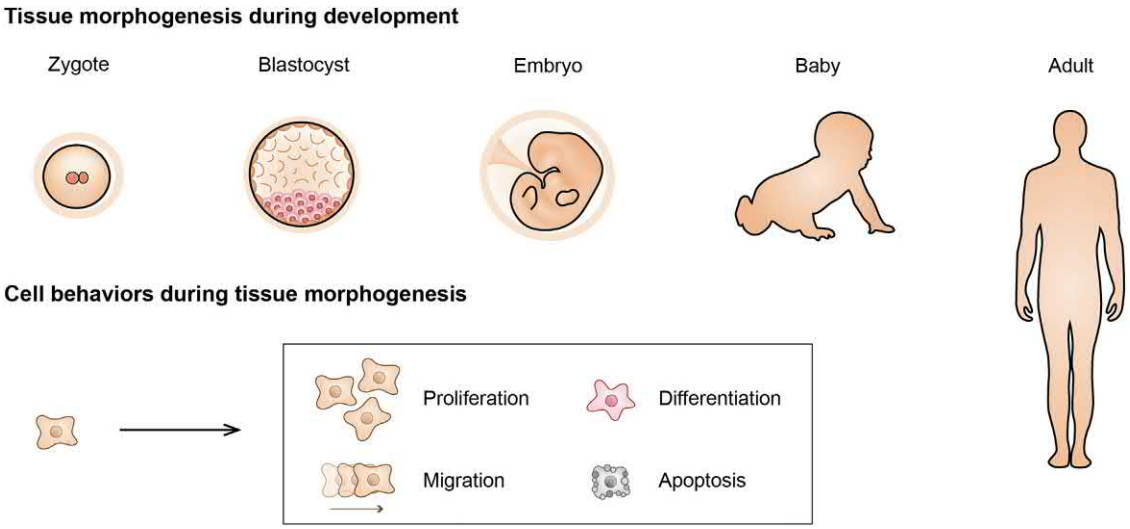

FIGURE 8.1 Overview of morphogenesis at tissue and cellular levels. Illustration of tissue morphogenesis occurring during the development of a unicellular zygote in a multicellular human adult organism. At the cellular level, tissue morphogenesis is the result of the coordination of multiple different cell behaviors, such as proliferation, migration, differentiation, and apoptosis.

soluble bioactive molecules, from the ECM via cell−ECM interactions, and from their neighboring cells via cell−cell interactions [8−10]. All these signals are integrated to instruct cell behaviors, which can simply remain at steady state or respond by a morphogenetic process (migration, proliferation, differentiation, apoptosis, etc.). In addition, when a cell modifies its behavior, its secretome and its interactions with the microenvironment and with neighboring cells are affected, which subsequently modify the signaling to other cells; this allows a tight spatiotemporal coordination of morphogenetic processes within the tissue [11]. In this section, we will first give the reader an overview of the molecular and cellular interactions involved during morphogenesis, before zooming out to a tissue-scale level, to highlight how tissues are interdependent and integrated in the body.

Morphogens as bioactive signaling molecules during morphogenesis

An important class of soluble molecules involved in tissue morphogenesis is called the morphogens [12]. They are bioactive signaling proteins secreted by cells that act in autocrine and paracrine fashion to control cell behaviors in the local microenvironment. Some of the morphogens are commonly referred as growth factors, as they are promitotic and thus induce cell proliferation or sprouting. For instance, the platelet-derived growth factor (PDGF), which is released in wounded microenvironment by platelet degranulation and secreted by immune cells, is a potent mitogen for mesenchymal cells, such as mesenchymal stem cells, fibroblasts, and vascular smooth muscle cells. PDGF is accordingly known to enhance tissue repair [12]. Moreover, growth factors oftentimes have multiple simultaneous biological activities and can, for example, trigger cell migration in addition to proliferation. In fact, PDGF also induces mesenchymal stem cell and fibroblast chemotaxis. Here, PDGF is taken as one example among many; various families of morphogens have been now classified (mainly based on their structural relation) and important efforts have been made to elucidate their biological roles during embryogenesis, tissue healing, and disease. As a consequence, many morphogens have been already characterized as being associated with particular mechanisms of tissue generation, including angiogenesis and lymphangiogenesis, neurogenesis and nerve sprouting, musculogenesis, osteogenesis and chondrogenesis, or in more organ-specific context, for example, hepatogenesis. Currently, in-depth studies on morphogens as well as their therapeutic use in regenerative medicine are under active investigation.

Morphogens are effective at a certain threshold concentration, commonly in the pico- to nanomolar range, which is considered a very low dose range [13]. More than the actual concentration, it has been shown that the formation of gradients of morphogens is fundamental to drive tissue growth in a coordinated way and induce cell patterning [13,14]. Gradient concentrations allow cells to receive direct spatial information about their position to a localized source (e.g., a secreting cell) (Fig. 8.2A). However, the question of how cells can perceive morphogens gradients and act accordingly is not yet fully elucidated and remains technically difficult to address. Morphogen gradient effects have been primarily studied in developmental biology; interestingly, it seems that the

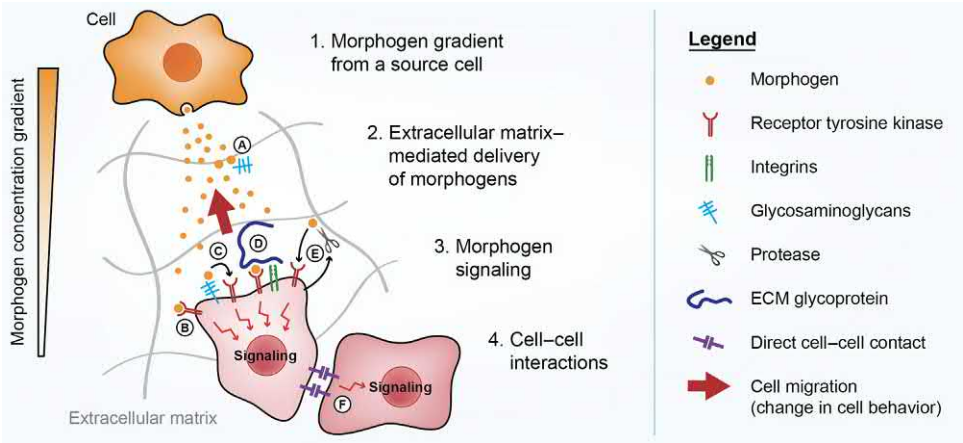

FIGURE 8.2 The ECM modulates morphogens release and signaling during tissue morphogenesis. Morphogens secreted by source cells create concentration gradients into the microenvironment, which are sensed by recipient cells. (A) Interactions between the ECM and morphogens control gradient steepness and morphogen release in the microenvironment. (B) At the cell surface, morphogens bind to their cognate RTKs and trigger intracellular signaling cascades to modulate gene expression and subsequent cell behavior. (C) Morphogens also interact with glycosaminoglycans (e.g., heparan sulfate) at the cell surface, from where they can be released to bind to their cognate receptors. (D) Clustering of RTK and integrins into complexes by morphogens bound to ECM glycoproteins can induce synergistic signaling that enhances morphogens regenerative effects. (E) Morphogens can additionally be released in a cell-mediated fashion, via the secretion of proteases that solubilize ECM-sequestered morphogens. (F) Morphogen-induced cell behavioral change can be communicated to neighboring cells via direct cell−cell communication, which allows behavioral coordination of multiple cells during morphogenesis. *ECM*, Extracellular matrix; *RTK*, receptor tyrosine kinase.

mechanisms of morphogen gradient sensing strongly depend on the particular morphogen of interest and even on the developmental stage. Among the main hypotheses, one stipulates that cells can have different response thresholds and so differentially respond according to their distance to the morphogen source. Furthermore, it has also been hypothesized that cells can sense concentration differences over their diameter, thus inducing cell orientation and polarization. While it remains unclear if cell fate determination is directly dependent on the presence of neighboring cells, it is thought that cells in the tissue can also regulate morphogen gradients through internalization and relaying such molecules and information to other cells, adding to the complexity of studying such mechanisms [14,15].

At molecular level, many morphogens activate cell surface receptor tyrosine kinases (RTKs) (Fig. 8.2B), which are strongly regulated by feedback loops to prevent a host of abnormal cell behaviors [16]. In the absence of stimulation by morphogens, RTKs accumulate at the cell surface, due to a faster endosomal recycling rate than their constitutive internalization rate. In contrast, upon activation, RTKs are internalized and sorted for degradation in the lysosomes, which reduces their presence at the cell surface and leads to cell desensitization [17]. Signaling through RTKs modifies cell gene expression, which can lead to alteration of the internal cellular structures, such as the cytoskeleton, and subsequent behavioral changes [18].

In addition to morphogens, the roles of other types of molecules are emerging in tissue morphogenesis; for instance, microRNAs have been shown to modulate multiple morphogenetic processes, notably in the context of brain development [19]. While not being the focus here, it is likely that the landscape of tissue morphogenesis signaling molecules will expand in the upcoming years.

The extracellular matrix as a key regulator of tissue morphogenesis

The ECM plays a major role during morphogenesis, in that it both regulates the spatiotemporal release of soluble morphogens to cells and provides cells with biomechanical and biomolecular signals through direct interactions [10,20,21]. First, morphogens can be specifically retained in the ECM depending on their affinity for ECM components. Many morphogens are known to bind to matrix glycosaminoglycans (GAGs) and are often referred as heparin-binding [22]. Because cell surfaces are also made of GAGs, morphogens can similarly be retained at the cell surface (Fig. 8.2C), before signaling to their cognate receptors. In addition to binding to GAGs, morphogens can also exhibit specific affinities for ECM glycoproteins, such as fibronectin, vitronectin, laminin, and fibrinogen [23−25]. Interestingly, fibrous collagens, which are core structural proteins of the ECM, do not seem to have strong interactions with morphogens. The specific affinities of morphogens for particular ECM components allow their temporal sequestration and release, as well as spatial patterning of the cell microenvironment. As such, the

ECM importantly regulates the formation and steepness of morphogen gradients in the microenvironment (Fig. 8.2A). Interestingly, it has also been shown that the biological effects of morphogens can be improved by the presentation by ECM glycoproteins. Indeed, ECM glycoproteins are multifunctional domain proteins that can display morphogen-binding domains close to cell integrin-binding domains. The proximity of these sites allows the copresentation of integrin ligands with morphogens, which can induce at the cell surface clusters of integrins with morphogen receptors. Such clusters can induce synergistic intracellular signaling, thus improving the biological cell response as compared to when morphogens are delivered without the copresentation (Fig. 8.2D) [26,27].

More than affinity-based release by the ECM, morphogens are also delivered by cell-mediated ECM degradation during morphogenetic processes. Upon cell migration or proliferation, cells secrete proteases that break down ECM components by enzymatic cleavage, which facilitates cell displacement in the tissue. By degrading the ECM, proteases importantly allow the release of matrix-sequestered morphogens (Fig. 8.2E) [28,29]. To counterbalance matrix proteases and protect the ECM from excessive degradation, cells in parallel secrete tissue protease inhibitors; the balance of both is responsible for regulating ECM degradation and renewal rates. In addition, matrix proteases not only accelerate the release of morphogens from the ECM, but they also unmask matrix biofunctional cryptic sites, which have been also shown to directly modulate cell behaviors by signaling through cell surface receptors. As an example, the cleavage of collagen IV by matrix metalloproteinase releases fragments that inhibit the proliferative effect of the vascular endothelial growth factor (VEGF) and migration of endothelial cells [30]. Exposure of matricryptic sites can also provide new adhesion sites for integrin receptors, to mediate direct ECM−cell interactions. For instance, at sites of inflammation, the thrombin-mediated cleavage of osteopontin renders available integrin $\alpha 9\beta 1$−binding sites that are involved in neutrophil migration [31].

In addition to degrading the ECM, cells are constantly renewing and remodeling it, which can lead to variation of the microenvironment composition and affect cell behaviors. For example, upon wounding, a provisional matrix made by fibrin clot primarily stops hemorrhage and is then replaced by a collagen III−based interstitial matrix, before being remodeled into a collagen I−based matrix over months [28,32]. The different compositions of the microenvironment define its biomechanical properties (e.g., stiffness, elasticity), which are transduced to cells by mechano-sensing cell surface receptors, such as integrins or cadherins, and directly affect cell responses; for instance, stiff environments can differentiate monocytes into myofibroblasts during scar formation [33,34].

Cell−cell interactions during tissue morphogenesis

Cell communication is essential to coordinate cell migration and structural organization during tissue morphogenesis. In tissues, cells usually connect to each other using stable cell junctions at steady state, namely, tight junctions, anchoring junctions, and gap junctions [8], although some cell types interact primarily with ECM components alone. Such junctions allow both exchange of biochemical signals between cells, through gap junctions, as well as biomechanical signals, mainly through cadherins in anchoring junctions. Importantly, cadherins have been shown to be critical for cell recognition and segregation during developmental stages, thus allowing tissue patterning; indeed, cadherins on one cell bind to the same cadherins on another cells (known as an homophilic binding), such that epithelial cells that exhibit E-cadherins can efficiently connect to other epithelial cells, but not to mesodermal cells, which display N-cadherins, for example [35].

Because cells thus communicate, the behavioral change of a cell in a tissue is necessarily perceived by its surrounding cells, which permits their coordination (Fig. 8.2F). As an illustration, during angiogenesis, the sensing of a VEGF-A gradient (secreted by hypoxic cells), by a specific endothelial cell, modifies its polarity and turns it into a tip cell, which migrates toward the source of VEGF-A. The tip cell induces a lateral inhibition in the surrounding endothelial cells, which then acquire a stalk cell phenotype. Stalk cells proliferate and follow the tip cell, leading to the formation of a blood vessel sprout that remains connected to the parent vessel [36]. As a second example, tissue growth is also highly controlled by mechanisms known as contact inhibition of proliferation and inhibition in locomotion [37]. Indeed, when cells collide, the formation of adhesion complexes at their membranes induces significant intracellular modifications, of their cytoskeleton notably, which inhibit their migration or proliferation and prevent pathological tissue growth. It is interesting to note that cancer cells are known to escape such regulatory mechanisms, which lead to the formation of tumors [37].

Tissues as integrated systems in the body

In the previous paragraphs, we detailed some key molecular and cellular interactions occurring during tissue morphogenesis. Here, we will rather replace tissue in the context of the whole body and discuss how tissues are interdependent upon one another. Such an aspect of tissue integration is particularly important to consider when engineering tissue, which will be the focus of the next section. Particularly, we will highlight the connections of tissues with the circulatory system, the immune system,

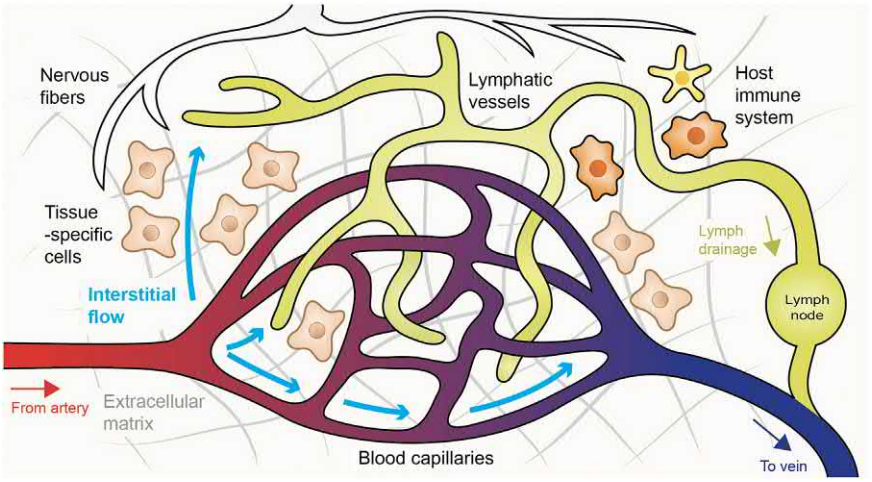

FIGURE 8.3 **Integration of multiple body systems in tissues.** In addition to tissue-specific structures, most of tissues in the body are irrigated by blood capillaries that deliver oxygen, nutrients, and signaling molecules to tissue-specific cells. Into the tissue the interstitial flow increases the bioavailability of such molecules to distant cells, which is further regulated by specific interactions within the ECM. Tissue fluid and metabolic cell waste are collected by veins and lymphatic vessels and return back to the systemic circulation. The immune and nervous systems, also present in most of the body tissues, fulfill important roles in maintaining tissue homeostasis, modulating or instructing tissue functions, notably via systemic feedback loop signaling, and in repairing tissue upon injury. *ECM*, Extracellular matrix.

and the nervous system, which are present in most of tissues (Fig. 8.3).

In addition to receiving signals from their local microenvironment, cells are affected by distant signals, primarily transported via the *circulatory system*. Almost all tissues in the body are irrigated by blood vessels, which bring oxygen and nutrients to cells and assist in regulating tissue temperature, to maintain cells alive. Furthermore, systemic signaling molecules such as hormones are secreted in the bloodstream to signal to distant cells. To reach cells within the tissue, molecules from the arterial blood either passively diffuse through the semipermeable vascular endothelial barrier or are actively transported from the apical to the basal side of endothelial cells by transcytosis [38]. Even outside of the vascular circulation, because the arterial circulatory system has a higher pressure than the venous one, tissues are constantly subjected to an interstitial flow [39]. This flow modulates the spatial and temporal patterning of the microenvironment, affecting molecular gradients and clearance, for instance [40]. Tissue fluid excess and cell metabolic waste are then mainly evacuated by the venous circulatory system. Another way through which tissue fluid and metabolic waste are drained is via the lymphatic system [41]. Like blood vessels, lymphatic vessels are also present in most of tissues and drain about 15% of tissue interstitial fluids (as compared to 85% for the venous system). The lymph collected by lymphatic vessels flows through lymph nodes before emptying back in the venous system at the cava vein level. In the case of pathogen invasion in a tissue, lymphatic vessels importantly allow antigenic molecule drainage and immune cell trafficking from the tissue to the lymph nodes, to efficiently activate the immune system [42].

Interestingly, the *immune system* is present and ensures surveillance in most tissues, which indeed contain circulatory and tissue-resident immune cell populations. The immune system plays a key role at steady state, in the context of healthy tissue renewal, in removing of apoptotic cells and debris by phagocytosis, as well as in immune surveillance, among other roles [43,44]. In context of inflammation, upon tissue injury, for example, immune cells secrete many cytokines and growth factors to recruit and instruct different cell types in the wound. In such cases, immune cells are essential to fight pathogens, clear tissue debris, resolve tissue inflammation, and guide subsequent tissue morphogenesis [45].

Finally, tissues are connected to the *nervous system*, with which they exchange sensory and motor signals to allow coordination at the whole-body level. Sensory fibers transmit efferent information from the tissue environment to the peripheral nervous system, and eventually the central nervous system in which signals from all tissues are integrated together. Information is relayed by many specific receptors, including proprioceptors, nociceptors, mechanoreceptors, thermoreceptors, and chemoreceptors, which allow precise monitoring of tissue changes. In response, motor fibers provide afferent motor signals to tissues, mainly to muscles and glands. In addition, the nervous system plays a role, not yet fully understood, in mediating tissue inflammation through modulation of the immune response, and so likely during subsequent morphogenesis [37]. It is also interesting to note that during development, the nervous and vascular circulatory

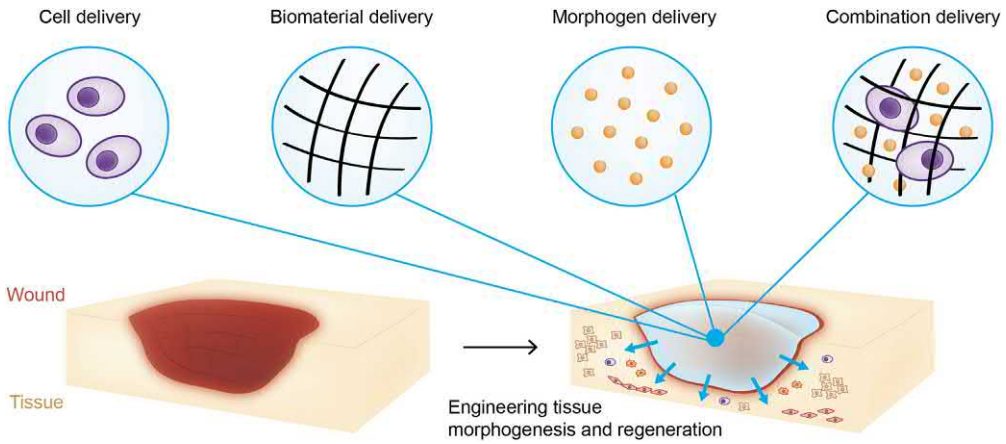

FIGURE 8.4 Common strategies to engineer tissue morphogenesis and regeneration. The field of tissue engineering develops many strategies to recover and repair tissue functions upon damage. To this purpose the delivery of tissue-specific or progenitors/stem cells, naturally derived or synthetic biomaterials, and bioactive signaling molecules as morphogens have been extensively studied, as stand-alone therapies or in combination. Such therapies aim at enhancing tissue regeneration upon administration, therefore inducing morphogenesis in the injured area.

networks share similar molecular signaling cues and codevelop together during tissue morphogenesis, each following the pattern of the other [46]. Consequently, the tight connection between the tissue and the circulatory, immune nervous systems controls tissue homeostasis and is essential to modulate the tissue response to environmental changes.

Engineering tissue morphogenesis

When engineering a tissue, one should keep in mind that it is the tissue functions rather than its structures that need to be ensured. However, because of the strong relation between tissue functions and structures, current tissue engineering trends are commonly based on biomimetic strategies that primarily aim at reproducing the physiological tissue morphology. For instance, three-dimensional organ bioprinting is mainly focusing on recapitulating organ structures in vitro that would eventually become functional upon implantation [47]. Other strategies, such as the engineering of implantable regenerative biomaterials, deliver signals that promote wound healing in vivo by recruiting the appropriate cell types to induce structure reconstruction. Letting the physiological tissue regenerate its own structure, through morphogenesis, could be an appealing approach to simultaneously induce tissue functions, although it might sometimes lead to only partial or no functional recovery depending on the delivered signals as well as on the etiology of the original tissue defect. Consequently, finding efficient ways to engineer functional biological tissues in vivo remains an important health challenge to date, mainly addressed by the fields of tissue engineering and regenerative medicine. Currently, most strategies to engineer tissue morphogenesis rely on the controlled delivery of cells, biomatrices, and bioactive signaling molecules, such as morphogens (Fig. 8.4), or a combination of those.

Cells as building units in tissue engineering

As cells are the primary constituents of biological tissues, direct delivery of cells to enhance tissue regeneration has been extensively explored [48,49]. Tissue-specific autologous cells can be extracted from the patient and expanded in vitro prior to implantation into the wound site, to promote healing. As clinical examples, autologous cultured keratinocytes or fibroblasts are used for repairing skin in burn patients [50], and autologous chrondrocytes into cartilage defect to repair hyaline cartilage [51]. Approaches based on the delivery of autologous cells have the strong advantage of being immune compatible to the patient and so would not be immune rejected upon delivery. Despite relatively good efficacy and safety, the process of culturing patient-derived cells in vitro can be long and expensive [52,53].

As an alternative strategy, stem/progenitor cells can also be extracted from the patient and delivery into wounds, wherein they can further proliferate and differentiate into functional tissue-specific cells to improve tissue healing. Particularly, autologous mesenchymal stem cells (MSCs) can be isolated from a patient with relatively easy procedures, such as from the patient adipose tissue [54]. Mesenchymal stem cells have been shown to promote reconstruction of various tissues, particularly cartilage, bone and muscle tissues [55]. Nevertheless, although MSCs can be extracted, isolated, and implanted into the patient over a 1-day period, in vitro expansion might still be required to obtain larger amount of cells.

For regeneration of tissues from other origins, for neural tissues, for instance, the use of less differentiated

embryonic stem cells might be appealing [56], although the embryonic source of such cells remains a strong limitation of this approach. In 2006 the key discovery that pluripotent embryonic-like stem cells could be induced from adult somatic cells opened a new perspective on the use of such stem cells for clinical applications [57]. In addition, the development of stem or fetal cell line banks with high regenerative potential can provide an alternative [53]; however, in this case, the cells' human leukocyte antigens need to be matched to the receiving patient to avoid immune rejection, as they are not directly extracted or derived from the patient's cells. Nevertheless, this approach, less personalized, might be more feasible at large scale for tissue engineering purposes considering current costs and technical challenges associated with personalized induced pluripotent stem cell (iPSCs)-based therapies.

While the most common strategy for cell delivery is by local implantation in the wound, the interesting properties of stem/progenitor cells to migrate into inflamed tissue upon systemic intravenous administration is now explored to target wounded sites and modify the local environment without the need of directly accessing the injured site, which might require surgery. Currently, such strategies are being tested in research and clinical trials [58,59].

Biomaterial scaffolds as artificial extracellular matrices

The relatively poor viability and engraftment of cells upon delivery into tissue has encouraged the use of biomaterial carriers for more efficient cell delivery. Indeed, many cell types are naturally adherent and die through a process called anoikis when they lose adherence. In such cases, biomaterials serve as artificial ECM to provide an environmental context to the cells, thus protecting them and guiding their fate within the tissue to regenerate [49].

In addition to being beneficial for use in combination with cells to deliver, the delivery of biomaterials may promote regeneration of the local cells in situ and tissue in the wounded site. Indeed, the major role of the ECM has inspired the study of a multitude of biomaterials for wound healing, which can be naturally derived or from synthetic origins [10]. The most complex material in terms of composition and closest to physiological environment is decellularized matrix [60] or cell-derived matrices [61]. Such matrices are derived from living tissue treated to remove the cellular content, yet preserving the structure and composition of the extracellular environment. Interestingly, decellularized matrices contain cell adhesion sites, mechanical and biomolecular signals to instruct and guide tissue morphogenesis upon implantation [62]. Decellularized matrices are often derived from allogeneic or xenogeneic origins, yet the removal of cellular content allows for controlled low immunogenicity. Currently, decellularized matrices are approved and used in many clinical applications, including for regeneration of bone, periodontal tissues, tendons, muscle, and other soft tissues [63].

Other naturally derived materials are derived from purified extracellular proteins, such as collagen- or fibrin-based materials [10]. Both collagen and fibrin are core structural proteins of the physiological ECM during homeostasis and in wounds, respectively. Thus similar to decellularized matrices, such environments provide a structural scaffold to support cell adhesion and migration, and subsequent tissue remodeling upon implantation. Collagen dressings are, for example, used for skin repair in burn patients, where they promote functional skin tissue regeneration rather than scarring [64,65]. Fibrin materials, on the other hand, have been widely used as tissue sealants for sustaining blood coagulation to prevent perioperative bleeding, in many regards mimicking the natural role of fibrin [66].

Biomaterials can also be derived from nonproteinaceous content of natural extracellular matrices, such as GAGs. Hyaluronic acid (HA)−based matrices are used for application in skin and hyaline cartilage repair in the clinic, for example, as well as in cosmetics [67]. Particularly, HA materials have a strong ability to attract and retain a large amount of water, keeping wounds and tissues highly hydrated, which is beneficial for healing. Although HA is a natural material, it has the advantage of being able to be produced biosynthetically, which avoids the need of animal sourcing. Other types of natural materials derived from nonmammalian organisms are also being explored in tissue engineering, such as chitosan- or silk-based materials [68,69].

In contrast to materials derived from living organisms, synthetic biomaterials offer many advantages in terms of ease of production, batch-to-batch reproducibility, and manufacturing at large scale, which are important to consider for commercialization of clinical products [21]. However, synthetic materials are often required to be engineered for cell adhesion and degradability, for which they are not naturally optimal. Interestingly, such properties of synthetic materials, along with their stiffness, elasticity, and shape, can often be tuned independently of each other, which offers the possibility of developing highly controlled microenvironments to precisely guide different cell behaviors. As such, synthetic materials can be highly tailored to their targeted biomedical applications. As an example, polyethylene glycol (PEG)−based scaffolds have been engineered with the arginine−glycine−aspartic acid (RGD) peptide, which is the most common minimal sequence allowing for cell adhesion [70]. In addition, incorporation of protease sensitive domains into these

materials, such as plasmin or matrix metalloproteinase cleavage sites, accelerate cell-mediated degradation and favors subsequent tissue remodeling [71]. Nevertheless, incorporation of multiple different domains into synthetic materials to enhance their biological properties increases in parallel their complexity, which might further complicate the regulatory path to clinical approval.

Morphogens as signaling cues in tissue engineering

Another motivation for the use of biomaterials in tissue engineering is to enhance drug delivery. Among the drugs, morphogens are potent candidates in regenerative medicine, as they can actively recruit cells from the own patient into the defect area and/or instruct them to guide tissue regeneration. However, the success of morphogen-based clinical therapy remains limited to date, due to cost-effective and safety issues [72,73]. Indeed, morphogens have been used at very high doses (in the order of milligrams, whereas physiological doses is ranging in pico- to nanograms) to accelerate wound healing, which in parallel induce adverse tissue remodeling, ectopic tissue formation, and tumorigenesis in distant sites from the treated area.

Retrospectively, the key physiological role of the ECM in regulating morphogen delivery, acting both for their local retention and allowing gradient formation, has been largely underestimated during these first trials therapies. This realization fostered the use and engineering of biomaterials for increased local retention of morphogens. Currently, the sequestration of morphogens into biomaterials has been achieved with relatively good success in preclinical research by various strategies, either based on biophysical and biochemical retention (e.g., porosity, viscosity, charge, and hydrophobicity) or on bioaffinity-based retention via material functionalization with moieties exhibiting specific affinities for morphogens [28]. Notably, many morphogens possess a natural affinity to GAGs and are as such referred as heparin-binding growth factors; functionalization of materials with heparin can be then exploit to increase the local sequestration of these morphogens [74]. On the other hand, proteins from the physiological ECM, such as fibrinogen, fibronectin, or laminin, also contain domains with specific affinities to morphogens, which can be incorporated into biomaterials to increase morphogen retention [75,76]. Because proteins contain more signaling information than GAGs, they can actively present morphogens to the cell surface and subsequently modulate signaling during morphogenesis. Of particular interest here is the synergistic signaling between integrins and growth factors, highlighted in The extracellular matrix as a key regulatory of tissue morphogenesis, which can be exploited to increase morphogen bioactive effects. As an illustration, the incorporation of a recombinant fibronectin fragment fusing a growth factor−binding domain to an integrin-binding domain into fibrin hydrogels enhanced the efficacy of VEGF-A, PDGF-BB, and the bone morphogenetic protein 2 in chronic skin wound healing and bone regeneration [26].

Not only can the biomaterial be designed for increased retention of morphogens, but morphogens can also be engineered for increased retention into biomaterials [24]. Morphogens can be covalently attached into materials, for example, which is the maximal degree of retention that can be achieved [77]. However, direct conjugation of morphogens into materials can impair their bioactivity and bioavailability to cells. Consequently, some strategies rather focus based on site-specific conjugation of morphogens, by modifying the morphogens sequences with substrate domain that can be covalently cross-linked into the material. For instance, transglutaminase-mediated enzymatic crosslinking of VEGF-A into fibrin or engineered PEG hydrogels has been developed by the fusion of a transglutaminase substrate sequence at the N-terminus of VEGF-A. Further incorporation of a matrix metalloproteinase (MMP) cleavage site between the crosslinking substrate sequence and VEGF-A allowed for the release of bioactive VEGF-A upon cell-mediated hydrogel degradation [78]. Using similar protein engineering strategies, growth factors can also be engineered with domains allowing high affinity but noncovalent retention into biomaterials. For example, morphogens that do not naturally bind to GAGs can be augmented with a heparin-binding domain [79]. Furthermore, morphogens have been recently fused to a domain displaying superaffinity for multiple ECM proteins, allowing strong retention into natural ECM-based biomaterials such as fibrin matrices, but also into the physiological ECM itself, which allow direct bind onto tissue upon delivery [25], thus limiting the need of exogenous carrier biomaterials.

Finally, it is likely that proper tissue morphogenesis and regeneration require the delivery of multiple and sequential morphogens, to recapitulate the natural wound healing cascade events. Codelivery and sequential delivery of growth factors have been explored in preclinical research [80−82] but might face regulatory hurdles to get approved in the clinic. Indeed, highly complex materials or with multiple bioactive compounds are subjected to longer and more expensive regulatory paths, which strongly limit their clinical translation.

Tissue remodeling in healthy and diseased environments

Delivery of cells, biomaterials, morphogens (or other bioactive signaling molecules), or a combination of those

constitutes to date the mainstream of research and development for guiding tissue morphogenesis in tissue engineering applications. Importantly, it should be kept in mind that anything delivered into the body may induce a host body reaction to the delivered moiety. Particularly, immune reactions can occur against foreign cells, biomaterials, or recombinant proteins [83,84]. Such reactions modify the microenvironments into which tissue morphogenesis is to occur and need to be considered at early stage in the design of specific therapy. While immune reaction can be dampened or limited by the use of poorly immunogenic materials, some recent research focuses on how to modulate immune cell responses at the wound location to induce a proregenerative microenvironment, in the perspective of developing immunomodulatory-based regenerative therapies [85].

Furthermore, it has been correlated that patients with a dysfunctional immune system, due to disease or pathology notably, are subjected to impaired physiological wound healing and tissue morphogenesis. In diabetic ulcers, for example, the wound remains stuck within a chronic inflammatory phase, characterized by a high content of proinflammatory cytokines and immune cells and increased level proteases [86]. In such dysregulated environments, delivery of cells, materials or drugs, and subsequent tissue remodeling will likely not lead to the same outcomes as in acute wounds. Therefore it is essential to consider the targeted pathophysiological environment to treat when developing therapies for specific applications of regenerative medicine.

Current focuses and future challenges

The regeneration of fully functional tissue upon wounding or organ failure is the aspiration of tissue engineering, which remains a challenge to date. Historically, early stages of regenerative medicine have explored tissue grafting to replace functional tissue, which still constitutes one of the main current clinical practices. Nevertheless, our better understanding of tissue morphogenesis encourages the development of biomedical strategies that deliver specific living cells, materials, or bioactive drugs to instruct the patient's own tissue toward regeneration at more cellular and molecular levels. In addition to promoting recruitment, proliferation and remodeling of tissue-specific or stem cells, particular efforts in the field of tissue engineering are dedicated to promoting tissue angiogenesis, as increased vascularization is known to enhance tissue healing. Indeed, reconnection of engineered tissues to the host circulatory system ensures long-term viability of the implanted or remodeled tissue. Recently, interest has also risen on controlling the host immune system response in tissue engineering therapies, considering both the difficulty of preventing immune reaction onset upon delivery of biological materials, as well as the key role of the immune system in orchestrating physiological tissue morphogenesis. Finally, fully functional engineered tissue would additionally require restoring connections with the host nervous system. To date, however, neurogenesis has been more extensively explored in the context of peripheral or central nervous system repair, as a first priority. It is likely that in the future, neurogenesis and the role of the nervous system during morphogenesis will be addressed in a broader context in tissue engineering.

Chapter 9

Gene expression, cell determination, differentiation, and regeneration

Frank E. Stockdale
School of Medicine, Stanford University, Stanford, CA, United States

Introduction

Studies of skeletal muscle development were the first to provide the principles for understanding the genetic and molecular bases of determination and differentiation. Molecular signals from adjacent embryonic structures activate specific genetic pathways within target cells. Families of transcriptional regulators are expressed in response to these signals that initiate important developmental processes within skeletal muscle precursors as well as in other tissues and organs. Both activators and repressors are essential to control the time and location in which development occurs, and self-regulating, positive feedback loops ensure that, once begun, development can proceed normally. An understanding of the mechanistic basis of the embryonic commitment to a unique developmental pathway, and the subsequent realization of the adult phenotype, is essential for understanding embryonic development as well as stem-cell formation and behavior and how these pathways might be manipulated for tissue engineering and therapeutic goals.

This chapter focuses on determination and differentiation, classical embryological concepts that emerged from descriptive embryology, and how understanding these has led to approaches to commitment of cells to new fates. It has been through the study of muscle development that the genetic basis of these processes was first revealed, laying out a mechanistic basis for understanding determination and differentiation. Following success in studies of skeletal muscle (reviewed in Ref. [1]), genetic pathways involved in the determination of other cell types, some of which are detailed in other chapters in this book, have also been uncovered, largely because of the underlying conservation of structure among the various effector molecules and mechanisms.

What is becoming increasingly clear is that stem cells are laid down in embryonic development concurrent with the formation of specific tissue types in most organs. These stem cells are the basis of tissue renewal and repair. They often are quiescent after embryonic and fetal development and only are activated in response to tissue renewal, damage, or cells loss or death. Like embryonic development, optimal deployment of stem cells is dependent upon cell−cell interactions such that the cellular environment restricts or facilitates stem-cell formation and activation.

Determination and differentiation

Determination describes the process whereby a cell becomes committed to a unique developmental pathway, which, under conditions of normal development, appears to be a stable state. In many cases, cells become committed early in development yet remain highly proliferative, expanding exponentially for long periods of time before differentiation occurs. Until recently, determination could only be defined post hoc. Prior to the discovery of transcriptional regulators, there were few markers to indicate whether or not a cell was committed to a unique phenotype. Thus determination was operationally defined as the state that existed immediately prior to differentiation, that is, before expression of a cell-type-specific phenotype. The identification of transcription factors that control differential expression of large families of genes changed this concept.

Determination and differentiation are coupled during embryogenesis, where a small number of initially pluripotent cells expand in number and enter pathways through which they form the diverse cell types of the adult. The process of differentiation describes the acquisition of the phenotype of a cell, most often identified by the expression of specific proteins achieved as a result of

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00010-1

differential gene expression. The differentiated state of a cell is easily determined by simple observation in most instances, because most differentiated cells display a unique phenotype as a result of the expression of specific structural proteins. Skeletal muscle cells are an extreme example of this, having a cytoplasmic matrix filled with highly ordered myosin, actin, and other contractile proteins within sarcomeres—the functional units of contraction—giving the fibers their cross-striated pattern. As development proceeds, there is a narrowing of the possible final cell phenotypes that individual cells can adopt, with the final cell fate (set of genes expressed) determined by factors both extrinsic and intrinsic to the cell (Fig. 9.1).

Determination and differentiation to a skeletal muscle fate begin in the somites of the early vertebrate embryo. Within the embryonic somites, two distinct anatomical regions contain muscle progenitors. Changes in gene expression responsible for directing cells to differentiate along particular developmental pathways result from the response to stimuli received from surrounding cells and the specific set of genes expressed in the cell itself at the time of interaction. For example, cells of recently formed somites have the potential to form either skeletal muscle or cartilage in response to adjacent tissues, and the fate adopted by a cell is a result of somite-cell location with respect to adjacent structures—the notochord, neural tube, and overlying ectoderm—that produce signaling molecules that determine phenotype [2–4]. Specified by signals from the neural tube and ectoderm, the dorsal portion of each somite forms an epithelial structure, the dermomyotome, which contains the precursor cells of all skeletal muscles that will form in the vertebrate body (with the exception of those found in the head). The medial portion of dermomyotome contains those precursors that form the axial or paraspinal musculature surrounding the vertebral column, whereas those cells of the ventral–lateral portion of the dermomyotome undergo a process of delamination and migrate into the forming appendages to produce the appendicular musculature of the limbs and body wall [3,4]. While the muscle fibers that form from the different regions of the somite are nearly indistinguishable, myogenesis in the axial and appendicular muscles is regulated by different effectors, demonstrating the complexity of determination and differentiation in the early embryo. These interactions not only result in the activation of muscle-specific structural and enzyme-encoding genes but also insure the continued expression of specific regulatory transcription factors which stably maintain the differentiated state.

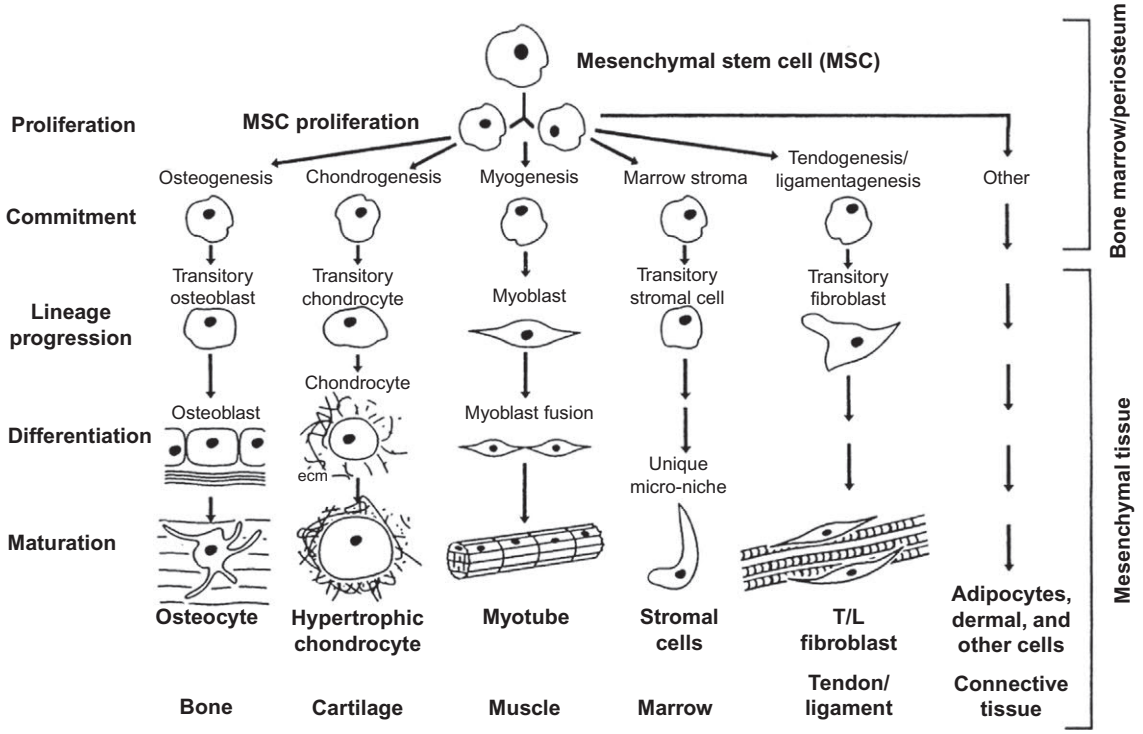

FIGURE 9.1 The process of commitment and differentiation.
Cells arise during gastrulation in the vertebrate embryo that subsequently produces all the different cell type of the body. Cells that can be designated as MSC proliferate and, in response to cues from the cellular environment, enter lineages that undergo differentiation and subsequent maturation into the mature cell types. *MSC*, Mesenchymal stem cells.

MyoD and the myogenic regulatory factors

It was not until late in the 20th century that investigators first demonstrated that cellular commitment to specific developmental fates could be determined by the expression of a single gene or a very small number of genes [5–9]. Improvements in tissue culture methods and rapid advances in molecular biology permitted the introduction of foreign genes into mammalian cells. The first gene capable of specifying a cell to a particular cellular phenotype was isolated and characterized in the laboratory of Weintraub [10,11]. They named this gene MyoD. Expression of MyoD is specific to skeletal muscle, and introduction of MyoD cDNA into fibroblasts of the 10T1/2 cell line converts them at a high frequency into stable myoblasts, which in turn differentiated into muscle fibers that express skeletal muscle proteins. MyoD was only the first of a family of myogenic regulatory factors (MRFs) to be discovered; others include Myf-5 [12], myogenin [13], and MRF4 [14]. Myf-5, MyoD, myogenin, and MRF4 are members of the basic helix-loop-helix (bHLH) family of transcription factors that bind to specific genomic sequences that control determination and differentiation of cells into skeletal muscle fibers during embryogenesis, postnatal myogenesis, and skeletal muscle regeneration [15]. This family acts in a hierarchical fashion that establishes the myogenic lineage as well as maintains the terminal myogenic phenotype during development and muscle regeneration [1].

Genetic experiments demonstrate that MyoD and Myf-5 establish the myogenic lineage, whereas Myf4 and myogenin mediate the expression of the terminal phenotype [16]. Muscle-specific transcription factors orchestrate the myogenic gene expression program by binding to particular sequences within the *cis*-regulatory elements of muscle-specific genes. [17]. These are short DNA motifs called E-boxes. The importance of MyoD and myf-5 to the determination of skeletal muscle was demonstrated when double knockout of these two genes in transgenic mice resulted in a nearly complete absence of skeletal muscle and myoblasts in offspring [16], whereas knockouts of one or the other do make skeletal muscle [18,19]. On the other hand, knockout of *myogenin* results in embryos with virtually no muscle fibers, but myoblasts do appear [20,21] suggesting that this gene is necessary for terminal differentiation. It is therefore believed that *MyoD* and *Myf-5* can compensate for each other and together act in a genetic pathway upstream of *myogenin* and *MRF4* to program all skeletal myogenesis. The role of the four MRFs has been reviewed [22].

MRF members share a common structure, a stretch of basic amino acids followed by a stretch of amino acids that form two amphipathic helices separated by an intervening loop (the bHLH motif). They are nuclear-located DNA-binding proteins that act as transcriptional regulators [1,17]. It has been demonstrated that the basic amino acids portion of each is required for DNA binding to the E-boxes and is essential for the myogenic conversion of fibroblasts to a skeletal muscle fate. The bHLH motif plays an essential role, because it is the basis for formation of heterodimers with other ubiquitously expressed bHLH proteins that facilitate DNA binding [17,23,24]. Sallee and Greenwald [25] reported that the ability of bHLH to activate lineage-specific programs of gene expression is so fundamental in differentiation that they were able to demonstrate bHLH proteins from humans activating the same functions in *Caenorhabditis elegans*.

As nature is conservative, it is not surprising that the bHLH motif was found in transcriptional factors, regulating the determination of cell types other than skeletal muscle. An example is the neurogenin family of bHLH genes. Based upon homology with MyoD, NeuroD (also known as BETA2 or NEUROD1 and 3) is one of the families of helix-loop-helix (HLH) transcription factors first isolated by the Weintraub laboratory and shown to act as a neuronal determination factor [26]. Introduction of the NeuroD gene into presumptive epidermal cells of Xenopus embryos or in human cells in conjunction with other transcription factors converts cells into fully differentiated neurons [27].

The neurogenins are a family of bHLH proteins expressed in neural precursors in the embryo prior to that of NeuroD, where they appear to function in facilitating the expression NeuroD. Determination of several different types of neuronal cells and the migration of neuronal cells are dependent on which neurogenin family member is expressed [28]. Neurogenins are known as the "proneural genes," because they are both necessary (by loss-of-function) and sufficient (by gain-of-function) to initiate the development of neuronal fate and to promote the differentiation of progenitor cells to acquire specific subtype identities [29]. It was subsequently shown that *neurogenin* 1, one of the three neurogenins, is required for the expression of a cascade of downstream bHLH factors, including NeuroD. Cells in different portions of the central and peripheral nervous are controlled by different members of this family and other bHLH genes. Ma et al. [30] have shown in the mouse embryos that loss of one of the three neurogenins, *ngn1*, leads to failure to generate sensory neurons of the inner ear. Like the MRFs, there are protein products of multiple bHLH genes, which activate other bHLH to control cell types. They act in both a positive and negative fashion and by interacting with other proteins to fine-tune differentiation [31,32].

Particular families of bHLH proteins can determine more than a single cell type. For example, NeuroD plays

an important role in the differentiation of pancreatic endocrine cells and of the retina in addition to other neural cell types [27,33–35]. In transgenic mice where NeuroD is knocked out, there are defects in multiple organs [36]. Pancreatic endocrine cells and neurons in the central and peripheral nervous systems die, resulting in cellular deficits in the pancreatic islets, cerebellum, hippocampus, and inner ear sensory ganglia. As a consequence, mice become diabetic and display neurological defects, including ataxia and deafness. These loss-of-function experiments suggest that the neurogenin family and NeuroD control expression of both common and distinct sets of molecules involved in cell survival and differentiation of different tissue types. But just like the MRFs, NeuroD does not function alone in neuronal differentiation and survival [37]. Additional bHLH proteins, including HES, Math-5, and Mash-1, have been shown to participate in the determination of neural cells as well. Differences in the expression of these various neurogenic bHLH proteins help to explain the diversity of neuronal cell types within vertebrate bodies. For example, genetic deletion of another bHLH protein encoded by the Mash-1 gene eliminates sympathetic and parasympathetic neurons and enteric neurons of the foregut [38].

Because cardiac muscle has so much in common with skeletal muscle, including a large number of contractile proteins, an exhaustive search was made for MyoD family members in the heart. Surprisingly, MyoD family members were not found in the developing heart, and thus they play no part in the differentiation of cardiac muscle cells despite the fact that many of the same genes for contractile proteins are expressed in cardiac as skeletal muscle cells. However, a different family of bHLH-containing factors, including dHAND and eHAND, were found in the developing heart. Unlike acting as determination factors, these bHLH factors are important for morphogenesis and the specification of cardiac chambers rather than for activation of contractile protein expression [39,40].

Negative regulators of development

In myogenesis and in other developmental pathways, there are both activators and repressors that act to modulate differentiation. These are found in both myogenesis and neurogenesis [41]. Acting as dominant negative regulators of the bHLH family of transcriptional regulators is a ubiquitously expressed family of proteins that contain the HLH structure, but lack the upstream run of basic amino acids essential for the specific DNA-binding characteristic of MyoD family members [42]. These transcription regulators are capable of dimerizing with MRFs. They are called inhibitors of differentiation (Id). These are a group of proteins that themselves do not bind to DNA but that can bind specifically with MyoD and bHLH products and in doing so attenuate ability of these proteins to bind DNA by forming nonfunctional heterodimeric complexes with them [42,43]. Thus in the case of myogenesis, they act to inhibit transcription of muscle-specific genes within proliferating myoblasts inhibiting the terminal differentiation program. Id levels decrease on terminal differentiation. Such associations with corepressor proteins and with proteins that titrate MyoD away from its DNA binding include not only the Id proteins but also other HLH proteins. These have been reviewed in Ref. [15,22].

Like myogenesis, neurogenesis is also regulated by repressors of the neurogenin family of bHLH activators [41]. An example is the HES family of HLH-containing proteins expressed in neural stem cells, where their presence prevents premature differentiation and permits proliferation of neuronal precursors. The interaction of unique sets of positively acting bHLH activators and negatively acting members of the HES family helps explain how different subsets of neurons undergo differentiation at different times during development, so that the complexity of the nervous system is produced [32,44,45].

MicroRNAs—regulators of differentiation

Activators of transcription and microRNAs (miRNAs) function during differentiation to modulate the expression of genes. Myocyte enhancer factor-2 (MEF2) proteins are a family of transcriptional activators that bind to A + T-rich DNA sequences found in several cells types and in many muscle-specific genes, including those encoding contractile proteins, muscle fiber enzymes, and the muscle regulatory factor, myogenin [46,47]. These are members of the MADs-box family of transcription factors. While some members of this family show a nearly ubiquitous distribution among tissue types, a few forms of the MEF2 family show expression that is more restricted to striated muscle. They do not act alone but act cooperatively with the MRFs in enhancing transcription of muscle-specific genes. Both MEF2s and MRFs bind to each other and to *cis*-modulating regions of the promotors of muscle-specific genes to enhance transcription [12,48,49]. So, while the MRFs are central to specification of cells to a myogenic fate, the MEF2 family acts synergistically to enhance transcription within the cells determined to this fate.

But not all regulation of differentiation is mediated by proteins. Another common method of control of differentiation is found in myogenesis and in most differentiating cells, which results in specification, maintenance, and regulation of complex regulatory circuits that have noncoding RNAs, including miRNAs [50]. Differentiation occurs not only through gene activation and transcription but also by suppression of transcription. The miRNAs sever

the suppressive function in differentiation at the posttranscriptional level. Rather than preventing or suppressing transcription, these RNAs prevent translation of messenger RNAs (mRNAs) within differentiating cells. miRNAs are incorporated into what are known as RNA-induced silencing complexes (RISC) that in turn alter the mRNAs that are translated [50]. A mature miRNA, incorporated into a RISC, guides the RISC to target complementary sequences usually present in the 3-UTR of mRNAs in the cytoplasm. The interaction of the miRNA, with its target site on the mRNA, typically has imperfect complementarity. The degree of complementarity influences the outcome of the interaction between the miRNA and its targeted mRNAs. The mechanism by which the miRNAs act is usually to repress protein translation by binding to specific mRNA, resulting in the mRNA ultimately being degraded.

Specific miRNA expression is initiated by the MRFs [51,52] to control production of skeletal muscle proteins within myogenic precursor cells. There are several miRNAs that are absent from undifferentiated myoblasts but are strongly upregulated upon differentiation [53]. MRF4 initiates the expression of miR-1 and miR-206. These miRNAs control translation of some of the muscle cell gene key transcripts. Experiments indicate that miRNAs can also modulate myogenic differentiation by affecting the translation of proteins not controlled by MEF2 or MRFs. An example is an increase of miR-1, a miRNA expressed in myogenesis. It accelerates myoblast differentiation by downregulating histone deacetylase 4 (HDAC4), a repressor of muscle differentiation [54]. By preventing the translation on HDAC4 mRNA, repression is released by miR-1 and differentiation proceeds. Thus by the repression of gene expression (transcription), for example, by Id proteins, the activation of gene expression by MRFs proteins, and the posttranscriptional repression of gene expression by miRNAs, the expression of characteristic of differentiating cells is fine tuned.

Pax in development

Much of what has been learned about the role of MyoD and myf-5 in the determination of skeletal muscle has come from studies on transgenic mice in which MRFs have been deleted [16,18–21,55]. The conclusion from this work was that MyoD and Myf-5 acted as redundant initial activators of myogenesis and as key players in commitment of cells in the early embryo to a myogenic fate. What then is the mechanism that initiates the expression of MyoD and Myf-5? Members of Pax family of transcription factor play this role early in somite maturation in the earliest stage of myogenesis. Pax3 and Pax7 are members of a DNA-binding family of proteins of primary importance to myogenesis. They bind to the regulatory regions of Myf-5 and MyoD and initiate their expression [56–59].

Pax3 plays the key role in early myogenesis while Pax7 predominates during muscle growth in the fetus and neonate and muscle regeneration in the adult [60]. In the double *Pax3*/*Pax7* mutant, cells fail to enter the myogenic program, leading to a major deficit in skeletal muscle [61]. Knockout of Pax3 alone leads to a complete absence of skeletal muscle, and the absence of MyoD expression and is the basis for placing Pax3 genetically upstream of the MRFs [62]. Thus while the MRFs control determination to the myogenic fate, members of the Pax family act downstream of these factors to dictate the expression of these master regulatory genes and thus to initiate entry into the myogenic program.

The second member of the Pax transcription factor family, Pax7, is a key element in the control of the growth of muscle and the potential for regeneration. Pax7 was isolated from satellite cells, a population of muscle-committed stem cells found in intimate association with mature muscle fibers. Satellite cells are responsible for muscle growth in the fetus and neonate and repair in the adult. Pax7 is specifically expressed in proliferative myogenic precursors, both embryonic myoblasts as well as satellite cells, and is downregulated at differentiation [63]. Transgenic mice lacking the Pax7 gene have normal musculature, with reduced muscle mass, but they have a complete absence or markedly reduced numbers of satellite cells [63,64]. These investigators found that in these Pax7 mutants, satellite cells, cells responsible for postnatal growth and regeneration of skeletal muscle, are progressively lost by cell death. These results suggest that specification of skeletal muscle satellite cells requires Pax7 expression or that Pax7 expression is responsible for survival of satellite cells. The interplay of the many factors that control the initiation and maintenance of myogenesis is shown in Fig. 9.2.

Satellite cells in skeletal muscle differentiation and repair

The reason that a discussion of skeletal muscle differentiation is so central to a basic understanding of cell differentiation is that this tissue unites concepts of tissue formation and tissue repair. The cell that unifies these is the stem cell of skeletal muscle called the satellite cell [65,66]. Among the first cells to be considered stem cells were the satellite cells of skeletal muscle initially described in 1961 by Alexander Mauro [67–69]. These cells lie just beneath the basal lamina that surrounds each muscle fiber within an anatomic muscle and above the plasma membrane of the fiber. These cells meet the definition of stem cells because they are self-renewing.

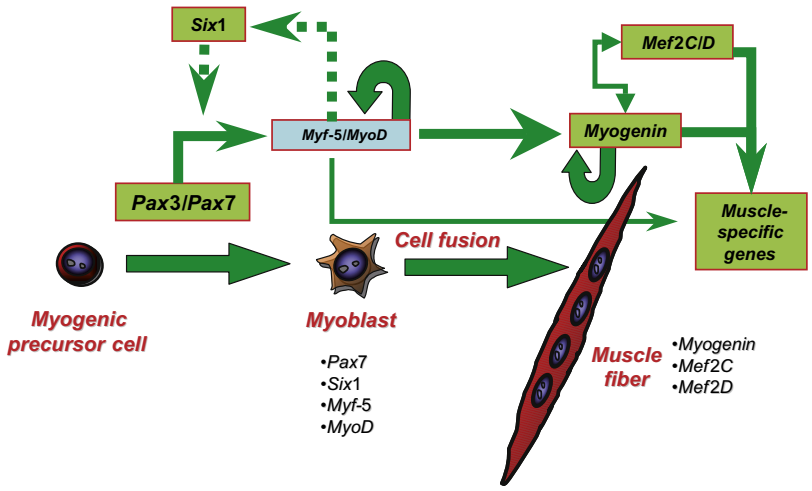

FIGURE 9.2 A regulatory network controls muscle cell differentiation. *Provided by Dr. Michael Rudnicki and modified.*

They are cells set aside in early muscle development, during which they contribute to fiber lengthening as fibers grow by cell fusion, as well as to the formation of additional fibers called secondary muscle fibers in the neonate [70] and to repair of muscle cells during regeneration. After neonate development, satellite cells remain quiescent unless fiber injury results in repair or regeneration. On the other hand, muscle hypertrophy, as in weight lifters, is primarily produced by expansion in size of existing fibers rather than fiber number. So satellite cells play little role in hypertrophy unless exercise injures fibers.

Satellite cells are located within special niches formed by the basal lamina. These niches keep satellite cells in a quiescent state until there is injury to the fibers of a muscle on which they lie. Injury results in the release of cytokines that initiate the proliferation and migration of the satellite cells on the surface of the injured fibers and on adjacent fibers. Satellite cells are distinguished from the nuclei of other cells within muscles because they express Pax7. The cell divisions of satellite cells are asymmetric—one daughter forms another satellite cell (stem cell) and is retained in the niche and the other goes forward as a myogenic cell that most often fuses with an injured fiber to reconstitute its multinuclear state, or occasionally, depending on the nature of the injury, to form a new fiber [71,72]. Thus while muscle regeneration is very limited in higher vertebrates, new fibers can form, and old fibers can be repaired while still retaining a supply of stem cells for future tissue repair. The challenge to investigators of tissue engineering with the goal of restoring muscle tissue is to develop strategies to facilitate extensive muscle stem-cell proliferation, cell survival, and efficient cell differentiation of transplanted cells. Attempts to expand normal myogenic cell populations for extended periods of time without losing ability differentiation in vivo have generally failed without transformation of the cells [73–75]. Equally challenging is gaining an understanding of the cells that form the connective tissue scaffolding of an anatomic muscle, if satellite cells are to successfully be used to treat neuromuscular disease, to combat ageing, or to reconstitute muscles following trauma [76,77].

Tissue engineering—repairing muscle and fostering regeneration by controlling determination and differentiation

Myogenesis is one of the most thoroughly studied systems where the detailed mechanisms of differentiations have been delineated. Skeletal muscle is also among the largest tissues in the human body. Because of its importance in ambulation, changes in muscle function place it in the forefront of clinical problems. Not only are there dystrophic diseases that compromise skeletal muscle function, but also this tissue is often severely damaged in civilian trauma and combat, and with ageing, muscle mass is lost. So, one would think that with such detailed understanding of how muscle cells originate, we would have strategies to combat these problems. Such strategies remain a challenge and only recently have studies revealed new options for employing our understanding of determination to solve problems of muscle bioengineering [77–79]. The principle challenges relate to the size of muscles when they need repair, the inability to produce large number of precursor cells for repair, the multiple cell types that must interact to produce an anatomically functional muscle, and the methods of delivery of cells for repair. Likewise, the three-dimensional aspects of muscle formation remain a challenge for tissue engineering [80].

Until recently, the most promising approaches to solve the problem of repair of skeletal muscle tissue damaged by disease or trauma were embryonic stem (ES) cells and

induced pluripotent stem (iPS) cells (iPSCs) [81]. There has been a flurry of experimental activity in model systems for regeneration and primary muscular diseases, which exploit these two types of cells [3,82–84]. ES cells are derived from the inner cell mass of preimplantation human and other vertebrate embryos. These cells can differentiate into a variety of cell types, including skeletal muscle, under the influence of factors added to culture media in which they are grown. On the other hand, iPSCs can be derived from many adult human cell types eliminating the ethical issues surrounding the use human embryos to derive stem cells. Using a limited number of genes, or by transfection with retroviruses, lentiviruses, or plasmids, such cells can be obtained through direct reprograming of human muscle cell types to propagate and to differentiate into muscle [82,85]. A downside of some iPS-like cells is that they can form teratomas when introduced in vivo [86]. Investigations in murine models have also identified a variety of other cells types that can differentiate into skeletal muscle, including bone marrow–derived side-population cells [87], mesenchymal stem cells [88], pericytes [89], $CD133^+$ progenitor cells [90], and mesoangioblasts [91]. These show a high myogenic propensity in vitro and in vivo, but their downside is that they are small populations of cells. In another approach, mouse and human satellite cells can be expanded under the influence of an inhibitor of a methyltransferase resulting in cell proliferation and can repopulate the satellite cell niche in normal and in preclinical models of muscular dystrophy [92].

Investigators have taken different approaches to produce cells that continue to proliferate, and ultimately differentiate, as well as give rise to cells with satellite properties [93]. In particular, these cells have been produced by manipulating the expression of PAX7 and MRFs, important factors in myogenic differentiation. But as noted in the discovery of the MRFs, the MyoD gene could directly convert fibroblasts cells into myogenic cells [10], but it was noted that these cells could not be propagated into large populations nor form satellite cells [94]. But investigators have shown that ectopic expression of MyoD, combined with exposure to small molecules, reprograms mouse fibroblasts into expandable myogenic progenitor cells [85]. These are designated as iMPCs. iMPCs express key skeletal muscle stem and progenitor cell markers, including Pax7 and Myf-5, and give rise to dystrophin-expressing myofibers upon transplantation in vivo into the muscle of mice with muscular dystrophy. iMPCs have the potential to (1) engraft in dystrophic and nondystrophic, injured muscles, (2) give rise to $Pax7^+$ cells (satellite cell like) within transplants, and (3) contribute to muscle regeneration in a serial-injury model. CRISPR/Cas9 technology could be used to restore dystrophin expression and such dystrophin-expressing iMPCs from patients with Duchenne muscular dystrophy could be used for cell therapy [85,95,96]. Thus human iMPCs may provide a source of cells for tissue engineering purposes to correct diseases or traumatic loss of muscle tissue.

There are advantages to using iMPCs or iPSCs in muscle repair. While the use of ES cells from humans is complicated by ethical considerations, iMPCs and iPSCs are not, because they do not require human embryos. These cells also have the advantage that each individual could have their own cells (autologous patient-specific stem cells) used to form iMPCs or iPSCs, thus obviating immunological rejection. But at least two hurdles remain to be overcome in tissue engineering of muscle repair—the size of muscles in humans anatomic muscles that require large numbers of cells for adequate repair and the array of other cell types that comprise a muscle. Ideally, transplanted myogenic cells must proliferate and persist in vivo and become co-opted into the satellite cell lineage for subsequent increase in fiber number or its repair. In any situation where cells for transplantation are encouraged to proliferate and differentiate in vitro following viral transfection, an important risk of problems rooted in insertional mutagenesis [97]. Despite these formidable problems, induced myogenic cells have become the favor cells for skeletal muscle transplantation. This approach has been exploited in several new models to form "muscles" where an anatomic muscle has had volumetric muscle loss [98]. Using gels and other matrices, human iPSCs can form three-dimensional "muscles" that perform contractile functions of normal skeletal muscle. Particularly interesting are studies that combine satellite cells, endothelial cells, hematopoietic cells, and fibro-adipogenic progenitors [99]. These can be combined with extracellular matrix proteins to form a hydrogel to attempt to restore function in models of volume loss. In these models of volumetric muscle loss, it has been shown that there is a return of many physiological functions to the damaged muscles, including innervation of the regenerating muscle. It has also been shown that the inclusion of an exercise program enhances structural repair, including innervation of the regenerating muscle [100–102]. Darabi et al. [97,103] and Mizuno et al. [104] have used induced cells from the mouse transfected with a gene (Pax7) fostering myogenic differentiation showing that these engineered cells are effective in engraftment, improving muscle function in disease models. As discussed by Rando and Ambrosio [77], engineering new muscles for repair attention has to be directed to the family of cell types and matrices that comprise an anatomic muscle. They make the point that efficient capacity to rebuild this tissue depends on additional cells in the local milieu, and without it, there is incomplete regeneration [79].

Conclusion

Determination and differentiation are in large part controlled by the expression of transcriptional regulators. These mechanisms begin early in development and involve the formation of cells that become committed to specific pathways of regulated gene expression. The regulators responsible were first characterized in studies committed to the differentiation of skeletal muscle development. The important proteins in the process are basic helix-loop-helix family proteins. Skeletal muscle development serves as a model for the mechanisms involved. Some other developing organs, such as the central and peripheral nervous systems, the pancreas, retina, and inner ear, employ very similar mechanisms and closely related members of the basic helix-loop-helix family of proteins to drive their development. But transcription alone does not control differentiation. Mechanisms that limit gene activation and transcription and miRNAs that restrain translations are crucial for the fine-tuning of differentiation. The progress in understanding differentiation of myogenic cells, their expansion in cell number, and transplantation techniques promises that basic understanding of determination and differentiation can lead to approaches to correct muscle fiber diseases and provide cells for muscle repair. Already our understanding of the mechanisms and effectors of determination and differentiation has been applied in strategies to engineer embryonic or adult-derived stem cells to address medical problems through transplantation. Particularly exciting are tissue engineering studies of transplanted myogenic cells combined with the many other cell types found in anatomic muscle and matrix gels as an approach to the problem of muscle volume loss.

Part Two

In vitro control of tissue development

Chapter 10

Engineering functional tissues: in vitro culture parameters

Jennifer J. Bara[1] and Farshid Guilak[1,2,3]

Introduction

Clinical disorders typically associated with musculoskeletal and cardiovascular tissues (i.e., osteoarthritis and myocardial infarction, respectively) often result in the loss of native tissue structural organization and mechanical function [1,2]. Tissue engineering is a rapidly growing field that seeks to restore the structure and function of tissues damaged due to injury, aging, or disease through the use of cells, biomaterials, and biologically active molecules (Fig. 10.1). Despite many early successes, there are few engineered tissue products available for clinical use, and significant challenges remain with regard to translating tissue-engineering technologies to the clinic for successful long-term repair of mechanically functional tissues. The precise reasons for graft failure are not fully understood, but they include a combination of factors that lead to the breakdown of repair tissues under conditions of physiologic loading.

Two critical aspects of tissue function in many tissue and organ systems are the transmission or generation of mechanical forces and the maintenance of blood circulation. In particular, articular cartilage (AC) and myocardium have highly specialized tissue composition and structure to allow for the specific mechanical and transport properties of these tissues. Although different in many respects, cartilage and cardiac tissues both perform critical biomechanical functions in vivo and lack intrinsic capacity for self-repair. Therefore cartilage and cardiac tissues are ideal targets for functional tissue engineering.

At the time of implantation, tissue-engineered constructs rarely possess mechanical properties that can

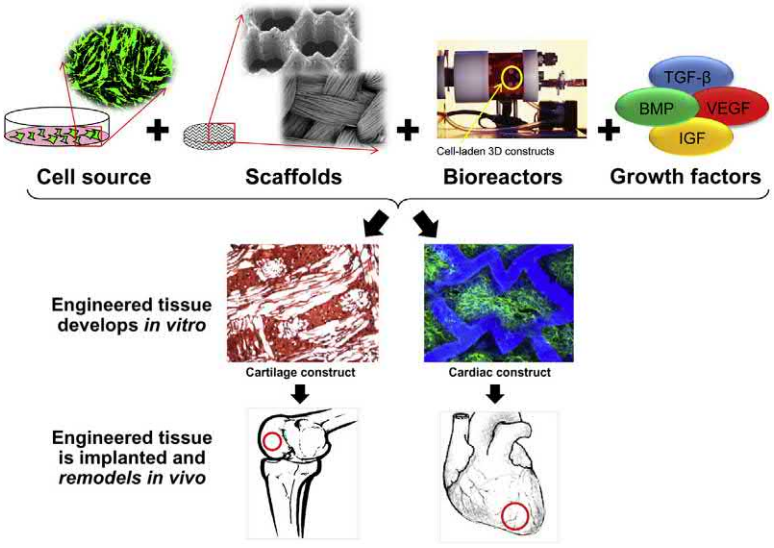

FIGURE 10.1 Strategy for engineering functional tissues in vitro.
Cells, scaffolds, bioreactors, and growth factors are used as tools to create functional engineered tissues. This chapter focuses on the in vitro culture of engineered cartilage and cardiac constructs that can be utilized for basic research and, potentially, for repair of damaged articular cartilage and myocardium. *Top panel: Scaffold images adapted from Engelmayr Jr GC, et al. withstand the high magnitudes of mechanical stresses experienced in vivo. For many native tissues, however, the potential range of in vivo stresses and strains are not well characterized, thus making it difficult to incorporate a true "safety factor" into the design criteria for engineered tissues. In addition, matching a single mechanical parameter, such as modulus or strength, is rarely sufficient, as most tissues possess complex viscoelastic, nonlinear, and anisotropic mechanical properties that may vary with age, site, and other factors [7].

A number of complex interactions must also be considered, as the graft and surrounding host tissues are expected to integrate and remodel in response to their changing environments postimplantation [8]. For example, convective transport of oxygen, nutrients, and waste products may become a limiting factor. Currently, most tissue-engineered constructs do not contain a functioning vasculature at the time of implantation, instead relying on either anastomosis of implanted capillary networks to the host vasculature or de novo angiogenesis to provide transport capability. Because oxygen has low solubility in aqueous media and diffuses over distances of only 100−200 μm, oxygen transport is often a limitation in cell survival within large, anatomically relevant grafts [9−11].

An evolving discipline referred to as "functional tissue engineering" has sought to address the aforementioned challenges by developing guidelines for rationally investigating the role of biological and mechanical factors in tissue engineering. A series of formal goals and principles for functional tissue engineering have been proposed in a generalized format [5,7,12]. In brief, these guidelines include the development of (1) improved definitions of functional success for tissue-engineering applications; (2) improved understanding of the in vivo mechanical requirements and intrinsic properties of native tissues; (3) improved understanding of the biophysical environment of cells within engineered constructs; (4) scaffold design criteria that aim to enhance cell survival, differentiation, and tissue mechanical function; (5) bioreactor design criteria that aim to enhance cell survival and the regeneration of functional tissue-engineered constructs; (6) construct design criteria that aim to meet the metabolic and mechanical demands of specific tissue-engineering applications; and (7) improved understanding of biological and mechanical responses of an engineered tissue construct following implantation. Since these guidelines were proposed, significant progress has been made toward developing in vitro culture systems and techniques to enhance graft mechanical properties and engineer functional tissues.

One of the key challenges in functional tissue engineering is optimizing the in vitro culture environment in order to produce three-dimensional (3D) implants that can meet the requirements of the in vivo milieu. In particular, the ability to precisely define and control in vitro culture conditions can be exploited to improve and ultimately control the structure, composition, and mechanical properties of engineered tissues. This chapter focuses on how advanced in vitro culture strategies, including the use of scaffold systems, bioreactors, growth factors, and mechanical conditioning, can influence the development and performance of engineered tissues (Fig. 10.1). Although the discussion addresses cartilage and cardiac tissues specifically, the concepts are also of relevance to other tissues and organs that serve some mechanical function (e.g., muscle, tendon, ligament, bone, blood vessels, heart valves, and bladder) and are the targets of tissue-engineering research efforts. The following sections of this chapter will consider key concepts, the importance of in vitro studies, and the influence of selected in vitro culture parameters on the development and performance of engineered tissues. Illustrative examples and alternative approaches for engineering cartilage and cardiac tissues are provided.

Key concepts for engineering functional tissues

Fundamental parameters for engineering functional tissues

Many tissue-engineering approaches involve the in vitro culture of cells on biomaterial scaffolds to generate functional engineered constructs. The working hypothesis is that in vitro culture conditions have a significant influence on the structural and mechanical properties of engineered tissues and therefore can be exploited to manipulate the growth and functionality of engineered tissues. In vitro *culture conditions* will refer to tissue-engineering scaffold systems, bioreactors, growth factors, and mechanical conditioning regimens that mediate cell behavior and functional tissue assembly [13,14]. *Scaffolds* will be defined as 3D material structures designed to perform some or all of the following functions: (1) promote cell-biomaterial interactions, cell adhesion, and extracellular matrix (ECM) deposition; (2) permit sufficient transport of gases, nutrients, and regulatory factors to allow cell survival, proliferation, and differentiation; (3) biodegrade at a controllable rate that approximates the rate of tissue regeneration under the culture conditions of interest; and (4) provoke a minimal degree of inflammation or toxicity in vivo [11,15]. *Bioreactors* will be defined as laboratory devices designed to perform some or all of the following functions: (1) provide control over the initial cell distribution on 3D scaffolds; (2) provide efficient mass transfer of gases, nutrients, and growth factors to tissue-engineered constructs during their in vitro cultivation; and (3) expose the developing constructs to convective mixing, perfusion, and/or mechanical, electrical, or other biophysical factors in a controlled manner [9,10,16−20]. *Mechanical*

conditioning will be defined as the in vitro application of dynamic mechanical loads (i.e., compression, tension, pressure, and/or shear) to cells, tissues, and/or 3D engineered tissue using custom designed systems. These fundamental in vitro culture parameters can be controlled independently or in combination to strategically meet the requirements of the specific tissue to be engineered.

Fundamental criteria for engineering functional tissues

The biological and mechanical requirements of an engineered tissue depend on the specific application. For example, engineered cartilage should provide a low-friction, articulating surface and be able to withstand and transmit load in compression, tension, and shear, whereas engineered cardiac tissue should propagate electrical signals, contract in a coordinated manner, and withstand dynamic changes in pressure, tension, and shear. In addition to tissue-specific requirements that serve as design principles for functional tissue engineering, there are fundamental criteria that all engineered tissues should meet (1) at the time of implantation, an engineered tissue should possess sufficient size and mechanical integrity to allow for handling and permit survival under physiological conditions; (2) immediately following implantation, an engineered tissue should provide some minimal levels of biomechanical function that should improve progressively until normal tissue function has been restored; and (3) after implantation, an engineered tissue should mature and integrate with surrounding host tissues.

Importance of in vitro studies for engineering functional tissues

Cells cultured in vitro tend to retain their differentiated phenotype and function under conditions that resemble their natural in vivo environment; these conditions may be generated using a combination of scaffolds, bioreactors, growth factors, and mechanical conditioning [5,7,12–14]. In vitro–grown tissue-engineered constructs can potentially be transplanted in vivo for tissue engineering and regenerative medicine applications or utilized as platforms for in vitro testing of cell- and tissue-level responses to molecular, mechanical, or genetic manipulations.

In vitro studies relevant to tissue engineering and regenerative medicine

In vivo models are essential for clinical translation of engineered tissues as they provide insight into the functional performance of engineered tissues. However, these models are complicated by high variability and biological and mechanical environments that differ from those existing in the human condition. To overcome these limitations, in vitro studies can be designed to understand the performance of the engineered tissue in vivo by (1) addressing the challenges of in vivo complexity in more controllable in vitro systems and (2) exploring how an in vitro–grown construct may behave when implanted in vivo. For example, tissue-engineered cartilage constructs pose a significant challenge with regard to variable and incomplete integration upon implantation in vivo [21,22]. To address the challenge of tissue integration, researchers have taken the approach of evaluating the integration of engineered tissues with native tissues using not only in vivo models [23] but also in vitro models (Fig. 10.2). In one study, cells were combined with three types of scaffolds [fibrin, agarose, and poly(glycolic acid) (PGA)], incorporated with explants of native AC and cultured as composites for 20 or 40 days [25]. The presence of native cartilage significantly altered cell proliferation and matrix accumulation in the composites. In addition, although engineered constructs based on all three scaffold materials adhered to the native cartilage, there were significant differences in the adhesive strength between the groups, suggesting that the type of scaffold may influence construct integration in vivo.

In another in vitro study, cells were combined with hyaluronan benzyl ester scaffolds, incorporated with three types of explants [native AC, vital bone, or devitalized bone (DB)] and cultured in rotating bioreactors for 4 or 8 weeks (Fig. 10.2) [24]. Engineered cartilage constructs interfaced with the solid matrix of adjacent cartilage without any gaps or intervening capsules. In addition, focal intermingling between construct collagen fibers and native cartilage collagen fibers provided evidence of structural integration (Fig. 10.2D–F). Interestingly, adhesive strength was higher for constructs cultured adjacent to bone than cartilage and highest for constructs cultured adjacent to DB (Fig. 10.2G). These findings could be explained by the differences in adjacent tissue architecture (histological features) and transport properties (diffusivity) [24]. Photochemical bonding has emerged as a potential tool for enhancing cartilage integration. Using the photosensitizer aluminum–phthalocyanine chloride, researchers were able to achieve improved shear strength between bonded native cartilage tissues, which persisted over a 1 week culture period [26]. Perfused bioreactors consistently yielded significantly higher amounts of glycosaminoglycans (GAGs) and total collagen in engineered cartilage cocultured adjacent to engineered bone than either engineered cartilage, native cartilage, or native bone [27]. These results suggest that the type of native tissue with which the engineered tissue is combined may influence construct integration in vivo. Collectively, information can be gleaned from in vitro studies with respect

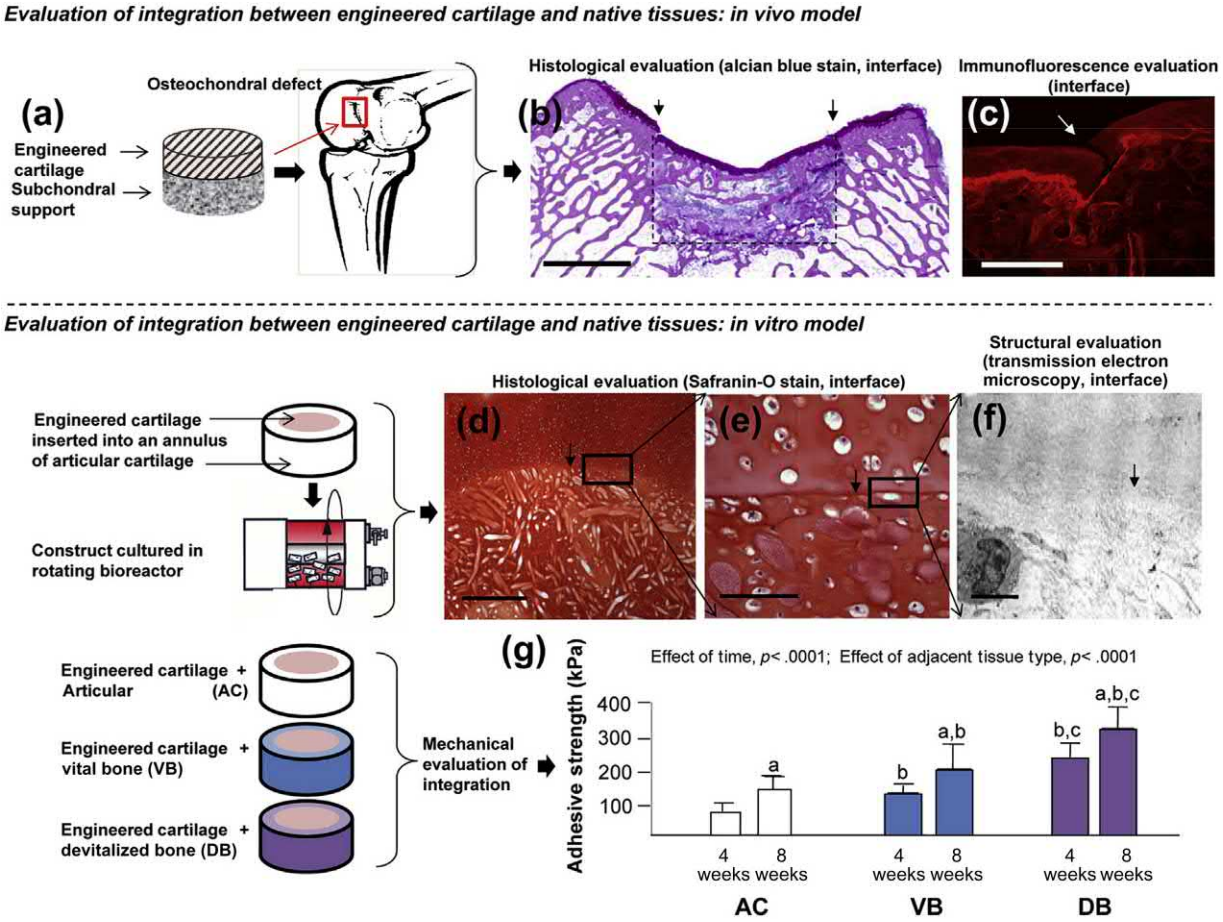

FIGURE 10.2 Studies of the clinically relevant problem of engineered cartilage integration.

to the integration potential of a tissue-engineered construct prior to in vivo implantation.

In vitro platforms relevant for high throughput screening of drugs and other agents

In vitro models can also be utilized to generate physiologically responsive tissue for screening pharmaceutical and therapeutic drugs (reviewed in Vandenburgh et al. [28]). This type of model can be designed for high throughput screening, thereby reducing the need for human tissue and organ harvest. Moreover, if based on human rather than animal cells (e.g., Schaaf et al. [29]), in vitro models can provide a more relevant system than in vivo animal models, which may differ significantly from the human case in their physiologic responses.

For example, a tissue-engineered drug screening platform referred to as "engineered heart tissue" was developed by combining neonatal rat heart cells with ECM components such as Matrigel and fibrin [30]. The cell−ECM−fibrin mixture was cast between two flexible posts such that maturation of the neonatal cells and condensation of the maturing tissue between the flexible posts yielded strips of cardiac-like tissue which contracted regularly. Pharmaceutical agents with known cardiac effects induced the expected changes within the

engineered heart tissue in a repeatable fashion, suggesting that engineered tissues of this type could be used for relatively high-throughput drug screening. Moreover, human embryonic stem cells (ESCs) were recently cultured to form engineered heart tissue that was successfully used to screen a panel of drugs with known proarrhythmic effects [29]. Engineered heart tissue may also be used as a surrogate cardiac tissue to explore in vitro the integration into native heart tissue of various cell populations, such as murine cardiomyocytes, cardiac fibroblasts, and murine ESC-derived cardiac cells [31,32]. These studies together suggest that engineered heart tissue can provide a valuable platform for screening cardiac pharmaceutical and cell therapeutics.

In vitro experiments, such as those described previously, are designed to elucidate cell- and tissue-level responses to molecular and mechanical stimuli and thus improve the understanding of complex in vivo phenomena and promote clinical translation of tissue-engineering technologies. In this context the in vitro culture environment plays a key role by allowing for controlled and reproducible test conditions that limit the variability associated with the in vivo environment.

Influence of selected in vitro culture parameters on the development and performance of engineered tissues

It is well-understood that traditional two-dimensional (2D) in vitro culture techniques cannot sufficiently recapitulate the microenvironment experienced by cells and tissues in vivo. Furthermore, physical forces are critical for the development of tissues and organs during embryogenesis and postnatal growth and remodeling. Therefore functional tissue-engineering strategies aim to recreate a 3D microenvironment in vitro that mimics the in vivo milieu through the use of scaffold systems, bioreactors, growth factors, and mechanical conditioning [5,7,12,14,17,33].

Culture duration

Cartilage tissue engineering

With the increase in vitro culture duration, chondrocytes assemble a mechanically functional ECM (e.g., Buschmann et al. [34]), and cardiomyocytes develop contractile responsiveness to electrical impulses (e.g., Radisic et al. [35]). For example, over a 40 day period of in vitro culture, constructs based on bovine calf chondrocytes and PGA scaffolds contained increasing amounts of GAG and type II collagen, and decreasing amounts of the PGA scaffold (Fig. 10.3A) [36]. In this system the relatively high rates of ECM synthesis and deposition by the calf chondrocytes approximately matched the relatively high degradation rate of the PGA scaffold, a finding that did not hold true when the same scaffold was studied with other cell types [e.g., bone marrow—derived mesenchymal stem cells (MSCs)] [14]. The structural and functional properties of engineered cartilage constructs can be improved to some degree by further extending the culture duration. For example, 7-month long cultures carried out in rotating bioreactors operated on Earth yielded engineered cartilage constructs with very high GAG fractions (~8% of wet weight) and compressive moduli (~0.9 MPa) that were comparable to normal AC (Fig. 10.3B and C), although the collagen fraction and dynamic stiffness of the 7-month constructs remained subnormal [37].

Optimal maturation of tissue-engineered cartilage in vitro may improve cartilage repair with respect to ECM quality and integration after implantation in vivo [38]. A recent study correlated engineered cartilage maturity with in vivo repair [39]. Engineered cartilage was prepared by

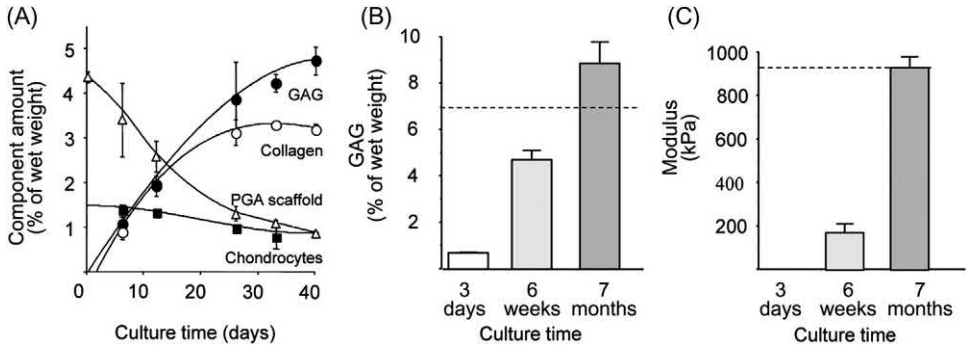

FIGURE 10.3 Effects of culture duration on the composition and function of engineered cartilage.
(A and B) Bovine calf chondrocytes were cultured on nonwoven PGA scaffolds in rotating bioreactors for up to 7 months. (A) Short term changes in the construct amounts of GAG (*closed circles*), total collagen (*open circles*), cells (*squares*), and PGA scaffold (*triangles*). (B and C) Long-term changes in construct amounts of GAG and Aggregate modulus (H_A), measured at 3 days, 6 weeks, and 7 months. Data are represented as mean ± SD. Dashed lines indicate average values obtained for native bovine calf cartilage. *GAG*, Glycosaminoglycan; *PGA*, poly(glycolic acid). *Adapted from (A) Freed LE, et al. culturing chondrocytes on ECM scaffolds for 2 days, 2 weeks, or 4 weeks. Constructs were then implanted into full thickness cartilage defects in rabbit knee joints. In this study the use of more mature engineered cartilage improved osteochondral defect repair; however, another study showed that prolonged in vitro culture of engineered constructs prior to in vivo implantation may lead to ECM degradation, resulting in suboptimal performance in vivo [40]. Collectively, these findings suggest that while in vitro tissue maturation may enhance the in vivo performance of the engineered tissue, the optimal in vitro tissue maturation conditions are likely to be cell type-, scaffold-, culture condition-, and/or animal model-dependent.

Cardiac tissue engineering

Engineered cardiac tissue slowly forms contractile units over time in culture, beginning with spontaneous beating of single cells or groups of cells. As the neonatal rat heart cells mature, elongate, and form networks, coordinated, coherent contractions develop throughout the construct [41,42]. For example, engineered cardiac tissue cultured for up to 8 days exhibited a temporal increase in contractile amplitude [35]. In another study, engineered heart tissue exhibited coherent contraction at 7−9 days in culture, increased in force of contraction between 9 and 15 days in culture, and then stabilized [30]. Cells within these constructs showed an elongated phenotype consistent with more mature cardiomyocytes. Extended in vitro culture supports tissue maturation as shown in a study where IPSC-derived cardiac tissues gradually acquired electromechanical function over a 4-week culture period [43]. However, increasing culture duration alone is not sufficient to produce myocardium with the same functional properties as native tissue. At present, maximal contractile force generation reported for engineered cardiac constructs remains more than an order of magnitude below that of adult heart muscle [33].

Biomaterials

Cartilage tissue-engineering biomaterials

Novel 3D scaffold designs have attempted to mimic aspects of native ECM using composite scaffold structures. As biomimetic physical and mechanical properties are difficult to achieve with a single, homogeneous material, several approaches for tissue engineering have employed composite scaffold systems, which are often designed with fiber reinforcement and layered structures [11].

Fiber-reinforced constructs for cartilage repair

This type of design typically utilizes a fibrous phase comprises a nonwoven, knitted, or 3D woven fabric within a cell-supporting phase comprises a hydrogel or sponge-like material. The cell-supporting phase generally provides a favorable environment for proliferation, differentiation, and ECM synthesis, while the fiber phase functions as a mechanical reinforcement and stabilizer for the construct.

For example, hydrogels known to support chondrogenesis (e.g., agarose, alginate, and fibrin) have been combined with degradable nonwoven or woven 3D scaffolds to engineer functional cartilage. To test the influence of a hydrogel cell-carrier system for chondrogenesis, nonwoven poly(lactic-*co*-glycolic acid) (PLGA) meshes were seeded with either dissociated bovine chondrocytes or with chondrocytes suspended in alginate [44] and then implanted subcutaneously in nude mice. The alginate cell carrier increased seeding efficiency by assisting in the retention and uniform distribution of cells throughout the pores of the nonwoven mesh. The fiber-reinforced hydrogel also yielded a physically robust construct that maintained its initial geometry over time, without a negative effect on ECM synthesis. Similar studies showed success when nonwoven PGA was either combined with a chondrocyte-laden fibrin gel [45] or with MSCs in a type I collagen and alginate gel [46].

Woven 3D fabrics embedded with hydrogels have also been utilized replicate the complex biomechanical behavior of native AC [47]. A microscale 3D weaving technique was employed to fabricate multiple layers of continuous fibers in three orthogonal directions (Fig. 10.4A−D). Composite scaffolds comprise 3D woven fiber bundles of PGA [47] or poly(ε-caprolactone) (PCL) [4] were used in combination with fibrin gel to mimic the physical properties of native AC, specifically, its inhomogeneous, anisotropic, nonlinear, and viscoelastic mechanical properties. Construct compressive mechanical properties and equilibrium coefficient of friction were found to be similar to those of native AC throughout the defined culture period (Fig. 10.4E−G). Further, constructs seeded with human adipose-derived stem cells (ASCs) supported the elaboration of ECM which stained positive for the presence of chondroitin 4-sulfate and type II collagen (Fig. 10.4H and I). In other studies the infiltration of this 3D woven PCL scaffold with a slurry of cartilage-derived ECM enhanced the chondrogenesis of ASCs while providing a mechanically functional construct that resisted cell-mediated contraction [48]. A unique advantage of this composite structure is that scaffolds can be designed and fabricated with predetermined control of site-dependent variations in mechanical properties and porosity within a biocompatible matrix.

Fiber reinforcement can also improve the mechanical properties of sponge-like scaffolds that otherwise have insufficient mechanical properties to support mechanical loading. For example, a scaffold comprising a web-like collagen micro-sponge and knitted PLGA fabric was fabricated for engineering cartilage tissue [49]. The knitted fabric provided the mechanical integrity lacking in the collagen micro-sponge, and the collagen micro-sponge

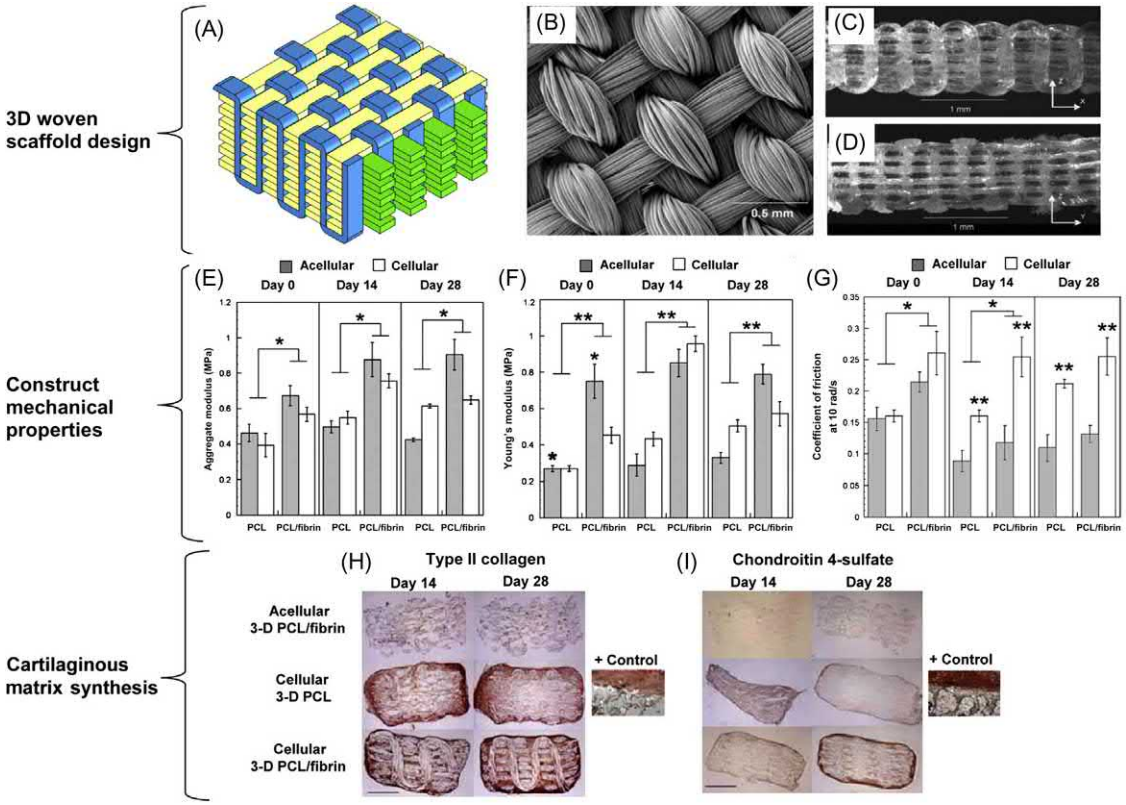

FIGURE 10.4 Structural and mechanical properties of a representative cartilage tissue-engineering scaffold.
Top panel: Fiber architecture of 3D orthogonally woven PCL scaffold. (A) Schematic and (B–D) scaffold weave and fiber morphology as shown with scanning electron microscopy [A—surface view, scale bar: 0.5 mm; B and C—cross-sectional view through the $X–Z$ plane (B), and $Y–Z$ plane (C), scale bar: 1 mm].

filled in the large pores of the fabric to facilitate uniform cell distribution and cartilage-like tissue formation. Similarly, reinforced PLGA foam scaffolds were produced by embedding short PGA fibers into the bulk polymer prior to foaming [50]. The mechanical properties of these scaffolds could be tailored for potential use in AC repair by adjusting the material composition [51]. Collectively, this work demonstrates that fiber reinforcement is a controllable design variable that can be manipulated in order to engineer scaffolds to suit the load-bearing requirements of an engineered tissue.

Stratified and osteochondral constructs for cartilage repair

AC has a remarkably heterogeneous, intricate structure and composition. Indeed, Raman spectroscopic analysis reveals a far more complex zonal hierarchy than previously realized, identifying six noncalcified zones on the basis of biochemical content and organization [52]. In an attempt to recapitulate the structural, compositional, and mechanical complexity of AC, which varies with depth from the tissue surface, several groups have designed stratified constructs (reviewed in Klein et al. [53]). This has been approached by layering biomaterials or by creating biochemical/macrostructural gradients. In one study a two-layered construct comprising a top layer of 2% agarose and a bottom layer of 3% agarose exhibited zonal differences in the compressive elastic modulus immediately after fabrication [54–56]. Fabrication of layered PEG-based hydrogels comprises chondroitin sulfate, matrix metalloproteinase (MMP)-sensitive peptides, and/or hyaluronic acid (HA), promoted the differentiation of bone marrow–derived MSCs into chondrogenic

phenotypes that resembled those found in native tissue zones [57,58].

Zhu et al. were able to create biochemical and stiffness gradients in PEG hydrogels by chondroitin sulfate methacrylation [59]. Encapsulated chondrocytes and MSCs demonstrated graduated gene expression profiles in accordance with material properties.

The calcified zone in AC provides an important mechanical buffer to the underlying subchondral bone plate. Using a novel MSC and chondrocyte coculture system, Kunisch et al. reported the long-term maintenance of bilayered constructs comprising a nonmineralized and mineralized zone. The authors combined mineralized tissue disks formed by MSCs predifferentiated along an endochondral pathway with chondral layer comprising chondrocytes encapsulated within fibrin/PEG hydrogels [60].

Other groups have succeeded in engineering cartilage tissues with depth-dependent biochemical and biomechanical properties by layering chondrocytes isolated from specific tissue zones within PEG [55] and HA hydrogels [56].

Since bone-to-bone interfaces are known to integrate more effectively than cartilage-to-bone interfaces, osteochondral constructs are considered a promising technique for repairing full-thickness AC defects. Early osteochondral repair studies focused on engineering a cartilage layer which could then be combined with a bone graft substitute [23] or decellularized bone [61]. Issues concerning tissue integration and limited graft function prompted the development of multilayered, integrated constructs with or without cells. A diverse range of osteochondral constructs have been reported, typically comprising a polymer/hydrogel chondral layer and an integrated calcium phosphate containing osseous layer [62–67]. In trilayered strategy, Levingstone et al. [68] investigated osteochondral repair in a rabbit model using constructs composed of collagen 1-hydroxyapatite, collagen 1-HA, and collagen 1-collagen 2-HA. At 12 months CT and histological analyses revealed improved healing using multilayered acellular scaffolds compared to empty defect/single synthetic polymer scaffold controls [68].

Other approaches have aimed to spatially regulate osteochondral tissue formation within a single, homogeneous scaffold using chondrogenic and osteogenic growth factors [59] or by genetically modifying cells [69]. In the later study, simultaneous chondrogenic and osteogenic differentiation of MSCs cultured in singular culture conditions was achieved by transducing cells in the osseous layer with a dual lentiviral vector which resulted in the overexpression of the osteogenic transcriptional factor Runx2 and inhibition of SMAD3-mediated TGF-β signaling [69].

- In summary, advances in biomaterials design and fabrication techniques have supported the development of stratified chondral and osteochondral constructs enabling tissue formation to be regulated in a spatial manner. Combining osteochondral constructs with cells and/or biologics allows a greater level of control over cellular differentiation leading to improved biological and biomechanical performance.

Bioinductive and bioactive scaffolds

In addition to providing a suitable biophysical and mechanical environment, biomaterials may be functionalized to deliver biological molecules to cells. Such systems enable directed differentiation of implanted cells or promote the recruitment of endogenous cells following in vivo implantation. This may be achieved by immobilizing proteins directly onto materials [70,71] or encapsulating within microcarriers [72]. By layering materials containing specific growth factors, several groups have been able to spatially induce chondrogenesis and osteogenesis within a single construct. Lu et al. [72] combined gelatin microcarriers and oligo poly(ethylene)glycol fumarate hydrogels to investigate the effect of insulin-like growth factor-I (IGF I) and BMP2 delivery on osteochondral repair in a rabbit model. Another group used a minipig model to assess endogenous TGF-β3-driven cartilage repair using electrospun HA versus PCL scaffolds [70]. Inducible systems, for example, mechanically activated microcapsule delivery, offer the possibility to initiate growth factor/drug release within dynamic mechanical environments [73].

Biologics may alternatively be delivered using a gene-editing approach by immobilizing a viral vector encoding a desired transgene(s) onto a polymer or encapsulating within a hydrogel. Primary human MSCs are effectively transduced within fibrin hydrogels by adenovirus [74]. Delivery of adeno-associated vectors have been reported using a variety of biomaterials, including alginate–poloxamer composites [75] and poly-ethylene oxide and poly-propylene oxide copolymers [76]. TGF-β3-driven chondrogenesis of MSCs was achieved using a lentiviral vector immobilized onto woven PCL scaffolds [77].

Postimplantation, tissue-engineered constructs must tolerate dynamic and often unfavorable environmental conditions. As such, researchers may wish to build in control mechanisms enabling cells to respond to environmental challenges such as inflammation. In the case of synovial joints the cytokine interleukin-1 (IL-1) is a key orchestrator of inflammatory processes contributing to osteoarthritis [78]. By immobilizing lentiviral vectors encoding the IL-1 receptor antagonist (IL-1ra), one group have succeeded in generating inducible scaffold-mediated delivery of IL-1ra [79,80]. The use of scaffold-mediated vector delivery systems offers the possibility for spatial

control of cellular differentiation within a single-cell population by targeting multiple transgenes [81]. Such approaches have the potential to deliver functional cartilage repair together with drug delivery to diseased joints. By providing the appropriate biological cues, bioinductive/bioactive scaffolds enable more precise control over cell behavior. Inducible and tunable systems offer the possibility for patient-tailored implants, improving the functionality and clinical application of engineered tissues.

Cardiac tissue–engineering biomaterials

Scaffolds designed for cardiac tissue engineering must meet very different requirements than those developed for cartilage tissue engineering. Cardiac tissue–engineering scaffolds should provide the necessary microvascular and mechanical properties to meet the demands of a continuously contracting tissue, considering the cellular, geometric, mass transport, and oxygen supply concerns of native cardiac tissue. Scaffold approaches for cardiac tissue engineering have been reviewed by several groups [11,82–84] and are discussed briefly here.

In pioneering work, Ott et al. developed a biomimetic scaffold through decellularization of adult rat hearts [85]. Decellularized hearts were repopulated by intramural injection and coronary artery perfusion with neonatal cardiomyocytes and aortic endothelial cells. Under pulsatile flow and electrical stimulation, contractile tissue was generated in vitro. Although this system for cardiac tissue engineering has proven successful in many respects, the efficiency of recellularization remains low and the mechanical stiffness of the decellularized and recellularized tissues remains considerably higher than that of native myocardium.

Many natural and synthetic materials have been examined for use in cardiac tissue engineering. As described previously, Matrigel, combined with fibrin and/or thrombin [30,86–88] or with collagen sponges [35,89], has been used to generate contractile-engineered cardiac tissue in vitro. When considering the mechanical requirements of cardiac tissue, collagen gels and sponges may lack the mechanical strength required to withstand suturing and/or repeated cycles of stretch and relaxation. On the other hand, synthetic polymers popular in other tissue-engineering applications (e.g., PCL and PLGA) may be too stiff to form engineered cardiac tissue that possesses appropriate contractile properties. Therefore the development of other scaffolds that more closely mimic the native structural, mechanical, and transport properties of cardiac tissue is an area of active research.

In order to design a scaffold to address some of the specific structural and mechanical requirements of cardiac tissue, an elastomeric scaffold with accordion-like honeycomb pores was microfabricated from poly(glycerol sebacate) (PGS) (Fig. 10.5) [3]. The accordion-like honeycomb pores were chosen as a first step toward mimicking the native structure of collagen within the myocardial ECM (Fig. 10.5A–C). These scaffolds, when combined with neonatal rat heart cells, yielded constructs with anisotropic mechanical properties that closely matched to the right ventricular myocardium, coordinated contractions in response to electrical stimulation, and allowed for some degree of elongation and alignment of the neonatal heart cells (Fig. 10.5D–G). In addition, finite-element modeling of these and other porous, elastomeric constructs allowed for the interrogation of the mechanical properties of various scaffold features [90].

Many other scaffold designs have also used PGS as an elastomer for cardiac tissue engineering. One study used laser cutting to produce microvascular channels in porous scaffolds for improved nutrient transport and oxygen diffusion [91], and another used PGS sheets either unmodified or coated with gelatin and subjected to mechanical stretch [92]. In a perfusion system where cardiomyocytes were cultured on laminin-coated PGS a significant correlation was found between scaffold stiffness and both contractile force and compressive modulus of engineered tissues [93].

As we strive to reproduce the complex structure and vascular network of the heart, researchers are combining multiple biomaterials with advanced scaffold fabrication techniques. Using poly methyl methacrylate beads and polycarbonate fibers, Madden et al. [94] fabricated bimodal scaffolds containing interconnecting microchannels permissive for vascular invasion. Architecturally, the scaffolds resembled that of native myocardium, supported the proliferation of ESC-derived cardiomyocytes and were able to integrate into rat myocardium following in vivo transplantation [94]. In another study, researchers synthesized a novel polymer poly(limonene thioether) to generate multilevel porous scaffolds using micromolding and porogen templating. Cocultured vascular and heart cells were able to spatially organize on the scaffolds to form contractile, prevascularized tissue [95]. In terms of scalability the next step from engineered contractile tissues is cardiac chamber fabrication. To this end, scale models of the human ventricle were engineered by pull-spinning PCL/gelatin nanofibers into ellipsoidal chamber configuration and populating with rat ventricular myocytes/IPSC-derived cardiomyocytes [96]. Engineered ventricles demonstrated contractility and responsiveness to pharmacological stimulus; however the observation of poor calcium handling ability suggested immature myocardial development. These studies illustrate the importance of biomaterial mechanical properties, topographical cues, and scaffold architecture as critical determinants of functional outcome in engineered myocardium.

Bioreactors and growth factors

Bioreactors, which are capable of initiating, maintaining, and directing cell growth and tissue development in a well-defined and tightly controlled culture environment, have proven to be crucial tools for 3D tissue culture. Tissue culture bioreactors represent a controllable model system for (1) studying the effects of biophysical stimuli and therapeutic agents on cells and developing tissues; (2) simulating responses of an in vitro−grown construct to in vivo implantation and thereby helping to define its potential for survival and functional integration; and (3) developing and testing physical therapy regimens for patients who have received engineered tissue implants. As described in the studies highlighted next, bioreactors have been used to (1) improve cell infiltration and distribution by dynamically seeding cells within 3D scaffolds, (2) facilitate cell expansion in order to mitigate unwanted phenotypic shift that may occur on tissue culture plastic, (3) overcome the limitations associated with oxygen and nutrient transport that are often observed in tissues cultured in static environments, and (4) enhance matrix synthesis and mechanical properties by biophysical stimulation of the developing constructs [16−18,20,97,98].

Cell seeding

Applying an appropriate cell type to a biomaterial scaffold is the first step in the tissue-engineering process, and the seeding technique may have a critical role in directing subsequent tissue formation [99,100]. Scaffold cell seeding has traditionally been done statically and performed manually using pipettes, but these static seeding techniques often lead to inefficient and spatially nonuniform

cell distribution within the scaffold [101], which may result in disparate ECM deposition throughout the construct [99,102]. In order to overcome the challenges associated with static seeding, bioreactor-based dynamic cell seeding techniques have been developed. Numerous types of bioreactors have been explored, including spinner flasks [103], wavy-walled reactors [104], and perfused vessels [105].

For some combinations of cells and scaffolds, dynamic cell seeding resulted in scaffolds with high and spatially uniform initial cell densities, which increased ECM deposition and compressive modulus in the resulting engineered cartilage [36,103,106]. For other combinations, perfusion of a cell suspension directly through a scaffold enabled spatially uniform seeding and enhanced tissue regeneration [101,105,107]. Engineered cartilage seeded in perfused bioreactors with alternating medium flow reportedly exhibited higher cell viability and uniformity than controls seeded statically and in spinner flasks [101]. Likewise, engineered cardiac tissue seeded in perfused bioreactors with alternating medium flow exhibited higher cell viability and spatial uniformity than controls seeded in mixed petri dishes [105].

With a view to scalable, clinical translation of engineered tissues, bioreactors are enabling researchers to streamline in vitro culture processing steps. By modifying perfusion rate, Tonnarelli et al. were able to perform cell seeding, expansion, and differentiation steps within a singular bidirectional bioreactor system for cartilage engineering [108].

Construct cultivation

Cellular apoptosis and the formation of necrotic regions within 3D engineered constructs cultured under static conditions suggest that diffusion alone does not provide sufficient mass transport of oxygen, nutrients, and wastes for cell survival within a construct. Bioreactors help to mitigate these mass transfer limitations and provide a controlled microenvironment for 3D construct development. Several groups have demonstrated that mass transport limitations could be minimized, cell viability, differentiation, and function enhanced, and matrix synthesis improved within engineered constructs with the use of bioreactors that induce convective mixing (spinner flasks [103,106] and rotating bioreactors [36,103,109]), and perfusion [17,18,89,105,110–113].

Convective mixing, flow, and mass transport are required to supply the oxygen, nutrients, and regulatory factors that are, in turn, required for the in vitro cultivation of large tissue constructs [9,10,114]. Different tissue types have different oxygen requirements, depending on cell type(s), concentrations, and metabolic activities. Oxygen is the factor that generally limits cell survival and tissue growth of engineered myocardium, due to its relatively low solubility, slow diffusion rate, and high consumption rate [10,115]. AC, on the other hand, an avascular tissue, has a lower requirement for oxygen than myocardium, a highly vascularized tissue. Experimental and modeling studies have correlated oxygen gradients within engineered tissues with morphology and composition [10,116,117].

Cartilage tissue-engineering bioreactors

A variety of bioreactors have been used to engineer cartilage constructs. Rotating bioreactors supported the growth of engineered cartilage constructs 5 to 8 mm thick based on bovine calf chondrocytes and PGS scaffolds [36,37,102,103]. More recently, human chondrocytes were expanded in 2D and then cultured on hyaluronan benzyl ester scaffolds in rotating bioreactors for up to 4 weeks [118]. While constructs cultured statically and in bioreactors contained similar amounts of GAG and collagen, the bioreactor-grown constructs exhibited a bizonal structure, consisting of a collagenous surface capsule deficient in GAG and an inner region that stained more positively for GAG. As compared to bovine calf chondrocytes, expanded human chondrocytes deposited relatively lower amounts of matrix. In another study a wavy-walled bioreactor was used to culture bovine calf chondrocytes on PGA scaffolds, and increased construct growth, defined by weight, cell proliferation, and ECM deposition, was observed in bioreactors as compared to spinner flasks [119]. Oxygen requirements for cartilage engineering within bioreactors are very much cell type dependent. While 20% oxygen tension is suitable for chondrocytes [120], lower oxygen tensions of $<5\%$ provide more favorable conditions for MSC chondrogenesis [121]. Hypoxia is a known regulator of MSC chondrogenesis in vitro [122] which is in accordance with oxygen gradient–driven lineage commitment of these cells during development [123].

In an effort to explore the influences of bioreactors and exogenous growth factors, an oscillatory perfused bioreactor providing slow, bidirectional perfusion was used to study cartilage constructs made by culturing adult human MSCs on 3D woven PCL scaffolds for 3 weeks (Fig. 10.6) [6]. Constructs cultured in bioreactors had higher aggregate moduli, higher total collagen contents, and similar GAG contents compared to constructs cultured statically (Fig. 10.6A and B). Constructs cultured statically in medium containing chondrogenic growth factors but not serum exhibited better chondrogenesis and more homogeneously positive matrix staining for GAG and collagen type II than otherwise identical medium containing serum (Fig. 10.6C–E). Constructs cultured in medium without chondrogenic growth factors and with

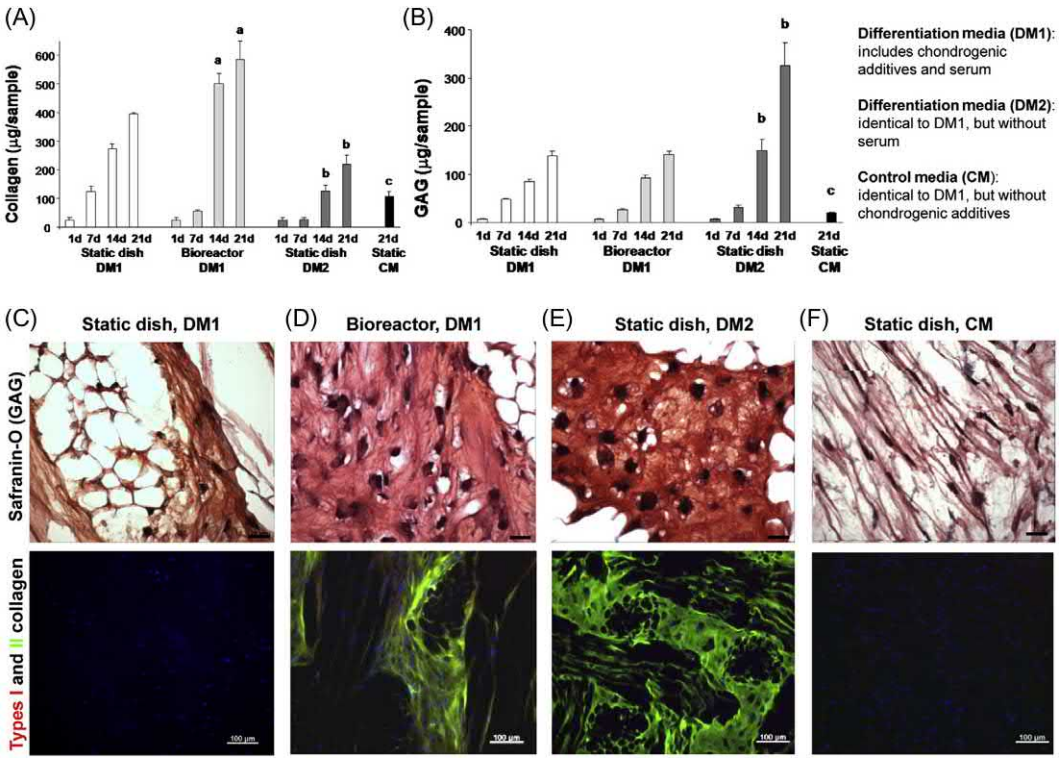

FIGURE 10.6 Bioreactors and growth factors influence the structure and composition of engineered cartilage.
Human MSCs were cultured on 3D woven PCL scaffolds in static dishes or bioreactors and in three different culture media (DM1, DM2, and CM) for up to 21 days. Top panel: Time evolutions of construct amounts of (A) total collagen and (B) GAG. Data are represented as mean ± SEM. [a]Significant difference due to type of culture vessel, [b]Significant difference due to presence of serum, [c]Significant difference due to chondrogenic additives, which included TGF-β3, (ITS), dexamethasone, and ascorbic acid.
Bottom panel: histological sections of 21-day constructs cultured (C) statically in DM1, (D) in bioreactors in DM1, (E) statically in DM2, and (F) statically in CM and stained with Safranin-O for GAG (top, scale bars: 20 μm) or immunostained for collagen type II (green) and type I (red, not seen) with DAPI (blue) counter-stain (bottom, scale bars:100 μm). *GAG*, Glycosaminoglycan; *ITS*, insulin-transferrin-selenium; *MSC*, mesenchymal stem cell; *PCL*, poly(ε-caprolactone); *SEM*, scanning electron microscopy. *Adapted from Valonen PK, et al.* Biomaterials*, 31(8): p. 2193, 2010 [6].*

serum did not exhibit chondrogenic differentiation (Fig. 10.6F). Together, these studies show that bioreactors and growth factors can influence cell morphology, proliferation, and ECM deposition in engineered cartilage.

Cardiac tissue-engineering bioreactors

In the case of engineered cardiac tissue, convective mixing in rotating bioreactors and spinner flasks supported the growth of a tissue-like surface layer ~100−200 μm thick [41,42,115]. Moreover, perfusion of culture medium directly through an engineered cardiac construct can significantly improve construct thickness and spatial homogeneity [89,105,110,115]. Specific design of perfusion bioreactors for cardiac tissue engineering is described in [17], and bioreactors designed specifically for electrical stimulation of cardiac constructs are described in [19]. In one example, perfused bioreactors enhanced the survival of heart cells cultured on porous collagen sponges by increasing the transport of oxygen and IGF-I (Fig. 10.7) [113]. Neonatal rat heart cells were seeded on scaffolds at high density by hydrogel entrapment, and then slow, bidirectional perfusion culture was carried out in an oscillatory perfused bioreactor for 8 days. Bioreactor grown constructs exhibited improvements over static controls with respect to several benchmarks, including reduced apoptosis, increased contractile amplitude, and increased expression of the contractile protein cardiac troponin-I (Fig. 10.7A−C). In the static control group (Fig. 10.7D), heart cells remained rounded and did not exhibit cross-striations, whereas in the bioreactor group (Fig. 10.7E), some cells were elongated and striated, albeit to a lesser degree than native adult rat ventricular myocardium (Fig. 10.7F). Moreover, perfusion of medium supplemented with IGF-I yielded further improvements in construct properties, presumably due to enhanced transport of growth factor to the heart cells within the 3D construct.

In another study, done in the oscillating perfused bioreactor, heart cells cultured on two-layered, 500 μm thick PGS scaffolds with fully interconnected accordion-like honeycomb pores exhibited increases in the gap-junctional protein connexin-43 and MMP-2, an enzyme associated

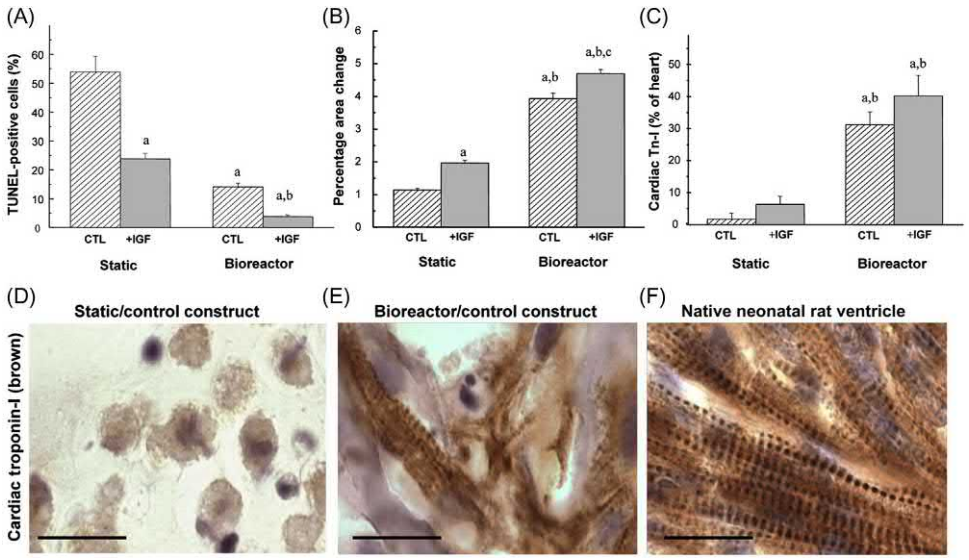

FIGURE 10.7 Bioreactors and growth factors influence the structure and composition of engineered cardiac tissue.
Neonatal rat heart cells were seeded in hydrogel and cultured on collagen sponge scaffolds either statically or in bioreactors in two different media (control, CTL, or with supplemental growth factor, IGF-I). Top panel: (A) Apoptosis (TUNEL-positive cells, percentage of total cells), (B) contractile amplitude (% area change), (C) cardiac troponin-I (Western blot, percentage of native neonatal rat heart). Data are represented as mean ± SEM. [a]Significantly different from static/CTL; [b]significantly different from static/IGF; [c]significantly different from bioreactor/CTL.
Bottom panel: Histological appearances of (D) static control construct, (E) bioreactor control construct, and (F) native neonatal rat ventricular myocardium immunostained for cardiac troponin-I (brown). Scale bars: 20 μm. *IGF*, Insulin-like growth factor; *SEM*, scanning electron microscopy. *Adapted from Cheng M, et al.* Tissue Eng, A*, 15(3): 645, 2009 [113].*

with tissue remodeling [124]. In other studies, sustained release and delivery of IGF [125] or sequential delivery of IGF-I and hepatocyte growth factor [126] enhanced survival and maturation of heart cells in a 3D model and protected against oxidative stress. Perfusion bioreactors are particularly useful for engineering and studying vascular structures. By combining cardiomyocyte-endothelial cell cocultured sheets onto vascular beds, Sekine et al. were able to generate fully perfusable vessels within a contractile tissue in vitro [127].

Together, these studies show that bioreactors and growth factors may work in tandem to enhance heart cell viability, contractility, and differentiation in 3D myocardial grafts.

Bioreactors and mechanical forces

Bioreactors can be used to apply biomechanical signals (shear, compression, tension, pressure, or a combination thereof) to growing tissues [128,129]. Chondrocytes are particularly responsive to mechanical signals and remodel the matrix according to the loads applied; thus the choice of loading regime can directly influence the development of the structure, composition, and mechanical properties of cartilaginous constructs (reviewed in Grad et al. [130,131]). Likewise, skeletal [132], smooth [133], and cardiac [33,86,87] muscle cells are quite responsive to mechanical signals.

Effects of hydrodynamic forces

Hydrodynamic forces associated with convective mixing can have a significant effect on the composition, structure, and properties of engineered tissues. For example, engineered cartilage cultured in rotating bioreactors had thinner surface capsules and higher fractional amounts of GAG than constructs grown in spinner flasks [103,109,134,135]. The flow field in the spinner flask was unsteady, turbulent (Reynolds number of 1758), and characterized by large spatial variations in the velocity field and maximum shear stresses [136]. In contrast the flow field in the rotating bioreactor (slow turning lateral vessel) was predominately laminar with shear stresses of ~ 1 dyn/cm^2 and a well-mixed interior due to secondary flow patterns induced by the freely settling constructs [134]. A model of tissue growth in the rotating bioreactor that accounted for the intensity of convection over 6-weeks of in vitro culture was used to predict the morphological evolution of an engineered cartilage construct [137]. In particular, the model predicted that high shear and mass transfer at the lower corners of a settling, discoid construct would preferentially induce tissue growth in these regions, and that temporal changes in construct size and shape would further enhance local variations in the flow field in a manner that accentuated localized tissue growth. The computed velocity fields and shear stress data corresponded well with the morphological evolution

of engineered cartilage, as shown by superimposing a calculated flow field on a histological cross section of an actual construct. The previous examples suggest that combining experimental studies and computational modeling of hydrodynamic shear stresses and concentration gradients in bioreactors may help to explain underlying mechanisms that control the growth of engineered tissue constructs.

Effects of mechanical tension, compression, and shear loading

It is well known that mechanical forces are critical for determining the architecture of native tissues, such as bone [138], and there is growing evidence that mechanical factors are important factors in determining stem cell fate [139]. In particular the role of in vitro mechanical stress in maintaining and promoting the chondrogenic phenotype has been the topic of several investigations, but the specific influences of different physical stimuli and their interactions with the biochemical environment are not fully understood. For example, dynamic compression caused a ~2-fold increase in cartilage nodule density and a 2.5-fold increase in GAG synthesis in stage 23/24 chick limb bud cells cultured in agarose gel [140]. Likewise, cyclic hydrostatic pressure significantly increased the amounts of proteoglycan and collagen in aggregates of human bone marrow–derived MSCs [141]. In another study, compression enhanced chondrogenic differentiation in mouse embryonic E10 stage cells embedded in collagen type I compared to unloaded controls, as shown by upregulation of SOX-9 and downregulation of IL-1β expression [142].

A variety of devices have been custom-designed and built to study the effects of mechanical conditioning (i.e., compression, tension, pressure, or shear) on cells and tissues in vitro (reviewed in Brown et al. [143], Darling et al. [144], and Waldman et al. [145]). For engineering cartilage, devices may apply dynamic compression (e.g., Buschman et al. [34], Mauck et al. [146]), hydrostatic pressure (e.g., Mizuno et al. [147], Toyoda et al. [148]), mechanical shear (e.g., Waldman et al. [149]), or a combination of dynamic compression and shear [150]. For engineering skeletal, smooth, and cardiac muscle tissues, devices typically apply dynamic tensile strain [86,87,128,132,133,151–154] or pulsatile hydrostatic pressure [155–158].

Mechanical effects on engineered cartilage tissue

In the case of engineered cartilage a number of studies have shown that mechanical conditioning can enhance chondrogenesis. Importantly, loading parameters, including duration, frequency, and strain rate, have a significant bearing on the responsiveness of chondrocytes and MSCs to loading [131]. Dynamic loading has been shown to increase GAG accumulation and ECM assembly, and, therefore, the mechanical properties of constructs based on bovine calf articular chondrocytes and a variety of 3D scaffolds, including agarose gel [34,146], PGA nonwoven mesh [159], and self-assembling peptide gel [160]. Similar results were also observed for adult canine chondrocytes in an agarose gel under dynamic loading conditions [161]. Application of dynamic loading was also investigated in a layered agarose construct, with encapsulated bovine articular chondrocytes, with varying mechanical properties (2% agarose vs 3% agarose) [162]. These results indicated preferential matrix formation in the 2% agarose layer and an increased elastic modulus in only the initially softer, more permeable layer (2% agarose) [162]. Although the aforementioned studies focused on cells encapsulated in hydrogels, similar results (i.e., increased ECM production and compressive modulus of construct) were found when dynamic loading was applied to calf chondrocytes cultured within a porous calcium polyphosphate scaffold. Overall, the response of chondrocytes to dynamic loading depended on the amount and composition of ECM in the developing construct [163], and in some studies loading increased both synthesis of new GAG and its loss into the culture media [160,164].

The influence of dynamic loading on engineering cartilage has also been investigated in MSC-laden hydrogel systems. In an HA-based hydrogel seeded with human MSCs, dynamic compressive loading enhanced cartilage-specific matrix synthesis and more uniform distribution, increased construct mechanical properties, and suppressed the expression of hypertrophic markers [165]. In another study [166], mechanical loading of MSC-laden agarose constructs prior to chondrogenesis decreased functional maturation and increased chondrogenic gene expression. In contrast, loading initiated after chondrogenesis and matrix elaboration further improved the mechanical properties of engineered constructs, but only when TGF-β3 levels were maintained and under specific loading parameters. Overall, these results demonstrated that the combination of dynamic compressive loading initiated after chondrogenesis and sustained TGF-β exposure may enhance the mechanical properties and matrix distribution of engineered cartilage constructs.

The effects of mechanical stimuli on engineered cartilage may vary among different scaffold systems. In one study, fibrin hydrogels seeded with chondrocytes were cultured under unconfined compression (static and oscillatory) [167]. Compared to the free-swelling control condition, static loading had minimal influence on matrix synthesis or construct stiffness. When comparing the constructs exposed to static versus oscillatory loading, the constructs cultured under dynamic conditions were found

to be softer with less matrix accumulation [167]. Although dynamic compressive loading often results in favorable outcomes in terms of engineering functional cartilage tissue, the scaffold material in which the cells are cultured may influence the effects of mechanical conditioning.

As researchers seek to recapitulate the complex mechanical environment of the joint, the influence of shear, hydrostatic pressure, and tensile forces has also been explored for cartilage regeneration. The application of shear stress is known to stimulate the expression of matrix molecules by chondrocytes [150] and produce constructs with higher amounts of ECM and higher compressive moduli than those exposed to compressive stress [149]. Shear, when combined with dynamic compression, is also a powerful driver of MSC chondrogenesis [168–171]. Likewise, application of dynamic hydrostatic pressure promoted chondrogenesis in 3D cultures of bovine [147] porcine [172] and human [148] chondrocytes. Importantly, cell source strongly influences the effect of loading regime on engineered cartilage constructs. For example, the response of chondrocytes to either oscillatory tensile loading [132] or dynamic compression [173] was shown to be dependent upon the tissue zone of AC (superficial, middle, and deep) from which the cells were isolated. In both aforementioned studies, matrix synthesis stimulated by loading was particularly evident in superficial zone chondrocyte populations. The results of these studies collectively suggest that loading conditions other than compression may enhance the properties of engineered cartilage constructs, and a combination of loading regimens may be necessary to engineer the different zones of AC (reviewed in Klein et al. [53]).

Electromechanical effects on engineered myocardium

In an attempt to bridge the gap between the functional properties of engineered versus native myocardial tissues, the incorporation of electro and/or mechanical stimulation has been investigated by several groups [174,175]. In the case of engineered myocardium, dynamic tensile and pulsatile loading can affect construct composition, contractility, and pharmacological responsiveness [28,86,87,128,132,133,151–153,155–157]. Cyclic stretch affects not only the structure (e.g., orientation of cells and collagen) [152] but also the mechanical function (i.e., contractility) [33,86,87,151] of engineered cardiac tissue. Recently, scaffolds have been specifically designed for mechanical stimulation in cardiac tissue engineering [154]. In this study, chitosan–collagen scaffolds with an array of parallel channels were seeded with rat neonatal heart cells and subjected to dynamic tensile stretch for 6 days using a custom designed bioreactor. Mechanical conditioning promoted cardiomyocyte alignment and elongation and increased cell-to-cell connections as evidenced by increased connexin-43 expression, although these results were dependent on high local stress conditions and were not achieved in areas of the scaffold with lower stress. Instead of using cyclic stretch to provide mechanical stimulation, some studies use pulsatile hydrostatic pressure. One such example used a bioreactor designed to provide physiologically relevant shear stresses and flow rates via pulsatile perfusion [158]. Culture under these pulsatile perfusion conditions enhanced the contractility of the constructs by increasing the contractile amplitude and lowering the excitation threshold.

Excitation–contraction coupling is critical for heart function and reliant upon correct electrical signaling between pacemaker cells via gap junctions. Electrical stimulation of engineered cardiac tissues enhances excitation-coupling by (1) promoting mature differentiation of cardiomyocytes leading to an increase in the number of spontaneously beating cells and (2) synchronizing electrical signal propagation [174]. Radisic et al. were the first to show functional improvement of cardiac tissues engineered using rat cardiomyocytes following continuous electrical stimulation for 5 days (2 ms, 5 V/cm, 1 Hz) [35]. Later studies identified that prolonged periods of electrical stimulation to IPSC-derived cardiomyocyte engineered heart tissues significantly improve sarcomere structure, calcium handling, and contractility [43,88].

In summary, electrical and mechanical conditioning can promote the maturation and functionality of engineered myocardium and is particularly relevant in the case of tissues engineered using differentiated stem cell populations. Such studies also emphasize the potential utility of bioreactors to provide mechanical conditioning in the form of stretch or pulsatile flow in studying and promoting in vitro construct formation.

Conclusion

Engineered tissue replacements must function to meet physiological demands, integrate with host tissue, and have the ability to withstand and adapt to dynamic mechanical and immunological challenges following transplantation. As such, functional tissue engineering requires consideration of multiple endogenous and exogenous variables that when controlled appropriately may work collectively to direct tissue formation. Incorporation of multiple elements (i.e., biomaterials, bioreactors, biological molecules, mechanical conditioning) results in increasingly complex experimental set-ups making comparison between studies challenging. While it would be difficult to standardize in vitro culture parameters, a consensus on outcome measures would enable better comparison between studies as we strive toward a common goal.

Biomaterials can provide structural, biochemical, and mechanical cues, and in combination with bioreactors, growth factors, and mechanical conditioning, these may enhance in vitro generation of functional tissue-engineered constructs. In addition to generating replacement tissues, in vitro tissue/organ models offer a platform from which to test physiological and pharmacological responses in environments mimicking those into which the constructs will eventually be implanted in vivo. Lastly, it is important to note that rapidly evolving technologies in genetics and materials science also may have a significant impact on the future of functional tissue engineering.

Acknowledgments

We would like to thank Lisa Freed, Kristen Moffat, and Rebekah Neal for their contributions to the previous version of this chapter. We also thank E. Tognana, F.T. Moutos, B. Estes, G.C. Engelmayr Jr., P. Valonen, and M. Cheng for contributing to the studies described in this chapter. This work was supported by National Institutes of Health Grants AR55414, AR48852, AG15768, AR50245, AR48182, AG46927, and HL107503.

Introduction

We review the principles of bioreactor design and its applications in the field of tissue engineering and regenerative medicine. We group bioreactors into two categories: (1) macrobioreactors, which are primarily utilized to grow functional tissues for implantation, and (2) microbioreactors, which are primarily utilized for drug testing, optimization of cell responses under various stimulations and models of disease. In the first part, we describe the principles of design and applications of macrobioreactors, with emphasis on mass transport of nutrients, oxygen, and regulatory molecules into the inner regions of the tissue engineered scaffold and the stimulations of various physiological biomimicry cues, which modulate cell fate and functional tissue assembly. We briefed on bioreactors for sustenance of cell functions in culture and cell manufacturing. In the second part, we describe special design principles for microbioreactors, especially fluidic control in microbioreactors through flow rheology, components, and integration of microfluidic system. We illustrated applications of microbioreactors such as drug testing/screening and models of diseases.

It has been widely established that the oversimplified in vitro two-dimensional (2D) culture models cannot represent the complicated human physiological or pathophysiological responses. Although advancements in three-dimensional (3D) culture systems are promising, the heterogeneous cellular complexity, along with the associated extracellular matrix (ECM) of the native tissue, could not be entirely recapitulated. Over the last few decades, bioreactors offer the engineering solution to recreate the physiological environment of tissue regeneration and are further improved to offer better in vitro and ex vivo culture conditions, to eventually develop into safe, upscalable, and reproducible tissue growth systems.

The most conventional top-down approach to engineering tissues include directing the metabolically active cells into 3D spatial arrangements offered by porous scaffolds, whilst offering the environmental conditions for the growth, differentiation, and maturation of the cells to functional tissues. Macrobioreactors are therefore designed to offer dynamic culture conditions that mimic the native environmental cues such as the biochemical/molecular factors, mechanical and microarchitectural cues. The controllable flow regime of bioreactor offers better oxygen and nutrient diffusion within tissue engineered grafts, which is critical to uniform cell distribution, differentiation, and maturation. Zhang et al. showed the viability of human fetal mesenchymal stem cells (MSCs) in tissue engineered grafts is greatly improved in a biaxial rotating bioreactor (Fig. 11.1) [1] equipped with tumbling and spinning motions mimicking the fetal gyroscopic motion in the mother's womb. Another dynamic bioreactor culture was shown to support stem-cell growth and differentiation uniformly throughout a 200 cm^3 engineered bone graft, the size and shape of the superior half of an adult human femur [2]. Apart from offering dynamic flow conditions for cell viability and differentiation, bioreactors have now evolved to offer biomimicking of human physiological conditions to generate in situ developed organ and tissues for human transplantation [3,4]. The macrobioreactors have found successful applications in developing 3D scaffold–based grafts for both research and clinical translation, recellularization of decellularized tissues, drug screening, and implant testing [5].

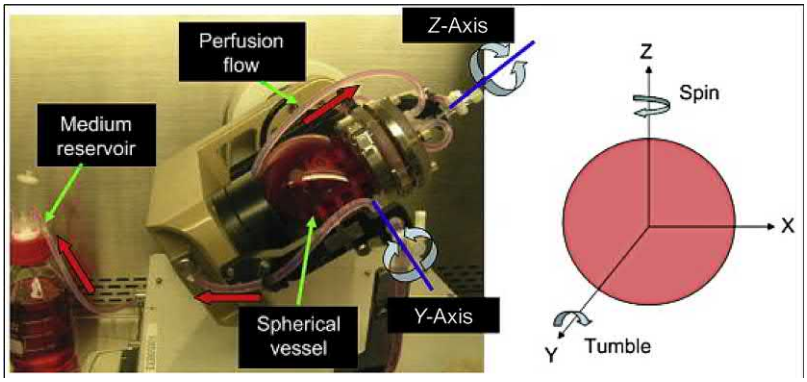

FIGURE 11.1 Biaxial bioreactor design: the bioreactor system consisted of a spherical culture vessel connected to the medium reservoir through tubings through which a perfusion flow is generated. The spherical vessel sits on an articulator which allows rotation in two perpendicular axes (*X* and *Z*). *Modified from Zhang ZY, Teoh SH, Chong WS, Foo TT, Chng YC, Choolani M, et al. A biaxial rotating bioreactor for the culture of fetal mesenchymal stem cells for bone tissue engineering. Biomaterials 2009;30(14):2694–704 with permissions from the publisher.*

While the top-down approach allows flexibility over the choice of materials for the scaffold, such as metals, polymers and ceramics, it does not allow the precise control over microstructure as it relies on the ability of the cells to form the native microstructure and hence not suitable for highly organized tissues with intricate microstructure such as the liver. Although designed to be porous, the scaffolds cannot be penetrated by cells due to diffusional constraints and hence limit cell delivery in large numbers. Another major disadvantage is the poor vascularization of such grafts in vivo, due to the absence of microstructures that facilitate the ingrowth of vasculature [6].

An alternate is the bottom-up approach, which takes advantage of the presence of repeating structural and functional units in tissues/organ. Bottom-up tissue engineering involves generating modules, composites of cells and the matrix, which are assembled to generate the graft. This approach allows precise control over the microstructure and is particularly advantageous when multiple types of cells are required to recreate the functional tissue. The modular assembly also ensures uniform cell loading throughout the graft and allows the accommodation of structures like channels that can facilitate vasculature. Several methods of module generation such as 3D cell–laden hydrogels using micromolding, photolithography and cell sheets, and assembly techniques such as photopatterning, random assembly, flow-directed assembly using microfluidics and random packing have been employed to create functional tissues [7]. Newer method of rapid prototyping–based 3D bioprinting has been extensively used in modular tissue engineering [8]. Scaffold-free approach involves the printing of cells in an ECM-based hydrogel matrix and allows precise microstructural control. This method allows the use of multiple cell types, which have been exploited to form endothelial cell–laden vasculature that allows vascularization and improved integration into the host tissue. Precise microstructural control that enables native tissue-like microstructure, incorporation of multiple cells types (parenchymal and mesenchymal cells), and the incorporation of vasculature have allowed the successful generation of functional tissues for bone [9], cornea [10], liver [11], skin [12], kidney [13], and heart valves [14].

Macrobioreactors

In 1994 in the United Stated alone, more than 18,000 organ transplants were performed with almost double the number of patients on the waiting list for a life-saving procedure [15]. Fast forward to 2017, there have been more than 34,000 organ transplants performed with more than 115,000 patients on the waiting list [15]. To meet this great demand, new strategies are needed to restore these damaged tissues. Tissue engineered substitutes generated in vitro could be the alternative to this. These substitutes should have organ-specific properties with respect to biochemical activity, microstructure, mechanical integrity, and biostability [16]. The generation of 3D tissue substitutes in vitro requires not only a biological model but also the development of new culture strategies such as the bioreactors [17,18].

The first bioreactor was developed in 1857 [19], but it has only been widely used in tissue engineering and regenerative medicine until the concept of tissue engineering was formally proposed and defined by the National Science Foundation (NSF) (United States) in 1987 [20]. The core of tissue engineering is the application of cell biology and engineering principles to develop biologically active human tissue substitute for restoration of tissue architecture and function after an injury or disease. The application of tissue engineering to construct engineered tissue is achieved mainly through the growth of cells in a variety of scaffold in vitro, later combined with certain kinds of cytokines, to promote the lineage commitment of cells and the formation of desired tissues or organs. Three key elements of tissue engineering: cells, scaffold, and cytokines are involved [16]. However, the surrounding environment in which the three elements interact in vitro is different from that in vivo, and the

three elements are usually combined, lacking the synchronization with various environmental factors such as mechanical stress and electric field.

Abundant evidence showed that the efficiency of substance exchange between engineered tissue and culture medium, the density and spatial distribution of cells inside, and the various environmental factors that the cells are exposed to play an important role in the development of engineered tissue. For example, due to the impedance of mass transfer, the "dead zone" phenomenon of cell necrosis occurs in the centrum of engineered tissue [1], and the maximum size of engineered tissue is greatly limited accordingly [21]. By the traditional manual cell seeding method, not only the cell load density is difficult to match the demand of the tissue substitute but also the cells are not evenly distributed uniformly in the tissue, which directly affects the quality of the engineered tissue. Tissue-engineering bioreactor is developed to mitigate above challenges, including large-scale cell manufacturing, massive and homogeneous cell growth in bulky tissue, high efficient supply of nutrients, and the removal of metabolites as well as essential environmental stimulations, imposed on cells [17]. In Table 11.1, we listed various commercial macrobioreactors with their advantages and disadvantages [22]. On the one hand, it can become an important means to investigate the modulations of different environmental stimulations on the 3D functional culture of specific cells and tissues. On the other hand, it is one of the keys to improve the quality of functional tissue and reduce production cost. Moreover, it is also a key step in the translation of output of tissue engineering from bench to industry for large-scale production and implementation of standard operating guidelines and procedures.

Design principles

Mass transport

Tissue-engineering methods are a promising strategy for overcoming the lack of organs for transplantation. However, its introduction into the clinical setting is mostly limited to thin tissues such as skin. One main clinical challenge hampering the widespread adoption of tissue-engineering strategies is the poor cell survival, particularly at the core of thick voluminous grafts [23]. Growth of thick cellular grafts in a static culture environment is challenged by mass transport (of oxygen, nutrients, waste products, and metabolites) that solely depends on passive diffusion within a cellular graft, which is often limited to short distances (100−200 μm), leading to inadequate nutrient supply that is required for cell survival [24].

To promote cell survival, bioreactors must provide adequate mass transport of nutrients, oxygen, and biochemical factors to the cells. They have to be efficiently transported from the bulk culture medium to the tissue surfaces (external mass transfer) and then through the tissue to the cells (internal mass transfer). Similarly, metabolites and CO_2 are removed from the cells through the tissue matrix to the surfaces and then to the bulk medium. In physiological settings, these functions are provided by the vasculature, which readily adapts to the changes in metabolic demands of the cells. Therefore consideration of mass transport of nutrients, oxygen, and regulatory molecules is essential for bioreactor design.

A constant supply of nutrients to cells is crucial for the development and growth of engineered tissues. In the case of primary and/or stem-cell cultures, the delivery of nutrients is essential to induce the differentiation and expression of a desired cellular phenotype. However, in tissues with clinically relevant sizes, the mass transport of nutrients into the engineered tissue is often insufficient to support the growth and development of all the cells within the tissue [25]. This may lead to a concentration gradient of nutrients with high concentrations at the surface and low concentrations in the center of the tissue [26]. Cells at the periphery will experience different environmental conditions compared to cells located in the center and may eventually lead to tissue necrosis in the central regions and nonhomogeneous tissue development throughout the construct [27−29].

In the human body, almost every cell is close to a blood vessel that provides nutrients for its survival. But cells in tissue engineered scaffolds where a vascular network is absent may only receive nutrients via diffusion, which is a slow process and over distances limited nutrients may result in poor cell proliferation or nonoptimal conditions for new matrix production [30]. An obvious strategy is to enhance vascularization of tissue engineered constructs, and this may be achieved by inclusion of angiogenic factors and through scaffold design. However, it must be noted that such approaches still ultimately are dependent on the mass transport of nutrients which in turn influences the rate of vascularization, which would take multiple days to weeks before the center of the implant becomes perfused [31,32].

In the field of tissue engineering the supply of nutrients is critical yet often overlooked [25]. Research in this field has focused to address these concerns, and the development of bioreactors is a promising approach to address the availability of reduced nutrients to the inner regions of the tissue engineered scaffold. In bioreactor systems, perfusion of the culture medium through the engineered tissue was widely utilized. The result is that nutrients are no longer only transported to the cells within the tissue by means of diffusion but also by convection. From Eq. (11.1) the contribution of perfusion to nutrient

TABLE 11.1 Table of comparison of commercial macrobioreactors.

Types of bioreactors	Advantages	Disadvantages
	Improved mixing within the media Low cost	Turbulence generated by the impeller can be detrimental for seeded cells and newly laid down extracellular matrix
	Low shear forces and high mass transfer	Nonhomogenous cellular distribution Cells at frontal zones are washed away by the oncoming perfusion flow with higher flow rates
	Low shear forces and high mass transfer (similar to perfusion bioreactors)	Nonhomogenous cellular distribution and extracellular matrix deposition In the free-floating culture, collision between scaffolds and bioreactor walls may induce cellular damage and disrupt cellular attachment and matrix deposition on the scaffolds
	Physiologic biomimicking of fetal biaxial rotation and microgravity experience. Shear forces and mass transfer controllable. Homogenous cellular population in scaffolds. Amenable to automation	Occupy more space and weigh heavier due to the biaxial fixtures for rotation

Source: Modified from Zhang ZY, Teoh SH, Teo EY, Khoon Chong MS, Shin CW, Tien FT, et al. A comparison of bioreactors for culture of fetal mesenchymal stem cells for bone tissue engineering. Biomaterials 2010;31(33):8684–95 with permission of the publisher.

transport is directly related to the velocity of the medium. In order for the contribution of perfusion to nutrient transport to become significant, the velocity should be high enough so that the Péclet number becomes larger than 1 (see Eq. 11.2) [25].

$$J_a = -D_a \cdot \frac{dc_a}{dx} + u \cdot c_a \qquad (11.1)$$

where J_a is the flux of component a (mol/m^2/s), D_a is the diffusion coefficient of component a in the medium (m^2/s), c_a is the concentration of component a (mol/m^3),

x means the distance (m) [33], and u is the bulk convective velocity of the medium (m/s).

Whether nutrient transport is dominated by diffusion or convection depends on the relation between the diffusion coefficient of the nutrient (D) and the flow speed of the medium (u). This relation between the contribution of diffusion and convection to the overall transport is described in the dimensionless Péclet number.

$$Pe = \frac{L \cdot u}{D} \tag{11.2}$$

where L is the characteristic length (m) (the distance over which diffusion takes place), D is the diffusion coefficient of the nutrient in medium (m^2/s), and u is the bulk convective velocity of the medium (m/s).

Tissue-engineering studies under 2D and/or static conditions has proven extremely difficult to promote the high-density 3D in vitro growth of cells that have been removed from the body and deprived of their normal in vivo vascular sources of gas exchange [34]. Delivering sufficient oxygen supply in 3D tissue constructs poses a challenge for tissue-engineering applications as the thickness and structure of the scaffold affect oxygen diffusion, which is essential for the survival of cells seeded within the scaffold [35,36]. The diffusion limit of oxygen in dense tissues, such as the skeletal muscle or bone, is less than 200 μm^2 [21,36,37] and poses a major problem for tissue-engineered cell constructs, since cells in the inner part of the scaffold are in danger of oxygen deprivation, which affects cellular functions of metabolism and differentiation for example [38].

It must be noted that oxygen concentration in air is about 21% while the physiological oxygen levels in the blood range between 10% and 13% [39]. Furthermore, oxygen levels vary depending on the tissue type and location. For example, oxygen levels in highly vascularized tissues such as bone and bone marrow are $\sim$5%−10% and $\sim$2%−7%, respectively, and is in contrast to avascular tissues such as cartilage $\sim$1%−6% [40,41].

The flow regime generated within bioreactors helps to overcome the limitations of oxygen diffusion within tissue-engineered grafts, which is critical in maintaining cellular survival within the graft and uniform cellular distribution [5]. The selection of the exact conditions of bioreactor cultivation that provide the necessary level of oxygen transport is in both cases supported by the use of mathematical models of oxygen supply and consumption within the cultured tissue. Tissue-engineering bioreactors seek to improve external mass transfer of oxygen. However, as each tissue has its own unique functions and characteristics, it should not be a one-size-fits-all approach.

Controlled delivery of bioregulatory molecules in cell cultures is essential to induce the expression of a desired cellular phenotype. Molecular transport is dominated by diffusion (an exception being transport through motor protein such as kinesin and dynein), while cell behavior is influenced by cell−cell and cell−matrix interactions, and cell-signaling pathways rely on the presence of promoters and inhibitors and their affinities for the receptors [42]. Although many of these molecules have been identified, the ability to specifically control cell behavior through multiple regulatory pathways remains a challenge. The capability to modulate regulatory factors can lead to the recreation of native-like environments and allow the quantification of cell−cell interaction, and the use of bioreactors together with innovative design can provide a solution to optimize cellular response.

In stem/primary cells for example the cell fate and tissue assembly during early development and tissue remodeling are regulated by multiple cues acting across over time. During development and regeneration, tissues are formed from coordinated sequences of stem-cell renewal, specialization, and assembly that are orchestrated by cascades of regulatory factors. Growth media provides the necessary nutrients for cell proliferation and/or differentiation, while metabolites are continuously released into the media. The ability to systematically ascertain specific culture conditions within the bioreactor vessel and subsequently regulate a feedback response is essential for achieving effective tissue growth [5], and the challenge is to accurately recapitulate this in a bioreactor by providing an environment where this can occur.

Computational fluid dynamic techniques can be used to design the optimal microenvironment for culture of cell-laden porous scaffolds in perfusion bioreactor. Such an example would be that of adherent bone marrow stem cells and nonadherent hematopoietic stem cells that predict the effects of microchannel-provided scaffolds with different geometries on fluid-dynamics and oxygen transport [43]. Advantages of computational simulations include the ability to modify and study the effects of bioreactor design with respect to the flow analysis, without having to develop and construct actual physical models, or to run a large number of experiments. This is coupled with the significant savings in time and costs. Furthermore, visualization of flow as enabled by the simulation package is a key factor in determining the efficacy of the system and allows for design optimization prior to bioreactor design and modifications [34]. In general, these simulations assist in identifying critical issues and problems, for example, in approximating the locations of recirculation zones. These zones may potentially damage cells and inhibit growth. Furthermore, these recirculating bodies may impede the flow of fluid into and out of the scaffold. The choice of flow regime is therefore of great importance.

Taken together, the mass transport of nutrients, oxygen, and regulatory molecules is critical to the growth and

survival of the tissue. Recent advances in bioreactor design have focused on mimicking the native environments and thus providing efficient mass transfer to growing tissue. Nevertheless, this is just one aspect of bioreactor design and the considerations of various stimulations and cell environment will be discussed below.

Physiological biomimicry cues

From the advanced knowledge of cell and developmental biology, we realize that cell as the seed of developing tissue and organ will remodel its microenvironment and also integrate into a functional whole orchestrated by surrounding hierarchal cascades of regulatory factors in vivo, temporally and spatially [44]. Therefore to construct a specific bioactive and functional engineered tissues in vitro, it is essential to mimic the native physiology of the tissue [40] such as shear stresses/hydrostatic pressure of a native blood vessel or the compression/torsion of the native cartilage [41]. In this section, amongst the various environmental stimuli equipped in bioreactors, we would like to highlight the role played by mechanical, electrical, and magnetic stimulations for tissue development in bioreactors (Fig. 11.2).

It is widely accepted that mechanical stress stimulation is an important factor regulating the physiological functions of cells and plays an important role in promoting the formation of specific tissue, especially in musculoskeletal tissue, cartilage tissue, and cardiovascular tissue. Based on the hypothesis that biomimicry of physiological mechanical loading will potentiate accelerated osteogenesis, Ravichandran et al. [45] demonstrated the application of physiological cyclic compressive loads on MSCs-laden 3D polycaprolactone-β-tricalcium phosphate scaffolds in bioreactor with physiological cyclic strain (1 Hz) of 0.22%. Results showed the enhancement of expression of osteogenesis-related genes (osteonectin and collagen type I) on week 1 and activity of alkaline phosphatase on week 2 after compressive loads of compressive groups on comparison with their static controls, respectively. Moreover, mineralization of compressive group was found to approach saturation on week 2 after compressive loads. The results provided a proof that biomimicry of physiological mechanical cues is essential for the maturation of engineered bone grafts cultured in vitro.

Maturation of cardiomyocytes differentiated from stem cells is important for regeneration of functional cardiovascular tissue. Ruan et al. investigated the effects of exogenous cyclic tensile stress on myocardial differentiation and maturation of human induced pluripotent stem (iPS) cell, exposed to uniaxial cyclic tensile strain with a frequency of 1 Hz, 5% elongation generated in FX-400T bioreactor [46]. By flow cytometric analysis, it was observed that cyclic tensile stress stimulation increased cTnT intensity by about 1.3- to 1.5-fold over their controls, suggesting that cyclic stress does have a significant effect on cardiomyocyte maturation. In addition, cyclic stress stimulation also increased the expression of β-MHC versus their controls. Concurrently, α-MHC gene expression significantly decreased with cyclic stress stimulation as compared to their controls, which corresponds to the increasing human gestational age.

Bioreactors equipped with torsional stress stimulation had been developed to study the formation of engineered ligament tissues and intervertebral discs [47,48]. Scaglione et al. [47] designed a compact bioreactor system to apply automated cell-culturing procedures onto engineered tissue under controlled torsion/traction regimes to recapitulate ligament mechanical environment in vivo. Fibroblast-laden poly-caprolactone-based scaffolds were exposed to a torsional stimuli consisted of forward/back-forward sequential cycles of 100 degrees from neutral position at a rate of 600 degrees/min. After 3 days

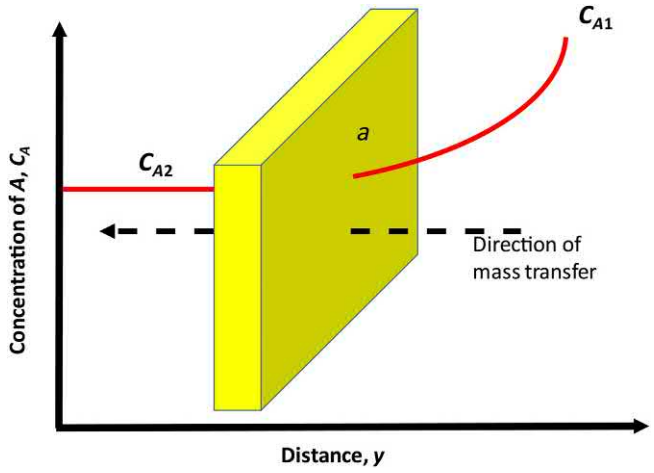

FIGURE 11.2 The concentration gradient of component "A" in a stagnant system (no convection) inducing mass transfer across area "a." The diffusion occurs in the direction required to destroy the concentration gradient of the molecular components "A." The concentration of "A," varies as a function of the distance y and $C_{A2} > C_{A1}$. *Adapted from Doran et al. (2013) with permission of Rouwkema J, Rivron NC, van Blitterswijk CA. Vascularization in tissue engineering. Trends Biotechnol 2008;26(8):434–41.*

of stimulation the cell morphology was partially changed with preferential orientation of cell actin filaments along the torsional direction as opposed to the random orientation of actin fibers in their controls. In addition, the mRNA expressions levels of collagen type I, tenascin, and collagen type III were 2-, 6-, and 31-fold higher in simulation groups compare to their controls, respectively.

To mimic the shear stress condition induced by blood flow in the human body such as the physiological interstitial flow over osteocytes during bone compression and the blood flow through arteries and veins, bioreactors applying shear stress stimulation were developed to improve the maturation and development of engineered tissues [49–51]. van Haaften et al. [50] developed a novel bioreactor that decoupled the effects of two types of hemodynamic loads: the shear stress and the cyclic stretch for developing vascular grafts. Two independent pumps were used to perfuse medium and to distend the electrospun polycaprolactone bisurea scaffold in a computationally optimized culture chamber. There was no preferential orientation in actin fiber direction for statically cultured samples, whereas a clear preferred actin fiber orientation was observed in samples exposed to shear stress or cyclically stretched samples. Moreover, the contribution of shear stress (1 Pa) overruled stretch (1.05 Pa at 0.5 Hz)-prompted cell proliferation (DNA/tissue) and ECM production (GAG/tissue).

Electrical signals are known to be one of important regulators of embryonic development on stem-cell division and differentiation and also play a critical role in healing wounds as a mediator to direct cell migration into the wound [52,53]. The integration of electrical stimuli in the bioreactor design resulted in improvement of the structure and functionality of engineered cardiac tissues [54]. Balint et al. (2013) reviewed the importance of endogenous electrical stimulation, methods of delivering, and its cellular and tissue-level effects in the engineering of nerves, cardiac and skeletal muscle. Visone et al. [52] developed a novel oscillating perfusion bioreactor (Fig. 11.3) in which neonatal rat cardiac fibroblasts–laden collagen tissue were cultured with a combination of bidirectional interstitial perfusion and biomimetic electrical stimulations. Result showed that electrical cues reduced the excitation threshold from

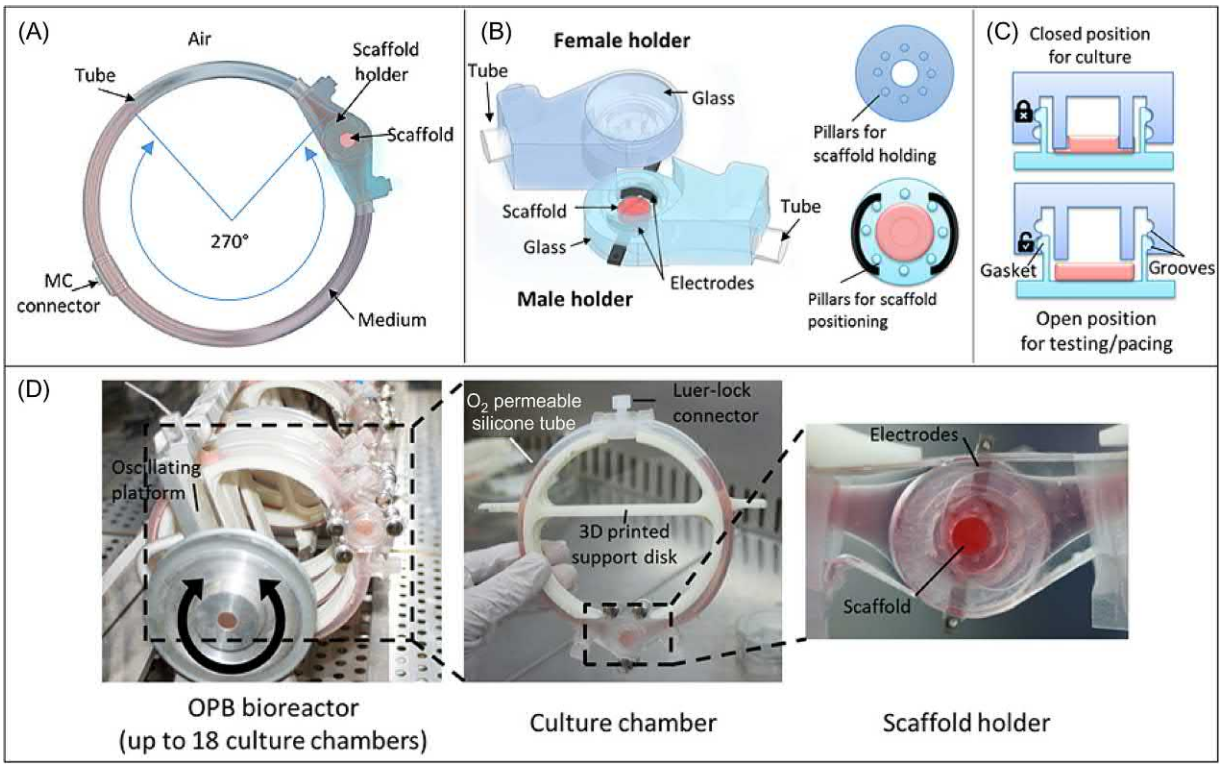

FIGURE 11.3 (A) Scheme of the bioreactor chamber including the scaffold holder and the connector; medium perfusion through the scaffold is achieved by bidirectional oscillation. 5.2 ± 0.95 V in perfusion only group to 4.35 ± 0.8 and 4.2 ± 0.5 V in electrical stimulation only group, perfusion and electrical stimulations group, respectively. Moreover, the gene expression of MYH6, indicative of immature cardiac phenotype, decreased only under combination of perfusion and electric stimulations condition, leading to an increased MYH7/MYH6 ratio versus their perfusion controls, implying a more adult-like cardiomyocyte phenotype achieved under the combination of stimulations.

Considerable research reports (Table 11.2) documented that magnetic field–specific pulsed electromagnetic field (PEMF) influences osteoblast and MSCs proliferation and differentiation through initiating several signaling cascades such as Ca^{2+}, Wnt/β-catenin, mTOR, and some growth factors [55–71]. Bassett et al. (1978) successfully used PEMF to treat nonunion fractures, and PEMF was approved as a noninvasive method for treating delayed union or nonunion fractures by the US Food and Drug Administration in 1979. Currently, PEMF has been used for bone and cartilage-related pathologies, including knee and cervical spine osteoarthritis [60,61]. Even though PEMF is still in its infancy, it holds great potential as a form of prospective, noninvasive treatment.

Fassina et al. designed a simple electromagnetic bioreactor (magnetic field intensity, 2 mT; frequency, 75 Hz) to stimulate osteosarcoma cells cultured in a 3D polyurethane scaffolds [69]. Results showed a high proliferation rate (approximately twofold), more matrix proteins production on scaffold surfaces, and more calcium deposition (approximately fivefold) in the electromagnetic stimulation groups as compared to their no stimulation controls. Consistently, RT-PCR analysis revealed the electromagnetically upregulated transcription of matrix proteins [decorin, fibronectin, osteocalcin, osteopontin, transforming growth factor-β (TGF-β), type I collagen, and type III collagen].

Recently, Mayer-Wagner et al. developed a novel bioreactor in where low-frequency electromagnetic fields (LF-EMF) and simulated microgravity (SMG) stimulations were applied to investigate chondrogenesis of MSCs [72]. The LF-EMF (sinusoidal, 15 Hz and 5 mT magnetic flux density) was applied three times a day for 45 minutes throughout the differentiation period of 21 days. MSCs pellets exposed to SMG and LF-EMF showed strong positive signals in both safranin-O and collagen type II staining compare to SMG alone and LF-EMF alone controls. Moreover, RT-PCR analysis revealed that LF-EMF/SMG induced a significantly higher COL2A1 expression compared to the SMG alone control but did not reach the no stimulation control level. Results demonstrated that combination of LF-EMF and SMG stimulations provided a rescue effect of the chondrogenic potential of MSCs, while LF-EMF stimulation alone did not interrupt any gene expression changes of MSCs.

Cell environment

Understanding, recreating, and controlling the overall native complex cell environment are a key to engineering tissues via bioreactors. Supplementing scaffolds that mimic the ECM, providing biophysical environment of the native tissue and modulating the spatial and temporal gradients of the regulatory factors, are some of the well-known methods to fabricate the cellular environment in macrobioreactor technologies.

3D scaffolds are used in combination with bioreactors not only as a substratum for cell growth but also for enhanced nutrient flow and oxygen diffusion to prevent formation of necrotic zones. Naturally occurring ECM carries inductive signals for phenotype determination of the cell, as well as vital for cell adhesion and growth [73]. Tissue engineered scaffold—corresponding to the natural ECM—are used in the bioreactors as a template for tissue regeneration. Decellularized ECMs that are derived from the native whole tissues are often considered the gold-standard of scaffold constructs. Decellularized matrix offers the native cell environment with the preserved micro- and microscale structural and functional ECM proteins that provides the necessary cues for cell adhesion, proliferation, and maturation. However, major challenges in employing the decellularized matrix for bioreactor technologies include the difficulty in sterilizing them without damaging the structural and mechanical properties and the host immunogenicity of the degradation products [74].

Synthetic scaffolds are being widely employed as tissue-engineering scaffolds for bioreactors, which offer advantages such as uniformity in batches, lack of host immunogenicity, and the ease of sterilization and further clinical translation. Main considerations of scaffold design include the size, geometry, porosity, density of pores, the windows connecting the pores, and the surface properties [75]. Either synthetic or natural polymers are chosen to fabricate the scaffolds. While synthetic polymers are more stable with longer shelf-life and can be readily sterilized, natural derivatives offer bioactive properties, with good biocompatibility and reduced toxicity [76]. Altering the composition, structure, and arrangement of the synthetic polymer scaffold constituents offer a wide range of properties such as porosity as well as tailored pore sizes, rate of biodegradation, and mechanical properties.

A wide array of scaffold fabrication techniques such as solvent casting/particulate leaching, melt moulding, freeze–drying thermally induced phase separation, gas foaming, 3D printing, and electrospinning are being employed to achieve a wide variables of scaffold architecture and design. Each approach has its own advantages and disadvantages, where, 3D printing and

TABLE 11.2 Research studies that applied magnetic field to influence cell proliferation and differentiation.

Magnetic field	Cells	Effect	Mechanism proposed	Ref.
PEMF, 3 ms, 50 Hz, 0.6 mT	MC3T3-E1	Prompted cell proliferation	PEMF regulates intracellular calcium ions	[57]
PEMF, 1.3 ms, 75 Hz, 1.5 mT	MSCs	Increased expression of osteogenic markers and transcription factors investigated	PEMF modulates Notch genes involved in osteogenesis	[62]
PEMF (from MED, Magdent)	MSCs	Increased cell proliferation and adhesion and the osteogenic commitment	PEMFs activated the mTOR pathway to stimulate osteogenic differentiation	[61]
PEMF, 67 ms, 15 Hz	Bone marrow macrophages	Inhibited osteoclast formation	Osteoblastic genes were stimulated by PEMF, including genes that inhibit osteoclastogenesis	[60]
PEMF, 6 ms, 15 Hz, 2 mT	MSCs	Prompted chondrogenic differentiation	PEMF-regulated calcium entry through transient receptor potential channels	[58]
PEMF, 5 ms, 15 Hz, 2 mT	MC3T3-E1	Enhanced cellular attachment, proliferation, and osteogenic differentiation in vitro Promoted osteogenesis, bone ingrowth, and bone formation in vivo	PEMF promoted skeletal anabolic activities through a Wnt/β-catenin signaling	[56]
PEMF, 1.3 ms, 75 Hz, 2 mT	MSCs	Prompted osteogenesis	PEMF enhanced intracellular calcium concentration	[63]
PEMF, 5 ms, 15 Hz, 0.96 mT	Osteoblasts	Increased protein adsorption and enhanced the initial osteoblast adhesion Accelerated osteoblast proliferation and differentiation	PEMF changed the electric potential gradients of the surface and induced surface polarization on the cell membrane	[64]
PEMF, 6 ms, 20–50 Hz, 2–5 mT	MCF-7 and MCF-10	Increased MCF-7 damage after PEMF exposure. No effect on MCF-10	Difference in intracellular calcium handling of Ca^{2+} in response to PEMF exposure	[65]
ELF-EMF, 18 Hz, 2.5 μT	Cardiac stem cell	Increased in the expression of cardiac markers	Intracellular Ca^{2+} accumulation and mobilization	[66]
PEMF, 48 Hz, 1.55 mT	MC3T3-E1 Osteoblasts	PEMF influenced proliferation and differentiation of osteoblast but not MC-3T3	Osteoblasts are more sensitive to PEMF compared with immortalized cells	[67]
PEMF, 300 μS, 7.5 Hz, 0.13 mT	Osteoblastic cells	Speed up apoptosis of osteoclasts	PEMF elevates the intracellular and nucleus Ca^{2+} concentration and increases endonuclease activity	[68]
PEMF, 1.3 ms, 75 Hz, 2 mT	Osteosarcoma cell line SAOS-2	Improved cell proliferation Increased gene and protein expression of osteogenic biomarkers Increased calcium deposition comparing with static culture	PEMF increases the cytosolic Ca^{2+} concentration	[69]
Sinusoidal MF, 50 Hz, 0.8 mT	ES-derived cardiomyocytesEmbryoid bodies	Increased the expression of the cardiac specific transcripts α-myosin heavy chain and myosin light chain	Coupling of MF with GATA-4, Nkx-2.5, and prodynorphin gene expression may represent a mechanism pertaining to ES cell cardiogenesis	[70]
PEMF, 300 μS, 7.5 Hz, 0.13, 0.24, and 0.32 mT	Bone marrow cells	Regulated the formation of osteoclast-like cells in bone marrow culture in magnetic field intensity–dependent manner	Correlations between osteoclast-like cells formation and cytokines depending on the induced electric field intensities	[71]

MSC, Mesenchymal stem cell; *PEMF*, pulsed electromagnetic field.

electrospinning are the widely used techniques [73]. Porous fabricated scaffolds are seeded with suitable cells and grown in a wide range of bioreactors, such as spinner flasks, rotating wall vessels (RWV), and perfusion bioreactors, to obtain the functional engineered tissue succedaneum.

The scaffolds or the substratum for the cells in culture for bioreactors are usually enriched with biological factors for cell fate determination. The biological factors required for the bioreactor-scaffold system depends on specific application of the scaffolds. For example, human embryonic stem cells were known to exhibit lesser cell differentiation, with more tendency toward self-propagation with pluripotency, when they were cultured with laminin 521 [77]. While culturing the neural stem cells in an injectable hydrogel of silk fibroin, IKVAV short peptide was observed to effectively improve the activity and differentiation of the cells [78]. For vascular tissue engineering of arteries, treatment with TGF-β, sphingosylphosphorylcholine, and bone morphogenetic protein-4 is required along with mechanical stimulation of the adipose derived stem cells in pulsatile perfusion systems [79]. Growth factors such as bFGF and EGF are known to promote the proliferation and controllable migration of stem cells. In neural cell culture, nerve growth factor and brain-derived neurotropic factor enhance the survival of cortical neurons and proliferation [80]. In cartilage tissue engineering, addition of growth factors TGF-β1 or IGF-I was known to greatly improve the mechanical properties of tissue engineered constructs of chondrocyte-seeded agarose hydrogels under dynamic deformational loading [81]. Overall, a plethora of biological factors can be used with the scaffolds and bioreactors to successfully engineer tissue constructs in vitro.

Controlled modification the biological and/or physical properties of the scaffolds is vital in guiding the cell migration, adhesion, growth, and differentiation [82,83]. Mimicking complexity of the native protein family in ECM is achieved by patterns of adhesive and nonfouling proteins, which further influences the spatial distribution of cells and formation of focal adhesions. In addition to the cell substrate, cell shape plays an important role in determining the cell fate and function [84]. Geometrical cues at micro and nanoscale therefore has varied responses on different cultured cells. Substrate stiffness is known to play a vital role in lineage specification of stem cells. For example, altering the elasticity of the polyacraylamide gels with coated collagen I or other adhesion proteins for cell attachment to mimic the in vivo–like matrix elasticity, soft matrices were observed to be neurogenic, stiffer ones were myogenic, and the more rigid ones were osteogenic [85–87]. Combination of mechanical and biochemical properties of the cell culture substrate enabled the study of plethora of cell environment suitable for specific tissue culture responses. Patterning techniques help to precisely control the microenvironmental assembly of mechanical and biochemical stimuli of the substrate. Few of the patterning techniques include

1. microcontact printing of alkanethiols and proteins on suitable substrates,
2. replica molding for fabrication of micro and nanostructures in polyurethane or epoxy, and
3. solvent-assisted micromolding of nanostructures in poly(methyl methacrylate).

Another key player in cell fate determination in bioreactors is the interaction with other cell types. The possibility of compartmentalization of cells in bioreactors provides a suitable platform for multiple population cocultures that are otherwise challenging to establish in vitro [88]. For example, MSCs are cocultured with endothelial cells for creating simultaneous calcification and vasculature of bone tissue–engineering scaffolds [89].

Sustainable bioreactors

Among the various design considerations for bioreactors, long-term sustenance of cell culture and flexibility over scalability is critical for allowing the translation of the technology to a clinically relevant setting. The scaling up of bioreactors is technically challenging because of the loss of microenvironmental control in large-scale processes, which impair cell functionality. For example, the increase in the shear stresses due to hydrodynamic forces required to achieve optimal mass transport and oxygen diffusion throughout the bioreactor might damage the cell membrane and the lead to loss of cell viability and functions. The trade-off, between the operating process parameters required to sustain large numbers of cells for long periods, and the control of the cellular microenvironment that affects the cell functions, has to be carefully considered for the cell type and the intended application.

An example for an effective bioreactor design, which integrates the microenvironmental culture parameters while allowing efficient scale up for functional hepatocytes, has been demonstrated by Xia et al. [90]. The primary hepatocytes were cultured in between layers of collagen. This sandwich collagen culture served two purposes: it provided the matrix cues which allowed the primary cells to regain polarity that is critical for the functioning of the hepatocytes and protected the hepatocytes from the shear by shielding the cells from direct exposure to flow. A total of 12 sandwiches were stacked and assembled into the bioreactor with holders and slits, the configuration allowed the serial flow of the culture medium without bypass. With a flow of 1 mL/min, the hepatocytes maintained viability and functionality in

terms of metabolic and transporter activities, and albumin and urea production in the bioreactor for 7 days. This was a significant improvement over the existing systems that did not support the survival and functionality beyond 3 days in bioartificial liver applications. Also the authors have proposed a clear strategy to scale up the existing model for use in clinics without drastic modification of the plate dimensions, which would have required recalibration of the fluid dynamics and with minimal priming volume. This is an ingenious example of an efficient bioreactor design that provides adequate microenvironmental control to preserve cell functions and allows for the sustenance of the large numbers of cells over long periods of time. Such strategies could be adopted to improve the efficacy, scale-up, and the sustenance of bioreactors for other cell types and applications.

Cell manufacturing quality attributes and process analytics technology

The advances in tissue engineering aimed to develop prosthesis, extracorporeal assist devices, tissue grafts, and whole organs necessitate optimal cell manufacturing processes to ensure the production of safe and potent cells suited for the desired application in clinically relevant numbers. Optimal cell manufacturing processes integrate several critical steps such as identification of legitimate sources of cells, isolation and purification of the appropriate cell types, large-scale expansion, storage, and retrieval of cells, all of which in compliance with the regulations of statutory boards. Cell manufacturing involves the large-scale expansion of cells in clinically relevant numbers without compromising the quality of the cells in terms of the efficacy and safety. Efficacy refers to the ability of the cells to perform the desired functions, while the safety concerns the undesired side effects of the cells when used in vivo. For instance, loss of the enzymatic function of hepatocytes on expansion compromises the efficacy; the activation of CAR T cells toward autoantigens while expansion critically compromises the safety. In addition to safety and efficacy the cell manufacturing process should include the control of the variability from batch to batch to reliably assess the performance in therapeutic applications.

Hence, the cell manufacturing processes must carefully consider the bioreactor design, nominate the critical quality attributes (CQA) and critical process parameters (CPP), and implement real-time monitoring, all based on the cell types and the applications. The CQA are the biological, physical, and biochemical attributes that can reliably predict the viability and functionality of the cells for the specific application and analyze the variability in the cell populations. The CPP are the operating parameters such as temperature, oxygen diffusion rate, shear stress, and pH, which can impact the CQA. The CPP have to be monitored and analyzed real time to provide feedback to avoid impairments of the CQA. The bioreactor design has to be optimized to preserve cell functionality and allow scalability. Taken together, the formulation of a cost-effective and an efficient cell-manufacturing pipeline requires a multidisciplinary approach harnessing the technical prowess of clinicians, biologists, chemical and process engineers, and data analysts. The National Cell Manufacturing Consortium is one such initiative by the NSF Cell Manufacturing Technologies involving collaborative efforts of hospitals, academic institutions, pharmaceutical companies, and the US government agency [91]. Another multiscale venture is the SMART CAMP (Critical Analytics for Manufacturing Personalized Medicine) involving interdisciplinary research groups (IRG) from MIT and Singapore (Singapore-MIT Alliance for Research and Technology). The SMART CAMP IRG is aimed at developing the technology for the manufacturing of cells for safe, effective, cost-efficient, and personalized medicine.

Future outlook

Microgravity bioreactor

With the advent of manned space flight, it was observed that the astronauts returning from space flight presented with several conditions such as musculoskeletal wastage, anemia, poor immune responses, retinal damage, cardiac insufficiency, and deregulated circadian rhythm [92]. These effects were attributed to the microgravity conditions in space flight (10^{-6} g in space compared to 1 g on earth) and the loss of the radiation shield presented by the atmosphere and the magnetic field of the earth. Several studies were initiated to understand the effects of microgravity on the human physiology, which involved experimentation of human cells in space flight. To circumvent the heavy expenses and long periods of space operations, systems and devices that could generate the microgravity conditions on earth were developed.

The objects aboard the spacecraft in orbital velocity are in a state of free fall; the gravitational force exerted by the earth is continuously counterbalanced by the momentum of the spacecraft [93]. Efforts were focused to facilitate microgravity conditions on earth by employing forces to counterbalance the gravitational force. The first generation of bioreactors SMG by rotating fluid-filled vessels on a horizontal axis, wherein the upward hydrodynamic drag caused by the rotation of the vessel counterbalances the downward forces of gravity [94]. The RWV bioreactor design was improved to achieve efficient and 3D cell interactions, reduce undesired hydrodynamic

shear stresses, and allow spatial colocation of particles of different rates of sedimentation and adequate mass transport and aeration [95]. The rotating wall perfused vessel (RWPV), the slow turning lateral vessel, and the high-aspect rotating vessel (HARV) bioreactors were consequently developed with improvements to the basic design to achieve the aforementioned criteria at microgravity conditions. In ground conditions, at unit gravity (1 g), the convective flow due to the differences in densities of the media and the cells provides sufficient mass transport to sustain cell viability. However, this is negligible in actual microgravity and the mass transport is entirely dependent on the diffusion, which is inadequate to sustain growing masses of cells. Hence for experiments in space or true microgravity, convective flow is intentionally introduced in the RWPV bioreactors to improve the diffusion and mass transport at the cell surface [96].

Toward the late 1980s, it was observed that cells tend to aggregate more when exposed to microgravity [97,98]. With the establishment of the SMG bioreactors, several studies were performed on cells from the cartilage, cardiac, and the gastrointestinal systems, which led to the quick realization that microgravity conditions promoted enhanced cellular interactions and efficient mass transport that led to the formation of cellular aggregates larger than those observed underground conditions. The close positioning of cells and the low shear stress environment likely promotes cell−cell contacts, which mature into cellular junctions that conduct various paracrine signals, which would otherwise be disturbed due to high shear forces operative in conventional bioreactors. These studies were able to identify and address several molecular phenomena influenced by microgravity involved in the differentiation of stem/progenitor cells and tissue development [99−101], metabolism [102−104], immune responses [105,106], wound healing responses [107,108], host−pathogen interactions [109], and cancer biology [110−112].

The effects of microgravity on bone were investigated in space, and it was observed that osteoblasts cells exhibited abnormal shape, reduced stress fibers, poor glucose utilization, and reduced prostaglandin synthesis in microgravity, which explained the osteoporosis observed in astronauts [113]. The HARV bioreactors were employed to understand the effects of hydrodynamic stresses on the proliferation, differentiation, and maturation of the bone marrow stem cells into osteogenic lineages. The bone grafts developed under hydrodynamic conditions repaired bone defects effectively in rat models with better osseointegration compared to grafts obtained from static growth [114]. This study elucidates the potential use of RWV bioreactors for bone tissue engineering. DiStefano et al. (2018) have optimized the rotary conditions for the differentiation of retinal organoids from mouse pluripotent stem cells. The study observed enhanced proliferation and the formation of larger organoids from the stem cells. Also, the differentiation of the retinal organoids in the RWV bioreactors mimicked the spatiotemporal progression of in vivo retinogenesis [115]. Chang and Hughes-Fulford [116] have observed that primary mouse hepatocytes formed 3D aggregates when cultured in RWV, as early as 24 hours compared to growth in conventional tissue culture dishes. The cells in the aggregates attained high functionality in terms of albumin secretion and CYP1A1 enzymatic activity. Interestingly, these effects were independent of cell proliferation and presumably mediated through enhanced cellular interactions. The hepatocytes in the RWV cultures exhibited a unique gene expression signature compared to developing or regenerating hepatocytes [116]. This study clearly implicates that 3D cellular contacts are critical to the functionality of the tissues, which could be induced and maintained by culturing cells in low-shear modulated microgravity bioreactors. Apart from the specific examples discussed above, several other tissue-engineering ventures have been pursued by employing the advantages of the microgravity bioreactors [117,118].

Taken together, RWVs create microgravity by the precise counterbalance of gravitational forces by the angular momentum due to the rotation of the vessels. This leads to quasistationary movement of particles with 3D spatial freedom, low hydrodynamic shear stress, colocation of particles, and efficient mass transport. Modulation of speed of rotation, perfusion mechanisms, and other working parameters allow efficient control over the aforementioned features to fit the cellular systems of interest and for explorations under true microgravity. These advantages allow the employment of actual and SMG bioreactors in investigating molecular mechanisms in various pathophysiological conditions, generate disease models, and in development of functional grafts for tissue engineering.

Real-time assessment in the bioreactor

Preclinical animal models are required for pharmaceutical testing, implant testing, and to understand human physiology and disease biology. However, animal maintenance is time consuming, labor intensive, and expensive [5]. With the guiding principles to Replace, Reduce, and Refine (3Rs) [119], bioreactors are seen as effective in vitro platforms for drug/implant testing with a hope to replace or reduce the use of animal models in the future. Over the past decade, significant improvements in design and construction of bioreactors have been made. Numerous design considerations to the mass transport, physiological cues, and cell environment have been made over the years; however, the ability to monitor the cellular growth, development, and differentiation of the engineered tissue

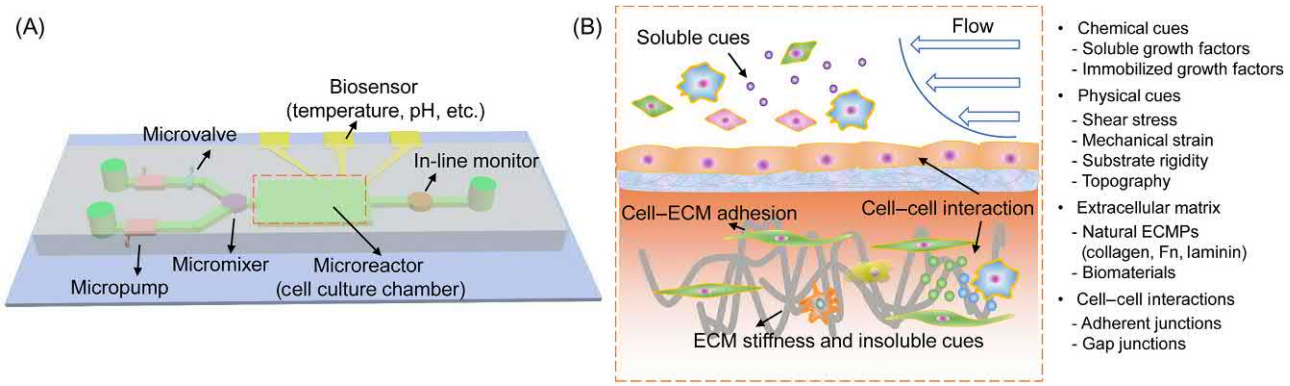

FIGURE 11.4 Some crucial design principles for the microreactors. (A) Different components of a microreactor include microreactor chamber; some fluidic control elements such as micropump, microvalve, and micromixer; biosensors; and in-line monitor element. (B) A detailed illustration of the influential factors for microreactor chamber.

in real time remains a challenge. Traditional methods for evaluating developing tissue in vitro are destructive, time consuming, and expensive [120]. As such, nondestructive, real-time evaluation of the engineered tissue is much desired. In addition, such a facility to image the grafts in the bioreactor environment would add value to the system in terms of evaluating real-time tissue growth and dynamics.

Photoacoustic imaging (PAI) is a laser-generated ultrasound-based technique that is particularly well suited to visualizing microvasculature due to the high optical absorption of hemoglobin [121]. PAI is a nondestructive imaging modality [120], providing the ability to monitor the formation of new blood vessels (angiogenesis) in the tissue engineered scaffold.

Magnetic resonance spectroscopy (MRS), magnetic resonance imaging (MRI), and magnetic resonance elastography (MRE) are noninvasive methods that can provide biochemical, anatomical, and biomechanical measures of tissue [122]. MRS can identify the changing molecular structure and alternations in the conformation of major macromolecules (collagen and proteoglycans) using parameters such as chemical shift, relaxation rates, and magnetic spin couplings. MRI provides high-resolution images whose contrast reflects developing tissue microstructure. These are well-established techniques that have been used to probe the structure and dynamics of biochemical changes in engineered tissues [123–125]. To fully maximize such techniques the engineered tissues should be grown in MR-compatible bioreactors. This will allow for seamless transfer of the samples in the bioreactor chamber for characterization using MRS, MRI, and MRE at the chosen time points and, thereafter, returning the chamber back to the bioreactor to continue cell growth and development.

Lastly, good manufacturing practice (GMP) should also be taken into consideration when designing the bioreactors for such imaging modalities. GMP adheres with stringent guidelines throughout the development and production phases with the intent to achieve quality and safety in the final cell-cultured product. The clinical implementation of bioreactors is expected to be faced with challenges to a certain extent, also due to the logistical set-up and the need for a strong team of well-trained and dedicated cGMP-certified personnel [5]. Whilst the more sophisticated the bioreactor approach, the more likely it is to reflect the natural physiological state, simpler designs are likely to be more operationally robust, so a compromise based on bioreactor complexity versus the essential functional parameters of the desired end-product will always be necessary [126].

Microbioreactors

Design principles

A microreactor for tissue engineering, with dimension smaller than 1 cm, is basically a microdevice in which the organisms are cultivated to recapture the key features of organisms and mimic the real microenvironment for optimal growth and metabolic activity of the organism. These microreactors are beneficial for biophysics researches, underlying the mechanisms of physiological and pathological processes, disease diagnosis and therapy, etc. Many factors need to be considered when designing and fabricating such microreactors, as shown in Fig. 11.4.

Flow rheology

The development of miniaturization technologies had promoted rapid progress in microelectromechanical systems, such as microfluidic chip. Generally, the microfluidic chips consists of microchannels for fluid flow to help mix of liquid and gas, as well as help mass transfer and biochemical reaction. Especially, for microreactors in tissue

engineering, the precise control of the microfluidic flow using micropumps, micromixers, and microvalves require some fundamental understanding of the flow rheology.

The main fluids in the human body that often mimicked in microreactors are blood, urine, tears, perspiration, synovial fluid in the joint, etc., among which most are Newtonian fluid while blood and synovial fluid sometimes can be regarded as non-Newtonian. In detail, blood behaves as non-Newtonian under low shear rates while Newtonian fluid under large shear rates. Synovial fluid, with function of joint lubrication mainly exhibits viscoelastic characteristics, which should be considered for tissue therapy for joint injuries [127,128]. In microfluidics, compared with Newtonian fluids whose viscosities is constant regardless of the shear rate, the rheological properties of non-Newtonian fluids which has nonlinear relationship between the fluid shear rate and its viscosity, are much more complex depending on the chemical compositions, mixture combinations, and many physical conditions such as flow rate and temperature [129]. Normally, the preprocessing (e.g., dilution, washing, enrichment) of the bioassay samples might potentially make a difference in the sample rheology parameters compared to their in vivo status. For example, cell samples are commonly put in buffers such as PBS or DMEM, which are of Newtonian fluid properties. Thus to sufficiently mimic an in vivo environment, rheology must be taken into consideration when designing the microreactors.

Laminar flow or turbulent flow is another factor of flow rheology need consideration for designing bioreactors, which are generally defined by the Reynolds number. Actually, the complex physiologic fluid flow in vivo usually travel through 3D deformable channels, in which distributed turbulent flow might mix with the stable laminar regions. An example is about the pulsatile blood flow, which generally can be regarded as laminar flow in a healthy circulatory system. However, during fraction of each cardiac cycle, small turbulence in the aorta is detected, which will be promoted by the occlusion or stenosis like the stenosis of a heart valve in the circulatory system. Besides, heavy breathing and coughing can also result in turbulent flow [130].

A microreactor system usually consists of some components, such as micromixer, micropump, and microvalve, which can control the flow in order to better control the bioreaction process. The microreactors have some unique advantages, for example, it offers a suitable platform for complex reactions with great performance on controlling the kinetics by improving the bioreaction conditions [131]. Different micromixers have been designed to improve the mixing efficiency including active and passive mixers based on whether need mechanical agitation or external forces. The active micromixers are designed utilizing perturbation force based on electrokinetic, dielectrophoretic, magnetic, and acoustic energy, which usually require special fabrication procedure [132,133]. Passive micromixers produce a laminate of multiple fluid flows, enlarging the interfacial region for fluid diffusion, which is effective for mixing but may cause high pressure drops [133,134]. In addition, the flow in microreactors is categorized into segmented flow and continuous flow, of which the segmented flow includes gas–liquid segmented flow and liquid–liquid segmented flow [135]. For gas–liquid segmented flow, flow modes depend on the surface velocities of gas and liquid. When gas bubble is between two liquid parts, the drag force at the walls enhances convective mixing with each part, narrowing residency time and promoting chemical homogeneity. In liquid–liquid flow, a large specific interface region for immiscible systems generates a short molecular diffusion distance and hinder the unwanted side reactions. While maintaining a continuous stream of the other, multiple pulses of one liquid allow diffusion and reaction to occur at multiple transverse interfaces [133,136,137].

Besides, micropumps and microvalves are also two important elements in microreactors. Micropumps performs well in generating temporal and volumetric fluid movement and on-chip integration can reduce the external hardware for operation, which can be classified as nonpowered and powered ones. In detail the nonpowered pumps (based on osmotic, diffusion, and response to environmental stimuli) do not require electrical actuation and therefore are usually in simple format, easy to fabricate, and possible for minimization. The flow rate mainly determined by the materials, fabrication methods, and is dependent on the fluid properties. Generally, the performance of these micropumps is limited by slow release rates and response [138]. Powered pumps (e.g., electromagnetic, electrostatic, piezoelectric, thermopneumatic, shape memory alloy) often actuated by electricity, heat, or liquid pressure [138,139], which usually have fast response time and large actuation force, with limitations of complex fabrication processes and high driving voltages [139]. Similarly, microvalves control timing, routing, and separation of fluids within a microfluidic device, which can also be categorized as active microvalves and passive microvalves. The active microvalves are divided into nonmechanical (based on hydrogel, paraffin, sol–gel, and ice), mechanical (based on shape memory alloy and thermopneumatic), and external microvalves (e.g., thin membrane or in-line microvalves) [140,141]. On the other hand, the passive microvalves also include mechanical and nonmechanical microvalves. The passive mechanical microvalves mainly work in line with polymerized gel or passive plug, while passive nonmechanical microvalves utilize the surface properties in the microchannels such as hydrophobicity [142,143].

Importantly, the performance of processes in microreactors can be analyzed by a wide variety of simulation software, which can save time and money when designing and fabricating a microreactor with some specific characteristics. In this process, some physical parameters should be early defined such as mass, heat, momentum transfer, kinetic equations as well as boundary conditions [144]. Based on the simulation and computation results, the designing can be optimized accordingly.

Cell microenvironment

Cells are the basic unit of living organisms, residing in a complex microenvironment maintaining cell viability and function and supporting 3D tissue development, where cells encounter complex cues from ECM, fluid stress as well as neighbor cells. These cues include chemical, mechanical, and topographical cues, which are the main determinants of cell phenotype [145,146].

In the cell microenvironment, soluble nutrients and oxygen are crucial factors for tissues culture in vitro. Research showed that there generally was a hypoxic, necrotic center surrounded by viable cells in cellular spheroids if diameter larger than 1 mm [147]. And incorporation of flow in microreactors promotes high mass transfer, which can regulate oxygen concentration, provide nutrients to promote 2D or 3D structure, and remove metabolic products [17]. It's clear that perfusion in microreactors is essential to maintain cell viability and function. However, shear stress is an important factor need to be considered as experimental studies on suspension-adapted mammalian cells found turbulent shear can cause more damages to cells than laminar shear of the same magnitude [148]. Results from studies of shear impact on adherent mammalian cells in 2D and 3D culture demonstrated multiple influences on cell attachment, cell proliferation, and cell differentiation [149–151].

The ECM consists of many proteins and polysaccharides, of which the local extracellular biochemical cues has shown to be an essential factor for tissue development and function, such as TGF-β for mammary branching morphogenesis [152], VEGF for angiogenesis [153], and Wnt proteins for embryo development [154]. Besides, tissues which are located distantly from each other can also have effective communication through circulating soluble factors. In addition, the spatially distributed ECM biochemical cues in vivo are also crucial factors for regulating dynamic cell behaviors, such as cell polarization and migration [155,156]. Many techniques have been developed to create micropatterns of ECM biochemical cues to help study how ECM biochemical cues effect cellular behaviors by dynamic cell–ECM and cell–cell interactions. It helps reveal the function of ECM biochemical properties on physiological and pathological processes, such as wound healing, tissue morphogenesis, and cancer metastasis [157].

Mechanical cues are another important factor for microreactors, which include the mechanical stiffness of ECM and cells or tissues, and the mechanical forces exerted. The ECM and cells or tissues stiffness is their intrinsic mechanical property, for example, mechanical stiffness of mammalian cells in vivo have a wide range from 0.1 to 50 kPa [85,86]. However, the mechanical properties of tissues under pathological condition can significantly alter. For instance, it's reported that compared with normal cells, the cancer cells in tumor stroma are about 5–20 times stiffer compared with their normal counterpart [158]. Besides, research show cancer progression is related with complex interactions between cancer cells and biochemical and biophysical cues of the ECM [159,160]. Importantly, mechanical force is recognized as an important regulator of cell physiological status and promotes the cell activities in bioartificial matrices, further helping in improvement of tissue regeneration in vitro [45]. Mechanical forces in microreactors can be generated from the flow in circulation and compression or stretching of materials contacted with cells. These aspects are essential for consideration when mimicking organ-specific biomechanical cues for microreactors [146,161].

Integration of multiple compartments

Cells in vivo reside in 3D complex microenvironment, including biochemical factors, external mechanical forces, ECM topography, and cell–cell interactions. In microreactor system the integration of multiple compartments helps mimic multiparameter extracellular environment to study the physiological and pathological process.

Recently, with advances in micro/nanofabrication techniques and biomaterials, integrated on-chip cell culture platforms have successfully reconstitute organ-level functions of lungs [162,163], kidneys [164,165], intestines [166], and other organ-on-a-chip models which have mimicked organ-level functions of bile canaliculi [167], cardiac muscle [168], vascular vessels [169], and neural network [170]. The integrative and multiparameter characteristics of in vivo cell microenvironment need consider the critical factors which are necessary for rebuilding specific tissue functions.

Single organ-on-chip systems exhibited importance of cell–cell and cell–ECM interactions in 3D environments. These systems can hardly mimic the interaction between different organs separated physically, but their communication through the circulation system is essential for their specific function. To mimic communications between different organs, Shuler et al. developed a microchip integrated different microtissue components to establish biochemical coupling [171,172], of which the hepatic

module was incorporated to study the metabolism related cytotoxicity of anticancer drugs [171]. Zhang et al. utilized a multichannel 3D cell culture microfluidic system to mimic multiple organs in the human body for potential applications in drug screening, where TGF-β1 was specifically controlled-released inside the lung compartment by gelatin microspheres mixed with cells [173].

Another example is the barrier function, which exists as a significant hallmark for epithelia layer and endothelia layer exhibiting functional and structural polarity. To duplicate the polarized cellular features a general method is using a triple layers structure with a semipermeable membrane located between the two microfluidic channels [174,175]. Based on this, when cells form a coherent monolayer on the semipermeable membrane, both biophysical and biochemical microenvironment cues such as flow rate, osmotic pressure, and cytokine concentrations could be changed independently in the two separate microfluidic channels on top and in the bottom [146].

In addition, many tissues in vivo are more or less affected by mechanical stretches, such as stretching of alveolar cells when breathing and stretching of vascular cells by blood pressure. Reconstructing physiological mechanical stretching is considered especially necessary for replicating functions of these tissues. Cell in situ stretching has already been realized in microreactors via nanomembrane deflection [176] or in-plane membrane stretching [174,177].

Many biomimicry organ-on-a-chip models are ultimately developed for translational researches such as drug screening. For example, Huh et al. developed the lung chip, which had been applied to research on pulmonary edema for developing potential new therapeutics [175]. Toh et al. developed a liver chip based on multiplexed microfluidic channels to maintain the cell synthetic and metabolic functions, aiming for in vitro drug toxicity to predict in vivo drug hepatotoxicity [178]. However, biomimicry organ-on-a-chip research is still immature, which can hardly mimic both organ structures and functions. Considering the current progresses in this field and the development of microengineered functional biomaterials, organ-on-chip platforms recapturing multiparameter microenvironments through integrating micro/nanoengineered biomaterials will benefit fundamental mechanobiology studies as well as translational medicine.

Types of microreactors

The microreactors commonly indicate the bioreactors with dimension smaller than 1 mm, with flow as a significant element, which can be divided into perfusion-based and diffusion-based ones.

For the perfusion chips, the simplest microfluidic configuration is using an internally connected microchannel network via assembly of capillary tubes or an on-chip microchannel network. Generally, chemicals (medium, nutrients, stimuli, etc.) are flowed into a microreactor through tubes connected with syringe pumps, and cell metabolism products and waste medium are collected in the outlets of microreactors. The perfusion-based microreactors show great efficiency in bioreactions, which provide high mass transfer and help cell communication via flow. However, some rheology problems need to be solved before designing and using a perfusion microreactor system, such as laminar flow and reducing the shear stress. With the advances in functional biomaterial, 3D cell culture can be integrated with such perfusion-based microreactors. For example, Domansky et al. and Powers et al. developed perfusion microreactors for studying morphogenesis of 3D tissue structures to direct the hepatic lobule. The morphogenesis of cells is regulated partly by the channel geometry and the chemicals on scaffold surface, which determines the relative values of cell−cell and cell−substrate adhesion force [179,180]. Generally, an optimized perfusion bioreactor for tissue engineering should balance the mass transfer of nutrients and the fluid shear stress within the scaffold pores.

With development of 3D ECM and hydrogel fabrication technologies with microfluidics, 3D cellular microenvironments can also be realized in diffusion-based platforms since most of the proteins and nutrients essential for cell survival are easily diffused in hydrogel [181]. The approach of hydrogel fabrication with microfluidics provides a higher efficient transport for medium and soluble factors, improving control of soluble factor gradients in 2D/3D cell culture, and enabling perfusion of an engineered tissue scaffold [182].

Components and integration into microreactors

In microreactors, fluid is a significant factor both for mass transfer and cell viability. A balance between mass transfer of nutrients and the fluid induced shear stresses is one of the essential factors for designing the microreactors. Some components, such as micromixer, micropump, and microvalve, were integrated with the microreactors for the purpose of fluidic control, which had been introduced previously. In addition to fluidic concentration the concentration distribution is also important factor in microreactors. Based on microfluidic method, stable chemical gradients can be feasibly generated in microreactors. For example, Torisawa et al. fabricated a microfluidic device to study chemotaxis of cancer cells, in which chemical gradient is determined by source and sink microfluidic channels [183]. Allen et al. used a microfluidic perfusion microreactor to generate oxygen gradients to study the regional variations in oxygenation on liver zonation [184].

Cell chambers is another essential component in microreactors, for which some general characteristics are necessary, such as sterilization and nontoxicity of the components, easy assembly and feasibility of parameter monitoring along the medium flow. In the past years, most microsystems for cell culture were designed for 2D monolayer cell culture, with the cell chambers mainly fabricated of PDMS, PMMA, and glass. Recently, biologically derived materials such as collagen gels and matrigel, and synthetic biomaterials such as hydrogels, have been developed for 3D culture in microreactors. Especially, the synthetic biomaterials provide a more controllable physical and chemical microenvironment as multiple parameters could be tuned such as porosity, crosslinking density, and the degradation rate [185,186]. Importantly, 3D ECM and hydrogel fabrication technologies can be integrated into in flow-competent platforms to construct 3D cellular microenvironments [181,187]. For example, a 3D hydrogel that enables spatial control defined by the chambers structure was used directly within cell culture chambers on chip [187]. To fabricate gels with the channels open during the casting process, a pneumatic actuation strategy was used. In another study, microfluidic channels were integrated with a hydrogel and ECM scaffold to mimic a vascular structure [188].

Due to the fact that tissue or cell culture is a dynamic process which could be effected by many parameters, such as temperature, pH value, humidity, nutrient concentration, oxygen concentration, biochemical, and mechanical stimuli. It is expected to endow the microreactors with custom on-line sensors to dynamically monitor and control these parameters. Except for the purpose of monitoring the microenvironment, microsensors can also be applicable for detect and monitor the cell physiological activities and behaviors, such as migration, immune activation, and metabolism. For example, Bavli et al. incorporate liver-on-a-chip system with microsensors to observe changes in glucose and lactate in order to real-time track the dynamics of metabolic adaptation to mitochondrial dysfunction, which allows detecting the chemical toxicity before any observed effects on cell or tissue viability [189]. Lind et al. focused on printing a readable heart-on-a-chip platform with embedded sensors for measuring the contractile force from the laminar cardiac tissue [190]. Zhang et al. developed an integrated modular physical, biochemical, and optical microsensors through a fluidics-routing breadboard, which can operate organ-on-a-chip units in a dynamic and automated manner [191].

Applications

While tissue engineering is traditionally associated with applications in regenerative medicine, it has more recently been explored as a method to develop physiological models of disease. These models have been proposed to have utility for a wide range of functions, including drug testing and screening, experimental models to study disease biology, as well as clinical prognostics and diagnostics for personalized medicine. Microreactors often take the form of "organ-on-chips" and a summary of the strengths and limitations of these systems are presented in Table 11.3.

Drug testing and screening

Newly developed drugs require extensive tests and evaluations before they can be allowed to enter the market. These activities typically include preclinical trials involving in vitro and animal models to study the biochemical and physiological effects; in order to proceed to trials in humans, the ensuing clinical trials often take many years and are extremely expensive. However, more than 90% of the new drugs are failed at this stage as they are unable to demonstrate real health benefits, suggesting the inadequacy of existing preclinical models to accurately represent the true safety and efficacy in humans. Reasons for this include the inability of traditional 2D cell cultures (most often used in early tests of compound efficacy and

TABLE 11.3 Summary of the strengths and limitations of organ-on-chips systems.

Strengths	Limitations
Provide perfusion flow to maintain three-dimensional tissue structures and simulate blood flow	Technically challenging to scale
Complexity allows greater approximation to physiological systems for modeling of ADME	Reproducibility compromised by complexity of system
Controllable flow conditions to match physiological parameters	Long-term cultures remain vulnerable to contamination
Accessibility of on-chip tissue for repeated sampling	Laborious procedures for preparation and maintenance of system

ADME, Absorption, distribution, metabolism, and excretion.

toxicity) to recapitulate the spatial complexity seen in vivo. In contrast, animal models often do not capture human-specific drug responses or specific features of a target disease. It follows that more stringent evaluation of drug responses may prove valuable as an approach to "fail" candidate compounds at an earlier stage, avoiding the heavy costs associated with attrition in the latter stages of drug development.

To this end, organs-on-chips models, in which tissue-specific cells are cultured within microfluidic devices, have been developed to provide biomimetic physiological analogs amenable to pharmacological modulation and monitoring of responses. Such models may have important applications in predicting tissue toxicity. To meet the need for assays of chronic hepatotoxicity, for example, advanced cell culture techniques have been developed that integrates incubator features into microfluidic devices, facilitating extended, continuous culture periods for maintenance of 3D hepatocyte cultures [192]. Following optimization of flow conditions to remove metabolic by-products and reduce shear stress on cultured spheroids, cellular viability, and functionality were demonstrated for on-chip hepatocyte spheroids after more than 2 weeks in culture. The resulting devices were used for acute and chronic repeat dosing drug safety testing of diclofenac and acetaminophen. Crucially, diclofenac toxicity is idiosyncratic and cannot be reproduced reliably in animal models; using the perfusion incubator liver chip model, the authors found a more sensitive chronic toxicity response compared to static controls.

Microfluidic devices containing multiple, connected organ compartments have been developed in the more ambitious "body-on-chip" models, which may be used to observe ADME (absorption, distribution, metabolism, and excretion) pharmacology. Four-organ chips have been developed comprising human intestine, liver, skin, and kidney equivalents, in which drugs could be delivered via a reservoir at the apical surface of the engineered intestinal wall to simulate oral administration [193]. The "absorbed" drug is sequentially delivered to liver, skin, and kidney equivalents, representing primary metabolism, secondary metabolism, and excretion, respectively. The amenability of the different compartments to repeated sampling provides the unique opportunity to evaluate pharmacokinetic and pharmacodynamics parameters in real time.

Experimental models of disease

Animal disease models are used in a variety of settings in basic research, such as studies on disease etiology and mechanisms of disease progression. Limitations of using animals for research include high costs, ethical concerns over the use of research animals, inability to recapitulate disease states faithfully, and limited tools for in vivo experimentation. Taking early events in bone metastasis as an example, animal models lack fidelity in reproducing bone metastasis events and are generally inaccessible to real-time, single-cell imaging [194].

The first organ-on-chip device was a lung model where the authors were able to demonstrate reproduction of a mechanically active alveolo-capillary membrane, the smallest functional unit in the lung [174]. Using this model, the team was able to demonstrate the nanotoxicity of inhaled silica nanoparticles. In addition, because the mechanical forces were externally controlled, the effect of mechanical strain on nanoparticulate uptake could be decoupled and independently assessed, leading to the finding that cyclic stretch increased nanotoxicity and associated inflammatory responses.

Pathological tissue may also be directly cultured on chip, as seen with models focused on representing specific steps in the cancer cascade. Cancer-on-chip models have been developed to study tumor growth, progression through epithelial-mesenchymal transition, intravasation into vasculature, and metastasis. In particular, cellular dormancy is a feature of disseminated tumor cells in the premetastatic niche and is believed to be influenced by proximity to perivascular niches and is often studied using 2D cell cultures [195]. To recapitulate this in lung-on-chip systems, lung cancer cells can be orthotopically introduced into the primary lung alveolar or small airway epithelial cells, which integrate into the tissue layers. Using this model, it was found that cancer cell growth was accelerated in the lung alveolus microenvironment compared to in the lung airway, where the inoculated tumor cells remained largely dormant [196]. Corollary to advancements in the development of multicompartmental body-on-chip systems, orthotopic primary tumor models may be generated in one organ chip and subsequently followed through the metastatic cascade. Such models will have critical utility in understanding cellular and molecular mechanisms and interactions across the various stages of cancer metastasis.

Prognostic/diagnostic tools

As a medical model, precision medicine (PM) proposes customized health care according to the individual patient. The motivation for PM arises from the recognition of a significant proportion of nonresponders within a patient population and the need to reduce prescription of treatment regimes that are ineffective or harmful. Indeed, an analysis of bone biopsies obtained from 189 patients with advanced, bone-metastatic prostate cancer showed that up to 89% of affected individuals had a "clinically actionable outcome" [197]. Thus genomic profiling, biomarkers, and biometrics may be useful in stratifying patients according

to the likelihood of response, in order to achieve personalization of their treatment regimes. These data, however, often only show a snapshot of a static time point and offer little in representing the complexity of the disease.

Functional testing, in which patient-derived tissues are used for evaluation of functional response to novel drug treatments, addresses this by recapitulating some of this complexity, such as heterocellular interactions. To generate personalized organs-on-chips for patients, primary tissue may be obtained and cultured on microfluidic systems. However, cells derived from primary sources have limited capabilities to grow and an alternative approach to transform patient-derived cells into iPS cells has yielded an alternative. These stem cells may also be further augmented through genetic modifications including reporter genes, raising the possibility of real-time monitoring. This technology and approach is still new however, and significant research and development must be undertaken to overcome existing limitations.

Summary

This chapter has explored the principles in developing bioreactors for tissue-engineering applications to mimic the native tissue environment and physiological functions. The bioreactor technologies include macrobioreactors that are primarily utilized to grow functional tissues for in vivo implantation, as well as microbioreactors, which is used to create native tissue-like environment for drug testing and other in vitro studies on biochemical and mechanical regulation of cell responses and tissue development. Clinicians, engineers, and scientists are aiming to continuously advance the bioreactor systems toward (1) developing a robust platform for generation of functional tissue grafts for clinical application, (2) studying diverse biological responses in tissue development and regeneration, (3) optimizing cell manufacturing processes for large-scale, standardized, and reproducible production of high-quality and clinically relevant cells for regenerative medicine. The advancements in specialized bioreactor designs are evident with the growing research on space bioreactors to simulate microgravity on earth so as to study the physiological responses of cells and tissues under such conditions, as well as the advent of integrating the real-time imaging in the bioreactors to monitor the graft development and the tissue growth and dynamics. Developments in the multiple organ-on-a-chip platform gives promise toward developing body-on-a-chip platforms for high throughput drug testing and screening. The nascent developments in the personalized patient-derived organ-on-a-chip platforms as prognostic or diagnostic tool would help to progress the future of bespoke medicine.

Chapter 12

Regulation of cell behavior by extracellular proteins

Amy D. Bradshaw[1,2]

Introduction

The extracellular milieu is a critical determinant of cell behavior in all tissues. Many factors comprise the environment and each factor contributes unique influences on cell behavior. For example, cell:cell contact, cell:extracellular matrix (ECM) interaction, and ECM composition influence cell activity. Environmental components act together to regulate cell surface protein activity, intracellular signal transduction, and subsequent gene expression, which leads to proliferation, migration, differentiation, and ultimately the formation of complex tissues. Matricellular proteins are secreted, modular proteins that are associated with the ECM, are known to influence cell adhesion, cell:ECM binding, and ECM structure and function [1]. This chapter will focus on matricellular proteins as modulators of extracellular signals. A unifying theme of matricellular proteins is to provide a link between the ECM and cell surface receptors, and/or cytokines and proteases localized in the extracellular environment, the activity of which might be affected by this interaction. Thrombospondins-1 and -2, tenascin-C, osteopontin, and secreted protein acidic and rich in cysteine (SPARC) are representatives of this class of proteins. A significant body of evidence points to these proteins as critical mediators of cell signaling pathways and ECM assembly and turnover. Consequently, strategies designed to recapitulate tissue conditions should consider the influence and addition of matricellular proteins to aid in the acclimation of cell populations to engineered environments. In addition, the widespread increases in expression of matricellular proteins in adult tissues undergoing ECM remodeling events, such as those in tissue repair, cancer progression, and fibrosis, identify matricellular proteins as recognized markers of disease onset and, in some cases, resolution (Table 12.1).

Thrombospondin-1

Thrombospondin-1 is a 450,000 Da glycoprotein with seven modular domains [2]. To date, five different paralogs of thrombospondin have been identified, termed thrombospondins-1−5. This chapter will review the two more characterized forms, thrombospondins-1 and -2. At least five different ECM-associated proteins are able to bind to thrombospondin-1: collagens I and V, fibronectin, laminin, fibrinogen, and SPARC [2]. Likewise, cell surface receptors for thrombospondin are multiple and include cluster designation (CD)36, CD47, and the integrin family of ECM receptors [3]. Given the significant number and variety of thrombospondin-1-binding proteins, it is of little surprise that a wide variety of functions have been attributed to this protein, some of which appear to be contradictory. Many of these disparities may, however, reflect dynamic interactions of thrombospondin-1, or cleaved fragments of thrombospondin-1, with other extracellular factors, which can influence cells in different ways to give rise to distinct cellular outcomes—a common theme in matricellular protein biology.

The antiangiogenic properties of thrombospondin-1 are well characterized [3]. In fact, thromospondin-1 was the first identified naturally occurring inhibitor of angiogenesis. In vitro, aortic endothelial cells transfected with antisense thrombospondin-1 cDNA generate twice as many capillary-like structures on a gelled basement membrane in comparison to control cells that produce higher levels of thrombospondin-1 [4]. In accordance, tumors grown in thrombospondin-1-null mice display enhanced angiogenesis accompanied by increases in tumor size. Increased expression of thrombospondin-1 by tumor cells results in decreased vascularization and an accompanied reduction in tumor progression by a number of different

A summary of the activities for the matricellular proteins described in this chapter. This table is not a complete list of all activities and receptors for the proteins nor all the matricellular proteins included. For references refer to the text. *bFGF*, Basic fibroblast growth factor; *CD*, cluster designation; *Col*, collagen; *EGF*, epidermal growth factor; *Fg*, fibrinogen; *Fn*, fibronectin; *HGF*, hepatocyte growth factor; *Ln*, laminin; *LRP*, lipoprotein receptor-related protein; *MMP*, matrix metalloproteinase; *PDGF*, platelet-derived growth factor; *SMOC*, SPARC related modular calcium-binding protein; *SPARC*, secreted protein acidic and rich in cysteine; *TGF*, transforming growth factor; *VCAM*, vascular cell adhesion molecule; *VEGF*, vascular endothelial growth factor. Growth factor abbreviations are defined in the text.

types of tumor-derived cells representing the potential translational applications for designing antitumor therapies with cell-binding sequences derived from thrombspondin-1 [5].

One mechanism by which thrombospondin-1 might influence angiogenesis is by promoting cell death in microvascular endothelial cells [6]. CD36, a thrombospondin-1 cell surface receptor, has been shown to be required for caspase-3-mediated induction of apoptosis by thrombopspondin-1. Antimigratory effects elicited by CD36 interaction with thrombospondin-1 in endothelial cells has also been demonstrated. A complex containing CD36 and β1 integrins on cell surfaces can collaborate in thrombospondin-1 (and -2) cell signaling [7]. In addition, interactions with the CD36/integrin complex affect vascular endothelial growth factor (VEGF) activity. In fact the balance between TSP-1 and VEGF in the extracellular space is proposed as an important cellular mechanism in angiogenic control [8].

Another thrombospondin receptor, CD47, has been implicated in cardiovascular function as a potent regulator of nitric oxide [9]. Engagement of CD47 by thrombospondin-1 inhibits NO production. As NO is known to be significantly decreased in cardiovascular tissues in aging, the age-dependent increase in thrombospondin-1 has been implicated as mechanism that might account for deficient NO signaling in chronic diseases of aging. As the first natural inhibitor of angiogenesis, characterization of the mechanisms by which thrombospondin-1 functions provides valuable insight into strategies to control blood vessel formation.

Thrombospondin-1, like many of the matricellular proteins, influences cytokine activity. For example, thrombospondin-1 has been shown to interact specifically with transforming growth factor (TGF)-β [10]. This interaction leads to activation of the latent form of TGF-β, presumably through a conformational change in the cytokine, which allows interaction with cell surface receptors [10]. Consequently, the presence of thrombospondin-1 in the extracellular milieu might affect the activity of this potent, multifunctional cytokine. Generation of a thrombospondin-1-null mouse lends support to the importance of thrombospondin-1-mediated activation of TGF-β in vivo. The phenotype manifest in the absence of thrombospondin-1 expression mimics to some degree the phenotype of the TGF-β − null mouse [11]. Specifically, similar pathologies of the lung and pancreas are observed in both mice and, importantly, thrombospondin-1-null mice treated with thrombospondin-1 peptides show a partial restoration of active TGF-β levels and a reversion of the lung and pancreatic abnormalities toward tissues of wild-type mice. Importantly, thrombospondin-1 is a potent chemoattractant for inflammatory cells. Therefore a reduction in active TGF-β levels in thrombospondin-1-null mice might be influenced by inflammatory cell recruitment.

The function of thrombospondin-1 in the activation of TGF-β appears to be of greater significance in some tissues in response to injury in adulthood rather than in development. For example, in the heart, thrombospondin-1-null mice have an altered response to both pressure overload (PO)—induced hypertrophy and to myocardial infarction in comparison to the response in wild-type animals although uninjured adult null hearts appear grossly normal. In hearts with PO an increase in the number of myofibroblasts is found in thrombopsondin-1 null versus wild type in the absence of increases in fibrillar collagen [12]. As myofibroblasts are frequently associated with sites of robust collagen production, the lack of increased collagen suggests that myofibroblast differentiation is impaired in the absence of thrombopsondin-1. In fact, thrombopsondin-1-null myofibroblasts from PO hearts are smaller and produce less collagen type I than those from wild-type counterparts. TGF-β is known to induce myofibroblast differentiation; hence, the authors of this study conclude that inefficient TGF-β activity in the absence of thrombopsondin-1 likely influences myofibroblast phenotype in PO hearts.

Thrombospondin-1 influences cell adhesion and cell shape. For example, it will diminish the number of focal adhesions of bovine aortic endothelial cells and thus will promote a migratory phenotype [13]. Thrombospondin-1, therefore, is proposed to modulate cell:matrix interaction to allow for cell migration when necessary. An intermediate stage of adhesion describes cell responses to counter-adhesive matricellular proteins and, as such, is predicted to promote cell motility [13]. Accordingly, thrombospondin-1 expression is observed during events such as dermal wound repair, when cell movement is required. Thrombospondin-1 is also expressed by many tumor cells and might facilitate metastatic migration [7].

Thrombospondin-2

Similar to thrombospondin-1, thrombospondin-2 inhibits angiogenesis in vivo. Recombinant thrombospondin-2 contained in pellets implanted in the rat cornea inhibits basic fibroblast growth factor (bFGF)—induced vessel invasion to nearly the same degree as thrombospondin-1 [14]. Thus the observation that the thrombospondin-2-null mouse appears to have a greater degree of vascularization in the skin is in accordance with the hypothesis that thrombospondin-2 might serve as an endogenous regulator of angiogenesis in mice [15]. In fact, the expression pattern of thrombospondin-2 is more consistent with the importance of this protein in vascular formation, as the mRNA for thrombospondin-2 is more closely associated with the vasculature in developing tissues, in comparison to that of thrombospondin-1 [16].

How might thrombospondin-2 mediate inhibition of angiogenesis? Abrogation of thrombospondin-2 expression results in increased amounts of matrix metalloproteinase (MMP)-2 activity [17]. Thrombospondin-2 binds to MMP-2 and facilitates uptake by scavenger receptors on cell surfaces. Hence without thrombospondin-2, MMP-2 levels accumulate in the extracellular milieu and result in significant decreases in cell adhesion. The increase in MMP-2 levels is correlated with decreased amounts of tissue transglutaminase on thrombospondin-2-null cell surfaces [18]. As transglutaminase is known to enhance integrin-mediated cell attachment and serve as a substrate of MMP-2, the increase in MMP-2 activity is proposed to elicit decreased cell adhesion in the absence of thrombospondin-2 by diminishing amounts of transglutaminase on cell surfaces. Hence, blood vessel formation appears to be sensitive to levels of MMP-2 in tissues. Likewise, tissue transglutaminase on cell surfaces might also contribute to angiogenic events.

Another observation from the thrombospondin-2-null mouse is that of altered collagen fibrillogenesis in the skin, relative to that seen in wild-type mice. The collagen fibrils in the null mice are larger in diameter, have aberrant contours, and are disordered [15]. Presumably this effect on collagen fibril formation contributes to less tensile strength of the skin in thrombospondin-2-null mice versus their wild-type counterparts. An intriguing relationship between aberrant collagen fibril morphology and decreased transglutaminase activity is suggested by the thrombospondin-2-null phenotype. Evidence also suggests that thrombospondin-2 is a profibrotic molecule. In the absence of thrombospondin-2, less collagen deposition is found in a murine cardiac graft model [19], whereas increased thrombospondin-2 levels in scleroderma fibroblasts contribute to increased collagen production through upregulation of miR-7 [20]. Evidence that changes in thrombospondin-2-null ECM might reside in differences in miR-29 expression is also reported [21].

In tissue engineering applications, ECM derived from the skin of thrombospondin-2-null mice supports greater cell migration versus that from wild-type mice when implanted subcutaneously in mice [22]. The decellularized dermal matrix is applied as either a slab or as comminuted powder delivered in silicone trays. Importantly, the thrombospondin-2-null matrix showed improves efficacy in healing diabetic wounds in a murine model. As diabetic animals have notably impaired healing ability, improvements brought about with the thrombospondin-2-null ECM has potential translational applications. In addition to the lack of thrombospondin-2, the dermis of thrombospondin-2-null mice also differs from wild-type skin in terms of levels of collagens, collagen cross-linking, proteoglycans, and matricellular proteins [21]. Hence, likely a variety of factors in addition to the

absence of thrombospondin-2 confer the improved wound healing capabilities of the decellularized matrix. These studies also highlight the influence that expression of one matricellular protein, in this case thrombospondin-2, can have on the overall composition of the ECM [21].

Thrombospondins-1 and -2 can act as negative regulators of cell growth. In particular, endothelial cells are susceptible to an inhibition of proliferation by both proteins, resulting in their classification as inhibitors of angiogenesis. However, the variety of cell surface receptors for thrombospondins allows for diverse signaling events in different cell types; consequently, there might be situations when thrombospondin appears to support angiogenesis as well [23]. Thrombospondin-1 has been shown to modulate the activity of at least two cytokines, TGF-β and hepatocyte growth factor (HGF): diminished activity, in the case of HGF, or enhanced activity, as seen for TGF-β. Finally, thrombospondin-1 can not only alter cell shape to promote a migratory phenotype but also inhibit migration. Such conflicting conclusions illustrate the importance of contextual presentation of matricellular proteins in various assays. Further characterization of the thrombospondins, including closer examination of the remaining family members (thrombospondins-3−5), will no doubt yield fascinating insight into this multifunctional gene family [24,25].

Tenascin-C

Tenascin-C is a matricellular protein with a widespread pattern of developmental expression, in comparison to a restricted pattern in adult tissues. In addition to tenascin-C, three other, less-characterized forms of tenascin have been identified: tenascin-R, tenascin-X, and tenascin-W [26]. This section will focus on tenascin-C, as the best characterized of the tenascin gene family. Tenascin-C consists of six subunits (or arms) linked by disulfide bonds to form a 2000 kDa molecule that can associate with fibronectin in the ECM [27]. Like thrombospondin-1, a number of different functions have been attributed to tenascin-C and, accordingly, a number of cell surface receptors appear to mediate distinct properties of this matricellular protein. Cell surface receptors for tenascin-C include annexin II and at least five different integrins receptors, of which $\alpha_9\beta_1$ demonstrates the highest affinity for tenascin-C [28]. While the integrins appear to support cell adhesion to tenascin-C, annexin II is thought to mediate the counter-adhesive function attributed to this protein. Hence, tenascin-C can act as either an adhesive or as a counter-adhesive substrate for different cell types, dependent upon the profile of receptors expressed on the cell surface.

Tenascin-C has also been shown to modulate the activity of growth factors: specifically, it promotes epidermal growth factor (EGF)−dependent and bFGF-dependent cell growth [29,30]. In fact, Jones et al. [30] have shown that smooth muscle cells plated in a collagen gel secrete MMPs that degrade the collagen to expose integrin receptor−binding sites. Engagement of these receptors induces tenascin-C expression; tenascin-C is subsequently deposited into the ECM and can itself serve as an integrin ligand. The deposition of tenascin-C leads to cell shape changes initiated by a redistribution of focal adhesion complexes concomitant with a clustering of EGF receptors on the cell surface. Presumably, clustering of the EGF receptors facilitates EGF signaling and thereby enhances the mitogenic effect of EGF. Conversely, when MMP activity is inhibited, tenascin-C expression is decreased and the cells become apoptotic [30]. Thus tenascin-C is able to modulate EGF activity such that the presence of this matricellular protein supports cell growth and its absence induces programed cell death.

Similarly, tenascin-C supports tumor metastatic colonization by breast cancer cells through suppression of cell apoptosis [31]. Tenascin-C expression by stromal cells as well as by metastasis-initiating breast cancer cells appears to protect tumor-derived cells from apoptotic stresses and thereby facilitates establishment of metastatic colonization in some tissues [32,33]. A function of tenascin-C in hematopoiesis following myeloablation in adult mice is also reported. Tenascin-C expression in the bone marrow niche microenvironment is required for regeneration of hematopoiesis after ablation but is not required to maintain steady-state conditions [34].

Given the widespread expression of tenascin-C in the developing embryo, the lack of an overt phenotype in the tenascin-C-null mouse is surprising [35]. In particular, the high level of tenascin-C expression in the central and peripheral nervous system had indicated that the absence of this protein might lead to neuronal abnormalities. Although no histological differences could be detected in the brains of adult tenascin-C-null mice, they displayed behavioral aberrations, including reduced anxiety and enhanced novelty-induced activity [36,37]. In addition, altered numbers of embryonic central nervous system stem cells are noted in the absence of tenascin-C expression, an observation confirming that the composition of the ECM is an important factor in cell differentiation [38].

The genetic background of the tenascin-C-null mouse is likely to be a major factor in the identification of tissues in which tenascin-C might be functionally important. For example, Nakao et al. [39] use three different congenic mouse lines to study the effect of Habu snake venom−induced glomerulonephritis in a tenascin-C-null background. Although the disease is worse in all tenascin-C-null mice in comparison to wild-type controls, each

line exhibits a different level of severity. Induction of the disease in one strain, GRS/A, results in death from irreversible renal failure [39]. Moreover, mesangial cells cultured from tenascin-C-null animals do not respond to cytokines, such as platelet-derived growth factor (PDGF) unless exogenous tenascin-C is included in the culture medium. Hence, tenascin-C can also modulate the activity of this growth factor as observed previously for EGF. Tenascin-C provides another example of a matricellular protein able to affect growth factor efficacy.

Although tenascin-C shows a limited pattern of expression in the adult, an induction of tenascin-C is seen in many tissues undergoing wound repair or neoplasia [40]. Thus tenascin-C, like the other matricellular proteins, is ideally suited to act as a modulator of cell shape, migration, and growth. Importantly, tenascin-C can be used as a marker of successful tissue repair. One mechanism by which tenascin-C influences cell behavior is through the modulation of fibronectin interaction with cells. Tenascin-C decreases cell adhesion to fibronectin through competition with a heparan sulfate proteoglycan, syndecan 4 [41]. Syndecan 4 is required for efficient cell attachment to fibronectin and for tenascin-C inhibition of adhesion to fibronectin. Hence, a scenario in which tenascin-C competes for syndecan 4 binding to fibronectin is consistent with these results. Certain proteolytic fragments of tenascin-C interfere with fibronectin assembly although full-length tenascin-C does not demonstrate inhibition of fibronectin fibrillogenesis [42]. Given the high levels of proteolytic activity in wounds, for example, cleavage of tenascin-C might be one mechanism by which regulation of fibronectin assembly is achieved. Interestingly, molecular phylogeny indicates that tenascin-C evolved prior to fibronectin; hence, tenascin-C is likely to have functions unrelated to fibronectin at some level.

Nonetheless, tenascin-C production is aligned with improved repair and resolution in many tissues. Fragments of tenascin-C have been exploited in bioengineering applications to enhance cell activity. For example, the integrin activating tenascin-C peptide, when incorporated into bioengineered gels, enhances neurite outgrowth, a quality that is improved in three-dimensional (3D) cultures [43,44].

The paucity of developmental abnormalities manifested in the tenascin-C-null mouse points to the greater importance of tenascin-C in remodeling events, which take place in response to injury or transformation. For example, tenascin-C has been shown to regulate cardiac neovascularization by bone marrow−derived endothelial progenitor cells in response to angiogenic stimuli in adult mice [45]. In addition, as mentioned, high levels of tenascin-C expression are frequently associated with several types of malignancies, including tumors of the brain and breast [26]. In fibrosis, tenascin-C expression is implicated in a positive feedback loop in fibroblasts that involve Twist1 and paired-related homeobox 1 (Prrx1) in which chronic activation of fibroblasts leads to excess collagen deposition [46].

Osteopontin

As the name implies, osteopontin was originally classified as a bone protein. A more thorough examination, however, reveals a widespread expression pattern for this protein with multiple potential functions [47]. Osteopontin associates with the ECM, as it binds to fibronectin and to collagens I, II, III, IV, and V. Osteopontin also affects cellular signaling pathways by virtue of its capacity to act as a ligand for multiple integrin receptors as well as (CD)-44 [47]. Thus osteopontin, like most of the matricellular proteins, is able to act as a bridge between the ECM and the cell surface. Since matricellular proteins might be synthesized, secreted, and incorporated into the ECM with greater ease than more complex structural ECM proteins that must be incorporated into fibrils and assembled into a network, a bridging function might be useful during remodeling events in the organism when rapid conversion of the cellular substrata is required for cell movement.

Osteopontin serves as an integrin ligand through an RGD sequence and a SVVYGLR sequence located near the thrombin cleavage site. Osteopontin is also susceptible to modification by ECM metalloproteases [48]. In support of osteopontin enhancing cell adhesion, Weintraub et al. [49] report that transfection of vascular smooth muscle cells with antiosteopontin cDNA reduces adhesion, spreading, and invasion of 3D collagen matrices. Addition of osteopontin to the collagen gel restores the capacity of these cells to invade the gel [49]. In addition, Senger et al. [50] report that endothelial cells treated with VEGF increase their expression of the integrin $\alpha_v\beta_3$, an osteopontin cell surface receptor, concomitantly with an increase in osteopontin. These investigators also show an increase in the amount of thrombin-processed osteopontin in tissues injected with VEGF and radiolabeled osteopontin. The significance of this result lies in the enhanced support of endothelial cell migration in vitro by thrombin-cleaved versus full-length protein [50].

In pulmonary hypertension, adventitial fibroblasts from pulmonary arteries demonstrate an activated phenotype characterized by high rates of proliferation and migratory potential. High levels of osteopontin expression are correlated with this activated phenotype [51]. Furthermore, silencing of osteopontin expression significantly reduces proliferation and migration in hypertensive fibroblasts, whereas increased osteopontin activity stimulated proliferation and invasion by normal fibroblasts [51]. Thus osteopontin is predicted to be a primary

determinant of the activated phenotype characteristic of adventitial fibroblasts in hypertensive lungs. Increased levels of osteopontin secreted by senescent fibroblasts also promote migration of mammary epithelial cells, a process linked to neoplastic progression and tumor development in aging tissues [52].

The capacity of osteopontin to influence cell migration might be linked to MMP activity. Osteopontin is a member of the SIBLING (small integrin-binding ligand N-linked glycoprotein) family of proteins that have been shown to bind to and regulate the activity of MMPs [53]. Osteopontin binds to recombinant proMMP-3 and active MMP-3. In addition, a decrease in MMP-9 activity has been reported in osteopontin-null myofibroblasts and vascular smooth muscle cells [54]. Hence, osteopontin serves to both influence extracellular protease activity as well as being susceptible to degradation and functional activity by proteases [65].

The promotion of cell survival is another property ascribed to osteopontin. Denhardt and Noda [55] have reported that human umbilical vein endothelial cells plated in the absence of growth factors will undergo apoptosis. If these cells are plated on an osteopontin substrate, however, apoptosis is inhibited [55]. Furthermore, rat aortic endothelial cells subjected to serum withdrawal undergo programed cell death, a response inhibited by an osteopontin substratum. In fact, it is the ligation of integrin $\alpha_v\beta_3$ by osteopontin at the cell surface that induces nuclear factor-kappa B, a transcription factor that controls a variety of genes through direct binding to their promoters. Thus osteopontin and other $\alpha_v\beta_3$ ligands can protect cells from apoptosis [56].

The function of osteopontin to influence inflammatory response is well documented. Expression of osteopontin is found to increase during intradermal macrophage infiltration, and purified osteopontin injected into the rat dermis leads to an increase in the number of macrophages at the site of administration. Importantly, antiosteopontin antibodies inhibit macrophage accumulation in a rat intradermal model after a potent macrophage chemotactic peptide is used to induce an inflammatory response [57]. Osteopontin expression is required for the development of an effective T_H1 immune response [58]. In glioblastoma, integrin $\alpha_v\beta_5$ highly expresses on glioblastoma-infiltrating macrophages. Wei et al. recently report that reduced levels of osteopontin associated with glioblastoma tumors lead to a significant decrease in M2 polarized macrophages in glioma [59].

The phenotype of the osteopontin-null mouse supports the hypothesis that osteopontin affects macrophage activity. Although the number of macrophages does not appear to differ significantly in incisional wounds of wild-type and osteopontin-null mice, the amount of cell debris was higher in wounds of the latter animals. Because macrophages are thought to be primary mediators of wound debridement, osteopontin is predicted to be important in the regulation of macrophage function [60]. Collagen fibril formation in the deeper dermal layers of wounded osteopontin-null mice also appear to be affected. Osteopontin-null mice have smaller collagen fibrils compared to wild-type controls. Similar to thrombospondin-2, osteopontin might affect collagen fibrillogenesis especially at wound sites, as no differences are seen in the size of collagen fibrils in unwounded skin [60].

The proinflammatory and profibrotic properties of osteopontin suggest osteopontin might contribute to human diseases in which inflammation and fibrosis contribute to pathological processes such as in systemic sclerosis (SSc). In fact, high levels of circulating osteopontin are present in patients with SSc. Osteopontin-null mice, when challenged with bleomycin to induce dermal fibrosis, exhibit significantly reduced levels of collagenous ECM and fewer macrophages [61]. Similarly, in a renal model of fibrosis, significantly less interstitial fibrosis and inflammatory infiltration occur in osteopontin-null mice in comparison with wild-type animals [62].

Another primary function of osteopontin is to serve as a negative regulator of calcification [63]. Osteopontin inhibits apatite crystal formation in vitro and facilitates resorption of cellular minerals. As shown in an in vivo model of ectopic calcification, the capacity of osteopontin to abrogate calcification is dependent upon the phosphorylation of osteopontin and the presence of the integrin-binding RGD sequence in osteopontin [64]. In mineralized tissues, osteopontin is an important factor in the regulation of bone turnover whereas in nonmineralized tissues, osteopontin might influence ectopic calcification events [65].

Osteopontin and its repertoire of cell surface receptors represent components of a pathway used by cells in need of rapid movement or migration. In addition, the ligation of osteopontin by certain cell surface receptors supports cell survival and thus provides a mechanism for a given tissue to protect a subset of cells, expressing the appropriate receptor, from apoptosis. Interestingly, an intracellular form of osteopontin has been implicated as the mediator of interferon-α production in plasmacytoid dendritic cells [66]. Recently, distinct roles of intracellular versus secreted osteopontin were uncovered in the regulation of myeloid versus lymphoid immune response to pathological insult [67]. That matricellular proteins might play vital roles inside the cell, which has been proposed for other matricellular family members as well, including recent reports on the thrombospondin family, represents an exciting area of research [25].

Secreted protein acidic and rich in cysteine

SPARC (BM-40; osteonectin) was first identified as a primary component of bone but has since been shown to

have a wider distribution [68]. Increased expression of SPARC is observed during development and in many adult tissues undergoing different types of remodeling. For example, SPARC is found in bone and in gut epithelium, two tissues that normally exhibit rapid turnover, and in healing wounds. An increase in SPARC is observed in the vast majority of fibrotic conditions and in association with many different tumors [69]. Like other matricellular proteins, SPARC interacts with the ECM by binding to collagens I, III, IV, and V [68].

SPARC has also been shown to bind to a variety of growth factors present in the extracellular space [70]. For example, SPARC binds to PDGF-AB and -BB and prevents their interaction with PDGF cell surface receptors. PDGF-stimulated mitogenesis is inhibited by the addition of SPARC [71]. SPARC can also prevent VEGF-induced endothelial cell growth, as it binds directly to the growth factor and thereby prevents VEGF receptor stimulation of the mitogen-activated protein kinases, Erk-1 and Erk-2 [72]. In vivo, regulation of VEGF activity by SPARC via VEGF receptor-1 occurs during choroidal neovascularization after injury [73].

Interestingly, a variety of mitogenic stimulators are inhibited by SPARC in culture, some of which do not necessarily associate physically with this protein. For example, SPARC is thought not to bind to bFGF, but SPARC inhibits bFGF-stimulated endothelial cell cycle progression [70]. Apparently, the effect of SPARC on cell proliferation is complex and could occur through (1) a direct prevention of receptor activation, and/or, (2) a pathway mediated by a cell surface receptor recognizing SPARC, and/or (3) changes in the structure and composition of the ECM that alters mechanical signaling to cells. To date, cell surface receptors for SPARC include stabilin-1 on macrophages and vascular cell adhesion molecule-1 on endothelial cells [74,75]. SPARC also affects integrin engagement on a number of different cell types. Furthermore, SPARC interaction with integrin heterodimers appears to be cell-type dependent [70].

Another significant effect of SPARC on cells in culture is its capacity to elicit changes in cell shape. Many cell types plated on various substrata retract their filopodia and lamellipodia and assume a rounded phenotype after exposure to SPARC. Bovine aortic endothelial cells, for example, are prevented from spreading in the presence of SPARC [70]. Clearly cell rounding could contribute to the inhibition of cell cycle mentioned previously; however, these two effects of SPARC appear to be independent. Motamed and Sage have shown that inhibition of tyrosine kinases reverses the counter-adhesive function of SPARC but has no effect on cell cycle inhibition [76]. Thus at least in endothelial cells, SPARC appears to mediate two aspects of cell behavior through different mechanisms. In support of SPARC as a regulator of cell proliferation, primary mesenchymal cells isolated from SPARC-null mice proliferate faster than their wild-type counterparts [77].

In addition to its effect on cell cycle, evidence shows that SPARC influences TGF-β-dependent pathways in some cell types. Mesangial cells isolated from SPARC-null mice show a decrease in collagen I expression accompanied by a decrease in the levels of the cytokine TGF-β1, in comparison to wild-type cells [78]. TGF-β is a known positive regulator of ECM synthesis. Addition of recombinant SPARC to SPARC-null mesangial cultures restores the levels of collagen I and TGF-β nearly to those of wild-type cells [78]. SPARC also promotes the TGF-β signal transduction pathway in epithelial cells [79]. In pericytes the absence of SPARC increased TGF-β-mediated inhibition of migration, an effect dependent upon the TGF-β receptor endoglin and integrin α_v [80]. Thus it appears that SPARC can act as a regulator of TGF-β activity and, perhaps by extension, represents one mechanism by which SPARC can influence collagen I production.

The targeted inactivation of the SPARC gene in mice has provided insight into SPARC activity in tissues. The majority of SPARC-null phenotypic abnormalities, however, are seen as aberrant ECM assembly. Early onset cataractogenesis reported in two independently generated SPARC-null mice appears to be caused by inappropriate basement membrane production by lens epithelial cells [81]. In the absence of SPARC, collagen IV, a SPARC ligand, is not localized to the outer border of the lens capsule, in contrast to its distribution in wild-type capsules [82].

Levels of fibrillar collagen are reduced in SPARC-null connective tissue, including skin, heart, fat, tendon, and periodontal ligament. In addition, collagen fibrils, as viewed by electron microscopy, are smaller and more uniform in diameter in comparison to those of wild-type tissues. Interestingly, many characteristics of the collagen phenotype in SPARC-null periodontal ligament are reversed through inhibition of transglutaminase [83]. Hence, SPARC is implicated in the formation of collagen cross-links mediated by transglutaminase. Supportive of a critical role of SPARC in collagen deposition, fibrosis in SPARC-null mice is decreased in tissues such as, heart, lung, kidney, liver, and skin [81]. Hence an established body of evidence demonstrates a function of SPARC in assembly and stability of fibrillar collagens and basement membranes. In tissue engineering applications, modulation of SPARC expression is predicted to contribute to ECM remodeling. For example, the inhibition of SPARC expression in pancreatic stellate cells grown as 3D engineered tissue results in robust remodeling of the deposited ECM [84].

Two studies have examined SPARC interaction with collagen I to define the SPARC-binding site(s) on fibrillar collagen heterotrimers [85,86]. Interestingly, SPARC

shares the identical fibrillar collagen−binding site with that of discoidin domain receptor (DDR) 2 and von Willebrand factor. Downstream signaling pathways activated by DDR2 engagement of collagen include increased cell proliferation and enhanced cell migration. Thus engagement of collagen I by SPARC is predicted to prevent collagen engagement by DDR2 (and by von Willebrand factor) and perhaps diminish DDR2-dependent cell activities, such as cell proliferation, in certain cells and tissues.

Once again, we see SPARC as an example of a multifunctional protein able to regulate cell shape and modulate growth factor activity. In addition, SPARC appears to be a key factor in ECM assembly in both basal lamina and connective tissues. Consistent with these functions, a homolog of SPARC termed SPARC-like protein 1 (hevin) is shown to be counter-adhesive and modulatory of ECM structure [68].

Conclusion

In addition to the proteins described here, others are also potential candidates for inclusion in the family of matricellular proteins. These include small proteoglycans, such as the matrix-associated protein and decorin, which has been shown to be an endogenous regulator of TGF-β activity, as well as certain members of the CCN gene family [87]. The CCN proteins are secreted, modular, and exhibit functions based, at least in part, on integrin-mediated mechanisms. While CCN1 (CYR61) enhances apoptosis in fibroblasts, endothelial cell adhesion to CCN1 promotes cell survival [87]. Periostin and other SPARC family members are also recognized as matricellular proteins [68,88]. Further analysis of these proteins and their actions will expand our comprehension of matricellular proteins and the functions they serve in regulating cell interaction with components of their immediate environment.

In any cellular environment, numerous extracellular signals are in place to control cell behavior. In adult tissues, injury and disease both lead to a wide-scale release of multiple factors, either secreted from cells or sequestered in the ECM, that are capable of eliciting potent cellular responses. Appropriately, an increase in the expression of many matricellular proteins is associated with pathological events. Hence, the matricellular proteins appear to be ideally suited to act as modulators of these extracellular signals. They are able to serve as bridges between the ECM and cell surface receptors, such that cell shape changes or cell movements can be initiated prior to matrix breakdown or synthesis. At least three matricellular proteins, thrombospondin-2, osteopontin, and SPARC, appear to participate in ECM deposition, either through the promotion of collagen fibrillogenesis or the enhancement of collagen production. Matricellular proteins can either inhibit or potentiate specific growth factor signal transduction pathways. Thus different growth factor effects may be amplified or subdued by the presence or absence of these proteins. The fact that multiple receptors exist for most of the matricellular proteins allows for diverse functional consequences for different cell types in a complex tissue in response to a matricellular ligand. A given repertoire of cell surface receptors can stimulate (or inhibit) a particular pathway in a cell-type-dependent manner. Apparently, evolution has fine-tuned these proteins to serve as specialized mediators of extracellular signals that provide a coordinated, efficient resolution of tissue injury.

Introduction

Branching morphogenesis is the developmental process by which many organs, including the salivary gland, lung, kidney, and mammary gland, generate tree-like architectures. This extensive branching process enables these developing organs to increase their epithelial surface area greatly to achieve sufficient tissue complexity for mediating secretion, exchange of gases, and excretion essential for life. Generating more branches requires constant remodeling of the extracellular matrix (ECM) [1]. Two cell populations essential for initiating the process of branching and ECM remodeling are epithelial cells and mesenchymal cells. The epithelium generates branches by expanding and repetitively subdividing the epithelium while maintaining stem and progenitor cells [2], and the mesenchyme generally provides the signaling required for the organ to complete the steps of organogenesis. There are, however, also important bidirectional epithelial−mesenchymal inductive signaling interactions during early development in order to initiate and coordinate branching [3−5].

The ECM secreted by mesenchymal and epithelial cells can influence the microenvironment from the earliest stages of bud initiation to the generation of extensive branching using mechanical as well as chemical signaling [6]. The ECM is not only necessary for maintaining structural support for developing organs, but it is also important for cell communication. ECMs can exist in many forms, but two major forms, basement membrane (BM) and interstitial matrix, are critically important during branching morphogenesis. Epithelial cells use the thin, dense, and sheet-like BM as their substrate, the functions of which include providing structural support and elasticity to the epithelium, as well as transmitting mechanical forces and chemical signaling to the tissue [7]. On the other hand, the interstitial matrix maintains and helps regulate spaces between cells, modulating chemical and mechanical communication between cells and within tissues [7].

This chapter will focus on the different ways in which the ECM plays roles in branching morphogenesis of the lung, salivary gland, and kidney as our primary examples for this process. It will also explore how cellular dynamics, the microenvironment, and signaling influence how this process varies between different branching organs. A key emerging principle relevant to tissue engineering is that even though there are similarities between the mechanisms of branching morphogenesis in different organs, there are also many striking differences in the specific details of the cellular mechanisms of tissue morphogenetic remodeling used by each organ, particularly in the specific signaling molecules involved in each type of branching morphogenesis. Consequently, approaches used for regenerative medicine, which are based on insights from developmental biology, may require organ-specific strategies.

The basis of branching morphogenesis

For proper branching morphogenesis, cells need to go through coordinated proliferation, migration, differentiation, and cell death [2]. Epithelial cells of branching organs rearrange to form lobular or tubular structures [8]. These structures can change during different stages of development or in response to physiological changes in some tissues, such as the tubular-to-lobular changes

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00014-9

observed in the mammary gland during lactation. However, not only do the morphologies of the structures vary between tissues, but the branching patterning itself can also vary between tissues. The branching patterns of lung and trachea are considered to be stereotyped or hardwired [9], because they follow the same predetermined sequence of branch generations (bottlebrush, planar array, and rosette) that are coupled with specific functions (scaffold, edge, and surface/interior) [10]. In addition, the patterns of signaling required to establish the timing, spacing between branches, and the positions of branches with respect to the mother branch are conserved between species.

This is not the case with tissues like the salivary gland or mammary gland. These two glands do not require a specific stereotyped order of steps to trigger branch formation as observed in the lung. In further contrast the kidney exhibits a hybrid phenotype, where it initially appears to be hardwired, but the later branching pattern varies between individual kidneys [11]. During the process of branching morphogenesis, organs create new branches by two events termed budding and clefting [8]. Budding refers to formation of a branch or stalk from the primordial epithelium or from the lateral side of a preexisting branch, while clefting refers to occurs to the splitting of a branch tip by a cleft to generate more tips.

Branching morphogenesis in the lung

As the clearest example of stereotyped or hardwired morphogenesis, the lung utilizes three modes of branching in a repetitive, predetermined series of patterns (domain branching, planar bifurcation, and orthogonal bifurcation) [10]. The repetitive pattern is believed by some to be conserved among different animal species. Others have challenged this concept, suggesting that branching can differ between organisms of the same genetic background, with branches after the first branch being the result of the epithelium reacting to growth of the mesenchyme with the aim of trying to fill spaces [12,13]. However, since both viewpoints consider the initial branches to be stereotyped and conserved among species, the principles of early lung branching can be understood from examining the morphogenesis of the *Drosophila* trachea, which demonstrates the sophisticated types of regulation of signaling needed for branching morphogenesis.

Budding of the *Drosophila* trachea starts when tracheal cells invaginate to form tracheal sacs. Cells around the tracheal sacs release a chemoattractant ligand called fibroblast growth factor (Fgf)/branchless (Bnl) [14]. As portrayed in Fig. 13.1, cells closer to the source of this ligand have higher expression of its receptor [fibroblast growth factor (FGF) receptor (FGFR)], and cells farther away have lower expression due to the decreased

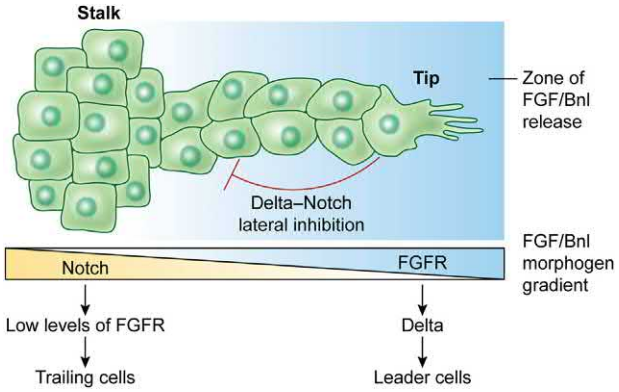

FIGURE 13.1 Budding in the *Drosophila* trachea. During bud initiation, epithelial cells sense the chemoattractant signal from a gradient of FGF ligand released by the mesenchyme. Epithelial cells closer to the site of release extend protrusions that help them monitor and interact physically with the microenvironment. These cells at higher FGF concentrations (closer to the region of FGF release) have higher expression of the FGFR and become leader cells. Higher levels of FGF near the leader cell also activate Delta in these cells, whereas lower levels of FGF activate Notch in the trailing cells. Enhanced expression of Notch leads to the downregulation of FGF signaling to establish trailing cell fate. Once both cell fates are established, there is collective migration of the trailing cells following the leader cells. *FGF*, Fibroblast growth factor; *FGFR*, fibroblast growth factor receptor.

morphogen gradient. Differential expression of Fgfr/breathless (btl) (the mammalian homolog is FGF10) determines cell fate by making the high-expressing cells the leader cells and the low-expressing cells the trailing cells [14–16]. The pattern of FGF10 expression is believed to be controlled by mesenchymal cell expression of patched1 (Ptch1, sonic hedgehog receptor), either directly through hedgehog signaling (Gli3 expression) or indirectly by Forkhead box F1 inhibition [17]. Higher expression of FGF in the tip leads to activation of Delta in the tip and Notch in the stalk. Through a process called Delta–Notch lateral inhibition, Notch activation in the stalk reduces the levels of FGFR, preventing trailing cells from turning into leader cells [8,15,16,18]. Leader cells have long dynamic filopodia at their leading edge that actively pull on the ECM [19], while the trailing cells respond to the pulling by migrating collectively for tissue elongation.

Actomyosin contractility mediates the change in epithelium shape to generate the initial bend for budding, as well as the rearrangement and deformation of the ECM during trailing cell collective migration [20]. Dickkopf (DKK) family members are expressed in the bud tips during development and are known to regulate Wnt/β-catenin signaling in this zone, preventing epithelial differentiation to form a lumen in this region [21]. In addition, DKKs become highly expressed in the zone undergoing clefting in mammals, contributing to the deposition of fibronectin for promoting branching [22].

Actin localization is also site specific. Actin accumulates at the basal membrane and small apical junctions of the leader cells, while the trailing cells only have higher actin on their apical surfaces [18]. In addition, the apical membrane of the leader cells is oriented perpendicular to the direction of branching elongation, while in trailing cells, it is parallel to the elongation [18]. The actin accumulation at the basal membrane suggests that there is a constriction of the dorsal epithelium or epithelial sheets during budding [20,23].

Turning to studies of mammalian lung, after bud initiation, epithelial cells undergo proliferation to increase the size of the tip [24]. The tip becomes flattened before clefting occurs. It has been suggested that in mammalian lung, bone morphogenetic protein (BMP)-Smad1/5/9 signaling helps regulate epithelial proliferation and apoptosis during clefting [25]. BMP4 is expressed in the tip to inhibit supernumerary formation of newer branch tips [26].

As described in Fig. 13.2, accumulation of fibronectin is found in the indentation sites of mammalian lung [27], suggesting that it may help determine the sites of clefting. In addition, the location of branching corresponds to locations of BM thinning [28]. Initiation of clefting in *Drosophila* is known to occur when a tip splits due to the divided localizations of FGF [29], allowing the mesenchyme to physically shape the cleft site. Whether this process occurs in mammalian lung development needs to be clarified. In fact, in mammalian lung development, mesenchymal cells positive for α-smooth muscle actin (α-SMA) expression have been shown to appear in the middle of the flattened epithelium, constricting the epithelium and constraining its expansion to the edges, thereby creating the first bifurcation. Disruption of FGF signaling results in smooth muscle covering the entire epithelium without increasing cell differentiation. In this case, even though the initial cleft can be formed, it cannot proceed to complete bifurcation [30]. These findings suggest that FGF signaling may not only help in shaping the epithelium by its localization but also by regulating smooth muscle growth and differentiation. FGF9 activity mediated through the FGFR1/2 receptor helps to maintain a population of undifferentiated smooth muscle cells and prevent α-SMA localization in the distal mesenchyme [31]. FGF10 allows for the differentiation of distal lung mesenchymal cells into smooth muscle by stimulating BMP4 upregulation in the epithelium [32].

Neuronal innervation in the lung is important for its mechanotransduction, maintaining pressure in the lung by generating muscle contraction and relaxation, which are important for lung growth. Although the first bifurcation will appear at embryonic day (E) 10.5, neurons are still undifferentiated at this point. It is not until E11 that nerves are detected in the smooth muscles. By E13, some of the neuronal projections extend to the mesenchyme, suggesting that there could be some neuronal signaling to the mesenchyme that might help regulate its growth/migration [33].

Once the first cleft occurs in the mammalian lung, the generally accepted stereotyped branching mechanism takes place, starting with domain branching controlled by a proximal-distal and circumferential system, which determines the next position of the branch. Domain branching occurs by budding, allowing the organ to generate new branches on the lateral side of preexisting branches in a

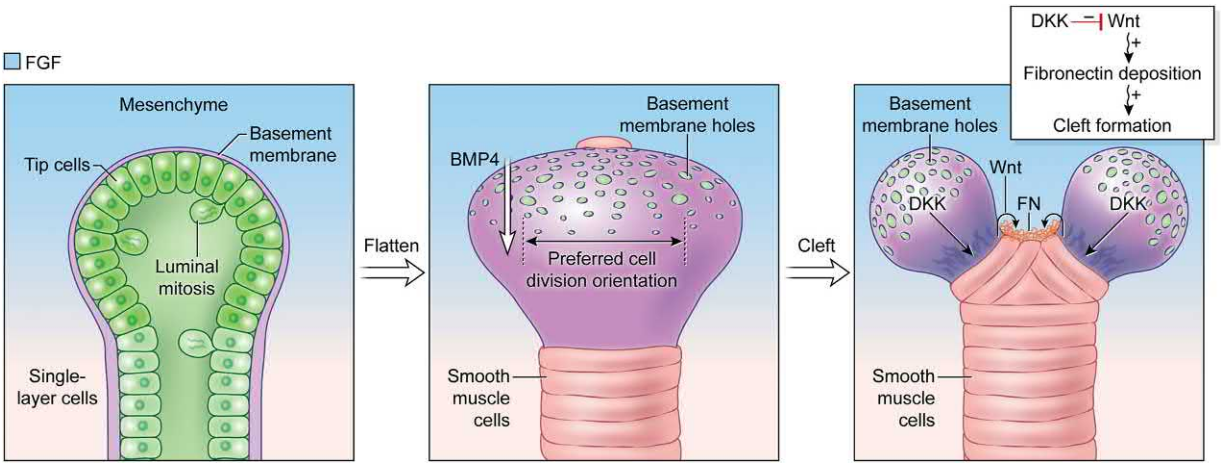

FIGURE 13.2 Cleft formation in the mammalian lung. The lung bud arises from a single layer of epithelial cells that proliferate and flatten prior to clefting. During bud outgrowth the axis becomes flattened and cells divide in parallel around it. BMP4 is expressed in the bud tip, helping to control bud outgrowth. The basement membrane becomes thinner and perforated by microscopic holes, enhancing flexibility for epithelial tip outgrowth and providing epithelial–mesenchymal contact sites. DKK is expressed in the bud tips, which downregulates Wnt signaling and promotes deposit of FN. Smooth muscle then differentiates and extends across the middle of the flattened epithelium, helping to deform the tissue to mediate the bifurcation. *BMP*, Bone morphogenetic protein; *FN*, fibronectin.

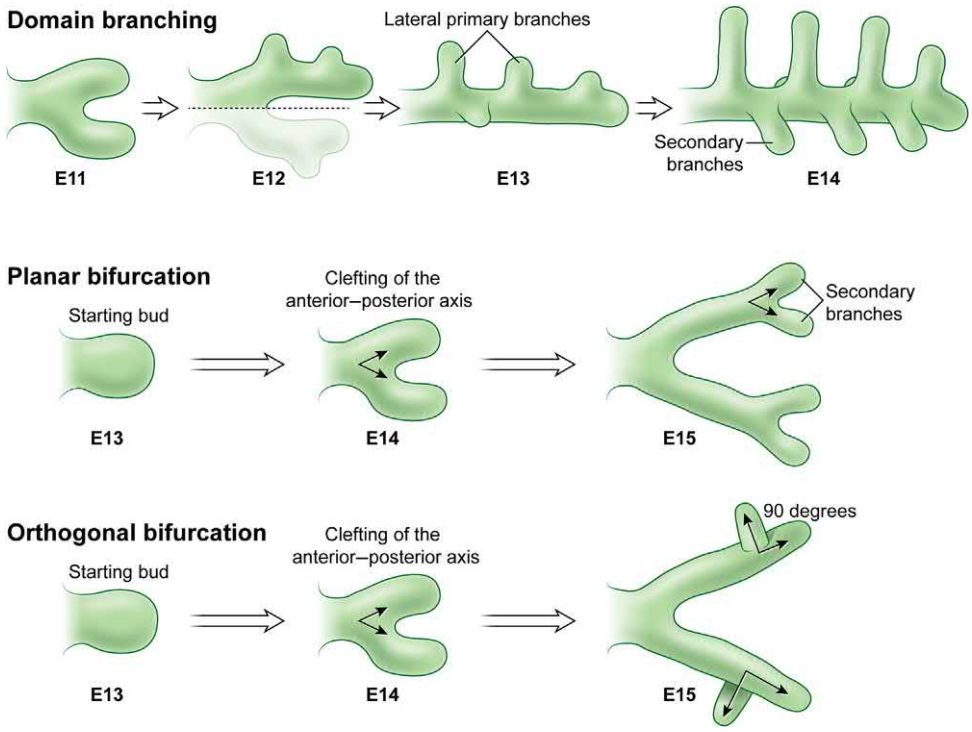

FIGURE 13.3 Branching types in the lung. The lung utilizes three different types of branching to increase its epithelial surface area and achieve complexity. The first type is called domain branching that is observed at approximately E (embryonic day) 12. A branch appears at the lateral surface of the first bifurcation, and its secondary branches appear between the initial parental branches in a proximal-to-distal pattern, thereby generating a structure that resembles a bottle brush. As the lung grows, planar and orthogonal bifurcations are visible at E13. Planar bifurcation generates new branches in a planar array through a series of tip expansions and splits along an anterior−posterior axis. In orthogonal bifurcation the initial branch is similar to that observed in planar bifurcation, except that the tip of a secondary branch is generated at a 90-degree angle (perpendicular) to the parental branch tip, resulting in new branches that face in opposite directions.

bottlebrush configuration. As depicted in Fig. 13.3, domain branching is observable at approximately E12 and continues in later embryonic stages. But as the lung develops further, other types of branching modes appear. One is planar bifurcation, in which there is an expansion of the tip followed by a split (clefting), creating a bifurcation along the anterior−posterior axis and then an additional bifurcation that generates planar arrays. The other mode of branching is orthogonal bifurcation, in which clefting is followed by a 90-degree rotation between rounds of branching to generate rosettes [10], where new branches point in opposite directions (Fig. 13.3). The surface area of the developing lung tissue therefore increases through the continued formation of new branches following a specific, stereotyped sequence of budding and clefting.

Branching morphogenesis in the salivary gland

In contrast to branching in the lung and kidney, salivary gland branching morphogenesis involves mesenchymal cells from the cranial neural crest, which aggregate around the epithelium [34]. Nevertheless, similar to branching in the lung, branch initiation in the submandibular salivary gland (SMG) starts with invagination of the epithelium toward the mesenchyme as a single bud (Fig. 13.4). FGF7/FGFR2b signaling induces widespread epithelial proliferation and budding in the SMG [35,36]. Budding is associated with the formation of a shallow cleft that will progress deep into the initial globular bud to divide it into new buds. The originally narrow clefts widen substantially as they reach the interior of the bud, thereby delineating the secondary duct, which elongates to generate the stalk. These steps of cleft formation, duct elongation, and subsequent lumen formation are essential to generate the final complex epithelial tree-like structure [27,36].

The SMG parasympathetic ganglion (PSG) develops in parallel with growth of the epithelium. The PSG is derived from neural crest cells, which migrate along chorda tympani nerves and differentiate into βIII-tubulin-expressing (TUBB3 +) neurons [37]. PSG innervation produces the neurotransmitter acetylcholine. Acetylcholine release by the ganglion increases transcription of the epidermal

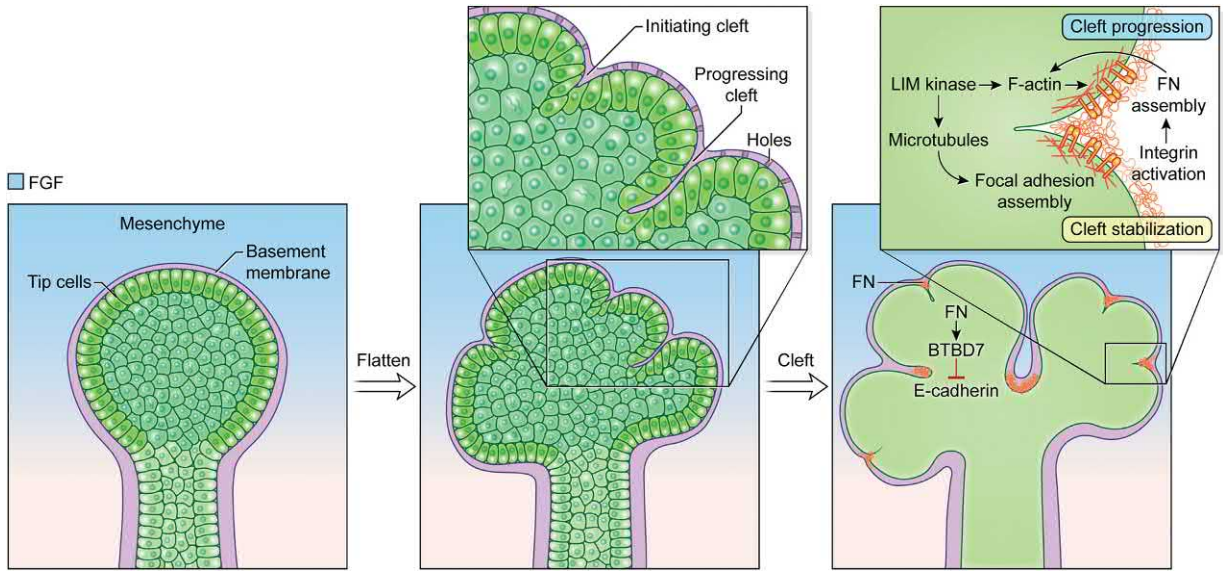

FIGURE 13.4 Cleft formation in the salivary gland. In contrast to the lung and kidney, the salivary gland bud is a multilayered epithelium. The outer tip and inner tip cells have different shapes and speeds of migration/motility, associated with differential BTBD7 expression. To generate a cleft the ECM penetrates the outer epithelial cell layer, with cell separation and insertion of the basement membrane into the bud interior. The basement membrane is thinner at the tip of the bud with microperforations, and it is thicker at the cleft, toward the base of the bud, and along the duct. Fibronectin is assembled by a LIMK-dependent pathway and inhibits E-cadherin through BTBD7 signaling, mediating the conversion of cell−cell adhesion to cell−matrix adhesion in the progressing cleft. Stabilization of the cleft is mediated by LIMK, which stimulates focal adhesion through stabilization of actin filaments and microtubule dynamics. *LIMK*, LIM kinase.

growth factor (EGF) receptor (EGFR), which results in increased cell proliferation [38]. Although the difference between salivary gland stem and progenitor cells is not yet clear [34], maintaining an undifferentiated population of epithelial cells is essential for formation of the correct branching pattern. This population of progenitor cells characteristically expresses keratin 5, a cytoskeletal protein. These K5-positive (K5 +) progenitor cells are located in both the SMG end bud and duct during development. K5 + progenitor cells are known to express Wnt. Wnt signaling from K5 + progenitor cells within the duct drives ductal differentiation and promotes gangliogenesis [37] by promoting neuronal proliferation and survival, as well as PSG formation and innervation [34]. K5 + progenitor cells are also present in the end buds, where Wnt signaling is suppressed by FGFR (Fig. 13.5). This Wnt signaling is negatively regulated within the epithelium by FGFR2b/mitogen-activated protein kinase (MAPK) signaling and is stimulated by neuregulin Erb-B2 receptor tyrosine kinase 2 (ErbB2/3)/phosphoinositide 3-kinase (PI3K)-dependent signaling [34]. The negative regulation via FGFR maintains the K5 + progenitor cells in the end bud and inhibits ductal fate and lumen formation [39]. Carbachol, an acetylcholine analog, can work together with heparin-binding EGF-like growth factor signaling to increase the proliferation of cells that are not K5 + positive, stimulating lumen formation [38].

The SMG epithelium maintains the PSG through production of the neurotrophic factor neurturin (NRTN). NRTN maintains functional innervation by promoting axonal outgrowth and expression of genes that are important for parasympathetic function. This PSG axonal outgrowth in turn influences morphogenesis by conserving cell−cell adhesion through stabilizing E-cadherin signaling in the end bud and maintaining proper neurotransmitter release [40]. If the PSG pattern is disrupted, it can affect branching morphogenesis by reducing the number of branches that are formed [38].

To complete the process of clefting, different cellular processes occur, including proliferation, cell−matrix adhesion, cell−cell adhesion, and migration [34]. During clefting of the salivary gland and other branched organs, fibronectin is expressed in the BM near the mesenchymal cells and epithelial cells that undergo clefting (Fig. 13.4). This expression of fibronectin can decrease the expression of E-cadherin, a cell−cell adhesion protein—a process believed to occur through the induction of the novel regulator BTBD7 [6,34,41]. BTBD7 has been shown to be expressed near the cleft and to be necessary for regulating the outer layer of highly motile semi-columnar epithelial cells during clefting [41] and has been reported to be essential for effective branching morphogenesis of salivary gland, lung, and kidney. BTBD7 induces the expression of Snail2, which contributes to loss of E-cadherin, though it may also mediate ubiquitination involved in E-cadherin degradation [6]. This mechanism affects the cleft epithelial cells that convert cell−cell adhesions to cell−matrix (especially BM) adhesion during clefting

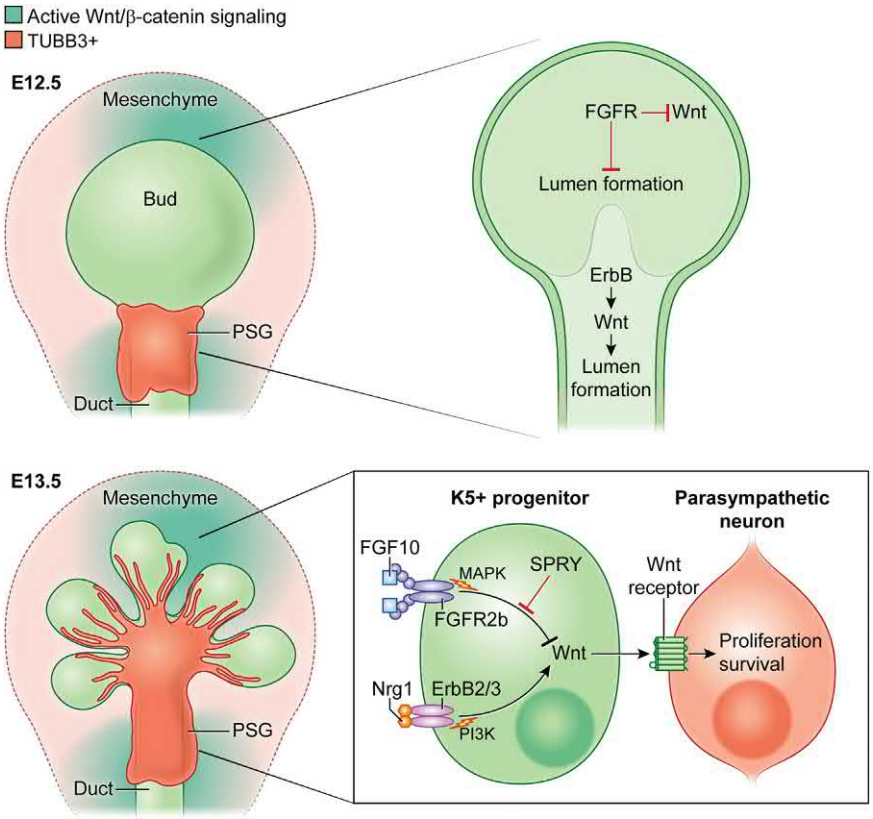

FIGURE 13.5 PSG development in the salivary gland. The PSG grows in parallel with growth of the epithelium. Wnt signaling is one of the mechanisms important for maintaining PSG nerve innervation. Wnt signaling mainly occurs in the mesenchyme near the bud tip and particularly in the ductal area. FGFR signaling inhibits Wnt signaling through downstream signaling that activates MAPK in the bud tip to prevent epithelial differentiation. In the duct, however, this signaling is inhibited by Sprouty (SPRY). Nevertheless, ErbB eventually upregulates Wnt expression in the duct, allowing cells to differentiate to form the lumen by downstream activation of PI3K. This same activation helps promote neuronal proliferation and association with the ductal epithelium. *FGFR*, Fibroblast growth factor receptor; *MAPK*, mitogen-activated protein kinase; *PSG*, parasympathetic ganglion.

[27,41]. In addition to this conversion, cytoskeletal contraction is a vital process for the progression of clefts. Rho-associated coiled-coil containing kinase (ROCK) regulates cytoskeletal contraction, while LIM kinase helps to regulate both actin filaments and microtubules to mediate cleft stabilization. Together these allow progression and proliferation of the cleft to continue [42–44]. Although proliferation plus cytoskeletal and ECM remodeling [34] are known to occur during clefting, in the salivary gland the first branch can still proceed without cell proliferation [8,45,46].

Expanding knowledge of the mechanisms of branching morphogenesis is now being applied to tissue engineering of salivary glands to maintain or restore function. For example, cell surface expression of c-Kit and other stem cell markers was used to isolate stem and progenitor cells from explanted salivary gland cells that had been expanded in vitro into small organoids termed salispheres. These isolated stem cells could be transplanted into the salivary glands of mice that had been X-ray irradiated to mimic the damage from clinical therapy for head and neck cancer. The transplanted stem cells could at least partially restore both salivary gland morphology and secretory function [47,48]. Furthermore, identification of growth factors that can stimulate salivary gland branching in explant cultures has provided a list of candidates that could promote gland stem cell protection or restoration after X-ray irradiation. Successful examples of the latter approach include treatment with keratinocyte growth factor, granulocyte-colony stimulating factor (G-CSF), or neurturin [49–51].

An alternative approach to cell-based tissue engineering for salivary gland regenerative medicine is to take advantage of the previously demonstrated capacity of embryonic salivary gland cells to self-aggregate and initiate budding morphogenesis [52]. Functional regeneration of mouse salivary gland function has been reported using dissociated and self-organized embryonic cells and even embryonic stem cells [53,54]. Notably, identification of two key transcription factors for normal salivary gland development, Sox9 and Foxc1, permitted a novel approach—infection of embryonic stem cells in vitro with adenoviruses expressing Sox9 and Foxc1 to force expression of these factors. When the authors incubated these treated cells with a cocktail of growth factors, they reported successful restoration of salivary gland secretory function in mice [54].

Branching morphogenesis in the kidney

The epithelial bud that initiates kidney branching arises during E10.5–11 in mice [55]. Before this ureteric bud

formation the edge of the epithelial tube needs to become pseudostratified to allow for rapid outgrowth in this region [56]. Interactions between the epithelium and the mesenchyme allow the cells to undergo clefting that occurs at E11.5. The complex tree structure arises by interactions at both gene and protein levels controlled primarily by the Ret/Gdnf, Wnt, and FGF signaling pathways. To initiate the process of branching the mesenchyme divides into two populations: one becomes the cap mesenchyme, while the other forms the stromal cells [57]. Pax2 protein is then highly expressed in the cap mesenchyme and in the epithelial bud. Pax2 positively regulates glial cell–derived neurotrophic factor (GDNF) that is then expressed in the cap mesenchyme, and its receptor GPI-linked protein (GFRα1) is expressed in both the mesenchyme and ureteric bud tip. GDNF expression activates the catalytic domain of the receptor tyrosine kinase RET in epithelial cells, helping guide the invasion and outgrowth of these cells into the mesenchyme (Fig. 13.6).

Budding in the kidney arises from a tubular outgrowth of the Wolffian duct [58]. To establish the bud tip, cells compete with each other, and the cell expressing the highest level of Ret becomes the tip [59,60]. Ret expression helps to maintain high levels of Sprouty1 in the Wolffian duct to prevent an excess of cells from becoming leader cells. Sprouty1 mediates this action by antagonizing GDNF/RET signaling in the duct [61]. BMP4 and transforming growth factor beta (TGF-β) have been shown to inhibit bud formation [62,63]. In the kidney, Gremlin 1 (GREM1) reduces the expression of BMP4 to allow budding to proceed.

The ligand–receptor pair GDNF/RET contributes to epithelial bud proliferation, cell survival, and branching of the epithelium. Although the mechanism is not yet entirely clear, some of the genes that are regulated by GDNF activation include two members of the Pea3 family of ETS transcription factors, Etv4 (Pea3) and Etv5 (Erm) [58]. Etv4 and Etv5 are expressed in the bud tips and have been shown to target Myb—in other organs, these transcription factors are known to promote the proliferation of progenitor cells and inhibit differentiation. Consequently, Myb signaling could be a mechanism used to maintain a population progenitor cells during clefting events. Similar to lung branching, in order for clefting to occur in the kidney, proliferation needs to occur at the tip, followed by deformation and tip-splitting events [8]. This deformation occurs as the bud tip, composed of a single layer of mitotic cells, undergoes a sequence of enlargement, flattening, and extension in opposite directions before splitting [64]. During cell proliferation, the premitotic cells separate from the single-layer ureteric tip and complete their cell division in the lumen before integrating back into the site of origin—a process termed mitosis-

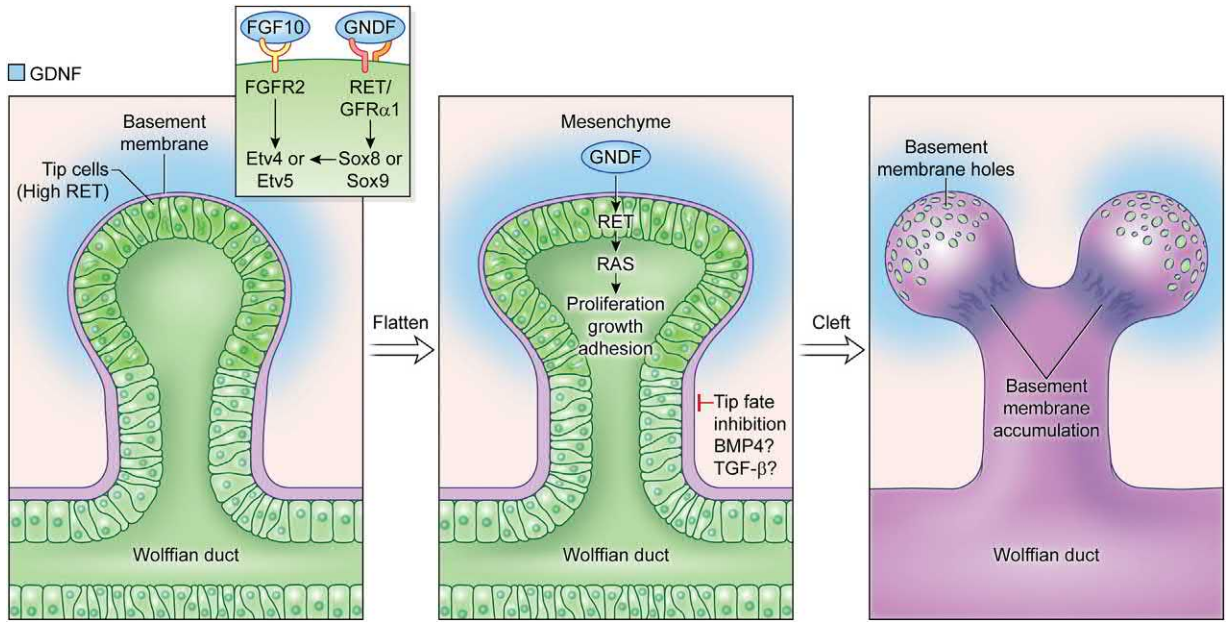

FIGURE 13.6 Cleft formation in the kidney. In the kidney the outer epithelial cells of the tip have higher expression of the Ret receptor than their proximal counterparts. GDNF is expressed in the cap mesenchyme and acts in parallel to FGF10 signaling to activate Etv4, which helps guide the migration of nephric duct cells with high Ret expression from the Wolffian duct to the site of the outgrowth to generate the tip of the first bud. For clefting to occur the pseudostratified tip flattens and proliferation increases due to the activation of Ras. It is believed that BMP4 and TGF-β are involved in preventing the trailing cells from becoming tips, and that they instead promote duct formation. *BMP*, Bone morphogenetic protein; *FGF*, fibroblast growth factor; *GDNF*, glial cell–derived neurotrophic factor.

associated cell dispersal [65]. Furthermore, a cell tracking study showed that during clefting of Ret-MADM6 clones, cells that have high levels of Ret and Etv4 remain closer to the tip compared to cells with lower expression, suggesting that this signaling guides cell movement at the tip [60].

Degradation of ECM components by matrix metalloproteinases is necessary for ECM remodeling to permit proper branching. Etv4 can transactivate the protease matrix metalloproteinase-14 (Mmp14). Mmp14$^{-/-}$ mice have kidney branching defects, and Etv4$^{-/-}$ and Etv5$^{-/-}$ mutants show a reduction in MMP14, suggesting that one of the roles of these transcription factors is to regulate ECM remodeling by maintaining appropriate levels of MMP14 [58]. In addition, the Met tyrosine kinase receptor is present in both the bud tip and mesenchyme, and it becomes downregulated upon Etv4 inhibition. Hepatocyte growth factor (HGF), which is expressed in the mesenchyme, is known to bind to Met and to activate downstream signaling important for cytoskeletal dynamics, focal adhesion, and cell−cell junction reshaping [66]. Both the EGFR and HGF have been implicated in kidney tubulogenesis. However, knockout of Met and HGF genes in mice does not reveal a significant reduction in branching. Nevertheless, Met$^{fl/fl}$ mutants have increased expression of EGFR, which suggests that HGF and EGFR may cooperate, and that the upregulation of EGFR could occur to maintain tissue homeostasis [66]. Other studies have shown that GDNF-induced Etv4 will activate Met in motor neurons and HGF in the mesenchyme can further induce Etv4. HGF is known to promote axonal growth and survival of motor neurons, which could occur by recruiting more motor neurons to the Etv4^{+} population [67]. Other signaling, such as Wnt-1 is also known to induce Etv4. In kidney, nerve innervation is linked with vascularization, suggesting that both are controlled by the same mechanism [68]. Consequently, Etv4 might be a mechanism by which nerve innervation occurs in the kidney.

Stalk elongation in the kidney occurs by convergent extension that is dependent on Wnt and planar cell polarity (PCP) signaling [69]. PCP promotes stalk elongation by orienting cell division [70].

Although the kidney does not follow a strict stereotyped branching pattern as in the lung, and the angles of the branches are not conserved, the extent of elaboration of "clades" or "lobes" is conserved and comparable between kidneys from organisms with the same genetic background. Branch growth between kidneys in embryos is similar at early stages with a shape that is relatively lobular with a bulging tip connected to short branches, but after E15.5, the similarities are no longer conserved. At E18.5, the branches become elongated and acquire a tubular shape [8]. Taken together, this information indicates that in later branching events, the kidney does not follow the stereotyped pattern of branch formation during development as described in the lung, since its pattern is not reproducible across developmental time. That is, by not following a strict stereotyped branching program, individual kidney branch points and branch shapes are not comparable between organs from different embryos at the same developmental stage [57]. Since even different mouse embryos display kidney shape differences, it is no surprise that there are differences between mouse and human kidneys at both structural and developmental levels.

Contributions of other cell types

As indicated in previous sections, epithelial and mesenchymal cells are not the only important contributors to branching morphogenesis. Neuronal innervation, smooth muscle, and blood vessels are examples of other cell populations that also play critical roles in achieving successful branching morphogenesis.

The interaction of the salivary gland PSG and epithelium is an excellent example of how two cell populations interact to promote development of each other. In salivary gland development the PSG maintains K5 + progenitor cells by acetylcholine and EGF signaling [38]. In contrast to the lung, the neuronal population in salivary gland can be observed even during formation of the initial bud. The PSG helps to develop the ductal epithelium by promoting lumen formation and ductal elongation via vasoactive intestinal peptide (VIP) signaling. Inhibition of the VIP receptor in salivary gland leads to an increase in ductal width correlated with an increase in tight junctions along the midline rather than toward the bud tip as the bud undergoes branching. In addition, glands in which VIP is inhibited exhibit impaired localization of nerve innervation. Increasing VIP expression results in increased concentration of tight junctions along the midline of buds undergoing clefting and an increase in nerve innervation around the duct relative to controls [71]. In the lung, innervation does not appear until branching has started [33,37], suggesting that it is important for the formation of subsequent branches but not for the first bifurcation.

Blood vessels have been shown to be important for mediating the stereotyped program of branching characterizing embryonic lungs. Inhibition of vascular signaling by a vascular endothelial growth factor (VEGF) decoy receptor decreases the angle of rotation of dorsal-ventral branching during domain branching from 90 to 40 degrees and reduces the number and length of such branches. However, there is a concomitant increase of ectopic branches, which affects the overall architecture of the lung and generates a flattened organ. Restoration of VEGF signaling after blood vessel inhibition results in a

similar phenotype rather than rescuing normal branching, suggesting that the physical presence of blood vessels is crucial and that it is not altered VEGF signaling that causes disruption of the stereotypic branching pattern in the lung [72].

In the pancreas, another branched organ, blood vessels do not contribute to branching as they do in the lung. The removal of endothelial cells or inhibition of VEGFR2 instead increases organ size and contributes to cell differentiation. Conversely, increasing VEGF signaling leads to a reduction of branching and overall pancreas growth. In addition, it leads to undifferentiated trunk epithelium, suggesting that the function of vascular endothelium in the pancreas is to maintain a population of undifferentiated epithelial cells during branching [73,74].

The nonstereotypic, relatively stochastic mode of branching of salivary glands is also modulated by endothelial signaling without blood perfusion [75]. Branching in this developing organ is inhibited by inhibition of VEGF signaling that reduces the number of progenitor cells and increases duct differentiation markers. Addition of exogenous growth factors (IGFBP2 and IGFBP3) can partially rescue branching, suggesting that endothelial cells may stimulate neighboring mesenchyme cells to produce these growth factors to modulate the differentiated phenotype and branching of the salivary epithelium.

MicroRNAs in branching morphogenesis

MicroRNAs are small (~22 nucleotides long) noncoding RNA transcripts that regulate numerous targets through binding to the 3'untranslated regions (UTRs) of target mRNAs and affecting protein production by interfering with mRNA translation. MicroRNAs can function locally by binding to a target mRNA within a specific group of cells or globally via extracellular vesicle delivery to affect multiple tissues throughout the body. MicroRNAs are important for maintaining homeostasis within tissues, but they have also emerged as important players during embryonic development. Dicer, an endoribonuclease that is required for correct microRNA processing, can be detected in the distal mesenchyme and epithelium, zones of high proliferation, and branching in development [76] and has been shown to be critical for branching morphogenesis, proper epithelial development, and angiogenesis. Dicer-null mutants show epithelium detachment from the mesenchyme, dilated branching tips, and fewer branches compared with controls. In addition, inactivation of Dicer causes an increase in FGF10 expression in the mesenchyme, which in turn affects other genes that are essential for lung branching [77]. During branching morphogenesis the location of FGF10 expression changes to stimulate the outgrowth of the bud, which does not occur in the Dicer-null mutant. The lack of a normal pattern of FGF10 expression results in arrest of new branch formation. However, which Dicer-dependent microRNA or microRNAs regulate the specificity of FGF10 location during branching morphogenesis remains unknown.

miR-17, miR-20a, and miR-106b have been shown to be important during lung branching morphogenesis. These three microRNAs are required for the regulation of mitogen-activated protein kinase 14 (Mapk14) and signal transducer and activator of transcription 3 (Stat3). Activation of both Mapk14 and Stat3 are important for maintaining E-cadherin expression levels needed for cell−cell adhesion. Downregulation of these microRNAs results in an abnormal branching pattern in lung explants with an increased number of terminal branches superimposed on one another, affecting the overall branching pattern [78]. There is also evidence that other microRNAs, such as miR-221 (antiangiogenic) and miR-130a (proangiogenic), influence airway branching by regulating vascular density. Alterations in these microRNAs alter vascular density by disrupting the communication between endothelial and epithelial cells, which in turn affects vascular patterning—but it also influences branching, with high expression of proangiogenic signaling resulting in an increase in branching and elevated expression of antiangiogenic signaling resulting in decreased branching [79].

Dicer has also been shown to be important for the maintenance of nephron progenitor cells and proper branching in kidneys. Dicer depletion results in branching deficiencies, including an absence of branching tips in the renal cortex correlated with a reduction of Wnt11 and c-Ret at the bud tip. In addition, inactivation of Dicer in renal Foxd1 + stromal progenitor cells disrupts elongation and segmentation of the nephron [80]. Among the microRNAs affected by Dicer inactivation, seven have been implicated in migration, proliferation, and activation of Wnt signaling. Loss of Wnt expression due to inactivation of Dicer leads to a reduction in ureteric bud branching [81].

Similar to the lung and kidney, microRNAs in the salivary gland, such as miR-21 and the miR-200c family, have been shown to play important roles during branching morphogenesis. miR-21 expression in the submandibular mesenchyme during branching morphogenesis results in the activation of MMPs, causing degradation of the ECM through downregulation of reversion-inducing cysteine-rich protein with Kazal motifs (Reck) and programed cell death 4 (Pdcd4) in the mesenchyme [82]. On the other hand, miR-200c expression in the epithelial end bud is important for the regulation of FGFR-dependent epithelial proliferation via targeting the very low-density lipoprotein receptor (Vldlr), its ligand reelin, and potentially via heparan sulfate (HS) modification [83]. In addition, there is evidence that microRNAs can affect branching locally

through local epithelial expression of miR-200c and globally via microRNAs expressed in mesenchymal cells that can regulate targets in epithelial cells through export of microvesicles. miR-133b has been found to be produced in the mesenchyme and delivered to epithelium. It has been suggested that miR-133b regulates end bud morphogenesis by targeting disco-interacting protein 2 homolog b (Dip2b), allowing end bud progenitor proliferation [84]. Although previous studies have shed some light on the different mechanisms by which microRNAs may regulate branching, many questions remain unanswered.

MicroRNA involvement in branching morphogenesis is an area of research that is understudied at the moment. We do not yet have a clear understanding of which specific microRNAs regulate transcripts that are essential for branching, how microRNA expression profiles in different cell populations affect cell dynamics, mechanical forces, and interactions with the ECM, nor how these interactions can result in embryonic lethality, organ failure, or disease later in life. MicroRNAs have the capacity to target multiple genes, making them an attractive tool for regenerative and disease therapy [34]. And a single mRNA transcript can be regulated by more than one microRNA, so understanding the many-to-many nature of microRNA regulation is the key to harnessing microRNAs for therapeutic applications.

Extracellular matrix components in branching morphogenesis

The BM is known to provide tissue separation and boundaries during development [7,85]. It is important not only for maintaining tissue boundaries and serving as a substrate for epithelial cells but also for providing biochemical and potential mechanical signals during branching morphogenesis. The BM is mainly composed of laminin, collagen IV, and proteoglycans, often in close spatial association with fibronectin. In this section, we discuss examples of how each of these components participates in branching morphogenesis.

Laminin

Laminins comprise the most abundant glycoproteins of the BM and have important roles in branching morphogenesis. Two key laminins are laminin 1 (now termed laminin-111) and laminins containing the α5 subunit (laminin 511 and laminin 521). Laminin expression correlates with epithelial development [86,87]. In salivary glands, laminin α1 decreases during development, while levels of α5 rise [88] The interaction of laminin γ1 and nidogen in the BM is important for epithelial−mesenchymal interactions during salivary gland branching morphogenesis. Antibody perturbation of the nidogen-binding site substantially reduced salivary gland bud number [89] and the reduction depends on antibody affinity to the binding site. Abnormal growth was observed in the treated glands, characterized by the absence of globular tips. These effects of disrupting the laminin−nidogen interaction could be partially rescued by the addition of exogenous EGF. Since EGF is important for nidogen synthesis, the rescue might result from increased levels of nidogen able to bind to laminin γ1 [89]. In addition, mesenchyme-free salivary gland epithelium has been shown to grow in laminin-1 nidogen gels supplemented with EGF and horse serum at rates comparable to cultures in full Matrigel with the same supplements. Although more collagen IV accumulates with epithelial cells cultured in Matrigel compared to laminin-1 nidogen gels, morphogenesis is comparable, suggesting that laminin−nidogen binding alone can support branching morphogenesis [90].

3-D cultures of pancreas treated with antibodies against laminin-1 display inhibition of ductal formation, indicating that this glycoprotein is also important for pancreatic epithelial cell differentiation to form ducts [91]. In kidney, laminin-1-deficient mice exhibit reduced ureteric branching, with a major reduction of apical tight junctions and defective BMs. Fewer branches are produced due to inhibition of ductal cell proliferation, and sometimes no ducts are produced [92]. Loss of laminin α5 can also result in defective branching morphogenesis of salivary gland, lung, and kidney [87], which indicates that the functions of different laminins in branching do not fully overlap—each has its own specific role.

Collagen

The two largest classes of ECM are the interstitial matrix and BM—each class contains specific collagen types. The interstitial matrix is composed primarily of fibrillar collagen I, important for structuring the physical spaces between cells and helping to modulate cell communication within tissues. In contrast, a major protein of BM is nonfibrillar collagen IV; BMs provide support for epithelial cells, as well as chemical and mechanical cues to the tissue [7,93,94].

In salivary gland, collagens I and III accumulate at the interlobular cleft, along with the collagen IV associated with the cleft BM [1,27,95]. Collagens I and III fibers are observed in the interlobular cleft before new branches are formed [45], suggesting that they may be important for stabilizing the interlobular cleft as the new branch forms [6,96−98].

In salivary gland epithelial explant cultures, treatment with collagenase to disrupt all collagen types results in a basal lamina that is either irregular or sparse with a decrease in collagen fibrils at the epithelial−mesenchymal

interface, and it abolishes branching [95,98]. The effects are reversible, since removal of the collagenase partially rescues gland branching [98]. In lung and kidney cultures treated with collagenase, branching is similarly abolished, and both types of embryonic organ cultures become flattened in shape. The collagenase effects are reversible here as well, since after reincubation with their mesechymes, lung and kidney branching is rescued [99].

Lungs or salivary glands treated with β-aminopropionitrile that inhibits extracellular collagen cross-linking do not show significant differences in branching compared to controls. Nevertheless, treatment with α,α′-dipyridyl or L-azetidine-2-carboxylic acid (LACA), which disrupts collagen synthesis and secretion, inhibits the generation of new branches; in addition, preexisting clefts in both lung and salivary gland fuse together, suggesting that collagen is necessary to stabilize the clefts. These findings suggest that collagen synthesis and secretion are important for branching morphogenesis, but collagen cross-linking is not [100].

The effects of collagenase or removal of mesoderm in reducing branching or flattening organ morphology are not found in development of the pancreas [99]. This suggests that not all branching organs require the same type of mesoderm- and collagen-dependent signaling for branching. Consequently, just as there is specificity in terms of types of growth factor signaling, there are also organ-specific requirements (or not) for these other developmental regulatory factors.

In salivary gland, opposite to the effects of collagenase, inhibition of endogenous collagenases increases bud number by enhancing cleft formation in the glands, accompanied by an increase in collagens I and III accumulation in the cleft and at the epithelial−mesenchymal interface [95,101,102]. The authors concluded that interstitial collagens I and III are essential to support branching either through structural support and/or serving as a scaffold at the epithelial−mesenchymal interface. However, it would be valuable to compare the effects of collagenase and collagenase inhibitors on levels of collagen IV, which was not examined in the original studies.

Collagen IV is thought to play a role in branching morphogenesis by providing structural support in the BM. However, as will be discussed in detail later, the collagen IV/BM at the bud tips needs to be thinned and perforated to permit bud expansion. Treating salivary glands with batimastat, a matrix metalloproteinase inhibitor, results in enhanced collagen IV accumulation at the end buds and reduced bud outgrowth. This treatment also inhibits formation of microperforations in the BM, which are probably necessary for epithelial−mesenchymal contacts during branching. In fact, the treated BM exhibits a reduction of distensibility and restricted epithelial extension. In addition, treating branching salivary glands with the myosin II ATPase inhibitor blebbistatin also results in accumulation of collagen IV and reduction of bud outgrowth, suggesting that both myosin II contractile function and collagen density are important during the remodeling of the BM to form microperforations and permit bud outgrowth [45]. Collagen IV proteolysis can also stimulate bud outgrowth by promoting cell proliferation. The protease-generated noncollagenous 1 (NC1) domain can stimulate bud outgrowth as a result of collagen degradation and release by endogenous membrane-type matrix metalloproteinase-2 (MT2-MMP) [103].

Collagen XVIII has also been shown to be an important player in lung and kidney branching. Collagen XVIII is suggested to act as a HS proteoglycan that regulates binding and release of growth factors at the BM. During branch initiation, collagen XVIII is expressed at the bud tips in lung but at the stalk in kidney. In a heterotypic recombination experiment in which ureteric epithelium was cultured with lung mesenchyme, kidney cells expressed collagen XVIII at the bud tips. However, a similar result was not obtained when lung epithelium was cultured with ureteric mesenchyme, as no induction of branching or altered collagen XVIII expression pattern was observed. These findings suggest that collagen XVIII may contribute to the stereotyped, deterministic signaling and branching observed in the lung [104].

Heparan sulfate proteoglycan

HS proteoglycan (perlecan) has a key function in the BM involving the regulated of release growth factors by binding and releasing them in specific patterns. HS plays critical roles in branching morphogenesis of salivary gland, lung, and kidney [2]. In salivary gland, HS has been shown to increase the binding affinity of FGF to FGFR and to increase FGF concentration in the ECM. HS works cooperatively with growth factors to shape the epithelium. Treating SMG with FGF10 alone leads to formation of ducts with thin end buds. In contrast, treatment with FGF10 plus HS results in ductal growth with wider end buds due to increased proliferation at the tip of the bud [105]. Therefore the HS−FGF−FGFR interaction is important for embryonic salivary gland proliferation and bud shape.

In mesenchyme-free lung epithelium cultures in Matrigel, treatment with FGF10 and sodium chlorate (an inhibitor of sulfation) affects the HS expression gradient and FGF10 local activation. The result is reduced expression of BMP4 in the bud tips and abolition of bud formation. Attempted rescue by treatment with O-sulfated heparins increased levels of BMP4 but failed to rescue lung budding, suggesting that even though O-sulfated HS is important for activation of FGF10, it is not the only player required for bud formation [106]. In kidney,

disruption of HS sulfation also results in reduction of branches and epithelial buds in a dose-dependent manner. Addition of excess exogenous sulfate with the chlorate inhibitor partially rescues the phenotype [107].

Fibronectin and integrins

Fibronectin is located in interstitial matrix and adjacent to BMs and plays key roles in the regulation of cell adhesion and migration. During branching morphogenesis, fibronectin concentrations are high at the BM and near cells undergoing clefting, associated with similar accumulations of BM at these sites; both fibronectin and BM move down into forming and progressing clefts [45,108].

Fibronectin is thought to contribute to the conversion of cell−cell adhesions to cell−matrix interactions by inhibiting E-cadherin via induction of BTBD7 [109,110]. The epithelial cells interacting with the BM at the periphery of buds during clefting appear more activated in terms of speed compared to cells in the bud interior [111]. In addition, when cells interact with the BM, there is an observed increase of fibronectin localization in these regions, suggesting that they can contribute to fibronectin deposition in the clefting sites [108]. In addition to epithelial cells and Wnt signaling, focal adhesion kinase (FAK) has also been shown to contribute to fibronectin deposition within the salivary gland cleft. Inhibition of FAK leads to a disorganized assembly of the BM, disrupting cleft formation and progression [112]. Myosin II is also known to be important, and its inhibition disrupts cleft extension and alters F-actin organization [112].

Inhibition of fibronectin in developing salivary glands results in nearly complete ablation of bud formation with an enlargement of the epithelial stalk; conversely, exogenous fibronectin can stimulate branching [27]. Fibronectin can be regulated by Wnt signaling. In lung branching morphogenesis, expression of the DKK family in bud tips was shown to block Wnt/β-catenin activity in the bud tips. Consistent with a role for Wnt signaling in promoting fibronectin accumulation at the cleft site, lung explants treated with the Wnt inhibitor DKK1 exhibit a decrease in cleft formation, reduction in branching, and enlargement of end buds, all of which are also observed after fibronectin inhibition [21]. In the kidney, fibronectin expression is observed in the ureteric bud with expression evenly between the tip and the stalk. However, fibronectin expression decreases during kidney maturation. Treating ureteric cultures with fibronectin results in an increase in cell migration and cellular elongation in a concentration-dependent manner and treating ureteric cultures with antibodies against integrin $\alpha_3\beta_1$ partially inhibits these fibronectin-dependent effects [113].

At the cell morphological level, changes in cell shape and migration are observed at sites of salivary cell−matrix contacts. The cells closest to the BM, the outer bud cells, have a columnar shape but are more motile, while inner cells have a more rounded shape. The outer bud cells exhibit high affinity for the BM, yet they are also highly motile as they translocate along its surface. When these cells leave the BM during mitosis (which often takes place in the bud interior), they change from columnar to rounded, but they eventually return to the BM and assume a more columnar, laterally motile phenotype. These associated velocity and shape changes comprise a dynamic process.

In the outer bud cells, E-cadherin is located at the cell−cell junctions but not at the regions of the plasma membrane in close contact with the BM. In contrast, E-cadherin is located around the periphery of the inner bud cells. Inhibition of $\alpha_6\beta_1$ integrins in the outer bud cells causes disruptions in interactions with the BM, slows lateral migration, and alters E-cadherin localization to mimic more closely the pattern observed in the inner bud cells. However, the inhibition of $\alpha_6\beta_1$ integrins showed no significant changes in the inner bud cells (which are not interacting with ECM), indicating that integrins help regulate velocity and shape in just the outer bud cells as they interact with the BM. Interestingly, inhibition of E-cadherin in outer bud cells has no major effect, whereas inner bud cells show a loss of cell−cell adhesion with an increase in speed, indicating that E-cadherin is important for stabilizing inner bud cells by maintaining cell−cell adhesions [111]. Similarly, in the developing pancreas, changes in cell shape and increases in cell displacement are observed in the cells that interact with the BM, while the other cells maintain a stable shape. Inhibiting cell−ECM interactions in pancreas explants inhibits branching morphogenesis: Deletion of the β1 integrin subunit disturbs cell−ECM interactions and affects ECM remodeling as indicated by a reduction in BM thickness. In addition, deletion of the β1 integrin subunit changes the characteristic F-actin alignment orientation from perpendicular to parallel [114]. Taken together, these findings point to the importance of a variety of ECM−integrin interactions and functions in branching morphogenesis of multiple organs.

Basement membrane microperforations

The BM provides the substrate under epithelia and separates epithelia from embryonic mesenchyme during development. The thickness of the BM changes during branching morphogenesis. Thinning of BM regions and microperforations becomes visible in areas of actively growing and expanding epithelium in salivary gland, lung, and kidney [7,45]. Previous studies had observed thinning of the BM in lung and kidney by the use of electron microscopy [115,116]. In thinner BM regions,

epithelial and mesenchymal protrusions are observed through the microperforations, allowing for mesenchymal–epithelial contacts [117]. These contacts might permit epithelial–mesenchymal inductive signaling [118] as well as stimulating bud growth and promoting overall expansion of the tissue [119].

The microperforations are present in end buds at the highest frequency during the period of rapid cell proliferation and bud expansion preceding the cleft [7]. Although microperforations are evident around the expanding end buds, they seem to be absent in both the cleft and around the duct, where epithelial expansion is not expected; in fact, there is more accumulation of the BM in these latter two regions (Fig. 13.7) [45,115]. Greater accumulation of BM components is consistent with higher basal lamina integrity at these sites, which is compromised at the distal portion of end buds due to the microperforations to permit expansion.

The BM is remodeled locally by dilatation and contraction of individual microperforations. These constant stretching processes at the microperforations are mediated by actomyosin-dependent physical distortion involving nonmuscle myosin II [45]. In embryonic salivary gland the microperforations are small enough to allow for protrusions from either epithelial or mesenchymal cells without intermixing of cells across the BM. This is not the case in the lung, where cell crossings are observed. BM microperforations in the lung can permit inflammatory cells to enter into the epithelium, suggesting that this mechanism in the lung (and potentially other tissues) may serve as a mechanism for cross-tissue interactions [117].

In addition, however, during branching, the BM is remodeled globally through translocation of the entire BM from the bud tip down to the secondary duct. Direct proteolysis is essential for both BM translocation and generation of microperforations, and protease inhibition prevents both the formation of microperforations and this translocation of intact BM [45]. As the organ grows, BM needs to be remodeled to allow for tissue expansion while still providing structural support and separation of epithelial from mesenchymal compartments. Stromal cells and epithelial cells that migrate during branching likely remodel the BM by releasing proteases and producing components of the BM. Glycosaminoglycans (GAGs) have also been shown to play a role in BM turnover. GAGs are degraded at a higher rate in the end buds during branching compared to the cleft regions, while in the stalk it remains constant [96]. An increase in GAG degradation also correlates with a decrease in basal lamina integrity, so the processes of GAG and protein degradation are likely to be linked.

In addition to GAG degradation in the end buds, salivary gland collagen IV has also been shown to be degraded as the result of proteolysis. Membrane-type matrix metalloproteinase-2 (MT2-MMP), a membrane-intercalated member of a collagenolytic enzyme family, is known to be responsible for collagen IV ECM degradation in embryonic salivary gland. MT2-MMP proteolysis releases NC1 domain fragments as a product of the proteolysis of collagen IV chains, which can further stimulate MT2-MMP and genes associated with proliferation to promote branching through its binding to β1 integrins [34,103].

ECM degradation and cell signaling have been postulated to increase not only distensibility but also cell tension [28] in the end buds. As the epithelium expands, it stretches the BM. The physical forces and perhaps the epithelial membrane protrusions likely contribute to generating the local BM perforations. Therefore degradation of the ECM is important for both global and local

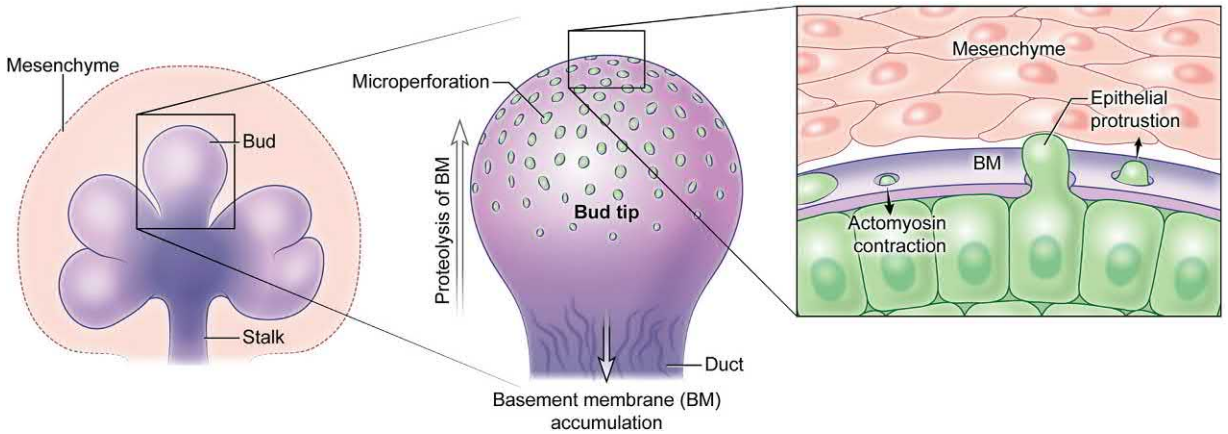

FIGURE 13.7 Basement membrane microperforation. During branching morphogenesis, microscopic holes of varying sizes appear in the basement membrane of expanding buds as a result of protease degradation of the basement membrane and actomyosin contractility. The epithelial cells extend protrusions through holes in their vicinity, and as they push outward, they dilate the perforations in the basement membrane. They eventually retract using actomyosin contractility. Both myosin II–mediated contractility and basement membrane microperforations contribute to the local and global remodeling observed in the salivary gland.

remodeling by influencing cell behavior and providing sites for the epithelial cells to extend protrusions and dilate the BM as they push through microperforations, generating regions of epithelial−mesenchymal contacts (Fig. 13.7). Once the microperforations disappear, BM accumulates to provide support to the gland and allow differentiation to begin. Therefore this phenomenon of global translocation of BM can provide support and help to shape the tissue [45].

Current evidence indicates that BM remodeling is mediated by an increase in protease activity plus myosin II mechanical forces. Myosin II is essential for maintaining the integrity of the microperforations during the translocation of the BM, allowing the cells to reshape and remodel the BM by actively pulling on it through actomyosin contractility [45].

Mathematical and computational models

In order to identify underlying mechanisms of branching morphogenesis, as well as to understand how they differ between different organs, researchers have generated mathematical and computational models that are beginning to provide new insights. These models have been primarily directed toward explaining how signaling mechanisms, geometry, or mechanical forces contribute to branching patterns.

Geometry

Fractal geometry has provided a conceptual basis for identifying mechanisms that may underlie the formation of branches in biological settings. Fractal geometry has been applied to lung branching by considering the lung as a fractal object lacking characteristic scale and having self-similarity [29,120,121]. Some of the modeling for lung geometry uses exponential models, starting with the premise that the lung is a dichotomous branch tree with a parental branch of greater length and diameter and an exponential decrease with every daughter branch due to maximizing entropy. Nevertheless, when this model was used to analyze more than 10 generations of branches, the exponential decrease could no longer accurately predict the diameter and length of subsequent branches. Therefore a renormalization model was developed in which the changes originally considered exponential were shown to be power-law decreases modulated by harmonic variation of the mean of the branch diameter [122].

Mechanical forces

A different type of model that focuses on mechanical forces during early lung branching predicts a linear relationship between epithelium growth and strain rate by the mesenchyme, consistent with the stress−strain rate of fluid flow. In this model the epithelium maintains a tangential stress similar to the surface tension between two fluids, in this case the mesenchyme and the luminal fluid [123]. However, the mesenchyme could be considered as two fluids itself, because there is dense ECM around the epithelium and the outer layer is less dense. There is also evidence suggesting that the branching in the lung is not determined by the ratio of viscosities but instead by residual mechanical stress [124]. Such residual stress could come from cross talk between the mesenchyme and epithelium, important not only for stimulating mesenchymal proliferation and epithelial bud outgrowth but also for governing internal forces. Since the mesenchyme will grow along with the epithelium, this factor, as well as the forces exerted by the boundaries of neighboring organs that compete to fill the available body space, could contribute to pressure gradients determining the overall position of the lung [125].

It appears that the first three generations of branches in the developing lung are stereotyped due to competition to fill the available spaces, but that there is some variability in angle and time of branch generation in later branch generations as the available space is occupied by the organ, accompanied by a relaxation of the stereotyped pattern. These concepts might also help to explain why kidney appears to be stereotyped or deterministic early in development, while the pattern is more stochastic at later developmental stages.

In addition to the mesenchyme, smooth muscle can also contribute to mechanical forces and constraints in developing organs. For example, smooth muscle has been shown to serve as an external physical constraint to epithelial expansion in the developing intestine, resulting in epithelial folding [126,127]. A similar mechanism involving differentiated smooth muscle as a girdle-type restraint around the tip of lung epithelium is thought to play a role in initiating the first cleft in lung. This first cleft is observed at approximately E10.5, but it is not until E11 that nerves are detected around the smooth muscle—this fact is most consistent with simple physical constraint of the expanding epithelium by smooth muscle cells rather than active contraction; the smooth muscle could subsequently become contractile but only after initial branching [33]. Nerve innervation and active smooth muscle contractility could contribute to lung mechanical forces after E11—contributing to fluid flow within the lumen through periodic smooth muscle contraction and relaxation.

Signaling mechanisms

A ligand receptor−based Turing model has been used to explain patterns of signaling and tissue remodeling during lung and kidney branching morphogenesis. This proposed

mechanism involved two factors—a ligand and a receptor—which have different diffusion rates, with their interaction leading to upregulation of receptor levels. The biological variables in this Turing model included the ligand, receptor, inhibitor, and cell differentiation. Application of this model to the lung has been used to explain clefting and stalk elongation. The initial process of bifurcation was modeled to arise as a result of the bud moving toward the activator (ligand). At some point, there could be insufficient receptor (substrate), and a new group of cells without bound ligand might then deviate their motion to fulfill the demand and promote branching. Stalk elongation would be explained as a result of lateral inhibition of new branch formation [128].

Application of the ligand receptor−based Turing mechanism to lung involved FGF10 and sonic hedgehog (SHH), and application of this analysis to GDNF-RET signaling in the kidney was also quite effective. It revealed that the pattern of branching observed in developing wild-type and mutant kidneys could both be predicted by the computational model. In addition, there was positive feedback between GDNF and Wnt11 to enable kidney buds to grow into close apposition to permit closely packed glomeruli [129]. This highly effective model does not yet, however, explain the shapes (length, width, and angle) of the branches, or how other factors, such as mechanics and the other cell types in these organs, work together to achieve efficient branching and the final organ architecture.

Agent-based models, such as cellular automata, consider epithelial cells as individuals instead of collective computational agents, allowing for single-cell studies [130]. Application of these models to GNDF signaling in the kidney suggests that GDNF-mediated proliferation is sufficient for generating branching, since proliferation independent of GDNF produces no branching, that is, GDNF is essential for ureteric bud initiation and overall branching [131]. Ideally, this model could be enhanced by incorporating the cell forces generated by mesenchymal cells that can contribute to branching.

In conclusion, mathematical, physical, and computational models are providing new, intriguing insights into the ways in which mechanical forces and biochemical signaling guide the complex branch structures of tissues. However, they do not yet consider all of the components known to be involved (mechanical, biological, and biochemical signaling) [124]. In order to achieve a better understanding of the process of branching morphogenesis, it will be valuable to integrate biological and biochemical experimentation closely with computational modeling, so that the novel predictions from models can guide experiments, and the biological results can refine the models.

Conclusion

Branching morphogenesis is a topic that has fascinated researchers for many years. This fascination arises from a desire to understand the dynamic changes in embryonic epithelia, signaling, and ECM that lead to complex tissue architecture and efficient function in compact organs. More recently, an understanding of branching morphogenesis has proven to be valuable for potential future regenerative medicine. An example of this involves salivary glands, the function of which is disrupted in Sjögren's syndrome and radiation therapy for head and neck cancer [132]. The effects of radiation therapy have been mimicked in mouse models, with effects on progenitor cells [51], cell proliferation [46], nerve innervation [40], and gland secretory functions [132]. Studies of branching morphogenesis in this gland established that even after dissociation of the gland into single cells, the cells retain the capacity to self-aggregate and regenerate into bud-like structures [52]. The subsequent identification of transcription factors that are involved in self-assembly has led to the development of an engineered salivary gland that upon transplantation into mice with salivary gland defects can restore secretory function of the glands [54]. These results provide promise to patients who suffer from xerostomia and indicate how an understanding of branching organs can help develop technologies and treatments to restore proper organ architecture and function. This and other examples in other organ systems provide hope that a better understanding of branching might eventually lead to engineering of organs that can reduce the waiting time for transplants and increase patient life expectancy for conditions, such as pulmonary diseases and kidney failure.

Advances in genome editing are providing tools that should enable the study of gene function [133] in organ explants and cultures. These and other manipulations should help elucidate biochemical signaling in branching organs. In addition, knowledge gained from understanding cell−cell interactions and cell−matrix interactions during branching can help in the development of biomaterials and microfluidic devices that better mimic the tissue microenvironment.

Advances in omics (including genomics and proteomics) are helping to identify subpopulations of cells important during gland branching [134]. This knowledge is helping researchers better understand which cells are playing important roles during branching in specific glands and verify whether the genes required to establish these cell populations are conserved across branching organs. In addition, advances in computational biology have helped design better predictions by integrating data from sequencing or other big data technologies with experimental data on mechanical, biological, and biochemical signaling to produce more accurate models.

Although these technologies have provided insight into the mechanisms of mechanotransduction, branching patterns, and biochemical signaling during branching, many questions remain. For example: why is a specific ligand–receptor signaling system used primarily in one organ but not in the others? How do tissues coordinate cleft formation with both local proteolysis and global translocation of BM? How do microRNAs regulate different aspects of nerve innervation, cell–cell interaction, and cell–matrix dynamics during branching morphogenesis? What are the advantages and disadvantages of one branching pattern over the other? Does the stereotyped branching pattern of the lung help increase later gas exchange in this organ? Why is kidney branching stereotyped initially, but not in later steps? Even more importantly, what could happen if these developmental mechanisms that are so crucial to proper organ structure and function are aberrantly activated during adulthood?

Chapter 14

Mechanobiology, tissue development, and tissue engineering

David Li and Yu-li Wang
Department of Biomedical Engineering, Carnegie Mellon University, Pittsburgh, PA, United States

Introduction

Mechanobiology is a field of biology that investigates the generation and response to mechanical signals by cells or tissues. In recent years, our understanding of mechanobiology has expanded to include not only the multitude of cellular responses to mechanical signals, but also how cells generate mechanical forces to communicate with their environment and neighbors. At the intersection of biology, physics, and engineering, mechanobiology has contributed greatly to both our understanding of biological phenomena such as morphogenesis, tissue regeneration, and cancer metastasis, and the development of medical applications such as implants, wound regeneration control, and tissue engineering.

This chapter covers the basics of mechanobiology with a focus on the human body, beginning with an introduction of the existence and generation of mechanical signals within biological systems. The discussion then focuses on the ability of cells to detect and respond to these signals, termed mechanosensing and mechanotransduction, respectively, followed by the underlying mechanisms that lead to responses in higher order structures such as tissues and organs. The chapter concludes with examples of how mechanobiology-derived design elements have been implemented in tissue and organ engineering.

Mechanical forces in biological systems

All biological systems receive mechanical signals from a range of internal and external sources (Fig. 14.1). Some of these sources generate localized forces confined to the immediate environment of a cell, while other sources generate macroscale forces that affect an entire tissue. A typical tissue comprises many distinct populations of cells, where mechanical forces may affect these populations similarly or differently, depending on tissue architecture and other compositional differences. The initiation, sustainment, and release of macroscale forces may each affect tissues and trigger coordinated responses. In addition, cells and tissue also use mechanical forces to sense the mechanical environment such as stiffness. In mechanobiology, the main forces of interest are tension, compression, and fluid shear.

Tension

Tension is a force met by the resistance of a material against an increase in its length. Some sources of tension are external, such as from physical tugging of the skin. Others arise within the body itself, exerted by tissues, such as muscle, upon themselves and/or other tissues.

Skin, organ linings, and other similar tissues comprise flat sheets of cells and are thus referred to as epithelial tissue. Epithelial tissues experience tension both constitutively from cell-generated forces and externally from external sources. One example of epithelial tension is the cyclical tension exerted upon the lining of the lungs during breathing [2]. This cyclical tension is necessary for the proper development and maintenance of the lung epithelium, as improper tension can cause defects such as fibrosis and emphysema of the lungs [3–5].

The human body also generates tension for its maintenance and movement. Skeletal muscles pull on tendons, other muscles, and skeletal components both constitutively and during voluntary movement. As a result, tendons, thick cords of connective tissue that connect skeletal musculature to the skeleton, are under constitutive tension. These tensile forces cause strengthening and remodeling responses in connective and other affected tissues [6–8].

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00015-0

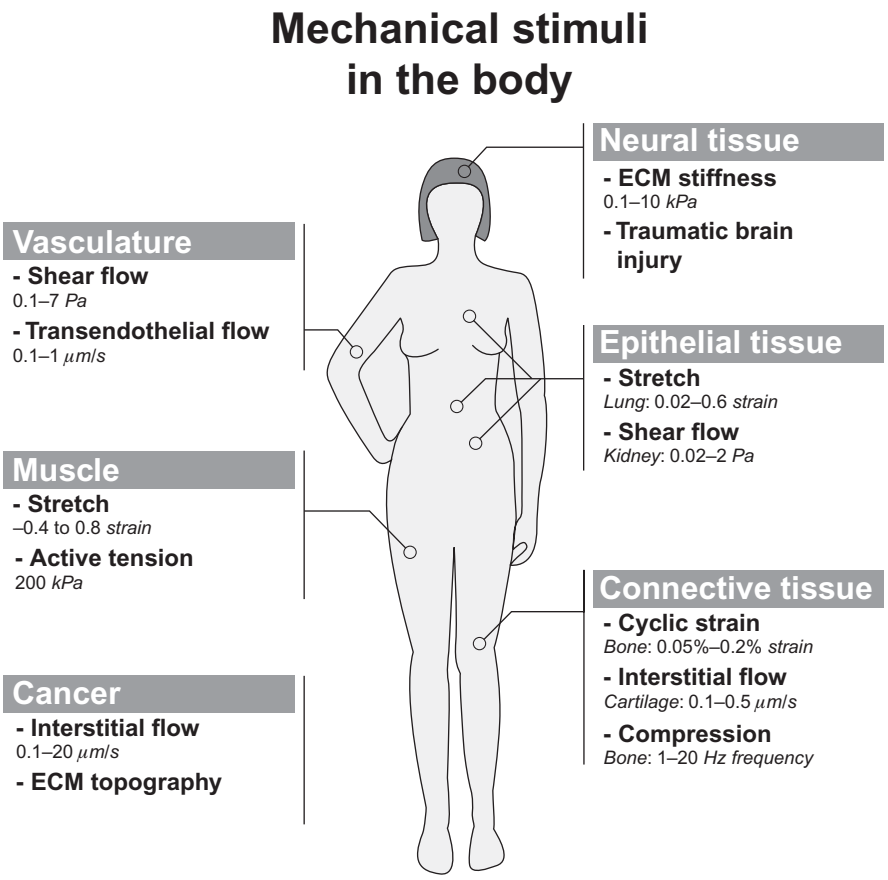

FIGURE 14.1 Mechanical stimuli found in various tissues inside the body. The main forces found in tissues are tension, compression, and fluid shear, which may allow cells and tissues to sense strain, stiffness, or other parameters responsive to mechanical forces. Excessive forces may cause damages such as traumatic brain injury from rapid compression. *Adapted from Polacheck WJ, Li R, Uzel SGM, Kamm RD. Microfluidic platforms for mechanobiology. Lab Chip 2013;13(12):2252–67 [1]. Published by the Royal Society of Chemistry.*

Compression

Compression, forces met by the resistance of a material against a decrease in its length, is exerted both as a constant, such as in the case of gravity while standing still, and variably as a result of motion [7]. Compression affects both soft tissue and bones. The repetitive compression–decompression cycles of walking exert variable mechanical stimuli superimposed on the constant forces of standing. Bones change their shape, density, and stiffness in response to changes in the conditions of mechanical loading, such as during space flights [9]. Improper loading conditions also cause osteoporosis, osteoarthritis, and fibrosis, while proper exercises assist in maintaining bone structure [9]. Compression also causes changes in interstitial fluid flow and contributes to fluid shear forces [7,9].

Fluid shear

Fluid shear is a drag force oriented parallel to the surface caused by the flow of fluid past a material. Both cardiac and smooth muscles operate by contracting around a fluid to direct flow, which causes heterogeneous patterns of pressure and shear stress to the vasculature [10]. Normal levels of blood pressure and shear flow help maintain the physiological condition of vasculature, while shear flow in the gastrointestinal tracks has been implicated in the release of serotonin and regulation of intestinal fluid secretion [11]. Conversely, abnormal fluid shear is believed to directly or indirectly cause atherosclerosis, cardiac fibrosis, and other systemic effects [12,13].

Both hearing and proprioception are driven by fluid flow against the inner surface of the cochlea. Hearing initiates with vibrations of the eardrum, which are transduced into patterns of fluid waves inside channels within the cochlea [14]. Head tilt is also transduced into fluid flow within three semicircular canals in a separate part of the inner ear, known as the vestibular system [15]. Mechanosensitive hair cells on the inner surface of these channels sense the fluid flow in both cases [14–16].

Shear force also occurs from interstitial fluid flow through solid tissues. In the brain, a link has been found between increased cerebrospinal fluid flow and the invasion of glioblastoma [17]. Similar findings have been found for other cancer cell types, suggesting that interstitial flow may play a general role in metastasis [18].

Cellular mechanosensing

The mechanotransduction of larger tissues is often dependent on the ability of their constituent cells to sense and

respond to microscale forces, termed cellular mechanosensing. Individual cells experience microscale mechanical stimulations as macroscale forces travel through the heterogeneous and complex tissue architecture. These microscale forces are characterized by a magnitude in the order of piconewtons and a spatial resolution in the order of microns. Even in the absence of macroscale forces, cells continuously exert microscale forces on the surrounding environment while sensing the feedback responses in a complex feedback loop. The combined architecture of the cytoskeleton, junctions, and microenvironments forms a complex, dynamic framework that allows cells to sense and respond to forces.

The cytoskeleton

All mammalian cells are enclosed in a cell membrane. Inside the cell, nucleus and organelles are suspended in a viscoelastic cytoplasm that allows for the intracellular transfer of forces. The generation, transmission, and balance of these forces are mediated by a dynamic proteinaceous network called the cytoskeleton, comprising three types of filaments known as actin filaments, microtubules, and intermediate filaments. These filaments, formed by noncovalent associations of monomeric subunits, are capable of spanning large distances within the cell.

Actin filaments, the predominant structure that transmits forces across the cell, are polarized, semiflexible chains. Different isoforms of the motor protein myosin may pull actin filaments along defined but different directions relative to filament polarity [19]. Actin, myosin, and accessory proteins, such as cross-linking factors, form a contractile network that both generates and sustains tension within the cell [20]. In addition, contractile bundles of actin and myosin, known as stress fibers, are prominent contractile structures often viewed as the counterpart of myofibrils in muscle cells [21,22]. Stress fibers terminate at one or both ends at focal adhesions, which are discrete transmembrane plaques that anchor cells to the substrate and allow the transmission of forces from stress fibers to the substrate for generating traction forces [23]. While stress fibers are most prominent in stationary cells, some migrating cells assemble transverse arcs of actin and myosin bundles behind the advancing edge without direct association with focal adhesions [23]. The contraction of these arcs serves to pull itself away from the curved advancing edge in a process called retrograde flow, which exerts tension through connections with other intracellular structures for driving directional transport during cell migration.

Microtubules are structural fibers composed of linear protofilaments associated laterally for forming long hollow cylinders. They are commonly perceived as rigid supports that are able to withstand compressive forces such as those generated by the actomyosin network. In addition, microtubules guide intracellular transport, where they provide a path for motor proteins, such as kinesins and dyneins, during the transport of vesicles [24]. Similarly to actin filaments, microtubules are dynamic and polarized structures, showing different rates of polymerization and depolymerization at their two ends. By binding to microtubules and affecting these rates, microtubule-associated proteins can modulate the organization of microtubules [25]. Regulation of the microtubule network affects the transport of organelles, signaling factors, and other important proteins for generating far-reaching effects, including polarization, migration, and proliferation [26]. In addition, microtubules interact with the actin cytoskeleton at focal adhesions and possibly other structures, where they may regulate the assembly and disassembly of actin structures [27].

Intermediate filaments are a family of related, cell-type dependent filaments that are laterally assembled from unit length filaments composed of octamers of tetramers [28]. Vimentin is largely expressed in mesenchymal cells, while cytokeratin is largely expressed in epithelial cells. Both interact with actin filaments and microtubules, desmosomes, and hemidesmosomes [29]. Intermediate filaments have been hypothesized to passively resist cellular deformation. Under tension, intermediate filaments may reorganize their protein conformation to increase their resistance to strain [30,31]. Individual cells have been found to respond differently to shear flow in vitro in the presence or absence of vimentin [32], and deficiencies in intermediate filaments are known to cause skin-blistering diseases [33,34]. A distinct class of intermediate filaments called lamins are expressed in most eukaryotic cells to form a shell around the nucleus, for the purpose of resisting nuclear deformation and transmitting mechanical signals between the nucleus and the surrounding cytoplasm [35]. Lamins are mechanically tethered to the nucleus through a mechanosensitive complex known as the linker of nucleoskeleton and cytoskeleton (LINC) complex, which also associates with actin filaments and microtubules [36] to possibly mediate the mechanical crosstalk.

Stretch-activated ion channels

Stretch-activated ion channels respond to membrane deformation and play critical roles in sensing vibration, pressure, and touch. A stretch-activated ion channel is composed of transmembrane proteins encapsulating a hollow channel that opens upon tension. Ions flow rapidly through an open ion channel, causing immediate changes in transmembrane potential and intracellular calcium concentration, which allow for rapid signaling responses in the order of milliseconds [37]. These channels are present

in the cochlea, smooth muscle, hair follicle cells, and cardiac tissue [37]. Examples of mammalian stretch-activated ion channels include the transient receptor potential family of channels and the recently discovered piezo channels [38,39]. These stretch-activated ion channels have been shown to mediate the sensing of fluid shear in cochlea hair cells and in small intestine epithelial cells during the development of microvilli [11,14–16].

Cell–cell adhesions

Cell–cell adhesions consist of discrete junction structures responsible for mechanically coupling cytoskeletons together and allowing the transmission of mechanical signals across a cell collective [40]. The majority of these anchoring junctions are found in epithelial and endothelial cells, although some are also observed in mesenchymal or cancerous cells [41].

Adherens junctions form transcellular mechanical linkages between the actin filament networks. Their primary component is a transmembrane protein family called cadherins, which generally bind to cadherins of the same type in neighboring cells. Different classical cadherin subtypes, such as E-cadherin, N-cadherin, and VE-cadherin, are expressed in different tissues and at different times in development [41,42]. The homophilic binding of these cadherins is a driving factor for cellular sorting and morphogenesis [41]. Upon intercellular binding and tension, cadherins undergo a conformational change that alters the binding properties of its cytoplasmic domains to cytoplasmic proteins, such as catenins, initiating signaling cascades [43]. β-Catenin is stabilized at the adherens junction under tension, which in turn inhibits nuclear relocation and transcription of several signaling factors in the Wnt signaling pathway [43]. At least some of the associated mechanotransduction processes involve changes in protein conformation. For example, α-catenin, which mediates the binding of β-catenin to actin, unfolds under force to expose binding sites for other actin-related proteins such as vinculin and α-actinin (Fig. 14.2) [44]. Interestingly, many of these proteins also associate with focal adhesions, suggesting that there may be crosstalk and shared mechanisms between cell–cell adherens junctions and cell–substrate focal adhesions [45].

Desmosomes form another type of mechanical linkage between cells through the associated cytokeratin networks [47]. Their primary components are transmembrane proteins called desmoglein and desmocollin, which bind to each other and to other desmogleins and desmocollins on the surface of adjacent cells. Their cytoplasmic domains bind to several accessory proteins such as desmoplakin, plakoglobin, plakophilin, and several catenins that are also associated with adherens junctions [47]. Desmosomes are predominantly found in tissues that experience intense mechanical stress, such as cardiac muscle, bladder, and epithelia. Recent studies suggest that desmosomes typically experience low levels of tension under normal conditions but are subjected to and withstand high tension under external loading [48,49]. As intermediate filaments do not generate contractile forces, desmosomes appear to be passive mechanical adhesions that protect the tissue against external forces [49].

Cell–substrate adhesions

In addition to contact with other cells, adhesive cells mechanically tether themselves to the substrate via cell–substrate adhesions. The substrate typically consists of secreted proteins called the extracellular matrix (ECM). Like cell–cell adhesions, the cytoplasmic side of these adhesions is also associated with the cytoskeleton and signaling proteins, which allows cell–substrate adhesions to respond to mechanical forces by affecting a wide variety of cellular pathways. The best characterized cell–substrate adhesions are focal adhesions and hemidesmosomes.

As described earlier, focal adhesions are transmembrane structures associated with the actin cytoskeleton and signaling proteins on the cytoplasmic side. The exterior side of focal adhesions binds to ECM proteins, such as fibronectin and collagen, via a family of transmembrane proteins called integrins [50]. Integrins are heterodimers of alpha and beta subunits. Different combinations of alpha and beta subunits form different heterodimeric complexes to allow the recognition of different extracellular ligands. Binding of integrins to ECM ligands triggers a conformational change that is sensed by intracellular focal adhesion proteins [51]. Focal adhesion proteins, including focal adhesion kinase, paxillin, talin, vinculin, zyxin, vasodilator-stimulated phosphoprotein, and α-actinin, interact with each other to form a complex network of signaling pathways for transducing mechanical signals [52,53]. Some of these proteins are known to respond directly to forces by changing the conformation and initiating signaling cascades. For example, stretching of talin and vinculin causes a conformational change, which then exposes additional binding sites for downstream signaling proteins (Fig. 14.3) [54–56]. Mechanical stimulus through focal adhesions also induces the phosphorylation of tyrosine residues on some of these proteins, which affects their interactions with other proteins [57,58]. Such events then lead to several key cellular responses, including adhesion, proliferation, migration, and differentiation.

Hemidesmosomes are predominantly found in epithelial cells, acting as linkages between the ECM and intermediate filaments such as cytokeratin. They are primarily composed of a specific integrin, α6β4, and plectin 1a,

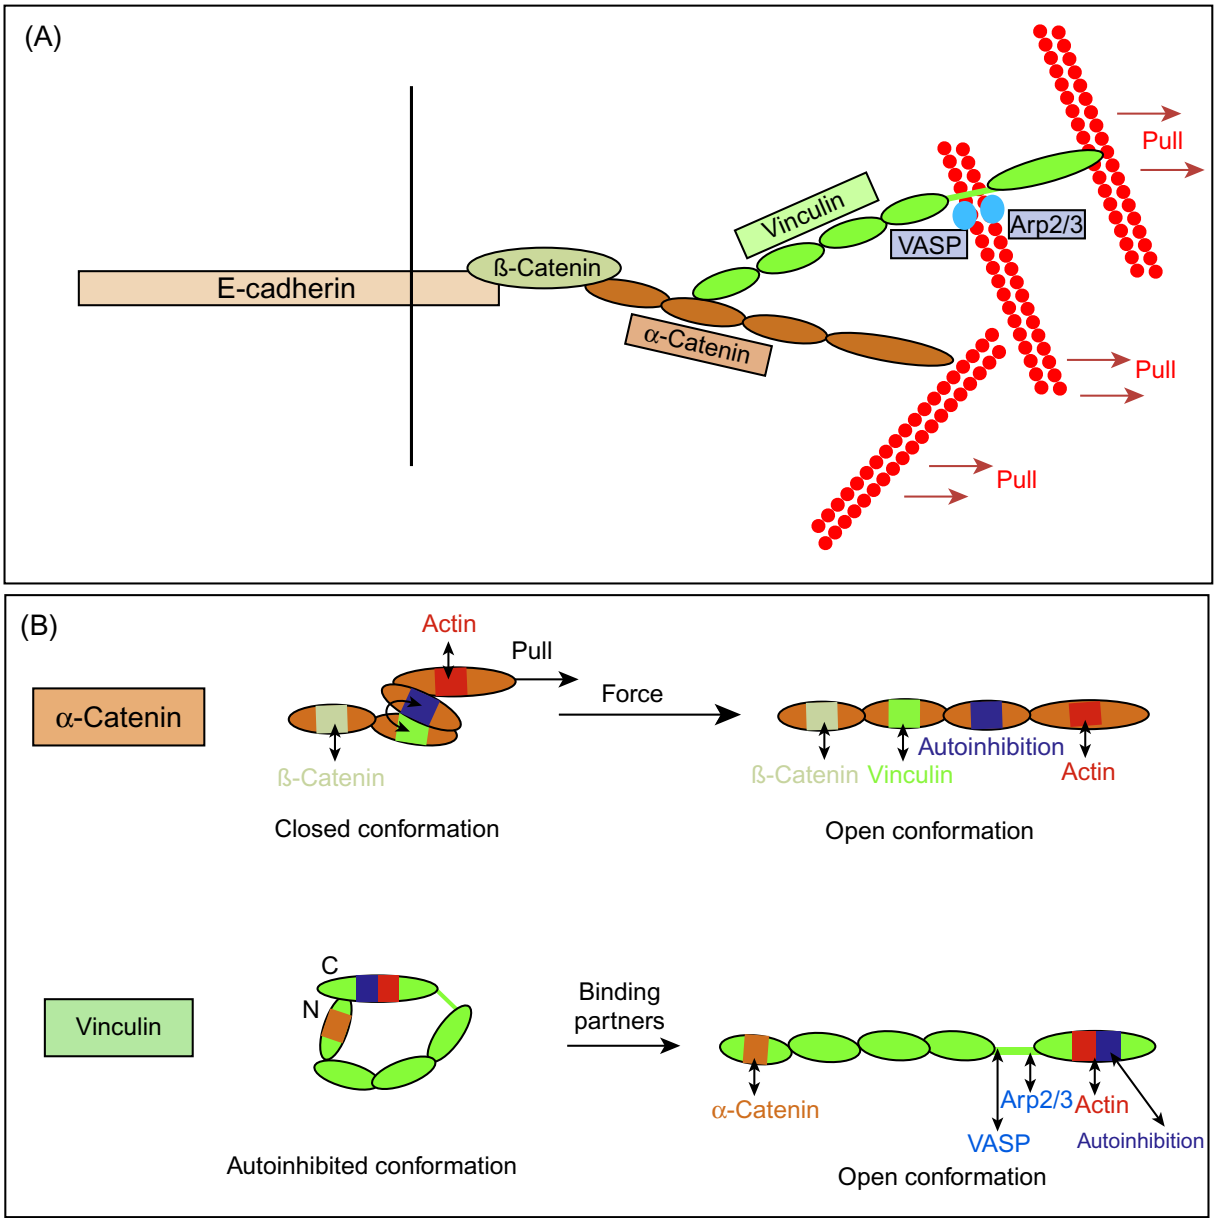

FIGURE 14.2 **Tension sensing at adherens junctions.** At nascent adherens junctions, E-cadherin interacts with two tension-sensing proteins: α-catenin and vinculin. Upon homodimerization with E-cadherin on opposing membranes, E-cadherin binds α-catenin on its intracellular domain and becomes linked to the contractile actomyosin network (A). In response to either external force or actomyosin contractility, α-catenin changes conformation and exposes a cryptic binding site to vinculin. Vinculin itself is also mechanosensitive. While typically existing in an autoinhibited state, it unfolds upon the binding of α-catenin to expose binding sites for downstream partners and to promote the maturation of adherens junctions (B). *Adapted from Roper K. Integration of cell–cell adhesion and contractile actomyosin activity during morphogenesis. In: Yap AS, editor. Current topics in developmental biology. Amsterdam: Elsevier; 2015 [46].*

which are both transmembrane proteins, along with their associated cytoplasmic proteins. Recent studies indicate that tension exerted by muscles or external pressure can induce hemidesmosomes to mature from punctate spots to larger stripes and activate intermediate filament phosphorylation in *Caenorhabditis elegans*, raising the possibility that vertebrate hemidesmosomes may also exhibit sensitivity to forces [60].

The extracellular matrix

The ECM is the complex extracellular scaffold of proteins that cells deposit and adhere to. Cell adhesion to the ECM is involved in the control of cell spreading, migration, and proliferation [61,62]. ECM is present in all solid tissues from bone to fat, showing a full range of stiffness. It serves several major roles at the tissue level: presenting

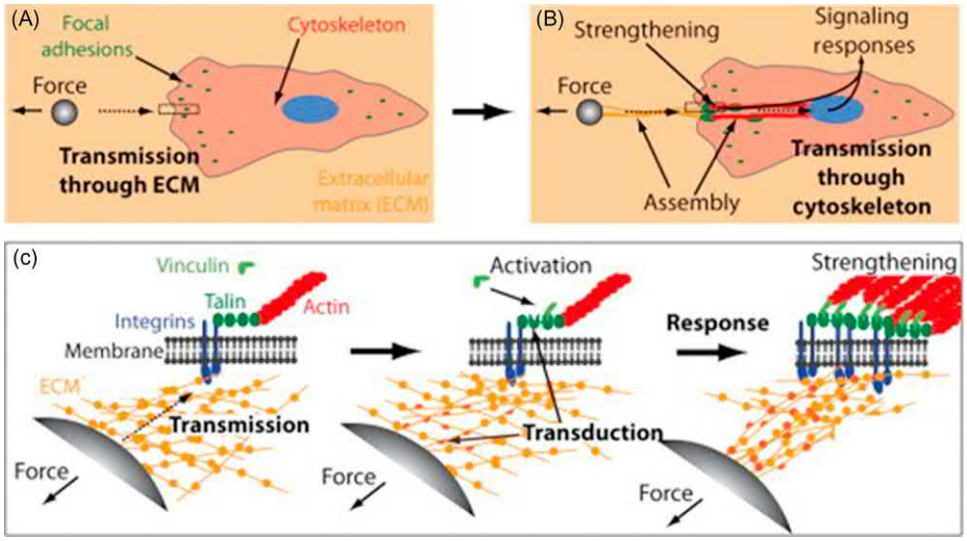

FIGURE 14.3 **Tension sensing at focal adhesions.** Mechanical properties, such as external tension, stiffness, or internal contractility, are transmitted through the extracellular matrix and sensed as tugging forces at nascent focal adhesions (A). These forces generate signals within the cell (B) that promotes the maturation of focal adhesions and strengthening of cell−substrate adhesions. At the molecular level, forces on nascent focal adhesions cause talin to undergo a conformational change (C) and expose cryptic binding sites for vinculin. Vinculin also contains cryptic binding sites for other focal adhesion−associated proteins that are exposed upon binding to talin. Other force-mediated pathways also contribute to integrin clustering and strengthening of mechanical connections with the contractile actomyosin network. *Adapted from Hoffman BD. The detection and role of molecular tension in focal adhesion dynamics. In: Engler AJ, Kumar S, editors. Progress in molecular biology and translational science. Amsterdam: Elsevier; 2014 [59].*

sites for cell anchorage and migration, protecting cells from direct impact of macroscale forces, converting and transmitting macroscale forces as microscale forces for cell sensing, providing mechanical signals such as stiffness, and serving as a reservoir of signaling molecules and enzymes [61,63]. A large body of evidence supports the role of ECM as an active player and therapeutic target in diseases such as fibrosis, atherosclerosis, aging, and cancer [63,64].

There are two major forms of organization for ECM. Connective tissue comprises fibrous three-dimensional (3D) meshes of fibrillar collagens, proteoglycans, and glycosaminoglycans [65]. Mesenchymal cells attach to and migrate along these fibers. Fibrillar collagens are the main structural component of ECM in connective tissues. The most abundant fibrillar collagen is collagen I, which forms thick, highly ordered fibers that are resistant to bending. Connective tissue also contains elastin, a loose, poorly organized protein that provides elasticity [65].

The second form is the basement membrane, which are sheet-like substrates that provide a two-dimensional (2D) surface for the attachment of epithelial and endothelial cells [66]. Basement membranes are composed primarily of collagen IV and laminin. Unlike collagen I, collagen IV forms thin meshworks instead of tight fibers, while laminin is a glycoprotein that self-associates to form sheets [67]. Both basement membrane and connective tissue contain proteoglycans and glycosaminoglycans, which are hydrophilic macromolecules that facilitate water retention. Additional proteins in ECM, such as fibronectin, thrombospondin-1, and tenascins, do not influence bulk mechanical properties of the tissue but nevertheless play important roles in modulating cell−ECM interactions and nanoscale mechanical signals [65,67].

ECM is considered a viscoelastic material, as it has both viscous and elastic properties [68]. The elastic properties of ECM are largely attributed to collagens and elastin, while the viscous properties of ECM are attributed to both the slippage of collagen fibers against each other and the restricted flow of fluid through proteoglycan and glycosaminoglycan networks [69]. Many forms of ECM contain a substantial amount of fluid, either in pockets or dispersed throughout the matrix. For example, the matrix in bone marrow contains interstitial fluid within channels termed lacunae and canaliculae, while cartilage contains fluid evenly distributed throughout the matrix [9,70]. Macroscale forces of tension and compression cause the ECM to exert differential pressures on these fluids, converting these forces into shear flow sensed directly or indirectly by cells. Through its structure and composition, ECM serves as a passive transducer of macroscale forces into mechanical signals.

The ECM also acts as a direct mechanotransducer through the exposure of cryptic binding sites and associated growth factors. Forces induce partial unfolding and

fibrillogenesis of ECM proteins, such as fibronectin, causing changes in cell−ECM adhesion and downstream responses [71]. In addition, forces promote the release of soluble factors, such as TGF-β and VEGF, that can regulate cell growth, differentiation, and ECM remodeling [72−74].

Cellular effects of mechanotransduction

Mechanotransduction is the conversion of external mechanical signals into intracellular chemical or physical events, which are directly responsible for the responses of tissues to bulk forces and other physical stimuli. Many fundamental behaviors of cells are affected by mechanotransduction, such as adhesion, spreading, migration, proliferation, differentiation, and cell−cell interactions within collectives [75].

Substrate adhesion, spreading, and migration

Many types of cells adhere dynamically to substrates through focal adhesions. Initially punctate in morphology, nascent focal adhesions are pulled by forces from the associated actin filaments toward the center of the cell against the resistance of the external substrate, generating tension that causes the focal adhesion to mature and grow larger [76,77]. Conversely, focal adhesions in the rear of migrating cells are weakened by the forces of forward migration generated elsewhere in the cell [50]. Cells are known to form larger and more mature adhesions on stiffer substrates due to increased tension. These adhesions are also more stable and show less turnover [50].

Upon adhesion to stiff substrate surfaces, many types of cells spread out by forming protrusions called lamellipodia and filopodia. Cells on a stiffer substrate are generally flatter and more spread out [78]. The application of cyclic stretching forces further causes cells to spread preferentially parallel or perpendicular to the direction of stretching, depending on the cell type and the rate and magnitude of stretch [79,80]. Cell spreading is regulated by the Rho family small GTPases Rho, Rac, and Cdc42. The activation of Rac and Cdc42 are associated with actin polymerization at the leading edge of lamellipodia, while Cdc42 activation is associated with the formation of filopodia [81]. In addition to GTP binding, the activation of both Rac and Cdc42 involves binding to the plasma membrane, which may involve microtubule-mediated transport in a mechanoresponsive manner [82].

Rho family GTPases also play a major role in cell migration (Fig. 14.4). Frontal protrusion during cell migration involves localized activation of Rho, Rac, and Cdc42 at the front of the cell. In addition, RhoA may play a role in the contraction leading to rear retraction (Fig. 14.5) [85]. The localization of Rho family GTPases is mediated by microtubules, which are asymmetrically distributed in migrating cells [82,86]. This notion is supported by the observation that pharmacologically-induced disassembly of microtubules disrupts cell polarity and directional migration [87−89].

Cells respond to not only external forces but also counter forces in response to the forces that they exert on the environment. The latter mechanism allows the cell to sense stiffness. Stiff substrates tend to enhance frontal protrusion [91−93], causing cells to migrate preferentially away from soft surfaces toward stiff surfaces. This phenomenon, referred to as durotaxis [91], is proposed to play an important role in liver fibrosis and cancer metastasis [94−96]. Recent studies show that cells tug on filopodia to sense the stiffness of the substrate in front of them before committing to protrusion [93]. Cells also migrate toward regions of less confinement in order to adopt a preferential, flatter morphology [97]. This response causes cells to avoid one-dimensional lines in favor of 2D surfaces. Inhibition of actomyosin contractility ablates the response, which supports the notion that contractile forces serve as a mechanism for probing the surrounding mechanical environment.

Cell−cell interactions in collectives

Cells often gather in groups in a multicellular organism, where they are mechanically connected to each other through cell−cell junctions. This allows mechanical responses of individual cells to be communicated to others in the collective, generating collective responses. Cell collectives exhibit diverse responses influenced by mechanical interactions between cells [98,99]. For instance, cells tend to migrate toward each other on softer substrates and separate from each other on stiffer substrates [100]. Cell collectives also respond to shallower gradients of stiffness than individual cells [101], possibly as a result of integration of responses from individual cells and/or positive feedback from cell−cell interactions. These responses then lead to the formation of higher order structures such as tissues. In some cases, such as during wound closure of embryos or epithelial monolayers, the process involves the formation of prominent contractile actomyosin bundles along the multicellular circumference of the wound [102−104]; the contraction of the bundles causes the wound to close.

Many of the responses of collectives involve coordinated movements, where the complex behavior is only partially understood. The well-known phenomenon of contact inhibition of locomotion, where cells polarize away from each other upon contact [105,106], likely represents only a small subset of responses to cell−cell interactions. In order to explain phenomena, such as collective migration, this response must be complemented by

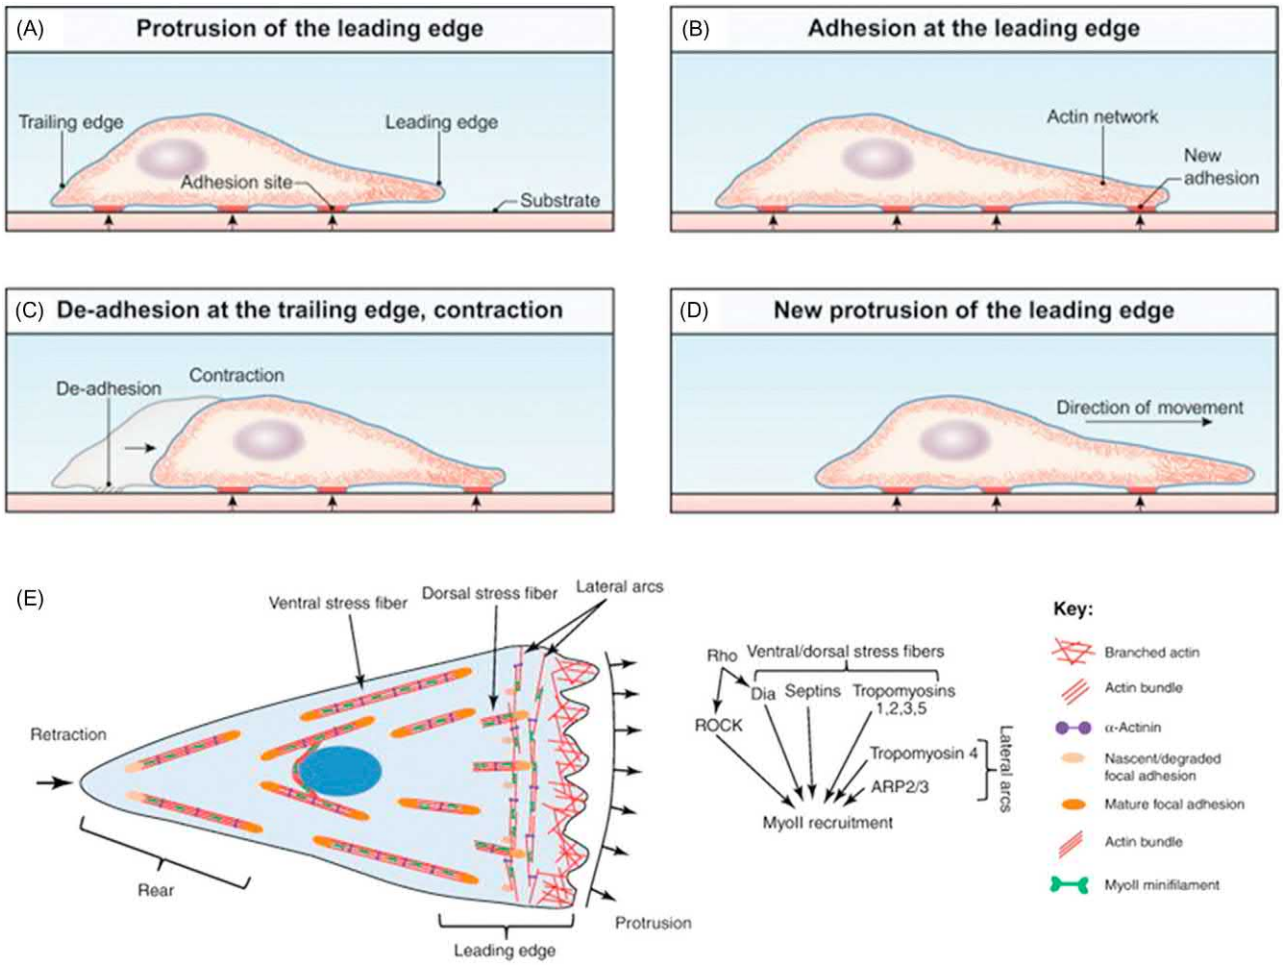

FIGURE 14.4 Mechanical processes involved in cell migration. Cells cycle through distinct processes during cell migration: protrusion of the leading edge (A), substrate adhesion at the leading edge (B), and contraction and release of adhesions from the trailing edge (C). These steps, including new protrusions from the leading edge (D), can occur concurrently, each driven by distinct components of the contractile actomyosin network (E). Actin is organized by myosin II, α-actinin, Arp2/3, and other actin-associated proteins to form the lamellipodia, filopodia, lateral arcs, and stress fibers. Several signaling pathways direct the recruitment and activation of the myosin II motor protein along the actin network to drive contraction and migration. *Adapted from Joo EE, Yamada KM. Cell adhesion and movement. In: Vishwakarma A, Sharpe P, Shi S, Ramalingam M, editors. Stem cell biology and tissue engineering in dental sciences. Amsterdam: Elsevier; 2014; Levayer R, Lecuit T. Biomechanical regulation of contractility: spatial control and dynamics. Trends Cell Biol 2012;22(2):61–81 [83,84].*

other responses. As originally proposed for the slime mold *Dictyostelium* [107,108] and recently observed with cultured mammalian epithelial cells [109], contact following of locomotion allows cells to follow the retreating edge of migrating cells upon head–tail contact. The complementary responses of contact inhibition and contact following may involve opposite mechanical signals upon the contact of different regions of the cell [105,110].

Proliferation and differentiation

Cell proliferation is also affected by mechanical signals. Matrix stiffness, cyclic stretch, and shear flow have all been found to promote proliferation and reduce apoptosis in a number of cell types [111,112]. Proliferation and apoptosis are jointly regulated by multiple mechanoresponsive pathways, including the MAPK pathway, the Hippo signaling pathway, and the MRTF–SRF pathway [112,113]. Defects in any of these pathways may compromise the control of cell growth and tumorigenesis.

MAPKs are activated by increasing substrate stiffness, cyclic stretch, or shear flow. Its downstream signaling cascade causes the relocation of transcription factors to the nucleus [114,115]. The Hippo signaling pathway involves the transcriptional coactivators YAP1 and TAZ, which relocate to the nucleus under increasing external force [116–119]. The MRTF–SRF pathway, with the involvement of myocardin, MRTF-A, and MRTF-B, is affected by mechanical signals through their effects on actin polymerization [120,121]. MRTF-A binds directly

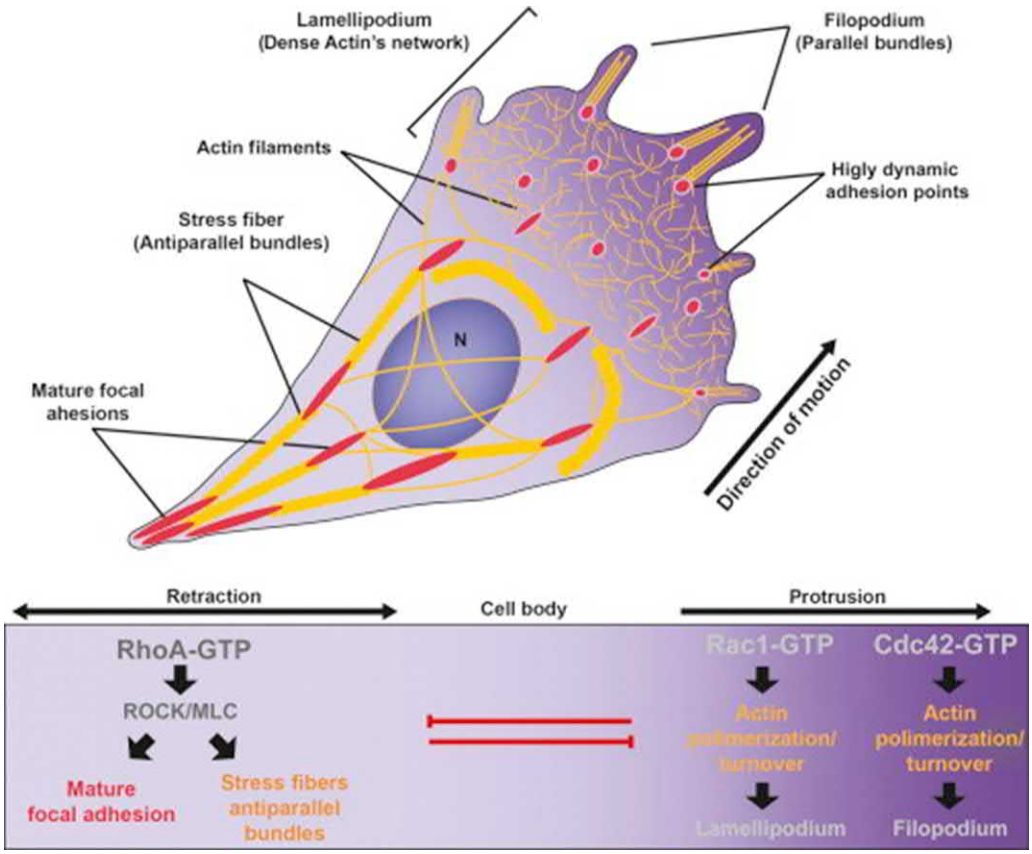

FIGURE 14.5 **Rho family GTPases contributing to cell polarity and actin reorganization.** A possibly oversimplified model of cell migration proposes distinct localization of different GTPases in different regions of a migratory cell to orchestrate the processes of protrusion and retraction. Rac and Cdc42 are found to be active in the leading edge, where they organize protrusions via lamellipodia and filopodia, respectively, while RhoA activities may promote rear contraction and release of mature focal adhesions. *Adapted from Barriga EH, Mayor R. Embryonic cell–cell adhesion: a key player in collective neural crest migration. Curr Top Dev Biol 2015;112:301–23 [90].*

to the actin cytoskeleton to regulate its assembly dynamics [122]. Internal or external stress on the actin cytoskeleton promotes actin polymerization and releases MRTF-A, which then relocates to the nucleus [75]. In all three pathways, the eventual effectors are transcriptional factors, which act to regulate gene expression [123].

Mechanical signals also affect differentiation. Softer substrates, mimicking that of the embryo, promote proliferation of various types of cells [124] as well as morphogenic activities such as neuronal branching [125]. In addition, mesenchymal stem cells differentiate toward neurogenesis, adipogenesis, myogenesis, or osteogenesis in a stiffness-dependent manner [125–127]. Cyclic stretching further guides the differentiation of muscle and tendon cells, while shear flow guides the differentiation of endothelial cells in blood vessels [128–130]. Force-mediated differentiation appears to be regulated by the same pathways that regulate proliferation and apoptosis [75], as both the MAPK and Hippo pathways play a role in the stiffness-sensitive differentiation of stem cells, while MRTF–SRF pathway plays an important role in the differentiation of fibroblasts to myofibroblasts [118,131,132].

Mechanotransduction in biological phenomena

The multitude of mechanotransduction pathways comprises a complex bidirectional signaling network that allows cells and tissues to respond and contribute to the mechanical makeup of the surrounding environment for generating a wide range of biological phenomena (Fig. 14.6). These include physiological phenomena such as wound healing and tissue morphogenesis, as well as pathological phenomena such as cancer metastasis. The examples described in this section serve to underscore the importance of mechanotransduction in biomedical science, engineering, and clinical medicine.

Wound healing

Wound healing involves coordinated migration of multiple cell populations in a manner highly responsive to mechanical cues [129]. After the initial inflammatory and coagulation responses, wounds are sealed by a soft provisional ECM composed primarily of fibrin (Fig. 14.7)

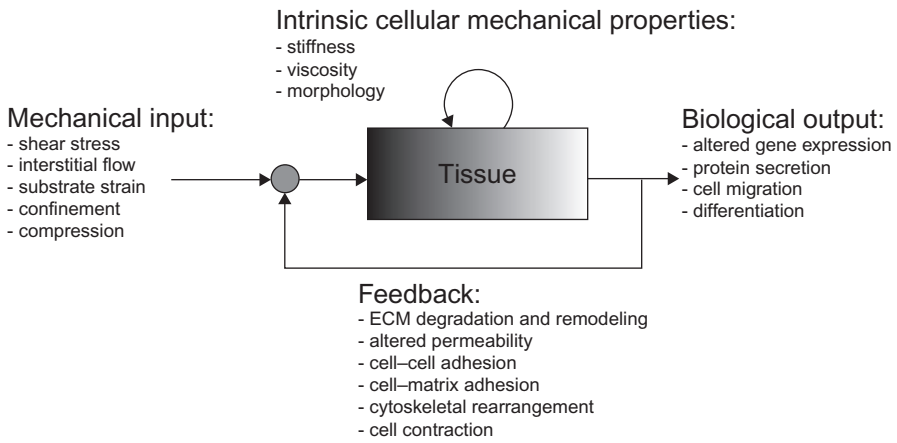

FIGURE 14.6 Conversion of mechanical input into biological output through mechanotransduction. Tissues respond to mechanical stimuli by changing both intrinsic mechanical properties and biological output. Some of these outputs affect the mechanical properties of the cell or tissue, which may constitute a feedback loop to modulate the response. This allows cells to respond to a combination of mechanical signals from both the external environment and themselves. *Adapted from Polacheck WJ, Li R, Uzel SGM, Kamm RD. Microfluidic platforms for mechanobiology. Lab Chip 2013;13(12):2252–67. Published by the Royal Society of Chemistry.*

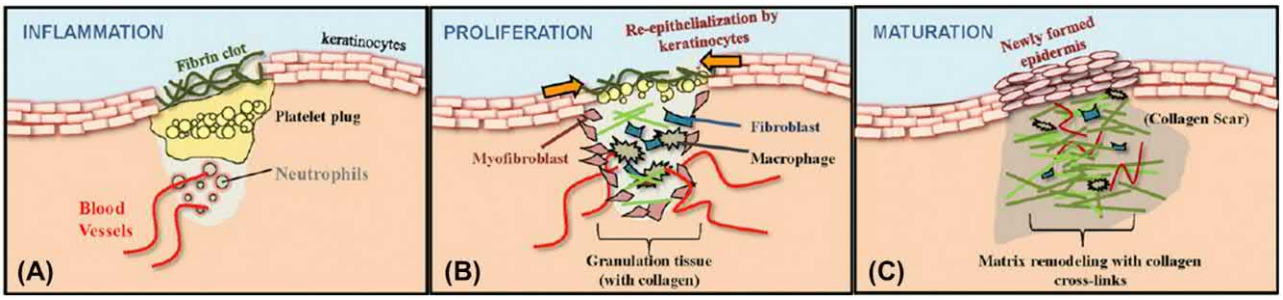

FIGURE 14.7 Progression and mechanics of adult skin wound healing. Shortly after wounding, the injury is covered by a soft provisional matrix consisting of fibrin (A). This is followed by the transformation of fibroblasts into myofibroblasts, which triggers the replacement of provisional matrix with secreted collagen (B), eventually forming stiff scar tissues (C). Simultaneously, the epidermis must migrate collectively to cover the wound (B) and prevent further infection through the compromised tissue. *Adapted from Nauta A, Larson B, Longaker MT, Lorenz HP. Scarless wound healing: from experimental target to clinical reality. In: Atala A, Lanza R, Thomson JA, Nerem R, editors. Principles of regenerative medicine. Amsterdam: Elsevier; 2011 [133].*

[133,134]. ECM stiffness and external tension are sensed by fibroblasts as tension across their focal adhesions [78], which induces their differentiation into myofibroblasts accompanied by the synthesis of collagen, alpha-smooth muscle actin, and profibrotic cytokines to effect permanent scar formation [135,136]. The deposition of collagen by myofibroblasts on the extracellular space further stiffens the matrix, driving a positive feedback loop between ECM stiffening and fibroblast transformation [137]. The mechanosensitive YAP/TAZ pathway is implicated in this pathway, as knockdown of their expression significantly inhibits wound healing [138]. In addition, myofibroblast contraction promotes further transformation of nearby fibroblasts through both integrin signaling and tension-mediated release of TGF-β1 from latent ECM reservoirs [139].

While some scar tissue is generally necessary to maintain tissue integrity, uncontrolled scar formation under pathological conditions may cause fibrosis, which can be cosmetically undesirable and, in the case of surgical adhesions, life-threatening [140]. Specifically, scars formed under excessive external tension have higher cellularity, vascularity, inflammation, and myofibroblast transformation [137], which may compound fibrosis through feedback loops between mechanical cues and matrix stiffening.

During wound healing, keratinocytes must also collectively migrate to cover the surface of the tissue [141,142]. These keratinocytes behave similarly to cell collectives in vitro, showing many of the same responses to mechanical cues. For instance, keratinocytes migrate more collectively and with greater speed and persistence across stiffer substrates [143]. Speed is essential for wound healing to limit infection. It is also beneficial for keratinocytes to migrate collectively because uncoordinated collectives leave gaps in between cells and compromise the integrity of the epithelium.

Thus tension and stiffness have both positive and negative effects on wound healing. While wounds close faster under tension, the risk of hypertrophic scarring is increased. Understanding the mechanical influences on closure speed and scar formation will assist in the identification of optimal conditions for accelerated healing with minimal scarification.

Tissue morphogenesis

Tissue morphogenesis is the process of organizing the spatial distribution of cells during embryonic development. During this process, cells undergo proliferation, migration, and differentiation to form complex tissues and organs. These processes are governed by both soluble factors and mechanical forces. Understanding how these conditions influence morphogenesis will assist not only in understanding many normal and defective developmental processes but also in recapitulating the regenerative mechanism for tissue engineering applications [144].

Embryos are subject to a complex system of forces that guide their development. Mechanical forces and responses play complementary roles in tissue morphogenesis. First, cells can generate forces to induce tissue-wide movements. Second, forces from both inside and outside of the tissue may serve as signals for cells to differentiate and migrate, and for nascent tissues to remodel into specialized organs. These cells may in turn generate mechanical signals or modify their mechanical environment to influence surrounding cells.

Cell-generated forces can lead to complex temporal and spatial patterns of mechanical contraction that orchestrate large-scale movements (Fig. 14.8) [144]. In epithelial cells, these forces are transmitted to neighboring cells through cell−cell adhesions located apically. When the tension across these adhesions is higher than the bending resistance of the supporting substrate, epithelial cells can cause the substrate to lift up and curl in the apical direction in a process termed apical constriction [145]. Apical constriction functions to guide tissues into many shapes such as folds, pits, and tubes [146,147]. In addition, several important developmental checkpoints require this process, as illustrated by neural tube closure and mesoderm invagination during gastrulation in *Drosophila* [146,148]. Actomyosin contractility also plays roles in other aspects of embryonic development, such as cell

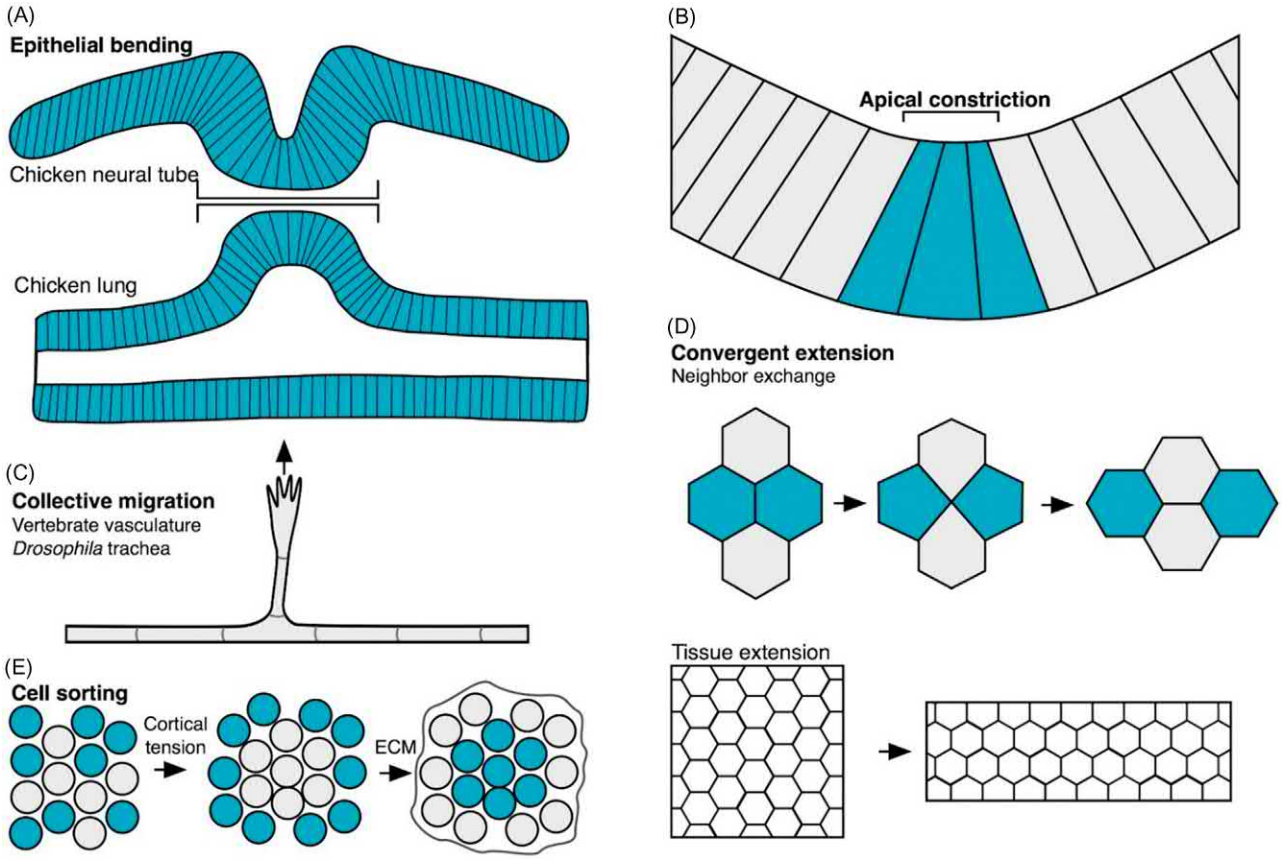

FIGURE 14.8 Mechanical interactions during tissue morphogenesis. Epithelial layers bend (A) during morphogenesis of the neural tube and lung in chicken embryos. This bending, termed apical constriction, can be initiated by actomyosin contraction of the apical epithelial layer of epithelia (B). Cells can also collectively migrate to form lumens in the vertebrate vasculature and *Drosophila* trachea (C). During tissue extension (D), cells rearrange the junctions with their neighbors to generate compaction in one direction and extension in another. Finally, cells can segregate themselves into discrete populations through cortical tension, differential binding among different cell types, and cues from the extracellular matrix (E). *Adapted from Roper K. Integration of cell−cell adhesion and contractile actomyosin activity during morphogenesis. In: Yap AS, editor. Current topics in developmental biology. Amsterdam: Elsevier; 2015.*

intercalation and collective migration, during elongation along the anterior–posterior body axis [144,149].

As organs begin to develop rudimentary functions, they generate macroscale forces that are sensed by cells within their own tissues and those in nearby tissues. These forces help reinforce differentiation and development into specialized organs [144]. One example is fluid shear stress, which modulates vascular remodeling and pruning in the mammalian yolk sac [150]. Fetal breathing–like movements also generate amniotic fluid flow in the developing lungs, which accelerates lung growth and pulmonary cell differentiation [151].

Other mechanical forces include the tension generated by developing muscles, which feeds back to promote muscle differentiation and strengthen cell–cell junctions [60]. Since bone is mechanically coupled to muscles, these forces also promote morphogenesis and strengthening of developing bones [152]. Together, these physical forces act to guide developing tissues toward proper morphogenesis and development.

Cancer metastasis

Cancer morbidity is closely associated with cell migration away from the primary tumor site and establishment of metastases in distal locations termed metastasis. For effective intervention of metastasis, it is important to understand how cancer cells navigate the complex environments. Recent studies have highlighted the importance of mechanical cues, such as matrix stiffness, topology, confinement, shear stress, and mechanical stretching, in metastatic behavior [153].

Tumors are mechanically distinct from normal tissues. They are typically stiffer, due to both an abnormally high concentration and alignment of ECM proteins [154] and the transformation of surrounding fibroblasts, termed cancer-associated fibroblasts, into myofibroblasts [155]. In addition, leaky vasculature from faulty angiogenesis causes an increase in interstitial fluid pressure, which is sensed as tension and shear flow within the tumor [156]. These mechanical cues are known to affect cancer behavior, albeit in a varied manner. Mammary cancer cells metastasize more successfully on stiffer substrates, while other cancer cells appear to lose the ability to respond to variations in stiffness [157,158]. The mechanical stretching induced by fluid pressure causes increased proliferation of some cancer cells through the YAP/TAZ pathway, while other cancer cells lose their responsiveness to shear flow [119]. The varied cancer cell responses to mechanical cues, paralleling their equally varied origins [153], represent one of the major challenges in cancer treatment.

Metastasis initiates with migration of tumor cells away from the primary tumor. The migration is facilitated by the concurrent migration of surrounding cancer-associated fibroblasts, which leave behind trails of highly aligned collagen and fibronectin fibers (Fig. 14.9). The stiffness of these ECM trails may further enhance the migration of tumor cells away from the primary tumor with a high persistence and velocity [159–161]. Distinct mechanical characteristics of tumor cells may facilitate their preferential invasion in certain tissues. For example, migration through the dense bone matrices may be facilitated by a deficiency of nuclear lamin A/C, which manifests as a thinner nuclear lamina, weakened nuclear lamina, and increased deformability of the nucleus to allow cells to squeeze through very small pores that are otherwise impassable to normal cells [162,163].

Cancer cells must navigate through the vasculature and establish themselves at new locations in order to successfully metastasize. Recent studies have suggested that clusters of cancer cells can leave the primary tumor and migrate in a collective fashion to establish metastases [165]. Observed in the circulation, these circulating tumor clusters have been linked to greater numbers of distal metastases and increased morbidity [166]. It is possible that the mechanical strength and integrity of cell–substrate and cell–cell adhesions of cell clusters generate favorable microenvironments to aid the survival of tumor cells [167–169]. Evidence further suggests that these clusters can rearrange themselves into linear trains to pass through thin capillaries and remain within the circulation, which allows them to establish themselves in other areas of the body instead of merely downstream of the circulation [169].

From the initial survival within the primary tumor site to successful metastasis, the behavior of tumor cells appears to be intimately associated with the mechanical cues they experience. Complete understanding of these processes will allow the development of new therapies to stop the uncontrolled spreading of malignant cells, particularly those from highly invasive cancers such as melanoma.

Mechanobiology in tissue engineering

A thorough appreciation of mechanotransduction mechanisms will also facilitate new engineering applications that require seamless integration with biological systems. It is now realized that mechanical incompatibility represents one of the major causes of failure of procedures or devices involving cell interactions. Recent advances in mechanobiology have paved the road leading to novel techniques and therapeutic developments. In this section, representative examples of tools and therapies that are reliant on an in-depth understanding of mechanobiology are highlighted.

Bone-implant design

Artificial implants are used to recapitulate bone and joint function in dentistry and orthopedics. These implants are

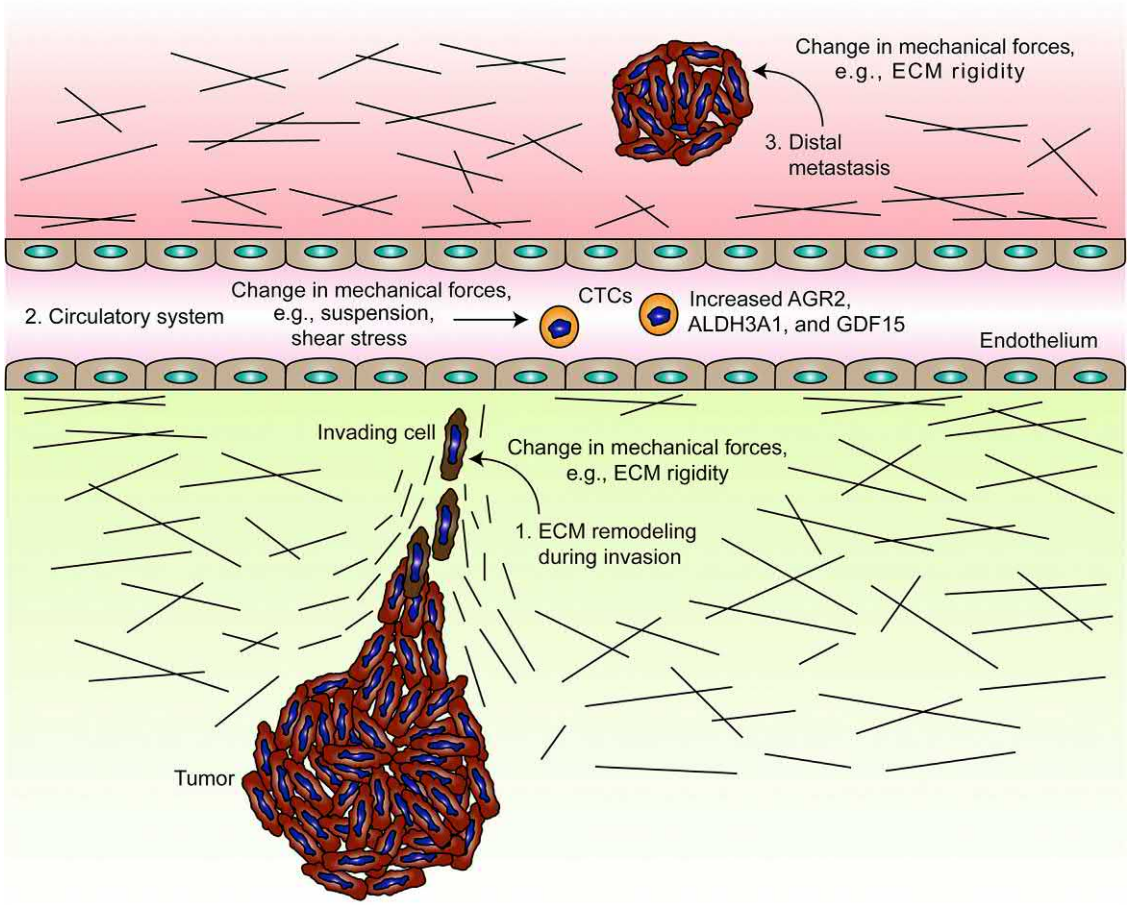

FIGURE 14.9 **Mechanical processes involved in cancer metastasis.** Cells of primary tumor and cancer-associated fibroblasts migrate out and remodel the local extracellular matrix, forming tracks of aligned collagen and fibronectin that promote further migration away from the tumor. After intravasation to enter the blood stream, these circulating tumor cells and clusters may use their actomyosin cytoskeleton and cell–cell adhesions to survive the shear flow and narrow constrictions in the circulatory system. The cancer cells then extravasate and establish secondary metastases, preferentially at sites that have mechanical properties ideal for their proliferation. *Adapted from Aw Yong KM, Sun Y, Merajver SD, Fu J. Mechanotransduction-induced reversible phenotypic switching in prostate cancer cells. Biophys J 2017;112(6):1236–45 [164].*

often made of rigid metals, such as pure titanium or titanium alloys, fastened to native bone [170,171]. After the initial implantation, the stability of the implant is determined by the ability of the body to grow and sustain normal bone structure around the implant in a process called osseointegration [172].

Osseointegration of bone implants requires both bone formation and bone resorption. The same mechanical cues that drive native bone remodeling turn out to also drive the stabilization of artificial bone implants. Native bone is subjected to cycles of compression during movement, which cause osteoblasts and osteoclasts to increase bone formation and decrease bone resorption, respectively [9]. Several techniques have been developed to promote osseointegration, such as coating the surface of the metal with hydroxyapatite, the main chemical component of the bone [173]. Both direct cyclic loading of the implant and loading the entire bone-implant composite have been shown to significantly improve the formation of bone at the implant interface, suggesting that mechanical cues may be used in conjunction with conventional pharmacological treatments to promote osseointegration [170]. These cues could be delivered through a surgical implant, through physical therapy or novel noninvasive therapies, such as whole body vibration [174].

Despite these efforts, the effective lifetime of artificial bone implants remains lower than desirable. Although mechanical loading of the implant promotes bone formation, bone resorption still occurs near the interface [170,175]. Currently, the metals used in these implants are at least an order of magnitude stiffer than the bones they are meant to replace [175,176]. In addition, the implants do not possess the same variations in stiffness that are present in native bone architecture [176]. These differences expose bone structures surrounding the implant to different mechanical conditions from those

seen in native bones, which leads to abnormal patterns of bone formation and resorption and weakening of the bone around the implant (Fig. 14.10) [175,177]. To mitigate these effects, implants are being designed that have comparable architecture and stiffness to native bones [178–180], based on the understanding that decreasing stiffness also tends to increase interfacial stresses between the bone and the implant to cause bone resorption [175]. To promote osseointegration and long-term stabilization of the implant, implants should present the same pattern and magnitude of mechanical signals to the surrounding tissue as the native bone [178–180].

Organs-on-a-chip

Organs-on-a-chip are microfabricated devices designed to recapitulate the function and morphology of an organ. The prevalent experimental models used in biological studies and drug discovery have been 2D culture systems and animal models. Conventional 2D culture systems, such as flat monolayers on tissue culture polystyrene, are inexpensive but fail to capture many of the physiological environmental cues that are important for generating the characteristics of cells in living organs. These spatiotemporal cues include mechanical, chemical, and electrical signals. In contrast, animal models are expensive and often overly complex for the purpose. The results from animal models also fail to apply to human patients in many cases due to cross-species differences. The organ-on-a-chip approach is intended to address the shortcomings of these conventional model systems by recapitulating many of the native environmental characteristics through the placement of cultured cells in microfabricated constructs [183].

A number of such organ-on-a-chip devices have been designed as models for organs, including bone, brain, blood vessels, and lungs [184–187]. In the process of recapitulating the native environment for each organ, several techniques have been developed to reproduce the respective mechanical cues (Table 14.1). For example, the native stiffness in the model organ is recapitulated by adjusting the stiffness of the polymeric materials used in the chip. Notable polymers used in organ-on-a-chip designs are polydimethylsiloxane and polyacrylamide; both have tunable stiffness depending on the composition of monomers and cross-linkers [91,188,189].

To recapitulate organs with cyclic patterns of tension, the device may incorporate cells cultured on flexible membranes undergoing cyclic stretching, which are stretched by applying vacuum to the compartment opposite from the cell [187,190]. A similar approach has been taken to recapitulate the cyclic patterns of compression that the musculoskeletal system are subject to, by using hydrodynamic expansion to exert compression on cell culture chambers [191].

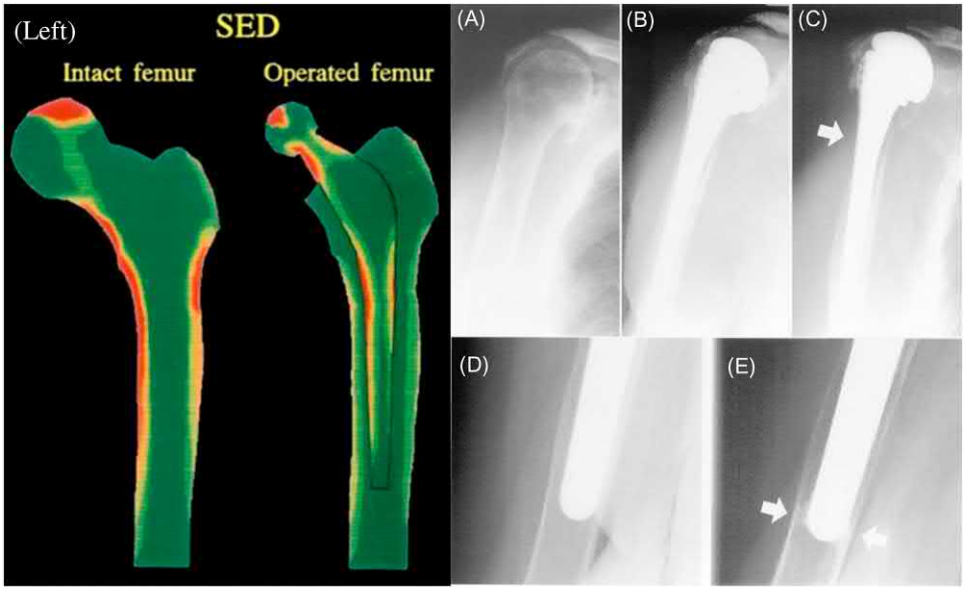

FIGURE 14.10 Stress shielding and abnormal bone remodeling resulting from unmatched mechanics of bone and implant. The strain energy density profile of bone tissue (left) in the proximal femur is drastically altered by the placement of a femoral stem implant, as shown here through finite element modeling of the native proximal femur and the composite after implantation. Differences in bone mechanics are felt by osteoblasts and osteoclasts in the bone tissue as differences in compression and shear flow. This results in abnormal patterns of bone resorption (A–C, *arrow* indicates site of bone resorption) and bone formation (D–E, *arrows* indicate site of bone formation) around the implant that are predicted by the differences in mechanics from finite element modeling. *Adapted from Sumner DR. Long-term implant fixation and stress-shielding in total hip replacement. J Biomech 2015;48(5):797–800; Nagels J, Stokdijk M, Rozing PM. Stress shielding and bone resorption in shoulder arthroplasty. When designing microfabricated devices to recapitulate the vasculature or interstitial tissue, it is necessary to recapitulate the fluid flow profiles that cells experience [192]. Model vasculature may be fabricated by seeding cells on the inner wall of a microfluidic channel. For interstitial tissues, cells may be seeded in a 3D scaffold perfused with fluid. Complex flow profiles may be reproduced through model vasculature or interstitial tissues using programmable flow pumps to create steady or pulsatile flows. In addition, laminar or turbulent flow profiles have been created by tuning the microfluidic channel tortuosity [193,194]. Computational fluid dynamics simulations have been used to help predict the exact fluid flow for a given microfluidic design or pump setting to allow rapid design and optimization [195].

Compared to cells without proper mechanical cues, cells cultured on systems incorporating optimal mechanical and chemical features display behaviors more closely

mimicking those in vivo, including proliferation, adhesion, and differentiation [1,183,187,190,191,194]. Much advancements are expected as the field of tissue engineering develops increasingly sophisticated approaches and devices to recapitulate critical features of physiological conditions.

Part Three

In Vivo Synthesis of Tissues and Organs

Chapter 15

In vivo engineering of organs

V. Prasad Shastri

Institute for Macromolecular Chemistry and Centre for Biological Signalling Studies, University of Freiburg, Freiburg, Germany

Introduction

Organogenesis is a phase during embryonic development that commences at the end of gastrulation and continues until adulthood and encompasses the process of organ formation from germ layers. Organogenesis requires intricate orchestration of transcription factors and signaling pathways and is under the control of spatiotemporal gradients of trophic factors, chemokines and cytokines. While some organs (e.g., skin, liver, and bone) and tissues (epithelial barriers) are capable of repairing and restoring cellular and physiological homeostasis, most tissues and organs are incapable of repairing following extensive injury as many of the signaling paradigms and regenerative processes that are active during development are not accessible in adulthood. Therefore the key to in vivo engineering of tissues lies in not only identifying cell populations that have pluripotency or capability of restoring the cellular complexity of a tissue (or organ) but signaling molecules that can drive cellular organization and homeostasis. Unfortunately, invoking such processes within the vicinity of diseased or damaged organ poses several challenges, including compromised vascularity, extensive loss of tissue volume, and importantly overcoming degenerative processes (soluble signals, signaling pathways) that are prevalent immediately following insult or disease onset.

Conceptually speaking, tissue engineering can provide a blue-print for organizing cells into functional units. However, the plurality of cells, each with their own unique signaling microenvironment and metabolic demands; and complexity of cellular organization for example in the liver, intestinal crypt, bone can never be faithfully replicated through a conventional tissue engineering paradigm. So, the engineering of tissues with high degree of cellular organization, vascularity, and innervation requires a more radical approach, the one that leverages the innate processes of repair and regulation found within the mammalian body to promote complexity from a well-defined (or a simplified) starting point.

Historical context

One could argue that the ultimate objective of tissue engineering as a discipline is to gain the technical competency to be able to invoke and control biological processes "on demand" and more specifically in a manner so as to drive regeneration and healing. Our own quest in the mid-late 1990s for developing a new paradigm for engineering complex tissues in vivo was motivated in an environment enriched by many successes in the laboratories of pioneers in the Cambridge and Boston area such as Prof. Langer, Prof. Vacanti, Prof. Bell, Prof. Yannas, and Dr. Bruke. For example, Yannas and Burke showed for the first time that a biomaterial with defined physiochemical characteristics could orchestrate the recruitment and organization of cells into a complex structure such as the skin [1–3]. This led to the first skin regeneration product that is still on the market. Incidentally, skin is the largest organ and one could argue that this was the first attempt to de novo engineer a tissue. Langer and co-workers had shown that cardiac myocytes when associated with a polymer scaffold can spontaneously contract and exhibit electrophysiology similar to native cardiac tissue [4]. These efforts solidified the tenets of tissue engineering (also referred to nowadays as regenerative medicine to place it in a broader context) and laid down the well-accepted approach of engineering tissue constructs by marrying concepts from materials science with cell biology, biological process engineering, and clinical-use parameters. During this phase, a huge emphasis was placed on scaffold design [5,6] and developing bioreactors [7] to control cellular environments based on a simplified notion of what a cellular microenvironment should encompass,

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00016-2

and it resulted in an ad hoc approach of incorporating fluid dynamics, soluble signal (growth factors, proteins) delivery, and biomechanical cues to control cell function. Concurrently, the access to totipotent cells and pluripotent cells [mouse and human embryonic stem cells and mesenchymal stem cells (MSCs)] solidified the narrative that ex vivo engineering of any issue type was within reach [8,9]. But time would tell that this conclusion was rather premature, and alternative approaches to engineering tissue are even more critical today than it was two-and-half decades ago. Nonetheless, in recent years there have been a few notable successes such as joint resurfacing using cartilage engineered from nasal chondrocytes [10]; however, the transplantation of engineered organs such as bladder remains close but elusive [11].

As stem cell populations were being identified, ways to control their phenotype became a prominent scientific endeavor, and the value of traditional 2D tissue culture in this effort was being questioned. Three-dimensional (3D) environments readily accessible with the tools of tissue engineering became therefore highly attractive. Studies showing lineage-specific differentiation of MSCs [8] and trans-differentiation of primary tissue-derived cells [12–14] (of which today there are numerous examples [15–17]) clarified the role for 3D culture in leveraging the benefits ushered in by stem cells. However, lack of access to reproducible and well-defined population of stem cells, and time consuming and costly isolation procedures, difficulties in getting cells to organize into anything with the semblance of tissues were seen as huge limitations. For example, although liver stem cells were identified and isolated [18–21], reconstituting liver-like structures from these cells was met with little success and the best outcomes were still attained by only using freshly isolated hepatocytes.

In the case of bone, a highly vascularized and innervated organ with a complex cellular composition and intricate architecture, bone cells (osteoblasts) alone are not sufficient to achieve this cellular complexity as vascularization and innervation which are central to the formation and structure of bone are not realizable in vitro. In this backdrop, many viewpoints emerged questioning the merits and demerits of synthetic materials as a scaffold versus biological materials such as collagen, the role of ex vivo manipulation and nurturing of tissue constructs using bioreactors versus leveraging innate biologically relevant repair paradigms (and processes), and also how much of engineering was necessary.

Nature's approach to cellular differentiation and organization

During development, the formation of *primitive streak* in the blastula is responsible for the initiation of bilateral symmetry, germ layer formation (i.e., it is in the primitive streak that endodermal and mesodermal progenitors arise) and anterior–posterior symmetry [22] through the out migration and organization of endodermal and mesodermal progenitors eventually resulting in the formation of a second embryonic axis. In fact, during development all mesodermal cells are generated in the primitive streak by epiblasts undergoing epithelial–mesenchymal transition [23,24]. It is well established that the formation of the primitive streak requires well-orchestrated gradients of WNTs, fibroblast growth factors (FGFs) [23,25], bone morphogenetic proteins (BMP 4 and BMP 7), and Nodal a mesoderm inducer from the transforming growth factor (TGF)-beta superfamily of proteins [22]. Likewise, the patterning of the limb buds during limb development commences with the condensation of MSCs into a mesenchyme and the formation of the apical ectodermal ridge, and signaling feedback loops between these two cell populations (epithelial and mesenchymal) leads to patterning and development of limbs [26,27]. So, it is clear that the cellular patterning and organogenesis require precise spatiotemporal control of soluble signals. Current strategies for delivering soluble signals such as FGF-2, vascular endothelial growth factor (VEGF), and BMPs [28], to name a few, depend on either controlled release systems (microspheres, liposomes, and nanospheres) or extracellular matrix–mimicking polymers to electrostatically bind and release morphogens and growth factors, and these have been explored in the induction of new blood vessels (angiogenesis) [29], bone repair, primarily in spinal fusion, and long bone defects where they have received United States FDA approval [30,31] and innervation with varying degrees of success [32,33]. However, signal gradients and pattern in vivo are seldom generated by varying the soluble signals (FGF, BMP, and WNT) but through positive and negative regulators of the soluble signals and their signaling pathway [22,24]. Furthermore, it is now well established that proximodistal and anteroposterior patterning is controlled by an epithelial–mesenchymal feedback loop involving four-dimensional patterning involving positive and negative feedback loops rather than varying morphogen thresholds [34]. Such complex signaling can be realized in part using gradient generating systems [35]; however, implementing such systems in vivo is a tall order. Another aspect of soluble signal delivery is that the responsiveness of cells to soluble signals can vary drastically. For example, while epithelial cells show saturation in WNT pathway signaling with increasing WNT3a concentration, MSCs show no such tendencies [35]. Also, delivery of a single or a cocktail of morphogens can lead to unintended consequences that may be difficult to reverse once initiated. So, it is clear that conventional approaches are less practical and therefore endogenous means of invoking and controlling signal gradients should be the way forward.

It is within this evolving landscape, an idea was conceived as to how one might approach this challenging task of engineering an entire organ in vivo by bypassing many of the steps (cell isolation and expansion, culturing in bioreactors, scaffolds and growth factor delivery) involved in traditional tissue engineering. This concept was called the in vivo bioreactor (IVB).

Conceptual framework of the in vivo bioreactor

Biological systems are inherently noisy [36], and this noise stems from thermal fluctuations that can alter protein structure, receptor−ligand binding rates, diffusion and the fact that activating a kinase can lead multiple proteins being phosphorylated, and they might in turn have more than one binding partner [36,37]. Randomness leads to probabilistic rather than linear outcomes in signaling. For example, if a niche is physically limited, only a few cells can reside in the niche and as a result the outcomes are governed by chance (roll of a dice). So, one way to impose order over chaos is to introduce a strong global cue, something that will synchronize the immediate cellular microenvironment. Hence, in a noisy environment, for a biological information to stand out, it has to be either super specific or overwhelming. That is, knowing which signal is important and how to boost it would be critical to drive the signaling cascade [38].

Therefore the cornerstone of the IVB concept is that biological systems are inherently noisy and hence even a single, but appropriate signal, could completely alter the entire signaling landscape. While, in biology, the signals that are considered relevant are biological in origin (growth factors, proteins, enzymes, RNA, microRNA, virus), the source of signal in the IVB paradigm can be biophysical in nature or can couple to the cellular microenvironment through *mechanosensing* elements to initiate a mechanobiology paradigm and is introduced from the outside into the cellular environment. Such signals (or cues) originate in the physiochemical attribute of intervention and thus ensures that this signal is localized, readily replicated and also finite (in quantity and time).

The challenge is in identifying a set of conditions under which cellular signaling can be controlled in a defined region so as to drive predetermined outcomes. The following four criteria are deemed necessary for the IVB paradigm to be operative and viable (Fig. 15.1):

1. Identifying a location (ectopic or orthotopic) in the body with an inherent source of pluri- or multipotent cells or progenitor cells.
2. Establishing a privileged microenvironment that excludes other cell populations.
3. Presenting a single biophysical or soluble cue that can overcome stochastic biological noise.
4. Defining a volume for the regenerative process.

At the time of the conception of the IVB, it was envisioned that a successful outcome would for the first time present an approach for an autologous solution for organ and tissue transplantation and addressing the core objective of tissue engineering.

Based on the above principles, thus far three distinct cellular organization processes leading to organ and tissue formation have been realized and are discussed here. Furthermore, the opportunity to explore the IVB paradigm in liver regeneration and restoring cellular and signaling homeostasis in brain tissue is presented.

In vivo bone engineering—the bone bioreactor

The first example of the IVB was the bone bioreactor published in 2005 [39]. Engineering bone has always been challenging and much of the effort in the late 1990s and even today has focused on a cell implantation approach, involving isolation of stem cells, preferably marrow-derived stem cells (MSCs), ex vivo expansion, and then associating cells with a scaffold (polymer or ceramic) and implantation of the cell laden scaffold at the site of injury. This approach basically fails to address a key aspect of osteosynthesis, which is vascularization and has to precede bone formation [40−42]. A decade and a half later, there is clear evidence that organotypic vasculature is critical for organ homeostasis [43,44]. So, the IVB concept was as much appealing then as it is now.

Bone formation proceeds during embryonic development by two distinct pathways: (1) the direction ossification by osteoblasts depositing matrix [intramembranous ossification (IMO)] and is the pathway by which flat bones such as the facial bones and skull are formed and (2) the conversion of a provisional cartilage matrix deposited by condensing MSCs by infiltrating bone progenitor cells [endochondral ossification (EO)] and is the pathway by which long bones are formed. Long bones have two membranes: the outer membrane called periosteum that faces the connective tissues and the inner membrane called endosteum, which faces the marrow cavity. The periosteum membrane is composed of an outer fibrous layer, which is highly vascularized, and inner *cambium* layer adhered to the cortical bone surface via Sharpey's fibers and rich in cells—the *periosteal cells*—that have many of characteristics of MSCs [45,46]. Interestingly, periosteum has been shown to play a role in fracture healing and necessary for EO process and is the source of many of the signals necessary for bone repair [45,47,48]. The subperiosteal space essentially meets two of the

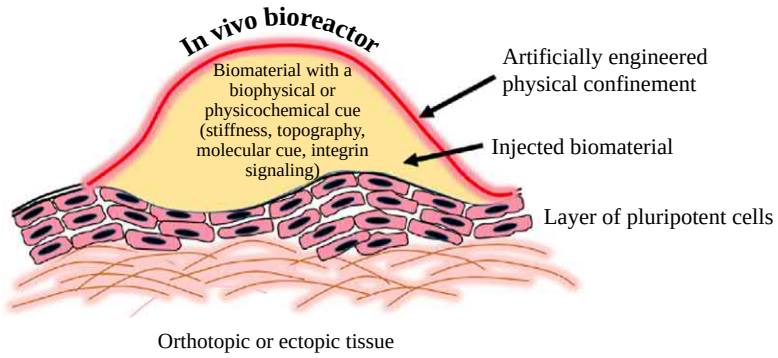

FIGURE 15.1 Schematic showing the various key elements of the IVB paradigm and their crucial roles in ensuring optimal engineering of organ or tissue. *IBV*, In vivo bioreactor.

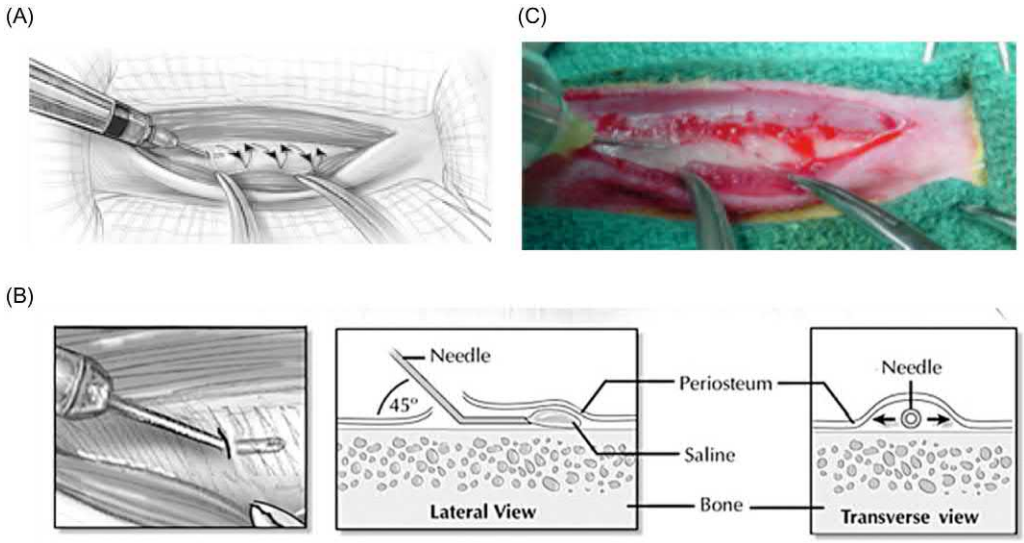

FIGURE 15.2 *Creation of the IVB.* Artist rendition of the periosteal hydraulic elevation procedure (A and B) and photomicrograph showing the needle insertion step in a tibia of a New Zealand white rabbit (C). A 25-ga need bent at an obtuse angle is inserted with the needle axis parallel to the tibial surface and needle opening facing down, thus ensuring that the needle does not pierce through and out of the periosteum. Through fanning motion, a desired breadth of the periosteum can be gently liberated from the underlying cortical bone surface, thus ensuring preservation of the pluripotent cell-rich cambium layer. *IBV*, In vivo bioreactor. *Reproduced with permission from Marini RP, Stevens MM, Langer R, Shastri VP. Hydraulic elevation of the periosteum: a novel technique for periosteal harvest. J Invest Surg 2004;17(4):229–33. Illustration by Fairman.*

criteria for an IVB, namely, it is a source of pluripotent cells and endogenous signaling molecules, it can easily be accessed surgically and can serve as privileged environment if properly manipulated. Surgical manipulation of periosteum is done using periosteal elevators, which are chisels that are used to peal the periosteum back from the cortical bone surface. This procedure, in addition to running the risk of damaging the bone surface and the cambium layer, is also invasive and moreover the area below the peeled back periosteum would be accessible to other infiltrating cells that could impede the healing response. So a new surgical technique called the *hydraulic elevation* was developed [49]. In this novel approach, the subperiosteal space is accessed using a needle inserted at an obtuse angle and Ringer's solution or saline is introduced under hand-pressure using a syringe attached to the needle and the desire area to be lifted is defined by varying the lateral position and the penetration of the needle (Fig. 15.2). This gentle method essentially lifts the periosteum from the cortical bone surface while preserving its structural and cellular integrity [49]. Periosteal explants obtained using this approach were shown to be fully viable in organ cultures ex vivo [50]. This approach ensured that the elevated periosteum represented a confined and privileged space for the introduction of the signal, and the volume for generation of neotissue could be easily defined by injecting a hydrogel.

Although periosteum is rich in growth factor and cytokines, insult to periosteum always results in chondrogenesis. Now the question was what could be an ideal soluble signal to introduce to influence periosteal cell fate? We theorized that, since in EO process, hypertrophy in chondrocytes and matrix calcification precedes bone formation, a calcium (Ca)-rich microenvironment might tip the

balance away from the natural tendency of periosteal cells to undergo chondrogenesis and toward bone formation. Interestingly, calcium can have proliferative effect on cells at certain concentrations [51] and calcium-related signaling events are essential for proliferation and organization of endothelial cells (ECs) [52,53]. Alginate gels that have a long history in cell encapsulation are a natural source of calcium, as calcium is necessary to induce ionic-crosslinking to form the gel. So, in theory, an injection of Ca-alginate should be sufficient to introduce a strong signal—calcium—within the confined subperiosteal space. To our surprise, injection of Ca-alginate within the subperiosteal space in the tibia of skeletally mature rabbits not only induced rapid proliferation of periosteal cells but also induced angiogenesis and exclusively direct bone formation with very-to-little cartilage matrix (Fig. 15.3A) [39]. Essentially, the formation of new bone within the bone IVB had all the hallmarks of IMO and recapitulated a textbook process for osteosynthesis (Fig. 15.3B) and over a 6-week period matured to exhibit microstructure similar to cortical bone (Fig. 15.3C). Importantly, the bone engineered within the IVB could be harvested without damage to the tibial surface and transplanted into a contralateral tibial defect where it underwent remodeling and fusion with the tibia. In validation of the IVB concept, a dominant signal can override stochastic biological noise; growth factors that can enhance bone formation were introduced but had no effect on the quality or quantity of new bone formed [39]. *To date, the in vivo bone bioreactor remains the only example of autologous bone engineering purely through the judicious choice and placement of a biomaterial without any cell transplantation or exogenous supplementation of growth factors.*

The formation of neobone within the IVB is counter intuitive for the following reasons. One, it does not obey Wolff's law which is, bone forms in response to load along lines of mechanical stress [54], and the bone formation in the IVB occurs from the periosteum that is not physically connected to the tibia and hence does not perceive any load from the tibial axis; second, as stated earlier, repair of long bones involving periosteum occurs through EO pathway, yet here in the bone IVB paradigm direct deposition of bone from periosteal cells that had undergone differentiation to osteoblasts was observed, that is, essentially an IMO pathway of bone formation. This confounding observation can be rationalized on the basis of a recent study by Sarem et al., where it was shown that high concentration of calcium results in hyperstimulation of extracellular calcium sensing receptor (CaSR) in MSCs, and this in turns leads to a massive downregulation in the expression of parathyroid hormone

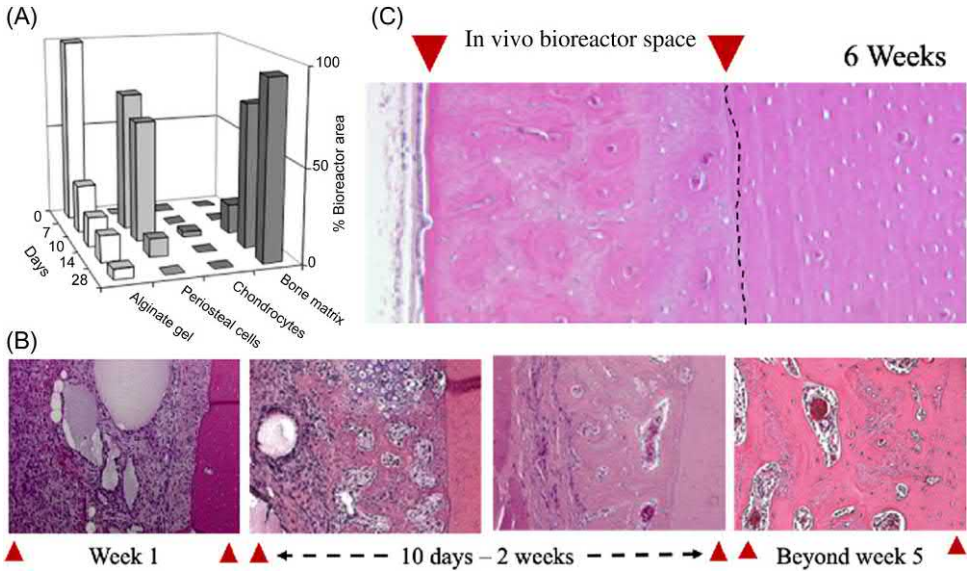

FIGURE 15.3 *Progression of osteosynthesis in bone IVB.* Graphical representation of the changes in cellular composition and resorption of alginate biomaterial over a 4-week period (A). The first 2 weeks are dominated by the proliferation of periosteal derived stem cells, followed laying down of bone matrix by these as they undergo osteogenic differentiation. This process shows clear inverse correlation with degradation of alginate. The absence of any significant population of chondrocytes confirms bone formation through the intramembranous ossification pathway. Hematoxylin–eosin stained sections of the IVB over time showing the cellular events and tissue remodeling occurring within the IVB over a 4-week period (B). Hematoxylin–eosin stained cross section of the IVB and the adjacent native tibia showing the maturation of bone and formation of cement lines and bone lacunae (C). The dashed line demarcates the native bone surface from the IVN environment. Note the absence of any fusion between the bone in the IVB and the tibial cortical bone. *IBV*, In vivo bioreactor. *Reproduced with permission from Stevens MM, Marini RP, Schaefer D, Aronson J, Langer R, Shastri VP. (PTH) 1 receptor (PTH1R), which is critical for MSC-chondrogenesis [55]. Furthermore, it was shown that the exposure of MSCs to synthetic PTH could reverse the effects of the CaSR−PTH1R differentiation axis in MSCs and partially rescue MSCs from entering osteogenic differentiation [55]. This finding could provide an additional strategy to control periosteal cells fate choices within the IVB environment through administration of agents that modulate PTHIR signaling.

In vivo cartilage engineering

Since periosteal cells can give rise to both osteoblasts and chondrocytes, we inquired if overwhelming the IVB environment with a molecule that can interfere with angiogenesis can alter the fate of periosteal cells. Suramin is a small molecule inhibitor of the TGF-beta superfamily of proteins [56] with a known role in interfering with blood vessel formation [57,58]. To remove calcium as a signal in the IVB, the alginate gel was replaced with a hyaluronic acid (HA)-based gel and then supplemented with Suramin and TGF-beta1. Within 10 days the IVB space was reconstituted with cartilage as opposed to bone further validating the basic tenets of the IVB paradigm (Fig. 15.4). Interestingly, TGF-beta1 administration alone and the HA gel by itself did not promote cartilage formation, suggesting that inhibiting angiogenesis was the key. However, Suramin as a signal to alter periosteal cell fate would never be clinically viable due to serious toxicity issues. We therefore explored if the inherent physicochemical properties of a biomaterial could be used to trigger chondrogenesis within the IVB. We hypothesized that a biomaterial that could restrict, inhibit, or interfere with vascular ingrowth could also yield similar outcomes as Suramin, by promoting hypoxia. Nonetheless, whether hypoxia would alter periosteal cell fate choice remained to be assessed.

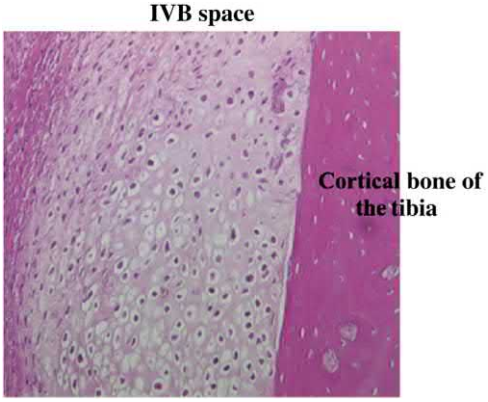

FIGURE 15.4 *The formation of cartilage in the IVB through inhibition of angiogenesis using Suramin.* Hematoxylin−eosin stained cross section of the IVB showing the presence of chondrocytes in the IVB space and the active proliferation of the cells from cambium. *IBV*, In vivo bioreactor. *Reproduced with permission from Stevens MM, Marini RP, Schaefer D, Aronson J, Langer R, Shastri VP. In vivo engineering of organs: the bone bioreactor. Proc Natl Acad Sci USA 2005;102(32):11450−5.*

Agarose, a polysaccharide derived from red sea algae [59], forms physically crosslinked hydrogels at physiological temperature and in vivo. More importantly, studies had shown that agarose is very well tolerated in vivo, and in fact is an inert material with no inherent biological activity, and can undergo degradation [60]. Furthermore, agarose appeared to have no propensity to induce angiogenesis at least in the short term [61]. Based on these characteristics, agarose was identified as the material of choice. Injection of agarose (2 w/v%) in the subperiosteal IVB in the tibia of skeletally matured rabbits resulted in a massive cellular response and the formation of a callus (Fig. 15.5A and B) which by day 21 was made up of hypercellular cartilage (Fig. 15.5C and D) [62]. Not surprisingly, HA gels supplemented with liposomes containing Suramin and TGF-beta 1 also yielded cartilage but offered no superior outcomes in terms of quality or quantity of the engineered cartilage. *The IVB approach remains a singular example to date of in vivo cartilage tissue engineering without cell implantation or growth factor supplementation and is currently being readied for first in human studies.*

In order to ascertain the role of hypoxia in chondrogenesis in the IVB, gene expression levels of hypoxia related factors: hypoxia inducible factor-1alpha and VEGF were quantified using quantitative real-time PCR. A statistically higher mRNA expression was found in tissues from IVB-injected with agarose, thus validating the working hypothesis and rationale for choosing agarose (Fig. 15.5E). A role for hypoxia in the induction of a chondrogenic lineage in periosteal cells was also confirmed in in vitro studies, where a 5−10-fold increase in chondrogenesis associated genes (collagen 2, Sox9, and aggrecan) was observed in cells cultured under hypoxia (0.2% O_2) versus cells cultured under normoxia (21% O_2).

While the engineered cartilage bore no resemblance to the organization found in adult articular cartilage, the hypercellularity of the engineered cartilage turned out to be important. When transplanted into full-thickness osteochondral defects in the tibia of skeletally mature rabbits the IVB generated cartilage was well integrated laterally and with the subchondral bone, and more importantly did not undergo any calcification even after 9 months. This may be attributed to the active remodeling of the hypercellular cartilage matrix as it strives to achieve cellular homeostasis. Such a process would involve apoptosis of cells and this would release not only signaling molecules, but enzymes and proteases that can actively remodel the extracellular matrix providing new space for deposition of

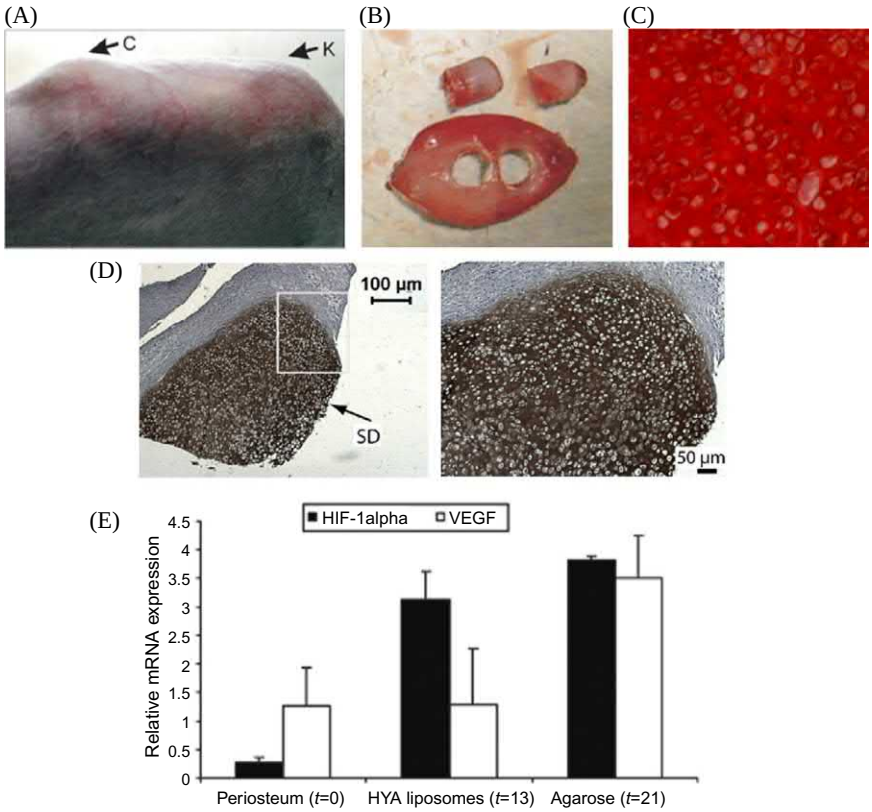

FIGURE 15.5 *Cartilage engineering in the IVB.* Injection of agarose in the IVB in the tibia of a skeletally mature New Zealand white rabbit leads to a string cellular response resulting a callus as early as 7 days which is mature by day 14 (A). new matrix by the chondrocytes. The ability to engineer large volumes of hypercellular cartilage "on demand" can also impact treatment of bone trauma. Ossification is the natural progression of cartilage once it undergoes hypertrophy. Martin and co-workers have exploited this biological process in a bone engineering approach; they have termed *developmental engineering* [63,64]. They have shown that cartilage engineered from marrow-derived MSCs and driven towards hypertrophy can undergo remodeling in vivo into bone and marrow components upon implantation in an ectopic site and using this approach they have also engineered an ectopic marrow with a reconstitute immune system [63–66]. The IVB paradigm therefore, could have far-reaching impact in treating skeletal trauma.

The ability to engineer in vivo, two fundamentally different tissues: *Bone*—which is an organ that is highly vascularized and innervated, and *Cartilage*—which is an avascular tissue; from the same pluripotent stem cell source through judicious choice of an injectable hydrogel was not only a first in exploiting biophysical and physicochemical attributes of biomaterial to influence stem cell fate but was also overwhelming proof that the basic principles of the IVB paradigm were well founded.

Induction of angiogenesis using biophysical cues—*organotypic vasculature engineering*

Angiogenesis is the key to ensuring that any engineered tissue integrates and remodels and achieves cellular homeostasis. Vasculature is the conduit for recruitment of endogenous cell populations [progenitor cells and immune cells (circulating monocytes, B-cells, T-cells, differentiated macrophages M1, M2) [67]]. Equally important is

the emerging evidence that paracrine signaling between ECs and organ forming cells may be the key to morphogenesis, and that vasculature is tailored to a specific organ—*organotypic vasculature*. As discussed earlier, it is now well established that vasculature precedes osteosynthesis and in this regard Adams and co-workers have shown that the type of vasculature is very critical for osteosynthesis [43]. They discovered a new capillary subtype in murine skeletal system that has distinct morphological, molecular, and functional properties, and these capillaries could be differentiated form normal capillaries by the expression of Endomucin (Emcn) as high Emcn expressing vessels and low Emcn expressing vessels, which they have termed H- and L-type vessels, respectively. They also observed an association between H-type vessels and osteoprogenitors cells and osteogenic processes and in aging mice, loss in osteoprogenitor cell population correlated with the loss in H-type vessels and increase in L-type vessels. Furthermore, they have shown that angiocrine signaling, osteosynthesis, and angiogenesis are coupled through EC-specific Notch signaling [44]. While these findings need to be validated in nonhuman primates and in humans, the evidence for a role of vasculature in organ formation is definitely strengthening. In addition, studies from Mooney's group have shown that angiogenesis can also have a positive effect on muscle innervation, formation of neuromuscular junctions, and muscle regeneration [68,69].

Based on this emerging body of evidence, a strong argument can be made that capillary networks are in a sense an organ, perhaps an organoid, as it has cellular and structural complexity, morphology, distinct physiological attributes, which has a role in cellular homeostasis and repair of an organ or tissue, and this goes beyond the conventional notion of a transport function. Engineering of *organotypic vasculature* (or tissue-specific form of angiogenesis) will therefore be the key to successful engraftment of cells and tissues and constitutes a huge unmet need in tissue engineering. Furthermore, transplantation of engineered microvasculature could be one way to induce regenerative mechanisms in vivo.

Angiogenesis, the formation of new blood vessels, is a complex process involving orchestrated released of trophic factors, and paracrine signaling between ECs and perivascular support cells (pericytes). There are several pathologies that are associated with loss of vascularity and vascular function and they include cardiac ischemia, hind limb ischemia, avascular necrosis, and diabetic ulcers. Pioneering efforts by Isner and Asahara in the mid-late 1990s led to the development of a clinical strategy to induce new blood vessels (collateral vessels) in ischemic tissues from existing vasculature using external cues, an approach they called *therapeutic angiogenesis* [70,71]. The idea was to inject a bolus of angiotropic factors such as VEGF or FGF to induce sprouting of existing vasculature and recruitment of resident endothelial progenitor cells [72]. This approach was later expanded to include direct myocardial (tissue) gene transfer using plasmid encoding for VEGF [73,74]. One of the challenges with local delivery of proangiogenic signals is that the sprouting and maturation of new vessels into normal or aberrant (angiomas) depends on local growth factor concentration [75] which is very difficult to modulate and control. ECs also lose their quiescence following injury and get primed toward external proangiogenic cues. However, maintenance (stabilization) of neovasculature is necessary for restoring vascular homeostasis, and in this regard, perivascular cells, that is, pericytes and vascular smooth muscle cells play a critical role in vivo in not only providing scaffolding but also paracrine signaling necessary for blood vessel sprouting and maturation [76]. In therapeutic angiogenesis however, vessels often fail to mature and they regress over time [77] due to inadequate recruitment of appropriate support cells. Therefore, control over cell fate, phenotype and recruitment is key for a successful pro-angiogenic therapy.

Numerous studies have demonstrated that in addition to soluble signals substrate or extracellular matrix stiffness [78], stochastic roughness (nanotopography) [79–81] can dictate cell shape, fate, and function. This paradigm termed—*mechanobiology*—involves invoking and controlling biological processes using mechanical and biophysical cues and represents the next frontier in control of cell function via physicochemical properties of biomaterial. Hydrogels are highly suitable for implementing mechanobiology paradigms as their mechanical properties can be tuned on demand by altering the characteristics of the crosslinks. Carboxylated agarose (CA) represents a new family of polysaccharides that yields physically crosslinked, injectable hydrogels whose modulus can be tuned from 10s of Pa to 10^5 Pa independently of concentration [82,83]. Using CA hydrogels of varying stiffness modified with the integrin binding peptide sequence arginine–glycine–aspartic acid (RGD) and supplemented with angiocrine factors as a screening platform, we discovered that apical–basal polarization in ECs could be induced within soft hydrogels with a modulus around 20–50 Pa [82]. This hydrogel stiffness incidentally corresponds to the mechanical properties of embryonic tissue [84,85]. Under these conditions, ECs migrated and organized themselves into free standing lumens over 100 μm in height comprising 3–5 ECs per lumen cross section. This organization, which is reminiscent of vasculogenesis, that is, the formation of blood vessels from endothelial progenitor cells (which is different from sprouting angiogenesis that is branching from existing vasculature), more importantly occurred in this gel environment in the absence of any support cells. Since CA gels without RGD did not promote polarization of ECs it was deemed that

signaling via integrins and mechanical coupling of ECs to the gel were critical. This demonstrated that apical−basal polarization and organization of ECs into three dimensional structures can be induced purely by matrix mechanics, that is, even in absence of mural support cells.

Encouraged by this observation we inquired if the mere introduction of a biomaterial with defined mechanical properties would be sufficient in promoting maturation and stabilization of neovasculature. Gels of two different stiffness, one with a shear modulus of 0.5 kPa (500 Pa) which is similar to the fibrin network in a blood clot (0.06−0.6 kPa [86]) and the other with a stiffness of 5 kPa which is similar to the gastrocnemius lateralis muscle (E of 11 kPa which corresponds to a shear modulus of around 3−4 kPa [87]), were injected in the mouse gastrocnemius muscle, and the neovasculature formed was characterized for morphological traits [diameter, vessel length density (VLD), and segment length], patency using lectin perfusion index and stability [88]. Both soft and stiff gels were capable of inducing new micro-vessels by 2 weeks, which were physiologically associated with appropriate mural cells, that is, pericytes [positive for nerve/glial antigen 2 (NG2) and negative for α-smooth muscle actin (SMA), and smooth muscle cells (positive for α-SMA)]. However, beyond 7 weeks when vessels become independent of angiocrine factors [75], only the gel environment with mechanically properties similar to fibrin clot was able to promote appropriate branching of the vessels as characterized by short segment lengths and higher VLD (Fig. 15.6A and B) [88]. Furthermore, soft gel environments also promoted long-term stabilization and patency of the newly formed vasculature as seen by the robust association of pericytes with the ECs (Fig. 15.6C). Quantification of pericyte coverage, which was done by computing the ratio of vessel length associated with NG2 + pericytes/total vessel length, revealed that vascular networks within the soft gels had a fivefold greater pericyte coverage compared to those within the stiff gels (Fig. 15.6E). As in the case with bone and cartilage engineered within the IVB, supplementation with either angiocrine factors or basement membrane components bestowed no additional benefits over the gel by itself. The fact that an avascular environment devoid of any inherent angiogenic properties could induce and stabilize new vessels once again confirms that biophysical attributes of a biomaterial alone are sufficient to invoke and control biological processes. The big question now is, how does the gel's stiffness influence vessel stability?

Since proliferation of ECs within the two gels could account for the observed outcomes, explants after 7 weeks were cryosectioned and immunostained for Ki67, a proliferation marker, which excludes quiescent cells [89] and it was found that vascular networks in both soft and stiff gels were essentially quiescent with at least 98% of ECs in the G0 phase (Fig. 15.6D). Having excluded proliferation as a contributing factor myeloid cells and specifically pro-maturative CD11b + monocytes within each gel environment were quantified. We found that the softer fibrin clot like gel recruited 40% higher CD45 + myeloid cells over stiffer gel environment, although the enrichment of CD11b + cells were similar in both gel environments. Further analysis revealed the presence, for the first time, of a hitherto unknown population of CD11b + cells that express the mechanosensing receptor Piezo-1, and more importantly this mechanosensing subpopulation of CD11b + was differentially recruited in the two gel environments, and furthermore, was detected at a higher frequency in the softer than in the stiffer hydrogels, representing 93.1% ± 1.4% of the total CD11b + cells in the soft gels versus 71.8% ± 2.4% in the gels with muscle-like stiffness (Fig. 15.6F) [88]. These findings demonstrated that the biophysical attributes of a hydrogel can also influence the recruitment of immune cells and more importantly provide a bias toward cell populations that are inherently sensitive to mechanical cues. Interestingly, Piezo-1-expressing CD11b + cells is found in the circulation of both mouse and healthy human donors, with surprisingly similar frequency, accounting for 35.0% ± 2.2% and 35.1% ± 9.1% of total CD11b + cells, respectively, and this bodes well for recapitulating the same outcomes in humans. Therefore, in addition to signaling via integrins [90],stretch-activated ion channel Piezo-1, which is also an integrin activating transmembrane protein [91], has a critical role in angiogenesis [92]. This observation when taken in context with the finding that gel stiffness modulates recruitment of CD11b + /Piezo-1 + monocytes provides a strong molecular biology link between the mechanical properties of the hydrogel and blood vessel stabilization and offers a novel direction for future efforts in developing transplantable vascular networks for organ engineering.

De novo liver engineering

In spite of the fact that liver is an organ with the most regenerative capacity, engineered livers have yet to materialize. Although significant progress has been made in producing liver-like organoids for drug screening [93], and there is also evidence that these organoids can expand in volume in an orthotopic site [94], engineering healthy liver tissue on demand remains an unmet need and enormous challenge. One could envision that the principles of IVB could also be leveraged to engineer sizeable amounts of healthy liver tissue at an ectopic site within close proximity to the liver. Anatomically speaking, liver has evolved to compactly fit in the abdominal cavity in close proximity to venous return of the blood to the heart. Therefore creating new volume in this tight cavity is

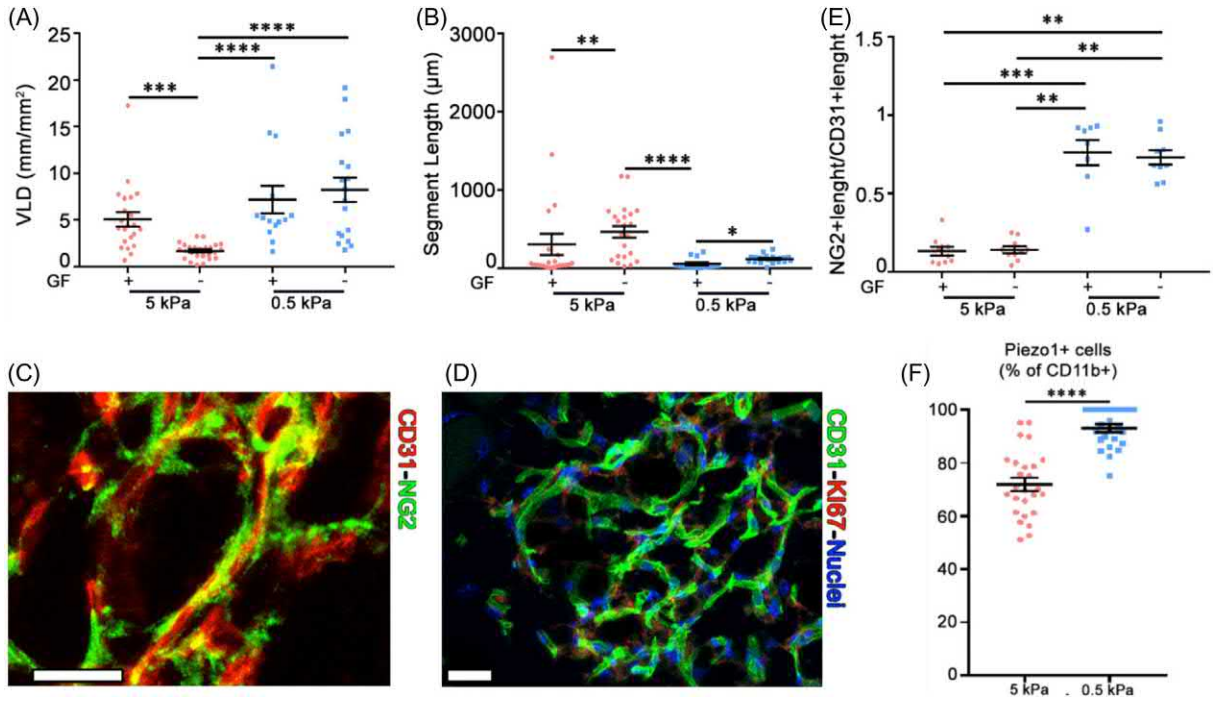

FIGURE 15.6 Morphological characterization of new capillaries formed within soft and stiff RGD-modified carboxylated hydrogels 7 weeks after injection in the gastrocnemius muscles of SCID mice: vessel length density (A), segment length (B), immunofluorescence staining of endothelium in the soft gel (0.5 kPa) (CD31, in red), pericytes (NG2, in green), smooth muscle cell (α-SMA, in cyan) showing intimate tight association of pericytes with ECs (C), immunofluorescent images of soft gels showing the presence appropriately branched and quiescent vasculature (D), pericyte coverage in vasculature within the gels, note the remarkably higher coverage of pericytes in the softer gel environment (E), quantification of recruitment of CD11b + /Piezo-1 + circulating monocytes within the soft and stiff gels (F). Scale bars = 20 μm. $*P < .05$, $**P < .01$, $***P < .001$, and $****P < .0001$ by Kruskal–Wallis test; $n = 4$ independent muscles per each group. *ECs*, Endothelial cells; *SMA*, smooth muscle actin. *Reproduced with permission from Forget A, Gianni-Barrera R, Uccelli A, Sarem M, Kohler E, Fogli B, et al. Mechanically defined microenvironment promotes stabilization of microvasculature, which correlates with the enrichment of a novel Piezo-1(+) population of circulating CD11b(+)/CD115(+) monocytes. Adv Mater 2019;31(21):e1808050.*

extremely challenging. Although like long bones the lobes of the liver are also ensheathed in a capsule of connective tissue called the Glisson capsule this membrane however is too thin (around 20 μm) to be manipulated surgically without causing extensive damage to the liver tissue [95]. Therefore an alternative would be the peritoneal membrane, which covers the liver on the diaphragmatic side and one could envision creating a privileged cavity, fully vascularized, using amniotic membrane (or amnion) as an artificially defined physical barrier—*the in vivo liver bioreactor*. Amnion is appealing as it is easily sourced from discarded placenta and so free of ethical issues, can be processed into a sterile product, has an extensive history of successful use in ophthalmology in corneal reconstruction [96,97] and also appears to be an immune-privileged tissue [98]. One could combine the implantation of organoids with an artificial amnion sac vascularized on the peritoneum as potential means of engineering healthy liver tissues. A key advantage of this approach over, for instance, implanting organoids directly into a liver lobe as explored by Bhatia and co-workers, would be that the evolution of the tissue will be free from the pathology inflicting the recipient. In the cornea, amnion has been shown to promote re-epithelialization as it functions as a basement membrane [97]. Since hepatocytes are epithelial cells one could envision that liver organoids could adhere and proliferate within such environment leading to organogenesis under more physiological conditions. Also, it has been shown recently that epithelial cells from the amnion possess many of the characteristics of hepatocytes, including secretion of albumin [99]. Furthermore, cells from the amnion are capable of differentiating into cells of the three germ layers and using freshly isolated amnion could prove advantageous to exploit this attribute [100]. Volumizing this artificially created amniotic sac (the bioreactor) with a hydrogel that can support rapid vascularization to meet the high metabolic needs of hepatocytes will be the key. Toward this objective the CA hydrogels offer couple of clear advantages, namely, they can be injected as a liquid and set in vivo, thus allowing precise manipulation of the artificial IVB site, and their ability to promote rapid ingrowth of blood vessels from exiting vasculature (sprouting angiogenesis) without the need for any proangiogenic soluble factors.

Repairing brain tissue through controlled induction of reactive astrocytes

Brain tissue is very challenging to repair and restore as it lacks an endogenous repair mechanism. Astrocytes, which constitute more than 30% of all the cells in the brain, are key players in maintaining brain function. Recent studies have shown that astrocytes play a prominent role in formation, function, maintenance, and elimination of synapses [101]. After brain injury and in brain pathology, astrocytes get activated and these reactive astrocytes (RAs) alter cellular and signaling homeostasis. Local delivery of molecules in theory can be used to alter cellular homeostasis in the brain. For example, it has been shown in vitro that treatment of primary murine midbrain cells with FGF and platelet-derived growth factor has a significant positive effect on the survival and maturation of dopaminergic neurons [102]. However, delivery of growth factors to the brain is challenging due to diffusion constraints [103], and therefore using resident cells as sources of soluble signals is more practical. Since RAs can either be neuroprotective or harmful, an alternative strategy is to leverage RAs at various stages of reactivity. Currently, researchers are actively researching how to isolate astrocytes at various reactive states, and if the reactive states of astrocytes can be used as a therapeutic tool in the treatment of CNS diseases and injury [104]. Isolating and manipulating astrocytes ex vivo is very tedious and costly, and standardizing such procedures for clinical use is even more challenging if not totally impractical. In this regard, understanding how to invoke different RA states in vivo and developing minimally invasive strategies to do so could provide a new avenue to repair and restore brain tissue and likely more acceptable clinically.

Blumenthal et al. have shown that astrocytes provide physical cues to neurons, and this is critical for proper neuron function [81]. Furthermore, this interaction between astrocytes and neurons was shown to involve Piezo-1. Loss of Piezo-1 activity in both neurons and astrocytes was found to be detrimental to their function. More interestingly, this study showed that biophysical cues in the form of stochastic nanoroughness has a prominent role in controlling astrocytes phenotype and this provides the basis for an intriguing idea, wherein carefully placed micro-implants of defined topography and/or stiffness can be used to invoke different types of RAs, thus driving local repair processes in the brain. Observations from our ongoing studies in controlling glial scarring round brain implants suggest that such an approach is very much feasible.

Conclusions and outlook

Organ engineering is coming of age as advances in cell and molecular biology, genetic manipulation (CRISPR/Cas9), and materials science coalesce. In this regard, the IVB paradigm presents new opportunities to engineer autologous tissue for transplantation. The advantages of bone and cartilage engineering using the IVB are that quality of the tissue can be assessed noninvasively using MRI before transplantation. In the case of cartilage, the ability to generate a large volume in the neighborhood of $5-10\,cm^3$ (extrapolation based on volumes obtained in rabbits) per injection provides an opportunity to carryout entire articular resurfacing. Furthermore, as discussed earlier, such hypercellular cartilage may also be useful in in vivo engineering of bone through activation of the EO program. Nonetheless, one of the challenges in translating the IVB into the clinic has been the resistance of clinicians to explore unconventional strategies for bone and cartilage repair. Our experience has been that the clinical mindset prevents implementation of solutions that involve two steps (or two procedures), namely, one to create the IVB and the second to harvest the tissue for transplantation, even though the first procedure can be minimally invasively carried out on an out-patient basis. It is anticipated that the first-in-human trials of the cartilage IVB will help in overcoming this perceived downside.

The ability to engineer vasculature on demand will be highly valuable in transplantation of islet cells and also engineering of secondary organ such as a "pancreas on a kidney" or "pancreas in a muscle." The kidney capsule, which is an immune privileged site, meets many of the requirements for an IVB. There has been significant progress to date in transplanting islet cells under the kidney capsule [105]. Kumagai et al. have shown the prevascularized islets can be engineered under the kidney capsule using autologous cells and that such prevascularized islet kidneys are much more efficient than nonvascularized islets at reversing hyperglycemia in swine [106,107]. One can envisage the engineering of a pancreas-specific vasculature and introducing islet cells associated with this vasculature under the kidney as a secondary source for insulin in individuals with type-1 diabetes. Finally, one can also envisage highly engineered implants that incorporate 3D printing with soluble signal gradient generators, for in vivo programming and harvesting of organ-specific cells derived from autologous (patient-derived) induced pluripotent stem cells, essentially turning the human body into a *cell on demand* factory. Such systems could be subdermally implanted for easy access to reprogrammed cells and removal of the implant.

Part Four

Biomaterials in tissue engineering

Chapter 16

Cell interactions with polymers

W. Mark Saltzman[1] and Themis R. Kyriakides[2]

[1]Deaprtment of Biomedical Engineering, Yale University, New Haven, CT, United States, [2]Department of Pathology, Yale University, New Haven, CT, United States

Scaffolds composed of synthetic and natural polymers have been essential components of tissue engineering since its inception [1]. Synthetic polymers are currently used in a wide range of biomedical applications, including applications in which the polymer remains in intimate contact with cells and tissues for prolonged periods (Table 16.1). Many of these polymer materials have been tested for tissue engineering applications, as well. To select appropriate polymers for tissue engineering, it is helpful to understand the influence of these polymeric materials on viability, growth, and function of attached or adjacent cells. In addition, it is now possible to synthesize polymers that interact in predictable ways with cells and tissues; understanding the nature of interactions between cells and polymers provides the foundation to this approach.

This chapter reviews previous work on the interactions of tissue-derived cells with polymers, particularly the types of synthetic polymers that have been employed as biomaterials. Its focus is on the interactions of cells with polymers that might be used in tissue engineering; therefore, both in vitro and in vivo methods for measuring cell−polymer interactions are described. The interaction of cells in flowing blood, particularly platelets, with synthetic polymer surfaces is also an important aspect of biomaterials design, but is not considered here.

Methods for characterizing cell interactions with polymers

In vitro cell culture methods

Cell interactions with polymers are often studied in vitro, using cell culture techniques. While in vitro studies do not reproduce the wide range of cellular responses observed after implantation of materials, the culture environment provides a level of control and quantification that cannot be obtained in vivo. Cells in culture are generally plated over a polymer surface, and interaction is allowed to proceed for several hours; the extent of cell adhesion and spreading on the surface is then measured. By maintaining the culture for longer periods, perhaps for many days, the influence of the substrate on cell viability, function, and motility can also be determined. Since investigators use different techniques to assess cell interactions with polymers, and the differences between techniques are critically important for interpretation of interactions, some of the most frequently used in vitro methods are reviewed in this section.

To perform any measurement of cell interaction with a polymer substrate, the polymeric material and the cells must come into contact. Preferably, the experimenter should control (or at least understand) the nature of the contact; this is a critical, and often overlooked, aspect of all of these measurements. Some materials are easily fabricated in a format suitable for study; polystyrene (PS) films, for example, are transparent, durable, and strong. Other materials must be coated onto a rigid substrate (such as a glass coverslip) prior to study. But since cell function is sensitive to chemical, morphological, and mechanical properties of the surface, almost every aspect of material preparation can introduce variables that are known to influence cell interactions.

Adhesion and spreading

Most tissue-derived cells require attachment to a solid surface for viability and growth. For this reason the initial events that occur when a cell approaches a surface are of fundamental interest. In tissue engineering, cell adhesion to a surface is critical because adhesion precedes other cell behaviors such as cell spreading, cell migration and, often, differentiated cell function.

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00017-4

TABLE 16.1 Some of the synthetic polymers that might be useful in tissue engineering, based on past use in biomedical devices.

Polymer	Medical applications
PDMS, silicone elastomers	Breast, penile, and testicular prostheses Catheters Drug delivery devices Heart valves Hydrocephalus shunts Membrane oxygenators
PEU	Artificial hearts and ventricular assist devices Catheters Pacemaker leads
PTFE	Heart valves Vascular grafts Facial prostheses Hydrocephalus shunts Membrane oxygenators Catheters and sutures
PE	Hip prostheses Catheters
PSu	Heart valves Penile prostheses
PET	Vascular grafts Surgical grafts and sutures
pMMA	Fracture fixation Intraocular lenses Dentures
pHEMA	Contact lenses Catheters
PAN	Dialysis membranes
Polyamides	Dialysis membranes Sutures
PP	Plasmapheresis membranes Sutures
PVC	Plasmapheresis membranes Blood bags
Poly(ethylene-*co*-vinyl acetate)	Drug delivery devices
PLA, PGA, and PLGA	Drug delivery devices Sutures
PCL	Electrospun materials
PEG	Tissue sealents Surface modification of materials
PS	Tissue culture flasks
PVP	Blood substitutes
Poly(*p*-dioxanone) and poly(omega-pentadecalactone-*co*-*p*-dioxanone) [2]	Sutures

PAN, Polyacrylonitrile; *PCL*, poly(caprolactone); *PDMS*, polydimethylsiloxane; PE, polyethylene; *PEG*, poly(ethylene glygol); *PET*, poly(ethylene terephthalate); *PEU*, polyurethanes; *PGA*, poly(glycolic acid); *pHEMA*, poly(2-hydroxyethylmethacrylate); *PLA*, poly(L-lactic acid); *PLGA*, poly(lactide-*co*-glycolide); *pMMA*, Poly(methyl methacrylate); *PP*, polypropylene; *PS*, polystyrene; *PSu*, Polysulphone; *PTFE*, poly(tetrafluoroethylene); *PVC*, poly(vinyl chloride); *PVP*, poly(vinyl pyrrolidone).

A number of techniques for quantifying the extent and strength of cell adhesion have been developed: a more complete description of these techniques with early references is available (see Chapter 6 of Ref. [3]). In fact, so many different techniques are used that it is usually difficult to compare studies performed by different investigators. This situation is further complicated by the fact that cell adhesion depends on a large number of experimental parameters, many of which are difficult to control. The simplest methods for quantifying the extent of cell adhesion to a surface involve three steps: (1) suspension of cells over a surface, (2) incubation of the sedimented cells in culture medium for some period of time, and (3) detachment of loosely adherent cells under controlled conditions. The extent of cell adhesion, which is a function of the conditions of the experiment, is determined by quantifying either the number of cells that remain associated with the surface (the "adherent" cells) or the number of cells that were extracted with the washes. Radiolabeled or fluorescently labeled cells can be used to permit measurement of the number of attached cells. Alternatively, the number of attached cells can be determined by direct visualization, by measurement of concentration of an intracellular enzyme, or by binding of a dye to an intracellular component such as DNA. In many cases the "adherent" cells are further categorized based on morphologically differences (e.g., extent of spreading, formation of actin filament bundles, and presence of focal contacts). This technique is simple, rapid, and, since it requires simple equipment, common. Unfortunately, the force that is provided to dislodge the nonadherent cells is often not controlled, making it difficult to compare results obtained from different laboratories, even when they are using the same technique.

This disadvantage can be overcome by using a centrifuge or a flowing fluid to provide a controllable and reproducible detachment force. In centrifugal detachment assays, the technique described earlier is modified: after the incubation period, the plate is inverted and subjected to a controlled detachment force by centrifugation. In most flow chambers the fluid is forced between two parallel plates. Prior to applying the flow field, a cell suspension is injected into the chamber, and the cells are permitted to settle onto the surface of interest and adhere. After some period of incubation, flow is initiated between the plates. These chambers can be used to measure the kinetics of cell attachment, detachment, and rolling on surfaces under conditions of flow. Usually, the overall flow rate is adjusted so that the flow is laminar, and the shear stresses at the wall approximate those found in the circulatory system; however, these chambers can be used to characterize cell detachment under a wide range of conditions.

Radial flow detachment chambers have also been used to measure forces of cell detachment. Because of the geometry of the radial flow chamber, where cells are attached uniformly to a circular plate and fluid is circulated from the center to the periphery of the chamber along radial paths, the fluid shear force experienced by the attached cells decreases with radial position from the center to the periphery. Therefore in a single experiment, the influence of a range of forces on cell adhesion can be determined. A spinning disk apparatus can be used in a similar fashion [4], including use with micro- or nanopatterned substrates [5]. Finally, micropipette techniques can be used to measure cell membrane deformability or forces of cell−cell or cell−surface adhesion [6].

There is a growing interest in the interaction of polymer nanoparticles with cells, particularly in the design of nanoparticles that interact with certain populations of cells after introduction into the body. One useful variation in the cell adhesion assay involves flowing polymer nanoparticles over a monolayer of cells that are firmly attached to a surface, usually a glass surface to allow visualization. As an example of this, microfluidic chambers allow the controlled delivery of nanoparticles suspended in fluids over the cell surface, making it possible to quantify the dynamics of polymer particle association with the cultured cells [7].

Migration

The migration of individual cells within a tissue is a critical element in the formation of the architecture of organs and organisms. Similarly, cell migration is likely to be an important phenomenon in tissue engineering, since the ability of cells to move, either in association with the surface of a material or through an ensemble of other cells, will be an essential part of new tissue formation or regeneration. Cell migration is also difficult to measure, particularly in complex environments. Fortunately, a number of useful techniques for quantifying cell migration in certain situations have been developed. As in cell adhesion, however, no technique has gained general acceptance, so it is difficult to correlate results obtained by different techniques or different investigators.

Experimental methods for characterizing cell motility can be divided into visual assays and population assays: a more complete description with early references is available in Chapter 7 of Ref. [3]. In visual assays the movements of a small number (usually $\sim$100) of cells are observed individually. Population techniques, on the other hand, allow the observation of the collective movements of larger numbers of cells: in filter chamber assays, the number of cells migrating through a membrane or filter is measured, while in under-agarose assays, the leading front of cell movement on a surface under a block of agarose is monitored. Both visual and population assays can be quantitatively analyzed, enabling the estimation of

intrinsic cell motility parameters, such as the random motility coefficient and the persistence time: these methods are described in Ref. [3].

Aggregation

Cell aggregates are important tools in the study of tissue development, permitting correlation of cell–cell interactions with cell differentiation, viability and migration, as well as subsequent tissue formation. The aggregate morphology permits reestablishment of cell–cell contacts normally present in tissues; therefore, cell function and survival are often enhanced in aggregate culture. Because of this, cell aggregates may also be useful in tissue engineering, enhancing the function of cell-based hybrid artificial organs or reconstituted tissue transplants [8].

Gentle rotational stirring of suspensions of dispersed cells is the most common method for making cell aggregates [9]. While this method is suitable for aggregation of many cells, serum or serum proteins must be added to promote cell aggregation in many cases, thus making it difficult to characterize the aggregation process and to control the size and composition of the aggregate. Specialized techniques can be used to produce aggregates in certain cases, principally by controlling cell detachment from a solid substratum. For example, stationary culture of hepatocytes above a nonadherent surface [10] or attached to a temperature-sensitive polymer substratum [11] has been used to form aggregates. Synthetic polymers produced by linking cell-binding peptides (such as RGD and YIGSR) to both ends of poly(ethylene glycol) (PEG) have been used to promote aggregation of cells in suspension [12].

The kinetics and extent of aggregation can be measured by a variety of techniques. Often, direct visualization of aggregate size is used to determine the extent of aggregation, following the pioneering work of Moscona [9]. The kinetics of aggregation can be monitored in this manner as well, by measuring aggregate size distributions over time. This procedure is facilitated by the use of computer image analysis techniques or electronic particle counters, where sometimes the disappearance of single cells (instead of the growth of aggregates) is followed. Specialized aggregometers can provide reproducible and rapid measurements of the rate of aggregation; in one such device, small angle light scattering through rotating sample cuvettes is used to produce continuous records of aggregate growth [13].

Cell phenotype

In tissue engineering applications, particularly those in which cell-polymer hybrid materials are prepared, one is usually interested in promotion of some cell-specific function. For example, protein secretion and detoxification are essential functions for hepatocytes used for transplantation or liver support devices; therefore, measurements of protein secretion and intracellular enzyme activity (particularly the hepatic P_{450} enzyme system) are frequently used to assess hepatocyte function. Similarly, the expression and activity of enzymes involved in neurotransmitter metabolism (such as choline acetyltransferase or tyrosine hydroxylase) are often used to assess the function of neurons. Production of extracellular matrix (ECM) proteins is important in the physiology of many tissues, particularly connective tissues and skin; the production of collagen and glycosaminoglycan has been used as an indicator of cell function in chondrocytes, osteoblasts, and fibroblasts. In some cases the important cell function involves the coordinated activity of groups of cells, such as the formation of myotubules in embryonic muscle cell cultures, the contraction of the matrix surrounding the cells, or the coordinated contraction of cardiac muscle cells. In these cases, cell function is measured by the observation of changes in morphology of cultured cells or cell communities.

High-throughput methods for the characterization of cell–polymer interactions

Cell–polymer interactions can be analyzed using methods that allow for many parallel measurements. For example, small spots of ECM proteins can be deposited onto glass slides—or other substrates—to allow for high-throughput screening of cell interactions with ECM proteins and protein combinations [14,15]. This microprinting method can also be applied to three-dimensional (3D) materials appropriate for tissue engineering [16]. Microarray printing of polymer and polymer blends allows for screening of interactions of cells with synthetic polymer surfaces, as well [17]. Although these methods allow for the parallel testing of many different cell/polymer combinations, the measurements of cell interaction are usually limited to light or fluorescence microscopy.

In vivo methods

The context of cell–polymer interactions in vivo is inherently complex due to the presence of blood, interstitial fluids, and the presence of multiple cell types in various activations states. Proteins from the blood and interstitial fluid adsorb to polymer surfaces in a nonspecific manner and provide a substrate for cell adhesion [18,19]. Thus it is believed that cells interact directly with this proteinaceous layer instead of the polymer surface, an assumption that explains the similar in vivo reactions elicited by a diverse array of polymers. Almost all implanted polymers induce a unique inflammatory response termed the foreign body response (FBR) [20,21].

The FBR can be divided in several overlapping phases that include nonspecific protein adsorption, inflammatory cell recruitment—predominantly of neutrophils and macrophages, macrophage fusion to form foreign body giant cells (FBGC), and involvement of fibroblasts and endothelial cells (Fig. 16.1). The end result of the FBR is the formation of FBGC directly on the polymer surface and the subsequent encapsulation of the implant by a fibrous capsule that is largely avascular. To date, the molecular and cellular determinants of the FBR remain largely unknown. However, recent studies have suggested specific roles for several proteins and a key role for macrophages in the FBR. It is now appreciated that the acquisition of specific activation states by these cells is a critical determinant of the FBR, and investigators have sought to influence this process to improve outcomes [22,23].

A number of implantation techniques in rodents and larger animals (typically rabbits, pigs, or sheep) have been adopted for the investigation of cell−polymer interactions. Most notably, short-term studies for the analysis of protein adsorption, inflammatory cell recruitment and adhesion, and macrophage fusion most often employ either intraperitoneal (IP) implantation or the subcutaneous (SC) cage-implant, also known as the wound chamber model. In the IP implant model a sterilized piece of polymer is placed in the peritoneal cavity through a surgical incision [24]. This model has been used extensively in the investigation of protein adsorption onto polymer surfaces and its impact during the early inflammatory response (0−72 hours). In general, due to the short duration, it is difficult to extrapolate the information obtained from such studies to the fate of the FBR. Implant studies of intermediate duration (days to weeks) have been executed using an SC cage-implant; in this system, a polymer is placed within a cage made of stainless steel wire mesh and then implanted through a surgical incision [25]. The SC cage-implant is useful because biologically active soluble agents can be injected through the wire mesh in the immediate vicinity of the polymer.

Both IP and SC implantations allow for the analysis of recruited, nonadherent cell populations, which are collected by lavage of the peritoneal cavity or aspiration of host-derived exudates from the cage. In addition, implant materials can be recovered and analyzed for the presence of adherent cells by various techniques, immunohistochemistry being the most reliable. Thus both implantation models can provide information regarding the migration of cells to the implantation site and the interaction of cells (adhesion, survival, and fusion) with the polymer surface. Other commonly used in vivo models for the analysis of cell−polymer interactions involve the implantation of test polymers directly into host tissues such as dermis (SC), muscle, bone, and brain. Generally, such studies have been carried for longer incubation periods (weeks to months). Furthermore, polymer-based constructs have been surgically implanted at sites where they are expected to perform biological functions, for example, vascular grafts [26,27], heart valves [28], stents [29], and cardiac patches [30]. Thus in addition to biocompatibility and toxicity, polymers can be evaluated for their role in function of a tissue or organ. The direct implant model can be considered the most representative for most polymer applications and can provide information regarding the FBR, such as inflammation (macrophage accumulation and polarization, FBGC formation),

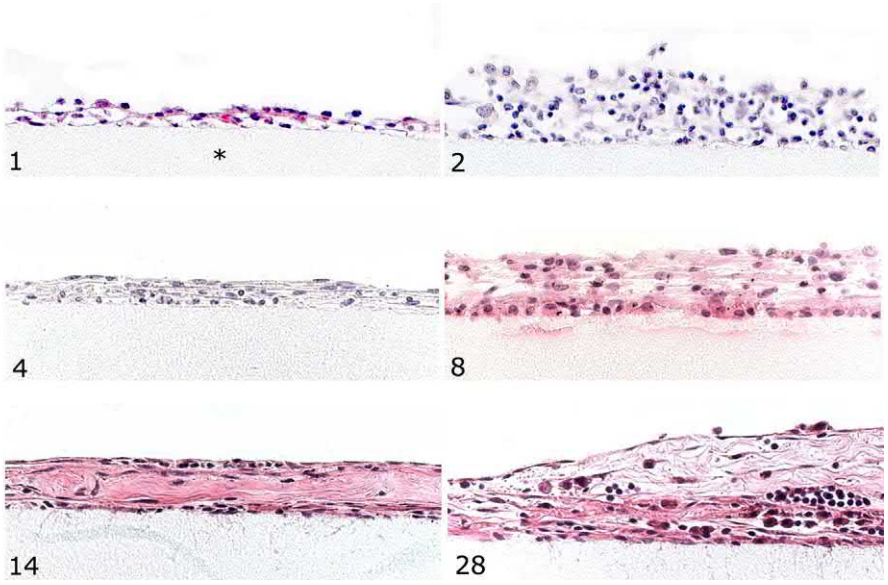

FIGURE 16.1 Development of the foreign body response. Representative images of hematoxylin and eosin−stained Millipore filter disks (mixed cellulose ester) implanted in the peritoneal cavity of wild type mice. The number on each panel indicates the number of days after implantation. In the first 2 days following implantation, the disks display loose and expanding layers of attached inflammatory cells. Between 4 and 8 days, the cell layers show increased organization that appears to coincide with the deposition of collagen fibers. Continuous deposition of collagenous matrix and an overall reduction in cellular content are characteristic of the 2- and 4-week time points. Original magnification 400 ×. * indicates the disk.

fibrosis (collagen content), encapsulation (capsule thickness), and angiogenesis (vascular density). Finally, in cases where the polymer is susceptible to degradation, additional analyses can be performed to evaluate the role of chemical and physical changes of the material in interactions with the tissue.

Cell interactions with polymers

Protein adsorption to polymers

A polymeric material that is placed in solution or implanted in the body becomes coated with proteins quickly, usually within minutes. Many of the subsequent interactions of cells with the material depend on, or derive from, the composition of the protein layer that forms on the surface. Polymers have been shown to adsorb a large number of proteins in vitro [31]. For example, proteomic analysis of polypropylene (PP), polyethylene terephthalate (PET), and polydimethylsiloxane (PDMS) incubated with serum identified immunoglobulins, transferrin, albumin, serum amyloid P, and complement C4, among other proteins, on the polymer surface [32]. The C3 component of complement has also been shown to adsorb to medical grade polyurethanes (PEU) and adhesion of inflammatory cells to the polymer was reduced in the presence of C3-depleted serum but not fibronectin-depleted serum [33]. In contrast, in vivo studies employing the IP implantation method suggest that adsorption of fibrinogen is the critical determinant of the FBR [34]. Specifically, adsorption and denaturation of fibrinogen on polymer surfaces might lead to the exposure of cryptic cell adhesion motifs (integrin-binding sites) that influence subsequent cellular interactions. Despite the recognized importance of adsorbed proteins, it is possible that direct contact between polymers and cells can have significant impact on cell function. Supporting evidence for such interactions was shown in study where large poly(methyl methacrylate) beads (150 μm in diameter) induced the production of a proinflammatory cytokine by macrophages in the absence of serum proteins [35].

Effect of polymer chemistry on cell behavior

Synthetic polymers

For cells attached to a solid substrate, cell behavior and function depend on the characteristics of the substrate. Consider, for example, experiments described by Folkman and Moscona, in which cells were allowed to settle onto surfaces formed by coating conventional tissue-culture PS (TCPS) with various dilutions of poly(2-hydroxyethylmethacrylate) (pHEMA) [36]. As the amount of pHEMA added to the surface was increased, cell spreading decreased as reflected by the average cell height on the surface. The degree of spreading, or average

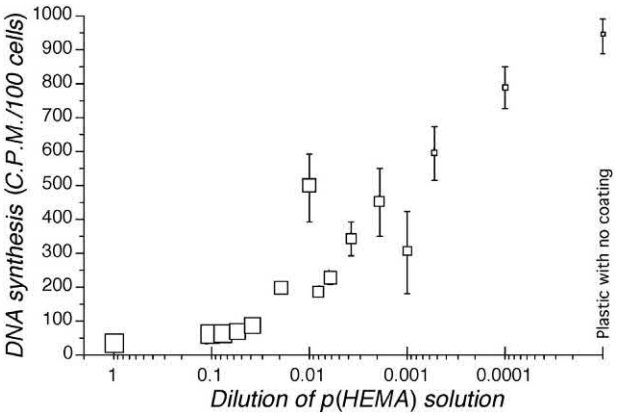

FIGURE 16.2 Cell shape and growth are modulated by properties of a polymer surface. Cell culture surfaces were produced by evaporating diluted solutions of pHEMA onto TCPS. The uptake of [^{3}H]thymidine was used as a measure of proliferation. The size of the symbol represents the relative cell height; small symbols represent cells with small heights, and therefore significant spreading, large symbols represent cells with large heights, and therefore negligible spreading. *pHEM*, Poly(2-hydroxyethylmethacrylate); *TCPS*, tissue-culture polystyrene. *Replotted from Folkman J, Moscona A. Role of cell shape in growth control. Nature 1978;273:345–9.*

height, correlated with the rate of cell growth (Fig. 16.2), suggesting that cell shape, which was determined by the adhesiveness of the surface, modulated cell proliferation. In these experiments, two well-known polymers (TCPS and pHEMA) were used to produce a series of surfaces with graded adhesivity, permitting the identification of an important aspect of cell physiology. These experiments clearly demonstrate that the nature of a polymer surface will have important consequences for cell function, an observation of considerable significance with regard to the use of polymers in tissue engineering.

Following an experimental design similar to that employed by Folkman and Moscona, a number of groups have examined the relationship between chemical or physical characteristics of the substrate and behavior or function of attached cells. For example, in a study of cell adhesion, growth, and collagen synthesis on synthetic polymers, fetal fibroblasts from rat skin were seeded onto surfaces of 13 different polymeric materials [37]. The polymer surfaces had a range of surface energies, as determined by static water contact angles, from very hydrophilic to very hydrophobic. On a few of the surfaces [poly(vinyl alcohol) (PVA) and cellulose], little cell adhesion and no cell growth was observed. On most the remaining surfaces, however, a moderate fraction of the cells adhered to the surface and proliferated. The rate of proliferation was relatively insensitive to surface chemistry: the cell doubling time is ~24 hours, with slightly slower growth observed for two very hydrophobic surfaces [poly(tetrafluoroethylene) (PTFE) and PP]. Collagen biosynthesis was also correlated with contact angle, with

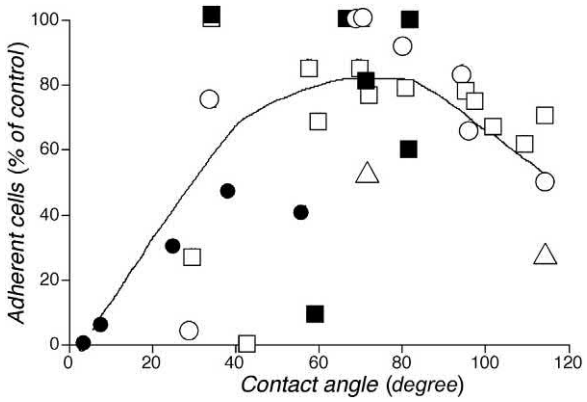

FIGURE 16.3 The relationship between cell adhesion and water-in-air contact angle: fibroblasts (*open squares*), L cells (*open circles*), endothelial cells (*open triangles*), and endothelial cells (*filled circles*). *Replotted from (fibroblasts) Tamada Y, Ikada Y. higher rates of collagen synthesis per cell for the most hydrophobic surfaces.

Results from a number of similar studies have been summarized previously, see Tables 12.1 and 12.2 in Ref. [3], for example. Some general conclusions emerge from this past work. For example, in a number of studies, cell adhesion appears to be maximized on surfaces with intermediate wettability (Fig. 16.3). For most surfaces, adhesion requires the presence of serum and, therefore, this optimum is likely related to the ability of proteins to adsorb to the surface. (In the absence of serum, however, adhesion is enhanced on positively charged surfaces, due to the net negative charge of most cell membranes.) Cell spreading on the copolymers of HEMA (hydrophilic) and EMA (hydrophobic) was highest at an intermediate HEMA content, again corresponding to intermediate wettability [41]; in this case, spreading correlated with fibronectin adsorption [41]. The rate of fibroblast growth on polymer surfaces appears to be relatively independent of surface chemistry. Cell viability may also be related to interactions with the surface, although this is not yet predictable. The migration of surface-attached fibroblasts, endothelial cells, and corneal epithelial cells is also a function of polymer surface chemistry, see Ref. [3] for more details.

Surface modification

Polymers can frequently be made more suitable for cell attachment and growth by surface modification. In fact, TCPS substrates used for tissue culture are obtained by the surface treatment of PS by glow discharge or exposure to chemicals, such as sulfuric acid, to increase the number of charged groups at the surface, which improves attachment and growth of many types of cells. Other polymers can also be modified in this manner. Treatment of pHEMA with sulfuric acid, for example, improves adhesion of endothelial cells and permits cell proliferation on the surface [42]. Modification of PS or PET by radio-frequency plasma deposition enhances attachment and spreading of fibroblasts and myoblasts [43]. The effects of these surface modifications appear to be secondary to increased adsorption of cell attachment proteins, such as fibronectin and vitronectin, to the surface. On the other hand, some reports have identified specific chemical groups at the polymer surface—such as hydroxyl (−OH) [44] or surface C−O functionalities [43]—as important factors in modulating the fate of surface-attached cells.

So far, no general principles that would allow prediction of the extent of attachment, spreading, or growth of cultured cells on different polymer surfaces have been identified. Correlations have been made with parameters, such as the density of surface hydroxyl groups [44], density of surface sulfonic groups [45], surface free energy [46,47], fibronectin adsorption [43], and equilibrium water content [48] for specific cells, but exceptions to these correlations are always found. Perhaps general predictive correlations will emerge, as more complete characterization of polymer systems—including bulk properties, surface chemical properties, and nanoscale topography (as described later)—are collected. But many commonly used polymer materials are complicated mixtures, containing components that are added to enhance polymerization or to impart desired physical properties, often in trace quantities. Lot-to-lot variations in the properties of commercially available polymers can be significant.

The surface chemistry of polymers appears to influence cell interactions in vivo. For example, the ability of macrophages to form multinucleated giant cells at the material surface correlates with the presence of certain chemical groups at the surface of hydrogels: macrophage fusion decreases in the order $(CH_3)_2N- > -OH = -CO-NH- > -SO_3H > -COOH$ $(-COONa)$ [49]. A similar hierarchy has been observed for CHO (Chinese Hamster Ovary) cell adhesion and growth on surfaces with grafted functional groups: CHO cell attachment and growth decreased in the order $-CH_2NH_2 > -CH_2OH > -CONH_2 > -COOH$ [50].

Layer-by-layer (LbL) assembly of nanofilms is a versatile approach for the control of surface properties to modulate cell attachment and function. In the most general technique, alternating layers of two polymers—one polycationic and the other polyanionic—are deposited onto a substrate to create a film of controlled thickness

and chemical properties. By using a cell attachment protein, such as fibronectin, as one of the polyelectrolytes, thin films that control cell adhesion to the substrate can be created [51]. Control of conditions during LbL assembly—such as solution pH—can create films with different physical structures, which further modulate cell interactions [52]. Covalent reactions between the polymers—produced either by addition of cross-linking agents after LbL film formation or during the assembly of the film using reactive polymers—allow for the creation of more stable films [53].

Biodegradable polymers

Biodegradable polymers slowly degrade and then dissolve following implantation. This feature may be important for many tissue engineering applications, since the polymer will disappear as functional tissue regenerates. For this reason, interactions of cells with a variety of biodegradable polymers have been studied. Biodegradable polymers may provide an additional level of control over cell interactions: during polymer degradation, the surface of the polymer is constantly renewed, providing a dynamic substrate for cell attachment and growth.

Homopolymers and copolymers of lactic and glycolic acid [poly(L-lactic acid) (PLA), poly(glycolic acid) (PGA), and poly(lactide-*co*-glycolide) (PLGA)] have been frequently examined as cell culture substrates, since they have been used as implanted sutures for several decades. Many types of cells will attach and grow on these materials. For example, chondrocytes proliferate and secrete glycosaminoglycans within porous meshes of PGA and foams of PLA [54]. Similarly, rat hepatocytes attach to blends of biodegradable PLGA polymers and secrete albumin when maintained in culture [55]. Neonatal rat osteoblasts also attach to PLA, PGA, and PLGA substrates and synthesize collagen in culture [56].

Cell adhesion and function has been examined on materials made from other biodegradable polymers. As an example, cells from an osteogenic cell line attach onto polyphosphazenes produced with a variety of side groups; the rate of cell growth as well as the rate of polymer degradation depends on side group chemistry [57].

The use of degradable polymers increases the complexity of analysis in the in vivo setting because their degradation products can cause excessive and prolonged biological responses. Depending on the material used, degradation products can be released by hydrolysis, enzymatic digestion, degradative activity of macrophages and FBGC, or combinations of these mechanisms. The effects of polymer-derived products that are released by hydrolysis or enzymatic digestion depend on the chemical properties of the polymer and are not difficult to determine. On the other hand the effects of products released due to cellular activities are difficult to predict, because the chemical and biological mechanisms responsible for their generation and release have not been established. Furthermore, the activity of cells, and thus the rate of release, can be influenced by several parameters such as local concentrations of growth factors. It is expected that biodegradable polymers should allow for the favorable resolution of the FBR after their complete disappearance from the host tissue. The disappearance of FBGC from implantation sites after degradation of polymers to microparticles smaller than 10 μm in size has been observed (Kyriakides et al., unpublished data). Furthermore, macrophages were observed to persist until the degradation of the polymer was complete. In SC implantation sites the formation of a vascularized collagenous work as a replacement for the polymer was observed. Presumably, the physiology of the implantation site, the acuteness of the inflammatory response, and the rate of polymer degradation all influence the nature of the FBR. Favorable in vivo results have been obtained with biodegradable elastomeric polyesters composed of poly(diol citrates) [58]. However, the duration of the FBR was shown to exceed 12 months in implanted compressed naltrexone-poly[*trans*-3,6-dimethyl-1,4-dioxane-2,5-dione] (DL-lactide) loaded microspheres [59].

In a direct application the combination of the biodegradable polymers PGA and poly(ε-caprolactone-*co*-L-lactide) has been used successfully as a vascular conduit in humans [60]. Replication of this approach in a rodent model has provided significant insights into cell−polymer interactions and their contribution to vascular remodeling [27]. Specifically, the process was shown to be dependant on the delicate balance between polymer degradation and native ECM deposition [61].

Synthetic polymers with adsorbed proteins

As mentioned earlier, cell interactions with polymer surfaces appear to be mediated by proteins, adsorbed from the local environment. Since it is difficult to study these effects in situ during cell culture, often the polymer surfaces are pretreated with purified protein solutions. In this way the investigators hope that subsequent cell behavior on the surface will be due to the presence of a stable layer of surface-bound protein. A major problem with this approach is the difficulty in determining whether surface conditions, that is, the density of protein on the surface, change during the period of the experiment.

As described earlier, cell spreading, but not attachment, correlates with fibronectin adsorption to a variety of surfaces. Rates of cell migration on a polymer surface are usually sensitive to the concentration of preadsorbed adhesive proteins [62], and migration can be modified by addition of soluble inhibitors to cell adhesion [63].

An RGD spacing of 440 nm is sufficient for integrin aVβ3-mediated fibroblast spreading and 140 nm for focal contact and stress fiber formation. J Cell Biol 1991;114:1089–100 [68,69].*

It appears that the rate of migration is optimal at intermediate substrate adhesiveness, as one would expect from mathematical models of cell migration [64]. In fact, a study showed a clear correlation between adhesiveness and migration for CHO cells [65].

The outgrowth of corneal epithelial cells from explanted rabbit corneal tissue has been used as an indicator of cell attachment and migration on biomaterial surfaces [66]. When corneal cell's outgrowth was measured on 10 different materials that were preadsorbed with fibronectin, outgrowth generally increased with the ability of fibronectin to adsorb to the material. Exceptions to this general trend could be found, suggesting that other factors (perhaps stability of the adsorbed protein layer) are also important.

Hybrid polymers with immobilized functional groups

Surface modification techniques have been used to produce polymers with surface properties that are more suitable for cell attachment [38]. For example, chemical groups can be added to change the wettability of the surface, which often influences cell adhesion (Fig. 16.3), as described earlier. Alternatively, whole proteins such as collagen can be immobilized to the surface, providing the cell with a substrate that more closely resembles the ECM found in tissues. Collagen and other ECM molecules have also been incorporated into hydrogels by either adding the protein to a reaction mixture containing monomers and initiating the radical polymerization, or mixing the protein with polymerized polymer, such as pHEMA, in appropriate solvents. To isolate certain features of ECM molecules, and to produce surfaces that are simpler and easier to characterize, smaller biologically active functional groups have been used to modify surfaces. These biologically active groups can be oligopeptides, saccharides, or glycolipids.

Certain short amino acid sequences, identified by the analysis of active fragments of ECM molecules, appear to bind to receptors on cell surfaces and mediate cell adhesion. For example, the cell-binding domain of fibronectin contains the tripeptide RGD (Arg–Gly–Asp) [67].[1] Cells attach to surfaces containing adsorbed oligopeptides with the RGD sequence and soluble, synthetic peptides containing the RGD sequence reduce the cell-binding activity of fibronectin, demonstrating the importance of this sequence in adhesion of cultured cells. A large number of ECM proteins (fibronectin, collagen, vitronectin, thrombospondin, tenascin, laminin, and entactin) contain the RGD sequence. The sequences YIGSR and IKVAV on the A chain of laminin also have cell-binding activity and appear to mediate adhesion in certain cells.

Because RGD appears to be critical in cell adhesion to ECM, many investigators have examined the addition of this sequence to synthetic polymer substrates. The addition of cell-binding peptides to a polymer can induce cell adhesion to otherwise nonadhesive or weakly adhesive surfaces. Cell spreading and focal contact formation are also modulated by the addition of peptide (Fig. 16.4). Since cells contain cell adhesion receptors that recognize only certain ECM molecules, use of an appropriate cell-binding sequence can lead to cell-selective surfaces,

1. Amino acids are identified by their one-letter abbreviation: A = alanine, R = arginine, N = asparagine, D = aspartic acid, B = asparagine or aspartic acid, C = cysteine, Q = glutamine, E = glutamic acid, Z = glutamine or glutamic acid, G = glycine, H = histidine, I = isoleucine, L = leucine, K = lysine, M = methionine, F = phenylalanine, P = proline, S = serine, T = threonine, W = trypotophan, Y = tyrosine, V = valine.

where the population of the cells that adhere to the polymer is determined by the peptide [68].

The presence of serum proteins attenuates the adhesion activity of peptide-grafted PEU surfaces [70], highlighting a difficulty in using these peptide-grafted materials in vivo. This problem may be overcome, however, through the development of base materials that are biocompatible yet resistant to protein adsorption. One of the most successful approaches for reducing protein adsorption or cell adhesion is to produce a surface rich in PEG. A variety of techniques have been used including surface grafting of PEG, adsorption of PEG-containing copolymers, semiinterpenetrating networks, or immobilization of PEG-star polymers to increase the density of PEG chains at the surface. Alternates to PEG—particularly hyperbranched polyglycerol (HPG)—may provide even better resistance to protein adsorption than PEG [71]. Polymer nanoparticles coated with HPG circulate longer after intravenous injection that identical particles coated with PEG, providing further evidence for the decreased interaction of HPG with proteins [72].

As an alternate approach, matrices can be formed directly from synthetic polypeptides. For example, genes coding the β-sheet of silkworm silk have been combined with genes coding fragments of fibronectin to produce proteins that form very stable matrices with cell adhesion domains (Pronectin F). Synthetic proteins based on peptide sequences from elastin have been used as cell culture substrates: in the presence of serum, fibroblasts and endothelial cells adhered to the surfaces of matrices formed by γ-irradiation cross-linking of polypeptides containing repeated sequences GGAP, GGVP, GGIP, and GVGVP [73].

Surface adsorption of homopolymers of basic amino acids, such as polylysine and polyornithine, are frequently used to enhance cell adhesion and growth on polymer surfaces. Similarly, covalently bound amine groups can also influence cell attachment and growth. Polymerization of styrene with monoamine or diamine containing monomers produced copolymers with ∼8% mono- or diamine side chains, which enhanced spreading and growth: diamine-PS > monoamine-PS > PS [74].

The immobilization of saccharide units to polymers can also influence cell attachment and function. As an example, *N*-*p*-vinylbenzyl-*o*-β-D-galactopyranosyl-(1−4)-D-gluconamide has been polymerized to form a polymer with a PS backbone and pendant lactose functionalities [75]. Rat hepatocytes adhere to surfaces formed from this polymer, via asialoglycoprotein receptors on the cell surface, and remain in a rounded morphology consistent with enhanced function in culture. In the absence of serum, rat heptaocytes will adhere to similar polymers with pendant glucose, maltose, or maltotriose. Similar results have been obtained with polymer surfaces derivatized with *N*-acetyl glucosamine, which is recognized by a surface lectin on chicken hepatocytes [76].

Films produced by LbL techniques can also be surface modified to modulate cell interactions. For example, for films that are assembled using covalent reactions, residual reactive groups can be used to attach small molecules that control the interaction of the film with cells. In one study, PEI films produced by covalent LbL assembly were further modified by coupling of small molecules. Coupling of hydrophobic molecules produced films that permitted cell attachment and growth, whereas covalent coupling of hydrophilic sugar groups reduced cell attachment, even in the presence of serum proteins [77].

Electrically charged or electrically conducting polymers

A few studies have examined cell growth and function on polymers that are electrically charged. Piezoelectric polymer films, which were produced by high-intensity corona poling of poly(vinylidene fluoride) or poly(vinylidene fluoride-*co*-trifluoroethylene) and should generate transient surface charge in response to mechanical forces, enhanced the attachment and differentiation of mouse neuroblastoma cells (Nb2a), as determined by neurite number and mean neurite length [78]. These observations may be important in vivo, as well. For example, positively poled poly(vinylidene fluoride-*co*-trifluoroethylene) nerve guidance channels produced greater numbers of myelinated axons than either negatively poled or unpoled channels [79]. Electrically conducting polymers might be useful for tissue engineering applications, because their surface properties can be changed by application of an applied potential. For example, endothelial cells attached and spread on fibronectin-coated polypyrrole films in the oxidized state, but they became rounded and ceased DNA synthesis when the surface was electrically reduced [80].

Influence of surface morphology on cell behavior

The microscale texture of an implanted material can have a significant effect on the behavior of cells in the region of the implant. This has long been observed in vivo. For example, fibrosarcomas developed with high frequency, approaching 50% in certain situations, around implanted Millipore filters; the tumor incidence increased with decreasing pore size in the range of 450−50 μm [81].

More recently, silicone breast implants have been associated with various complications including the development of breast implant−associated anaplastic large cell lymphoma. Epidemiological studies show that the disease

occurs at a much higher frequency in patients with textured versus smooth implants [82].

The behavior of cultured cells on surfaces with edges and grooves is different than behavior on smooth surfaces. In many cases, cells oriented and migrated along fibers or ridges in the surface, a phenomenon called contact guidance from early studies on neuronal cell cultures [83]. Fibroblasts orient on grooved surfaces [84], with the degree of cell orientation depending on both the depth and pitch of the grooves. Not all cells exhibit the same degree of contact guidance when cultured on identical surfaces: a comparison of cell responses to surfaces with grooves and edges, collected from early studies, is provided in Table 12.3 of Ref. [3]. These measurements are relevant to design of materials for tissue engineering: adhesion and initial migration of an osteoblast cell line was examined on materials with grooves ranging in pitch from 150 to 1000 nm and found to be optimal on grooves of intermediate spacing [85]. Cultured stem cells behave differently on grooved surfaces, when compared to smooth surfaces, which appears to be secondary to changes in integrin assembly, focal contact formation, and cytoskeletal organization [86].

Other textures also influence cell behavior. For example, substrates with peaks and valleys influence the function of attached cells [87]. PDMS surfaces with 2−5 μm texture maximized macrophage spreading. Similarly, PDMS surfaces with 4 or 25 μm^2 peaks uniformly distributed on the surface provided better fibroblast growth than 100 μm^2 peaks or 4, 25, or 100 μm^2 valleys.

The microscale structure of a surface has a significant effect on cell migration, at least for the migration of human neutrophils. In one study, microfabrication technology was used to create regular arrays of micron-size holes (2 μm × 2 μm × 210 nm) on fused quartz and photosensitive polyimide surfaces [88]. The patterned surfaces, which mimicked a structural element of 3D network (i.e., spatially separated mechanical edges), were used to study the effect of substrate microgeometry on neutrophil migration. The edge-to-edge spacing between features was systematically varied from 6 to 14 μm with an increment of 2 μm. The presence of evenly distributed holes at the optimal spacing of 10 μm enhanced migration by a factor of 2 on polyimide, a factor of 2.5 on collagen-coated quartz and a factor of 10 on uncoated quartz. The biphasic dependence on the mechanical edges of neutrophil migration on 2D patterned substrate was strikingly similar to that previously observed during neutrophil migration within 3D networks, suggesting that microfabricated materials provide relevant models of 3D structures with precisely defined physical characteristics. Perhaps more importantly, these results illustrate that the microgeometry of a substrate, when considered separately from adhesion, can play a significant role in cell migration.

Use of patterned surfaces to control cell behavior

A variety of techniques have been used to create patterned surfaces containing cell adhesive and nonadhesive regions. Patterned surfaces are useful for examining fundamental determinants of cell adhesion, growth, and function. For example, individual fibroblasts were attached to adhesive micro-islands of palladium that were patterned onto a nonadhesive pHEMA substrate using microlithographic techniques [89]. By varying the size of the micro-island, the extent of spreading and hence the surface area of the cell was controlled. On small islands ($\sim$500 μm^2) cells attached but did not spread. On larger islands (4000 μm^2), cells spread to the same extent as in unconfined monolayer culture. Cells on large islands proliferate at the same rate as cells in conventional culture, and most cells attached to small islands proliferate at the same rate as suspended cells. For 3T3 cells, however, contact with the surface enhanced proliferation, suggesting that anchorage can stimulate cell division by simple contact with the substrate as well as by increases in spreading.

A number of other studies have employed patterned surfaces in cell culture. Micrometer-scale adhesive islands of self-assembled alkanethiols were created on gold surfaces using a simple stamping procedure [90], which served to confine cell spreading islands. When hepatocytes were attached to these surfaces, larger islands (10,000 μm^2) promoted growth, while smaller islands (1600 μm^2) promoted albumin secretion. Stripes of a monoamine-derivatized surface were produced on fluorinated ethylene propylene films by radio-frequency glow discharge [91]. Since proteins adsorbed differently to the monoamine-derivatized and the untreated stripes, striped patterns of cell attachment were produced. A similar approach, using photolithography to produce hydrophilic patterns on a hydrophobic surface, produced complex patterns of neuroblastoma attachment and neurite extension [92]. A variety of substrate microgeometries were created by photochemical fixation of hydrophilic polymers onto TCPS or hydrophobic polymers onto PVA through patterned photomasks: bovine endothelial cells attached and proliferated preferentially on either the TCPS surface (on TCPS/hydrophilic patterns) or the hydrophobic surface (on PVA/hydrophobic patterns) [93]. When chemically patterned substrates were produced on self-assembled monolayer films using microlithographic techniques, neuroblastoma cells attached to and remained confined within amine-rich patterns on these substrates [94].

Cell interactions with polymers in suspension

Most of the studies reviewed in the preceding section concerned the growth, migration, and function of cells attached to a solid polymer surface. This is a relevant paradigm for a variety of tissue engineering applications, where polymers will be used as substrates for the transplantation of cells or as scaffolds to guide tissue regeneration in situ. Polymers may be important in other aspects of tissue engineering, as well. For example, polymer microcarriers can serve as substrates for the suspension culture of anchorage-dependent cells and, therefore, might be valuable for the in vitro expansion of cells or cell transplantation [95]. In addition, immunoprotection of cells suspended within semipermeable polymer membranes is another important approach in tissue engineering, since these encapsulated cells may secrete locally active proteins or function as small endocrine organs within the body.

The idea of using polymer microspheres as particulate carriers for the suspension culture of anchorage-dependent cells was introduced by van Wezel [96]. As described earlier for planar polymer surfaces, the surface characteristics of microcarriers influence cell attachment, growth, and function. In the earliest studies, microspheres composed of diethylaminoethyl (DEAE)-dextran were used; these spheres have a positively charged surface and are routinely used as anion-exchange resins. DEAE-dextran microcarriers support the attachment and growth of both primary cells and cell lines, particularly when the surface charge is optimized. In addition to dextran-based microcarriers, microspheres that support cell attachment can be produced from PS, gelatin, and many of the synthetic and naturally occuring polymers described in the preceding sections. The surface of the microcarrier can be modified chemically, or by immobilization of proteins, peptides, or carbohydrates.

Suspension culture techniques can be used to permit cell interactions with complex 3D polymer formulations, as well. For example, cells seeding onto polymer fiber meshes during suspension culture often results in more uniform cell distribution within the mesh than can be obtained by inoculation in static culture [97].

In cell encapsulation techniques, cells are suspended within thin-walled capsules or solid matrices of polymer. Alginate forms a gel with the addition of divalent cations under very gentle conditions and, therefore, has been frequently used for cell encapsulation. Certain synthetic polymers, such as polyphosphazenes, can also be used to encapsulate cells by cation-induced gelation. Low-melting-temperature agarose has also been studied extensively for cell capsulation. Methods for the microencapsulation of cells within hydrophilic or hydrophobic polyacrylates by interfacial precipitation have been described [98], although the thickness of the capsule can limit the permeation of compounds, including oxygen, through the semipermeable membrane shell. Interfacial polymerization can be used to produce conformal membranes on cells or cell clusters [99], thereby providing immunoprotection while reducing diffusional distances.

Hollow fibers are frequently used for macrocapsulation; cells and cell aggregates are suspended within thin fibers composed of a porous, semipermeable polymer. Chromaffin cells suspended within hollow fibers formed from the copolymer of vinyl chloride and acrylonitrile, which are commonly used as ultrafiltration membranes, have been studied as potential treatments for cancer patients with pain [100], Alzheimer's disease [101], and retinitis pigmentosa [102]. Other polymer materials—such as chitosan, alginate, and agar—have been added to the interior of the hollow fibers to provide an internal matrix that enhances cell function or growth.

Polymer nanoparticles are rapidly becoming important materials for drug delivery and tissue engineering, but little is known about how particles with diameters in the range of 50−200 nm interact with cells. When PLGA nanoparticles ($\sim$100 nm diameter) were suspended over monolayers of airway, intestinal, or renal tubular epithelial cells, particles were internalized as soon as 30 minutes after first exposure, becoming widely distributed through the intracellular space over a 24 hour period [103], but the extent of nanoparticle internalization varied among the epithelial cell types. PS nanoparticle interactions with model cell membranes depend on particle size, shape, and surface chemistry, as well as membrane composition, which may be a factor in the variable interactions of particles with different cells [104]. Although multiple mechanisms of nanoparticle entry into cells have been suggested, endocytosis is important in most cells, although it is not the only mechanism, as shown with endothelial cells [105]. In another example, PS particles (20 nm diameter) translocated—in the apical to basolateral direction—through monolayers of cultured alveolar cells, with particles carrying a positive surface charge moving more effectively than particles with a negative surface charge, apparently by transcellular, nonendocytic mechanisms [106].

Proteins absorb readily to the surface of polymer nanoparticles, as they do to all polymer surfaces. The presence of surface-bound proteins influences the interaction of nanoparticles with cells [107]. Particle shape may also have an influence on polymer particle interactions with cells [108], although there are few studies that have examined the effect of shape, particularly for particles with diameters less than 1 μm. As in other systems, tethering of ligands to the polymer surface can influence nanoparticle interactions with cells, including enhancing association and internalization [109].

Cell interactions with three-dimensional polymer scaffolds and gels

Cells within tissues encounter a complex chemical and physical environment that is quite different from commonly used cell culture conditions. 3D cell culture methods are frequently used to simulate the chemical and physical environment of tissues. Often, tissue-derived cells cultured in ECM gels will reform multicellular structures that are reminiscent of tissue architecture.

Gels of agarose have also been used for 3D cell culture. Chondrocytes dedifferentiate when cultured as monolayers but reexpress a differentiated phenotype when cultured in agarose gels [110]. When fetal striatal cells are suspended in 3D gels of hydroxylated agarose, ~50% of the cells extended neurites in gels containing between 0.5% and 1.25% agarose, but no cells extended neurites at concentrations above 1.5%. This inhibition of neurite outgrowth correlates with an average pore radius of greater than 150 nm [111]. Neurites produced by PC12 cells within agarose gels, even under optimal conditions, are much shorter and fewer in number than neurites produced in gels composed of ECM molecules [112].

Macroporous hydrogels can also be produced from pHEMA-based materials, using either freeze-thaw or porosigen techniques. These materials, when seeded with chondrocytes, may be useful for cartilage replacement [113]. Similar structures can be produced from PVA by freeze-thaw cross-linking. PEG-based macroporous gels were used as a scaffold for endothelial cells to form microvessel networks in vivo [114]. Although cells adhere poorly to pHEMA, PVA, and PEG materials, adhesion proteins or charged polymers can be added during the formation to encourage cell attachment and growth. Alternatively, water-soluble, nonadhesive polymers containing adhesive peptides, such as RGDS, can be photopolymerized to form a gel matrix around cells (see Ref. [115], for example).

Fiber meshes and foams of PLGA, PLA, and PGA have been used to create 3D environments for cell proliferation and function, and to provide structural scaffolds for tissue regeneration. When cultured on 3D PGA fiber meshes, chondrocytes proliferate, produce both glycosaminoglycans and collagen, and form structures that are histologically similar to cartilage [116]. The internal structure of the material, as well as the physical dimensions of the polymer fiber mesh, influences cell growth rate, with slower growth in thicker meshes. Changing the fluid mechanical forces on the cells during the tissue formation also appears to influence the development of tissue structure.

In addition to fiber meshes, porosity can be introduced into polymer films by phase separation, freeze drying, salt leaching, and a variety of other methods (reviewed in Ref. [117]). It is now possible to make porous, degradable scaffolds with controlled pore architectures and oriented pores [118,119]. Fabrication methods that provide control over the structure at different length scales may be useful in the production of 3D tissue-like structures.

Most methods for producing fiber meshes are limited to producing fibers ~10 μm in diameter, which is much larger than the diameter of natural fibers that occur in the ECM, and also larger than many of the features that are known to be important in orienting or guiding cell activity. Electrospinning techniques can be used to make small diameter fibers and nonwoven meshes of a variety of materials including poly(caprolactone) (PCL), PLA, collagen, and elastin mimetic polymers.

Cell interactions unique to the in vivo setting

While cell interactions with polymers in vitro can be described by examination of cell behaviors—such as adhesion, migration, or gene expression—or the coordinated behavior of cell groups—such as aggregation, cell interactions with polymers in vivo can lead to other responses, involving cells that are recruited to the implantation site and remodeling of the tissue space surrounding, or even within, the polymeric material. Inflammation, the FBR, and angiogenesis are three examples of these more global responses to an implanted material.

There is much still to learn in this area, but it is clear that both the implant material and the physiology of the implant site are important variables. A study describing a relatively simple experiment, in which ePTFE implants were placed in adipose tissue, in SC tissue, or epicardially illustrates the variability of these responses [120]. Moreover, studies in monocyte chemoattractant protein (MCP-1)-null mice have shown that the extent of the FBR was dependant on the implantation site [121,122]. This short section introduces these physiological responses to implanted materials.

Inflammation

The implantation of polymers through surgical incisions means that an initial component of the FBR involves a wound healing−like response and it is reasonable to assume that the early inflammatory response is mediated, at least in part, by wound-derived factors. Analysis of inflammatory cells has been pursued in several implantation models and was shown to involve predominantly neutrophils (early) and monocyte/macrophages (late). In addition, dendritic cells and T cells have been implicated in the response, but their roles are not as clearly defined [123,124]. Subsequent to their recruitment, these cells are believed to utilize adhesion receptors to interact with adsorbed proteins. Studies in mice that lack specific integrins or fibrinogen have provided supporting evidence for

this hypothesis [125–127]. Specifically, short-term (18 hours) IP implantation of PET disks in mice that lack fibrinogen indicated normal recruitment but reduced adhesion of macrophages and neutrophils to the polymer. In the same study, analysis of the response in mice that lack plasminogen indicated no changes in cell adhesion to the polymer despite a reduction in the recruitment of both cell types in the peritoneal cavity. Thus in addition to fibrinogen for adhesion, inflammatory cells can utilize plasminogen for migration/recruitment. Moreover, studies in mice lacking plasma fibronectin displayed altered FBR [128]. More recently, it was shown that polymer–macrophage interactions can lead to activation of the inflammasome leading to the secretion of the proinflammatory cytokine interleukin (IL)-1β [35]. In the same study, it was shown that mice that lack components of the inflammasome mount reduced FBR suggesting that initial interactions between cells and polymers are critical determinants of the FBR. Surprisingly, the chemokine CCL2 (also known as MCP-1) was shown not to be important in monocyte/macrophage recruitment in long-term implants in the subcutis [121]. However, CCL2 was shown to be important for macrophage fusion leading to FBGC formation. Subsequently, it was shown that CCL2 was critical for the recruitment of inflammatory cells in the FBR when implants were placed in the peritoneal cavity of mice [122]. Consistent with the notion that macrophage responses are critical in the FBR, IP implants in CCL2-null mice displayed minimal encapsulation.

FBGC can cause damage to polymer surfaces through their degradative and phagocytic activities and, thus, pose a significant obstacle to the successful application of polymer-based biomaterials and devices. In vivo studies have identified a critical role for IL-4 in the formation of FBGC [25], but the regulation of macrophage fusion is not fully understood [129]. Studies in rodents have enhanced our understanding of this process by implicating tumor necrosis factor and the nuclear factor-kappa B pathway [22]. Moreover, polymer (PCL)-mediated release of the inhibitor BAY-11 resulted in partial attenuation of FBGC formation [130]. On the other hand, several studies have focused on the role of polymer surface chemistry on macrophage function and FBGC formation. For example, analysis of macrophage adhesion, apoptosis, and fusion on hydrophobic (PET and BDEDTC-coated), hydrophilic (PAAm), anionic (PAANa), and cationic (DMAPAAmMel) surfaces implanted in the rat cage-implant model revealed that PAAm and PAANa induced more apoptosis and reduced adhesion and fusion [131].

Fibrosis and angiogenesis

Unlike wound healing, the resolution of the polymer-associated inflammatory response is characterized by the excessive deposition of a highly organized collagenous matrix and a striking paucity of blood vessels [132,133]. The collagenous capsule can vary in thickness but usually exceeds 100 μm, presumably to limit diffusion of small molecules to and from the polymer. The dense and organized nature of the collagen fibers in the capsule could play a role in limiting blood vessel formation. Implantation studies in mice that lack the angiogenesis inhibitor TSP2 indicated that an increase in vascular density in capsules surrounding PDMS disks was associated with significant loosening of the collagenous matrix [134]. However, a direct link between the arrangement of collagen fibers in the capsule and blood vessel formation has not been established. Interestingly, the modification of the PDMS surface from a hydrophobic to a hydrophilic state altered its cell adhesive properties in vitro but did not cause a change in the FBR in vivo [134]. Such observations underscore the significance of in vivo evaluation of cell- and tissue–polymer interactions. Reduced encapsulation of PDMS (silicone rubber) disks and cellulose Millipore filters implanted SC has been reported in mice that lack SPARC (secreted protein, acidic, and rich in cysteine), a matricellular glycoprotein that modulates the interactions of cells with the ECM. Interestingly, mice that lack SPARC and its close homolog, hevin, display diminished vascular density in encapsulated Millipore filters (type HA, mixed cellulose ester) [135]. Taken together, implantation studies in genetically modified mice suggest that members of the matricellular protein group play critical roles in the FBR [133,136]. The process however, can also be influenced by parameters such as polymer special geometry and porosity. Comparison of the FBR elicited by expanded and condensed PTFE showed similar encapsulation but more mature fibrous capsule formation in the latter [137]. In addition, the effect of polymer porosity in the FBR was examined in SC-implanted PTFE membranes in rats where it was shown that the vascular density could be increased in capsules surrounding polymers with a pore size in the range of 5 μm [138]. However, it is unclear whether the same porosity would enhance the vascular density of capsules surrounding other polymers. In fact, Sussman et al. showed that pHEMA scaffolds with 34 μm pores were able to modulate macrophage activation and reduce fibrosis and increase vascularization [139].

More recently, charge distribution on polymers has been shown to attenuate the FBR. For example, poly(carboxybetaine methacrylate) (PCBMA) hydrogels were shown to completely resist encapsulation [140]. Similarly, coating of implantable glucose sensors with a zwitterionic polymer (poly-methacryloyloxyethyl phosphorylcholine) resulted in reduction in noise associated with reduced FBR [141].

Finally, an additional concern with polymer encapsulation is the presence of contractile cells, myofibroblasts,

which can cause contraction of the capsule and misshape or damage polymer implants. For example, silicone-based breast implants have been shown to be susceptible to this phenomenon [142].

Chapter 17

Polymer scaffold fabrication

Matthew L. Bedell*, Jason L. Guo*, Virginia Y. Xie, Adam M. Navara and Antonios G. Mikos
Department of Bioengineering, Rice University, Houston, TX, United States

Introduction

A multitude of polymer-processing techniques has been used for the fabrication of tissue engineering scaffolds (Table 17.1), which typically serve as temporary structures in place of extracellular matrix (ECM) for the attachment, proliferation, and differentiation of cells. Traditional processing methods have been sufficient to create scaffolds with interconnected porous architecture for nutrient and waste transport as well as the migration of cells and have often incorporated biochemical cues for tissue development in the form of natural polymers, ceramics, or growth factors. However, these scaffolds are typically uniform in composition, limited in the complexity of physical features, and difficult to scale-up in production. Thus more advanced scaffold fabrication techniques have been needed to accomplish the goal of producing tissue- and patient-specific scaffolds in the fields of tissue engineering and regenerative medicine [2]. To address this need, three-dimensional (3D) printing (3DP) technologies have emerged as a collection of powerful processing methods that can create scaffolds of highly defined physical architecture, with the potential to deposit multiple material/ink compositions in a spatially defined manner at high resolution. 3DP technology thus allows for the creation of more highly biomimetic scaffolds that recapitulate both the physical and biochemical features of native tissue ECM. Bioprinting, in particular, is a set of 3DP strategies in which living cells and/or biologically active molecules are encapsulated within the ink to be printed, differing in practice from the fabrication of scaffolds out of purely acellular materials and then seeding cells post-printing [3–5]. In this approach, bioinks, or the cell-containing materials, are often printed in tandem with cell-free support materials to allow for the creation of mechanically stable scaffolds as well as the introduction of cell patterning [5]. Bioactive compounds, such as growth factors and peptides, are often incorporated within the bioink itself to enable localized differentiation of cells to the desired phenotypes. Generally, the principle of 3DP and bioprinting techniques is that individual layers of the scaffold are deposited one by one according to a digital model generated through computer-aided design (CAD) software such as AutoCAD or SolidWorks. The CAD model itself can be designed by the user to match the size and shape of a tissue defect or even acquired from 3D, patient-specific scans using techniques such as magnetic resonance imaging or computed tomography [6]. When designing the digital model for printing, tissue engineers must take into account and replicate not only the overall morphology of the tissue defect but also the necessary porous architecture for a tissue engineering scaffold, as discussed later [3]. The user must also specify the locations for the deposition of different materials/inks, which can be defined either in the model itself or in the printer software [2].

The overarching goal of utilizing 3DP for tissue engineering is to deposit materials, bioactive factors, and/or living cells with precise layer-by-layer spatial control to create biologically functional 3D structures [6], all of which will be discussed in this chapter. For the sake of ensuring that the printed cells remain viable, these bioink components need to be thoroughly screened for their effects on cell morphology, phenotype, and viability, as cells will respond directly to environmental cues present in the bioink [7,8]. The materials themselves, whether cell-encapsulating or cell-free, must be tunable in mechanical and architectural properties to create scaffolds that match the physical and mechanical properties of native tissue [6]. The processing conditions of the printer also play a large part in final cell viability, and so testing

TABLE 17.1 Methods of scaffold fabrication.

Technique	Description	Advantages	Disadvantages
Rapid prototyping: 3DP	CAD-modeled deposition of material and/or cells, layer-by-layer stacking to create a 3D scaffold	Wide variety of materials, highly defined porosity and architecture, accurate repeatability, allows incorporation of bioactive molecules and cells	High-throughput manufacturing not available, time consuming process
Fiber bonding	Polymer fibers are heated and fused at points of intersection	Simple procedure, high surface area-to-volume ratio promotes cell attachment	High processing temperatures, limited control over porosity
Electrospinning	Voltage is applied to spin polymer fibers in a nonwoven mesh	Very fine fiber thickness maybe achieved	Limited control of fiber deposition and porosity, poor mechanical integrity
Solvent casting/ particulate leaching	Porogen incorporated into polymer and solidified, porogen is later dissolved/leached	Minimal material needed for procedure, high porosity, allows incorporation of composite materials	Pore structures not interconnected, residual solvents or porogens, detrimental to bioactivity
Melt molding	Polymer and porogen heated in mold, solidification and removal from mold, porogen leached out	Control of shape with mold, flexible geometry, allows incorporation of composite materials	High processing temperatures, lack of pore interconnectivity
Membrane lamination	Thin layers of porous polymer are chemically fused	Defined contours and geometries, no visible boundary between layers	Necessary to define shape for each layer, time consuming, cytotoxic solvents
Extrusion	Polymer is heated and forced through a die, forms 3D profile of die's cross-sectional area	Ability to fabricate tubular structures	High temperatures or pressures needed
Freeze-drying	Polymer solution is emulsified, emulsion poured in mold and frozen	Some pore interconnectivity	Lower porosity than most other procedures, scaffold and pore size limitations
Phase separation	Polymer dissolved in solvent, bioactive molecules added to make homogenous mixture, cooling and freezing separates phases, solvent sublimed	Potential for drug delivery applications, bioactive molecules protected from solvents	Residual solvents, limited pore sizes
High internal-phase emulsion	Water-in-oil emulsion following HIPE standards, monomers from organic phase used to synthesize and cross-link polymer scaffolds with pores	Injectability, good pore morphology, biodegradable polymers maybe used	Limited polymer types, high processing temperatures
Gas foaming	Compressed polymer is exposed to high pressure gas, pores form with decreased pressure	Eliminates need for organic solvents, improved cell adhesion	Lack of pore interconnectivity, limited pore sizes
Peptide self-assembly	Designer peptides form into complex geometries (spheres, fibers, and sheets) via hydrophobic/hydrophilic interactions	Maybe designed to promote various cell behaviors, compatible with in vitro culture	Expensive materials, design expertise required, limited scaffold size
In situ polymerization	Polymer is injected at site and polymerizes or cross-links after implantation	Immediate implantation possible, minimal processing necessary	Limited mechanical properties, limited porosity, harmful polymerization by-products, limited material choice

3DP, 3D printing; *CAD*, computer-aided design; *HIPE*, high internal phase emulsion.

biocompatibility of a bioink extends beyond studies of the material itself and must also include the dynamic behavior of the bioink during the printing process. Common processes for ensuring cytocompatibility and characterization methods for cell viability and activity will thus be discussed later in this chapter.

Design inputs: materials, processing, and cell types

Creating biomimetic scaffolds using 3DP requires careful consideration of not only the cell-encapsulated and cell-free scaffold materials themselves, but also the processing methods for these materials and the types of cells that are to be encapsulated within the scaffold. For example, not only would the polymer need to be sterile filtered and/or prepared in a sterile environment but also the nozzle, cartridge, and print platform would all need to be sterilized and the printer would also require operation within a sterile environment, such as a biosafety cabinet, since they all interface with live cells that are being handled for culturing, and ideally, later implantation for regenerative medicine and tissue engineering applications. After all these precautions are taken to minimize potentially damaging effects to living cells, the successful preservation of cellular metabolism and differentiation must be characterized in these bioprinted structures [9,10]. The results of investigations into cell morphology or activity of the included biological factors can then be compared to what is considered acceptable for specific cell lineages, to ensure that proper environmental conditions are utilized during printing. This section thus describes the various design parameters of a 3DP scaffold ranging from material selection to processing technique and cell types, as well as the different means of characterizing cell viability and activity within printed scaffolds.

Materials and inks

Designing multilayered scaffolds for 3DP requires the use of specific materials with both mechanical and biological properties that mimic those of the target tissue [11]. These biomaterials can be either synthetic or natural polymers that mimic the various properties of living tissue, ranging from architectural and mechanical features to biochemical cues for tissue development. The selection of materials also depends on the 3DP technique used. Extrusion-based printing often involves heating of the material to its glass transition or melting temperature, so any cells or additional compounds in the ink must be able to withstand the thermal stress, and it may thus be favorable in the case of cell encapsulation to extrude polymers with low glass transition temperatures. Thus material selection involves not only the mimicry of native tissue properties but also the consideration of other parameters such as cell type and processing method.

Synthetic polymers, such as poly(lactic acid) (PLA), poly(ε-caprolactone) (PCL), nylon, polycarbonate, and poly(vinyl alcohol), are among the most commonly used materials in 3DP technology because their tunable properties allow for the formation of highly defined or complex scaffolds [11]. A summary of some of the most commonly printed synthetic polymers and their unique advantages and disadvantages for printing can be found in Table 17.2. Polyesters, especially PLA and PCL, have low melting points that allow for increased printability and processability during the 3DP process. These polymers also have the advantage of undergoing hydrolysis during in vivo conditions, which allows biological excretory pathways to eliminate the polymers and their degradation products over time. Synthetic polymers can also be combined with additives, such as biomolecules or ceramics, to maximize the effectiveness of specific desired properties. For example, combinations, such as PCL/chitosan and PCL/β-tricalcium phosphate (TCP), can increase the cartilage and bone-specific bioactivity, respectively, of the printed scaffold [25]. Synthetic polymers are also advantageous because they are typically biologically inert and allow for minimal unwanted cell interactions after cells are seeded or deposited around them. However, cells cannot be encapsulated in many synthetic polymer inks, such as PCL and PLA, because these synthetic polymers have high melting temperatures that require the extrusion to be performed at temperatures much higher than 40 °C or with the usage of organic solvents, both of which are not viable for cells [26]. To tackle the temperature issue, cells can be printed using a layer-by-layer technique where they are encapsulated in a secondary protein or natural polymer ink that is printed simultaneously at low temperature [11]. Alternatively, some water-soluble synthetic polymers, such as poly(ethylene glycol) (PEG), can be used for cell encapsulation when extruded at low temperature in hydrogel form [9].

Natural polymers and proteins are less tunable than synthetic polymers, but they have greater bioactive properties that provide tissue-specific cues for targeted regions of the scaffold. A few commonly printed natural polymers are summarized in Table 17.2. These natural polymers are typically processed by mild printing conditions and are incompatible with high temperatures and strong organic solvents due to degradation or denaturation of the proteins or polymers [11]. Natural polymers, such as agar/agarose, have been used to print biocompatible hydrogels that are suitable for cell encapsulation [18]. Collagen and other matrix-derived proteins can be used to create biomaterial scaffolds with specific peptide sequences that promote cell−matrix interactions and cell function. Similarly, the protein fibrin, a natural polymer with blood-clotting

TABLE 17.2 Commonly printed synthetic and natural polymers for tissue engineering.

Polymer	Compatible 3DP methods	Properties	References
PCL *Synthetic polymer*	• Stereolithography • LAB • Extrusion	• Exhibits well-established biocompatibility • Contains hydrolysable ester bonds • Enables long lifespan—can safely degrade in body at rate similar to that of new bone formation	[12–14]
PGA, PLA, and PLGA *Synthetic polymer*	• Stereolithography • Extrusion	• Exhibits well-established biocompatibility • Contains hydrolysable ester bonds • Enables shorter lifespan, but tunable depending on comonomer ratio and molecular weight	[12,14,15]
PEG derivatives *Synthetic polymer*	• Stereolithography • Extrusion	• Exhibits well-established biocompatibility • Provides hydrophilic and very bioinert material • Can be covalently cross-linked by various methods	[12,14–16]
PVA *Synthetic polymer*	• LAB	• Provides high mechanical strength • Experiences minimal thermal degradation	[12,17]
Agar/agarose *Natural polymer*	• Extrusion	• Exhibits well-established biocompatibility • Provides low viscosity for printing • Provides large gelling temperature range	[12,18]
Alginate *Natural polymer*	• Extrusion	• Exhibits well-established biocompatibility • Allows for fast ionic cross-linking	[12,16]
Collagen/gelatin *Natural polymer*	• Extrusion • LAB	• Exhibits well-established biocompatibility • Supports cell–matrix interactions • Solubilizes in water at body temperature (gelatin)	[12,19]
Fibrin *Natural polymer*	• Extrusion	• Provides blood-clotting properties • Provides strong tissue adhesion • Possesses low mechanical strength	[12,19]
Hyaluronic acid *Natural polymer*	• Extrusion	• Mimics soft tissue ECM • Provides high viscosity and highly hydrated environment	[9,20–22]
Starch *Natural polymer*	• Inkjet printing	• Forms viscous paste when heated	[23,24]

3DP, 3D printing; *ECM*, extracellular matrix; *LAB*, laser-assisted bioprinting; *PCL*, poly(ε-caprolactone); *PEG*, poly(ethylene glycol); *PGA*, poly(glycolic acid); *PLA*, poly(lactic acid); *PLGA*, poly(lactic-co-glycolic acid); *PVA*, polyvinyl alcohol.

properties for wound repair, has high adhesion properties that can promote both cell attachment and tissue integration [19]. Natural polymers, however, are typically too weak to mimic the natural mechanical environment for harder tissues and will also struggle to maintain the integrity of the 3DP scaffold in harder tissues and load-bearing settings [15]. This limitation also prevents many natural polymers from being used to print architecturally complex structures [15]. People have addressed these weaknesses by cross-linking polymers, such as fibrin and collagen, after printing. Chemical cross-linking with glutaraldehyde or ultraviolet (UV)-induced cross-linking postprinting, for instance, can be used to strengthen many natural polymer scaffolds [27]. Coprinting natural and synthetic polymers has also been used to strengthen natural polymer scaffolds. By printing synthetic polymers, such as poly(α-hydroxyacid)s, with natural polymers, such as collagen and hyaluronic acid, researchers have developed hybrid scaffolds that retain the superior qualities of each component. These hybrid scaffolds have the bioactivity and ECM-like qualities of natural polymers while possessing the higher mechanical strength and tunability of synthetic polymers [15]. Overall, 3DP scaffolds that utilize both natural and synthetic polymer inks have been used to address the unique advantages and drawbacks of each to create scaffolds that maximize mechanical strength and integrity while retaining biocompatibility and bioactivity for the tissue of interest.

When selecting biomaterials for printing, one must also consider the degradation kinetics and breakdown products of the material. The speed of degradation should ideally match the rate of matrix regeneration produced by encapsulated and native cells, and more in-depth discussion of these can be found in other chapters of the book. The biological effects of a bioink polymer's degradation can also be wide-ranging. Polyesters, such as PLA and

PCL, for instance, degrade to acidic byproducts that can decrease the local pH around the scaffold. Thus while the degree of degradation in certain synthetic polymers can be more easily controlled by changing parameters, such as molecular weight, the oligomers and monomers that result from their breakdown have the potential to be inflammatory or cytotoxic [6]. This also means that synthetic polymers must be printed at temperatures low enough that they do not experience thermal degradation, which can result in acidic or otherwise cytotoxic monomers and oligomers being present in the printed fibers. Generally, printing at temperatures slightly above the glass transition or melting points is sufficient to avoid any thermal degradation, while producing a low-viscosity melt is suitable for deposition [28].

Processing and cell viability

The usage of 3DP techniques introduces many new external processing conditions that affect cell viability and function, such as in situ polymerization and cross-linking, process temperature, additional pressure or force during deposition, and shear stress, many of which are not typical considerations for traditional studies that seed cells after printing is complete [20,29–32] (see Fig. 17.1 for a summary of these factors [30]). The cross-linking of a bioink's polymer network can enhance the elastic moduli of printed geometries to the point where they possess sufficient mechanical integrity to be handled without damage, and this increase in the stiffness of the ECM can also induce biomechanical cues that drive differentiation down particular cell lineages [6,33]. Depending on the photoinitiator and polymerization system, additional UV or visible light maybe used in conjunction with successive layer fabrication [6]. Extended exposure to UV light is known to have a cytotoxic effect on cell cultures [29,34–36]. To avoid subjecting the cells to UV light, certain studies have employed the use of "partial cross-linking" before the bioink is extruded so that the solution is self-supporting on the build platform, with full cross-linking completed later with additional exposure to the chosen mechanism, such as UV light or calcium ion chelation, to give the construct its full structural integrity [37–39].

Besides the chemical additives and reactive components of a bioink, the dynamic behavior of the bioink itself as it is displaced from the cartridge to the build platform also impacts cell viability. For example, it is known the acellular polymer viscosity has a substantial impact on the injectability of the solution [26,40]. A more viscous solution requires a greater pressure to achieve extrusion through a fixed nozzle diameter, and this would consequently exert greater shear stress on both the material itself and the encapsulated cells near the walls of the nozzle [37,41]. Thus printing cells within a near-liquid polymer solution is advantageous because of a lower required deposition pressure, but that bioink material must be gelled enough to ensure a homogenous cell distribution, as gravitational forces cause cells to settle to the bottom of suspensions when the material viscosity is low [30,42] Alternatively, if a bioink is composed of shear-thinning materials, the resulting drop in polymer viscosity under shear force can decrease the cytotoxic wall forces throughout an extrusion process and preserve cell viability [43,44]. Laser-assisted and inkjet-based bioprinting methods avoid the same degree of shear stress experienced in extrusion bioprinting due to the lack of ink needing to be

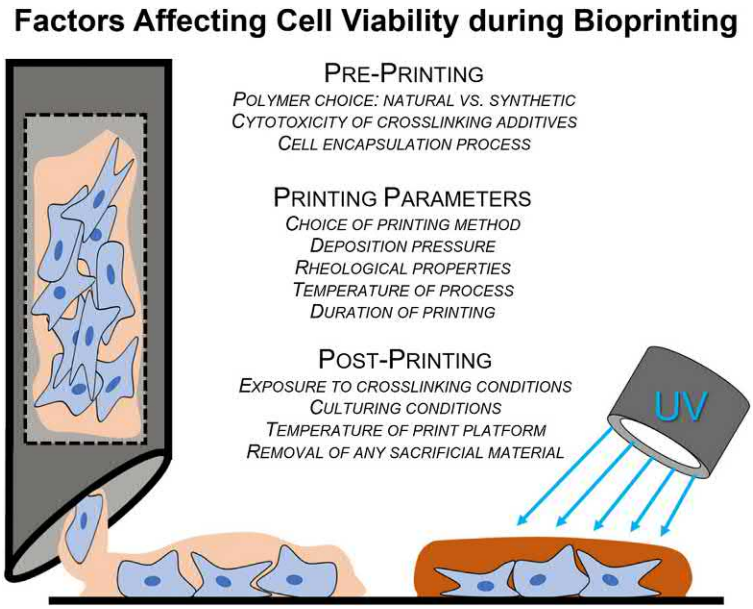

FIGURE 17.1 Preprinting conditions and bioink properties, selection of printing parameters, and postprinting conditions all impact cell viability. These factors can also directly affect subsequent cell proliferation, cell differentiation, and functional tissue formation.

pushed through a nozzle assembly, but these methods have slower processing times and are not able to print with the same cell densities as extruded bioinks [4]. As a result, the biocompatibility of any bioprinting method, especially if it involves shear stress from a printing nozzle or UV irradiation for photo-crosslinking, should always be ensured via thorough characterization of cell viability or comparisons with in vitro control cultures to determine the impact of processing effects [6,9,10,45].

To observe the effect that cross-linking a bioink matrix has on the encapsulated cells' viability, studies typically must first perform rheological analyses to assess the degree of change on the mechanical properties of a material. In photo-crosslinkable bioinks, for example, the effect of varying degrees of cross-linker on resulting shear storage and loss moduli of the raw materials can be measured using a UV-compatible rheometer, where the obtained results would allow for tuning of the balance between printability and desired mechanical stiffness [38,44]. Concurrently, an assessment of the cytotoxicity effect of cross-linking reagent exposure during culturing without the additional factors of applied mechanical forces would identify the upper limit of what can be included in the bioink formulation [9,46]. As discussed in the next section, histological assays, proliferation assays, or fluorescent microscopy utilizing immunofluorescent antibodies that bind to surface markers that indicate the appropriate cell phenotype maybe performed after printing to determine viability and the resulting cell differentiation pathways among cross-linked scaffolds [9,31].

Instead of removing cytotoxic cross-linking mechanisms, some researchers have opted to instead focus on methods that protect cells from these effects during the printing or cross-linking process. One tool commonly employed is the encapsulation of cells in microparticles consisting of cross-linked gelatin, a common natural hydrogel material in which many cell types have been shown to remain viable [2,3,9]. By combining this proven viability with the ability to tune the degradation of the cross-linked polymer network, microparticles allow cells to remain viable during the additional stresses encountered during bioprinting and then are suited to allow for cell migration and proliferation throughout the printed construct via degradation of the network [47–49]. Also, the use of microgels and nanogels, which are aggregates of small polymeric particles in a suspension, creates a viscoelastic environment that is robust enough to be mechanically self-standing after printing, but also has shear-thinning properties that allow it to be extruded without harming encapsulated cells [21]. Supramolecular assembly and guest–host chemistry have been used to create an encapsulating hydrogel material that reversibly binds upon extrusion, allowing for the increased display of cytocompatible shear-thinning properties [20,44].

Alongside in situ polymerization, cross-linking reagents, and damaging shear stress, temperature influences the choice of materials that maybe used for cell-based printing applications. While synthetic polymers have the strength to mimic the mechanical properties needed for supportive tissue applications, such as bone, most of these hydrophobic plastic materials cannot be extruded in liquid form at near-ambient temperatures, as discussed earlier [40,43]. However, since bioink and hydrogel extrusion can be performed at ambient temperature, bioprinted constructs can be fabricated in a normal laboratory setting [37,41,50]. While it is now commonplace in research to combine cells and supportive matrix material during fabrication of living composites, recent investigations have tried combining these separate living and supportive materials through the parallel printing of hydrogel-laden cells and rigid, supportive scaffolds for more robust tissue engineering constructs. The integrated tissue–organ printer (ITOP) is one system that utilizes multiple functional nozzles to print cell-laden hydrogels alongside rigid, biodegradable synthetic polymers in intricate patterns to ultimately fabricate living, human-scale constructs [51].

Cell types and biological interactions

Due to the large variety of environmental factors, processing conditions, and bioink components, researchers must also consider the tolerances of a particular cell type when choosing bioprinting as a method of scientific investigation. Previous studies in the area of bioprinting use cell types that are known to be capable of substantial proliferation and are very robust, such as fibroblasts or transformed cell lines, because they have been shown to tolerate the stresses incurred during construct fabrication, such as UV irradiation and shear stress mentioned in the previous section [6]. As an example of challenges with printing multiple cell types, consider the osteochondral unit. Within this singular structure, there are two supportive biological materials that lie on opposite ends of the spectrum of mechanical properties within the musculoskeletal system: bone and cartilage. While trabecular bone has an elastic modulus on the order of 10 GPa, hyaline cartilage has an elastic modulus on the order of 1 MPa, and so these cells experience markedly different magnitudes of compressive forces in vivo [52–55]. Hyaline cartilage is much softer because its structure consists mainly of water (68%–85%), followed by Type II collagen (10%–20%), and proteoglycans (5%–10%), whereas subchondral bone is predominantly Type I collagen impregnated with nanocrystallite particles of carbonated apatite and forming a much more reinforced composite [54]. Because of the different microenvironments of these cells, subjecting them to forces during printing that are outside

the range of biomechanical stimulation that they naturally experience in vivo may trigger undesirable effects, such as subphysiological or supraphysiological gene expression or cellular hypertrophy, which then causes the printed tissue to be functionally different than the corresponding native tissue [56].

Instead of using mature and fully differentiated cells for cell therapies, the use of stem cells, especially bone marrow−derived human mesenchymal stem cells (MSCs) (hMSCs), has been employed for many bone and cartilage tissue engineering studies [57]. hMSCs are relatively abundant, and if given certain stimulation and biological factors, can differentiate along osteogenic, chondrogenic, or myogenic pathways [58−61]. As discussed in this chapter, bioprinting can allow for the increased control needed for engineering complex tissues, such as positioning stem cells and chondrocytes in stratified layers of a hydrogel for cartilage tissue engineering, but this control should not sacrifice the utility that the undifferentiated stem cells provide [62]. For example, even moderate shear stress was found to have an effect on stem cell differentiation [63]. Therefore in order to maintain the desired undifferentiated state, it is best to use bioprinting methods that reduce the amount of shear stress experienced by cells, such as laser-assisted bioprinting (LAB) and inkjet printing. A well-characterized microvalve-based system has been used to study this safeguard, showing how below a certain threshold of shear stress, the chosen hMSC phenotype is unchanged by the forces experienced during inkjet bioprinting [31]. Within LAB, different conditions for the formation of the microscopic inkjet during cell printing may also be used to ensure high MSC viability in printed cells [64].

While MSCs with osteogenic growth factors are typically the most common cell type used for bioprinting bone tissue, printing of osteoblasts directly has also been employed [57,65,66]. In one study, researchers printed an acellular PCL framework and then seeded the scaffold with osteoblasts and chondrocytes suspended in alginate [66]. The osteoblast cells proliferated, but the chondrocytes did not, despite being viable. One challenge with chondrocytes is that they usually require a supportive matrix for stabilization [57]. In addition, it must be considered that primary chondrocytes are prone to losing their viability and functionality [66]. Therefore bioprinted constructs must be robust enough to be cultured for the extended periods of time necessary for chondrocytes to proliferate before clinical translation is considered.

Another cell−material interaction that is important to consider is the potential for matrix remodeling. This phenomenon is influenced both by the capability of a cell to direct and modify its microenvironment and the suitability of the encapsulating materials for these cell-directed changes. For example, natural polymer hydrogels have a myriad of natural binding sites, biochemical cues, and endogenous factors present, which are known to promote cellular metabolisms closer to that of the native physiology. However, when studying the isolated metabolic pathways or signaling mechanisms involved in this cause-and-effect relationship, these natural polymers are harder to tune due to the diversity in the assortment of confounding factors from ECM cues being presented, as well as the batch-to-batch variability from natural material sourcing [67]. Synthetic polymers typically offer no binding sites and must be modified to possess the biochemical cues that work with native cell remodeling processes [67,68]. The foundation for the mechanisms in these processes includes matrix metalloproteinases (MMPs) and changes in cell-binding domains and integrin expression [69]. Migration of cells is necessary for healthy tissue metabolism as the population grows and proliferates, and what makes this possible is integrin-binding that provides traction for cells to move and penetrate the extracellular environment, which can either be proteolytic, as in the case of main enzymes involved in ECM remodeling, or nonproteolytic [69−71]. This, in order to prevent implant dehiscence or failure in the mechanical properties of implanted cellular composites, the inclusion of MMP-degradable components must be considered at the cellular level and should be tuned to match the remodeling and degradation capabilities of that cell type's biology for the targeted tissue [72,73].

Besides MMP-degradable linkages, polymers can be synthesized or conjugated with certain bioactive factors to tune scaffolds to be more tissue-specific. Whether these are chemical moieties, added cell-adherent peptide sequences, or suspended ceramic materials, bottom-up approaches such as these can be used with both naturally sourced and synthetic polymer materials to control cell−polymer interaction. For example, in osteochondral tissue engineering, printed scaffolds are often designed to be osteoinductive, meaning that they are stimulating for undifferentiated cells toward a bone-forming cell lineage, or osteoconductive, which permits bone tissue to grow on the scaffold surface [74,75]. To both trigger differentiation and subsequent pre-osteoblast activity, scaffolds can be tailored to stimulate these effects of calcium and bone tissue deposition over time through the inclusion of bioceramic materials, such as hydroxyapatite or β-TCP, where cell-directed processes fortify scaffolds to be in the range of stiffness comparable to human bone [72,75−77]. The added complexity and strength of these bioactive, composite scaffolds demonstrate a synergistic effect between stimulated cellular behavior and resemblance of the final scaffold to the target tissue.

Assessment of cell viability and activity

To determine the degree of cytotoxicity or bioactivity of scaffolds and cell-laden constructs, a variety of different

approaches can be employed. Since cell seeding, attachment, spreading, and migration may take place over a period of multiple days, scaffolds are typically assessed for viability within a few hours up to 1 day from fabrication. Here, "viability" is strictly an assessment of whether cells survived the printing process within bioinks or if the scaffold material was cytotoxic. One technique that has been in use for decades is a "live-dead stain" [78,79]. Calcein acetoxymethyl is a molecule that can penetrate cellular membranes, and once cleaved by intracellular esterases of living cells, its products give a strong green fluorescent signal [80,81]. Ethidium homodimer-1 or propidium iodide cannot penetrate cell membranes of living cells, but they are able to bind to the DNA of dead cells with disrupted membranes and give off a strong red fluorescent signal [80,81]. With laser scanning confocal microscopy able to quantify the signals in a target volume, many bioprinting research studies utilize this assay within their printed constructs [21,29,31,32,39,55,64,66,82–89]. To take a closer look at the pathways triggering cellular death, terminal deoxynucleotidyl transferase dUTP nick end labeling staining with fluorescent-activated cell sorting [90] or immunohistochemistry protocols targeting caspase-3 can indicate the degree of apoptotic function in a cell population [91–93]. Another cellular stain, trypan blue, can be used as a cell-excluding stain as it penetrates dead cell membranes and fluoresces, but it is variable and not as greatly utilized [94].

Proliferation and prolonged healthy cell function, which is just as important as cells' immediate state upon going through the 3DP process, is typically assessed in vitro at least 1 day to 1 week after seeding/encapsulation, with some studies extending the culturing period to even 2 or 3 weeks [31,32,39,51,60,66,82,83,86,87,89,95]. Common ways to assess proliferation focus on mitochondrial-based activity in the cell, such as the MTS assay [83]. Other methods look at mitosis, such as methods detecting KI67, which is a protein heavily correlated with proliferation because it is present in all phases of the cell cycle except G0, which is where quiescent cells remain [95–97].

To achieve the goal of engineering cell populations for replacing or regenerating particular living tissues, researchers must subsequently ensure that the cells associated with the fabricated composites are functioning in the desired way that mimics their targeted native activity. There are many ways to assess cellular phenotype, and since both recapitulating anatomic complexity and observing any reorganization of the microenvironment are often of primary concern, many of these techniques rely on different imaging modalities. For example, immunofluorescent staining for expression of certain surface markers can assess if the cellular phenotype matches with that of a certain cell lineage [31,51,95]. This surface-tagged epifluorescence can be combined with 4′,6-diamidino-2-phenylindole or rhodamine phalloidin stains for illustrating cell nuclei and filamentous actin, respectively, to reveal individual cell morphology and the degree of cell spreading on a scaffold or within a matrix [61,83]. Other assays can indicate specific phenotype by confirming a unique aspect of a cell's metabolism, such as alkaline phosphatase activity or looking at mineralization of the scaffold, which are unique to the structural environment created by and necessary for osteoblast proliferation and bone regeneration [56,76,98,99]. Visual qualification through histological analysis can also reveal cell phenotype and any resulting organization of the greater tissue microenvironment in microscale slices of fixed tissue. Common reagents for assessing ECM morphology through immunohistochemistry include hematoxylin and eosin for labeling nuclei and intra/extracellular proteins and membranes; toluidine blue for coloring nuclei and polysaccharides, among others; Masson's trichrome stain for connective tissue studies; Alizarin red S or von Kossa stains for calcium deposition and matrix mineralization; alcian blue or periodic acid–Schiff staining for polysaccharides or carbohydrate-based macromolecules such as those in cartilaginous glycosaminoglycans [51,89,100]. Also, in applications, such as the engineering of cartilage tissue, it is common to apply a Safranin O histological stain when working with chondrocytes to qualify the typically high degree of proteoglycan deposition [56,82].

Scaffolds and cell–matrix composites can be screened for the degree of distribution of both cells or other included noncellular materials, such as bioceramics or microparticles. Scanning electron microscopy (SEM) is a high-resolution method of visually assessing cellular morphology, cell distribution, and spreading, but this method requires more expensive equipment [89]. If a ceramic material is included, such as when hydroxyapatite or β-TCP particles are used to tune degradation for bone tissue engineering applications, micro-computed tomography (μCT) can reveal the degree of dispersion within the printed fibers, whereas SEM would not be able to assess internal properties [72].

3D printing systems and printer types

In 1984 3DP was first patented by Charles Hull for what is now strictly referred to as stereolithography (SLA)-based printing, and 3DP has since evolved into an umbrella term that covers methods of fabrication that build one layer at a time using polymers, metals, or composite materials such as carbon fiber [6,101]. For the modern tissue engineer, there is now an abundance of cutting-edge 3DP technologies at one's disposal for fabricating complex, tissue-specific constructs containing living cells or biological materials. Due to processing

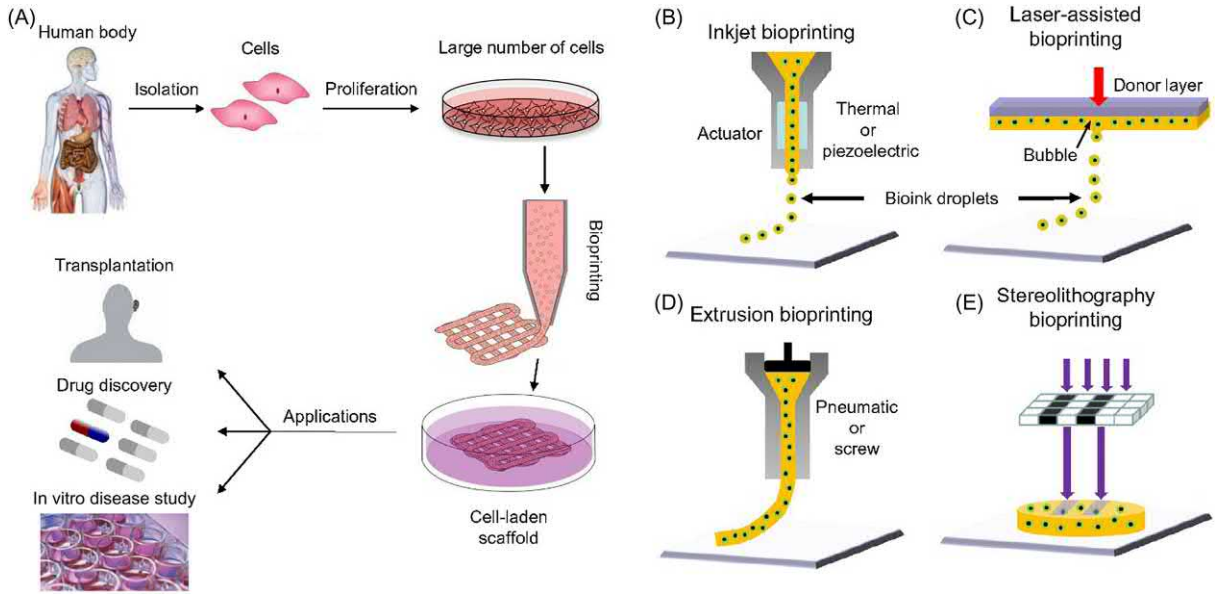

FIGURE 17.2 Bioprinting methods. (A) For human therapeutic applications the typical workflow of bioprinting would involve the isolation and expansion of human cells prior to printing the desired cell-laden scaffold. These scaffolds could then ultimately be used as therapeutic devices themselves, as a testing platform for drug screening and discovery, or as an in vitro model system for disease. (B) Inkjet printers eject small droplets of cells and hydrogel sequentially to build up tissues. (C) Laser bioprinters use a laser to vaporize a region in the donor layer (top) forming a bubble that propels a suspended bioink to fall onto the substrate. (D) Extrusion bioprinters use pneumatic or manual force to continuously extrude a liquid cell−hydrogel solution. (E) Stereolithographic printers use a digital light projector to selectively cross-link bioinks plane by plane. In (C) and (E), colored arrows represent a laser pulse or projected light, respectively. *Reproduced with permission from Mandrycky C, Wang Z, Kim K, Kim DH. 3D bioprinting for engineering complex tissues. Biotechnol Adv 2016;34:422−34.*

considerations mentioned earlier and their effect on cell viability and function, the bioprinting of cell-encapsulated inks is limited to cytocompatible methods, namely, liquid or soft polymer−based modalities [4,22]. The choice of printing modality is also an important one, as the technology-specific limitations discussed later may make one method more suited for recapitulating a certain tissue type than another. The main categories of modern bioprinting methods can be divided into inkjet printing, extrusion, LAB, and SLA (Fig. 17.2). The following section will discuss the advantages and disadvantages of each method, which are summarized in Table 17.3 [2,102].

Inkjet printing

Since it was understood that liquid-like materials were more easily manipulated and allowed for the encapsulation of living cells, researchers leveraged technologies and commercialized devices that already had been optimized for the deposition of liquid materials. Inkjet printers, such as the HP Deskjet, were among the first devices to be utilized for bioprinting in tissue engineering since their modular design with interchangeable, refillable cartridges enabled multimaterial printing, which is a key feature of the most advanced modern bioprinters [106−109]. Also, translating the operation from printing documents to printing on substrates made *X*/*Y* operation and control straightforward, so control over the *Z*-axis could be added through high-tolerance, robotic operation of a piston or rod [108,110,111]. The inkjetting mechanism inherent to this technology provides a cell-friendly way of printing that is contactless and has little to no shear-stress force exerted upon the cell, avoiding these limitations that are associated with other bioprinting methods [31,64]. Some early attempts to utilize inkjet printing for tissue engineering applications involved vascular printing [46,106]. Specifically, printing vessel−like structures that support physiological flow conditions could be achieved by modifying the fine-deposition settings of the inkjet printer to allow printing over void space [46].

The latest innovations within inkjet bioprinting focus on overcoming material or process limitations, such as viscous materials clogging the nozzle and the inability to print high cell densities, and leveraging this method's strengths, which is its speed of deposition (∼10,000 drops/s) [112]. One study utilized a bioink composed of hMSCs suspended within a combination of gelatin methacrylate (GelMA) and PEG to increase the printability of GelMA, which has been shown to be useful in tissue engineering applications, but has high viscosity which limits its use in inkjet bioprinting [56,113]. Inkjet bioprinting has also successfully been applied to *in situ* bioprinting, which applies the printing process directly to a wound or defect and bypasses the need for a bioprinted construct to

TABLE 17.3 A brief summary of common 3D printing (3DP) and bioprinting methods.

	Inkjet	Extrusion	Laser-assisted bioprinting	Stereolithography
Advantages	Can print low-viscosity materials, fast fabrication speed, low cost, high resolution	Accessible and straightforward equipment operation, most capable of multimaterial printing, can print highest cell densities	High resolution, works with depositing biomaterials in a solid or liquid phase	Nozzle free—can avoid shear forces and potential clogging, printing time independent of complexity, high accuracy and resolution
Drawbacks	Unable to provide continuous flow due to jetting mechanism, poor construction of vertical structures, low cell densities	Only applicable for viscous bioinks, but high-viscosity/shear stress may have a cytotoxic effect	High cost of laser-based equipment, possible damage of cells due to laser irritation	UV/near-UV light source's cytotoxic effect, lack of easy multimaterial printing, damage to cells during photo-curing
Cost	Low	Moderate	High	Low
Resolution	~20–100 μm	~100–200 μm	~10–150 μm	<10 μm
Print speed	Fast	Slow	Medium	Fast
Supported viscosity	<10 mPa s	$30–6 \times 10^7$ mPa s	1–300 mPa s	No limitation
Cell density	Low	High	Medium	Medium

UV, Ultraviolet.

be separately cultivated and implanted [114]. By printing directly within a cartilage defect, researchers could control the exact position of chondrocytes with gene expression mimicking the native physiological environment and also avoid suturing or gluing implants, which typically yields inconsistent clinical results [82]. In an attempt to devise a more effective treatment for burns and skin wounds, amniotic fluid–derived stem cells were bioprinted within a fibrin-collagen gel directly into the wound site and yielded better wound closure and reepithelialization than bioprinting the gel alone [115]. These studies indicate inkjet-based bioprinting can be leveraged to treat clinical needs in novel ways that mimic physiological complexity.

Extrusion printing

Most bioprinting techniques under current investigation utilize direct deposition of cells and biomaterials through extrusion powered by pneumatic pressure, a piston, or a screw that provides deposition force. This is the most common technique employed by commercial bioprinting systems for tissue- and organ-printing studies [3,4,22]. Extrusion-based bioprinting (EBB) can be utilized in tandem with traditional polymer melt extrusion systems known as fused deposition modeling (FDM) that have been long employed for traditional supportive scaffold fabrication techniques in tissue engineering [40,43,51,116]. Due to the nature of FDM printing, including the relatively low cost of its components and the straightforward printing method with melted plastics, relatively large supportive scaffolds can be fabricated to create human-scale constructs of anatomical sizes with structural integrity [51].

Extrusion-based methods have been shown to bioprint constructs with the highest cell densities because of their ability to displace dense, concentrated bioinks from the print cartridge through the use of applied physical or pneumatic pressure [3,4,6,22]. Using this capability, some researchers engage in a "top-down" approach, simultaneously printing cells and complex architecture to create functional organ mimics—still, for achieving full-scale organ recapitulation, it has been estimated that 1–10 billion functioning cells, either primary in nature or fully differentiated into the desired physiological tissue phenotype, are needed to cross this therapeutic threshold, depending on the tissue type's characteristic cell density and size [117]. The need to sustain cellular proliferation in constructs of this size poses a new challenge, since diffusion of oxygen and nutrients is highly limited after several hundred micrometers below the tissue surface [117]. Instead of attempting to print everything at once, methods

to incorporate vasculature have been thoroughly investigated in the literature as a "bottom-up" approach to overcome the formation of a necrotic core inside thicker and/or denser cell constructs. These include direct printing and incorporation of open network channels and pores [51] and the use of sacrificial materials that create channels after their removal [118–121], as discussed in detail later. Bottom-up approaches rely less on constructing a rigid, finalized design of a vascular network, and instead rely on stimulation of endothelial cells to promote capillary and vasculature formation through incorporated growth factors or optimization of degradable matrix properties to allow for anastomosis to occur [122].

Laser-assisted bioprinting

Considering the large selection of material choices for cell-based printing, there is a variety not only in the materials themselves but also in the location where each resides on the spectrum of nonviscous, flowing materials to viscous, self-supporting gels that need minimal additional processing. Because of this diversity, it can be hard to apply certain materials within the realm of inkjet and EBB, as nozzle clogging has been seen in both printing modalities [26]. There is also an opportunity to improve resolution—for example, in EBB, resolution of the construct is generally limited to the diameter of the nozzle tip that is used for bioink displacement onto a substrate. LAB has been utilized to overcome these issues seen in other printers and increase resolution [123,124]. LAB works by utilizing the focused energy of a precisely positioned laser pulse to penetrate the optically transmitting side of the substrate that holds the cell-laden material, which then strikes an interlayer that prevents the full energy of the laser to reach the cell-laden material below but transfers enough energy to rapidly volatilize part of the lowest layer, causing a cell-containing droplet to be ejected downward onto the substrate below [105,123,124]. This multilayered material is known as a "ribbon," and the properties and thickness of the substrate, the interlayer, and the vaporizing polymer in which the cells reside combine to affect the energy transfer of the incident laser beam, and so all are important factors in modulating the volume, size, and speed of the resulting droplet [105,125].

Because of the microscopic control offered by galvanic mirrors and focusing lenses, LAB can be used to position individual cells on a substrate for finely constructed patterns [105,126]. Still, because LAB controls such a fine amount of volume with each laser pulse, larger constructs that are human scale would take an incredible amount of time to fabricate due to the number of layers that would be required in the *Z*-axis, and so this is more suited for the cell-patterning applications mentioned previously [125]. The latest innovations within LAB focus on utilizing its superior accuracy and precision in how cells and biomolecules can be deposited and patterned on a substrate. The relationship between the characteristics of the laser beam striking the transfer medium and the resulting shape and dynamics of the ejected bioink droplet pulse was elucidated and was shown to be capable of optimization for ensuring high viability in printed cellular constructs [64]. With this method, mesenchymal stromal cells have been printed within a collagen–hydroxyapatite mixture directly into the calvaria defects of living mice, and the results showed that different microscopic arrangements of cell constructs impacted bone tissue regeneration [127]. LAB's advantages were also leveraged in the study of cancer cell dynamics during angiogenesis through the creation of an ex vivo model via the precise printing of cancer cells over intact microvascular networks [128]. The relationships illustrated in these and similar studies were only possible through the exclusive degree of control over microscale cellular positioning that is offered by LAB.

Stereolithography

SLA has also been investigated to print living cells for translation into tissue engineering applications. SLA, which was the original 3DP method invented by Hull in 1984, is a method of constructing 3D objects through the curing of one layer of photopolymer at a time, which occurs when a UV layer traces a cross section of the object on the surface of a vat of prepolymer resin [101]. One of the advantages of SLA and dynamic light processing (DLP) printing, the adjacent 3DP technique that uses cross-sectional photomasks instead of a scanning laser, is their ability to cure hydrogels with a very high resolution, as discussed later [83,129]. Also, a recent development called "continuous liquid interface printing (CLIP)" combines the free radical-inhibiting effect of oxygen diffusing into the printing area with the speed of DLP has yielded unprecedented speeds for the construction of 3DP objects, though CLIP has yet to be shown with biological applications [129]. One disadvantage of light-initiated printing methods is that the process necessitates exposure to UV or near-UV light as well as how photoinitiators, monomers, or reactive diluents are in direct contact with cells. Depending on the specific chemistry or wavelength of curing light, these aspects involved in photo-curing resin have been shown to be potentially cytotoxic [29,34–36,94]. Limiting the duration of UV light exposure or using initiators that are activated by longer wavelengths of light can avoid damage to embedded cells [29,36]. Also, where EBB can easily print multimaterial constructs through the use of separate print cartridges, the structure of nearly all vat polymerization systems associated with SLA technology does not allow multiple

materials to be used at the same time. In spite of this, some studies have pushed through this barrier by changing resin vats between layers or printing with SLA around a previously extruded thermoplastic scaffold, creating patterned or layered constructs that possess different materials within a single structure [83–85].

As we discuss SLA for bioprinting, it is again important to note the distinction between a 3DP scaffold that is later seeded with cells and a bioprinted construct where the structural material also encapsulates living cells. The former has a long history of extensive investigation in the tissue engineering discipline, but the latter is more novel and has only become common in scientific studies of the past 5 years. In the earliest study attempting to combine modern SLA methods with encapsulated cells, researchers were able to demonstrate how this technique is able to fabricate constructs with well-distributed, living cells within the printed PEG-diacrylate (PEG-DA) material [86]. Later, another study investigated photo-curing hydrogels with a UV laser and demonstrated the potential for this SLA method by showing long-term viability of encapsulated cells [83]. More recently, a study utilized bioinks that were photo-crosslinked in the presence of visible light, avoiding the cytotoxic effects seen with shorter wavelengths of UV light [36,87]. This PEG-DA/GelMA-based system was used to fabricate constructs with 50 μm resolution with encapsulated, living cells that remained 85% viable after 5 days of culture [87]. With such high resolution and control, SLA also has the potential to make more clinically relevant constructs that mimic physiological complexity. One group presented a novel hybrid 3D printer (Hybprinter) that was capable of cross-linking a soft, cell-containing hydrogel material via DLP in the same layer that a supportive PCL framework was extruded, and a perfusable scaffold was fabricated for the investigation of better tissue engraftment and vascularization strategies [85].

Open source and commercial 3D printing systems

Though bioprinting machines built from the ground-up for a particular study may be able to create highly complex and innovative breakthroughs in complex scaffold fabrication [51], these results are hard to replicate without the same custom printer and consequently may represent a barrier to entry for further advancement by other research teams due to the high-cost and time-consuming effort involved in manufacturing bespoke robotic components and software. Open-sourced 3DP hardware aims to enable researchers and scientific advancement through knowledge-sharing communities and low-cost equipment. Two such printers that have a history of use in the literature are the RepRap and the Fab@Home, which have a modular design, can be easily modified to suit a particular printing study, and can even print iterations of themselves for continued low-cost maintenance [130,131]. There are accessories available that allow for polymer cross-linking, live dimensional error analysis, and direct printing into tissue defect models, making this system suitable for engineering complex tissues [37,38,131]. For example, the RepRap system has been used to tailor fiber diameter, pore size, and porosity in the printing of biodegradable scaffolds for bone tissue engineering [130]. Fab@Home-based printers have also seen used in tissue engineering applications [37,38,132], further demonstrating the research potential of low-cost, accessible 3DP technologies.

To continue this trend of cultivating a community committed to sharing resources and lowering barriers to entry for the sake of pursuing life-saving science, it would be beneficial for tissue engineering studies based on 3DP to be able to share the source code or 3D modeling files that were used to print that study's constructs. Without access to such files, including anatomical reconstructions or detailed organ microarchitectures that are converted to printable STL files, other research groups lacking the medical facilities or equipment to reference the same physiology encounter a barrier in recapitulating and validating their attempts to mimic the necessary tissue-specific, biologically relevant complexity [133]. To assist in overcoming this potential barrier for reproduction and scientific advancement, the National Institutes of Health founded the 3D Print Exchange in 2014 for open-source sharing of medically relevant, scientifically accurate files for anatomical models, custom labware, and replicas of biological molecules [133,134]. All of the materials on this database are uploaded by registered users that can be contacted for more information, and no payment is required for access or to obtain any files. The combination of this freely accessible resource and inexpensive printing systems, which can be modified by tissue engineering researchers and hobbyists alike, has the power to accelerate progress within the already revolutionary field of bioprinting.

While not as affordable as the open-source systems, commercial bioprinters have begun to appear on the market with widespread, international availability. Because of the cost-prohibitive nature of the laser-based equipment in LAB as well as both LAB and inkjet-based printing's limitations in fabricating larger-sized constructs with high cell densities, most of these products are extrusion-based machines [3,4,22]. Many of these printers come with features that enable researchers to pursue their studies with the accuracy and precision through capabilities such as self-calibrating printheads, proprietary software for the creation of 3D objects, and training programs as part of

the package. The ITOP system mentioned previously was one of the first in-depth demonstrations of printing multiple ink formulations of distinct composition in order to fabricate heterogenous, living tissue constructs [51]. Commercial printers are packaging these novel features and bringing them to widespread scientific audiences to enable researchers to achieve similar results by lowering the barriers to entry via singular, commercialized products. This accessibility is augmented by the significant decrease in price expected for many of these commercial products in the next 2 years [135]. One feature included by many bioprinting machines, which is necessitated by the environmentally sensitive nature of cells, is a sterilizable print chamber [136,137]. Some commercially available printers even include a full biosafety cabinet, which provides a level of biosafety engineering control required by certain biological studies [136,137]. Another useful feature for tissue engineers is the ability to use multiple materials to replicate heterogenous tissue complexity. Commercial printers have achieved this via the inclusion of multiple print heads that can be interchanged during printing with different functionality, including photocrosslinking, imaging, and extrusion of both soft hydrogel-like material and rigid support thermoplastic material [51,66,136,137]. The use of temperature control in a single print cartridge or a controllable temperature difference between the cartridge and print platform is another useful feature included in modern bioprinters [136,137]. It is especially useful in the case of investigating bioprinting with thermogelling materials, where low temperature is needed to maintain an extrudable state, alongside traditional thermoplastics, which require high temperature for printability [51,66,138]. The very latest, most advanced bioprinters push the envelope past traditional extrusion- or SLA-based methods into optical techniques that borrow from advanced, multiphoton microscopy. One example of this technology is the joint CELLINK−Prellis Holograph-X Bioprinter, which is capable of printing fully formed structures inside other already-polymerized layers through multiphoton polymerization with living cells embedded in the printable material [139]. This ability to prevascularize a bioprinted tissue and add complexity during fabrication is meant to break through barriers that have prevented researchers from making organ-like constructs that are orders of magnitude larger than previously investigated 3D spheroid constructs [2,139].

Print outputs: patterning, resolution, and porous architecture

By careful selection of tissue-specific design inputs and utilization of the appropriate 3DP systems, tissue engineers have created heterogeneous, multilayered scaffolds which more accurately recapitulate the biochemical and architectural properties of native tissue [11]. Nearly all tissues of interest to tissue engineers exist in a heterogeneous environment, in which blood vessels, connective tissue, and more interface with the target tissue to produce a milieu of biochemically and physically diverse properties [11]. Some tissues, such as the osteochondral unit, comprise multiple tissue phenotypes and zonal architectures, though traditional tissue engineering scaffolds have not fully mimicked the gradual transition in physical and biochemical properties, which occurs from bone to cartilage (see Fig. 17.3). Within these tissues, physical properties such as porosity and surface roughness may vary, in addition to the distribution of different biochemical cues such as growth factors and glycosaminoglycans. Thus the ability of 3DP and bioprinting to replicate these microenvironments relies on optimizing outputs such as the

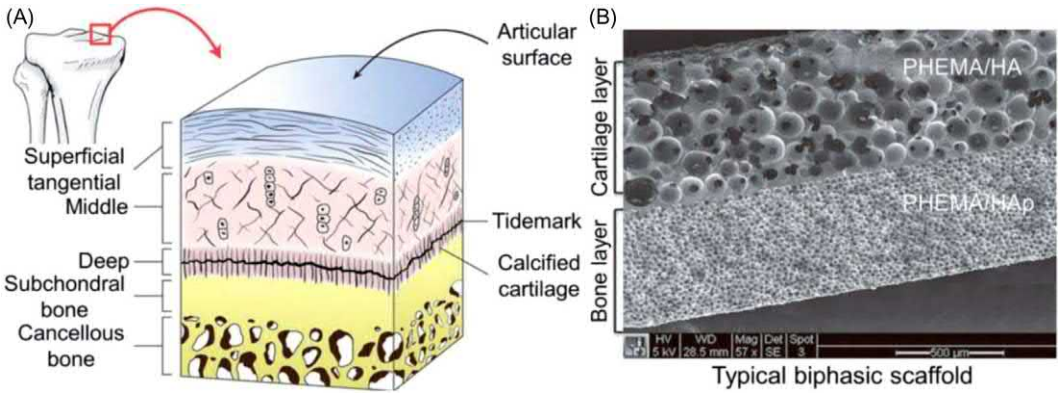

FIGURE 17.3 The osteochondral unit as an example of multilayered, heterogeneous tissue. (A) The distinct tissue phenotypes and physical architectures seen in the osteochondral unit, showing the gradual bone-to-cartilage transition. (B) A traditional bilayered scaffold mimicking the distinction between bone and cartilage, but not the transitional layers. *Adapted with permission from Li X, Ding J, Wang J, Zhuang X, Chen X. Biomimetic biphasic scaffolds for osteochondral defect repair. Regen Biomater 2015;2:221−8 [140].*

patterning of multiple inks, the deposition of high-resolution physical features, and the creation of interconnected porous architectures. After printing, it is crucial to then assess the physical features of the scaffold and confirm adherence to the intended architectures.

Printing/patterning of multiple inks

One key development in 3DP and bioprinting is the creation of printers that can deposit multiple inks in tandem. Commercial and custom-designed printers, as discussed previously, have now been developed with the capability to handle multiple material/ink cartridges or even multiple printheads for when different materials have distinct print conditions [11]. The ITOP system, for instance, uses a multicartridge module to deposit cell-encapsulated hydrogels, sacrificial cell-free hydrogels, and PCL in tandem and ultimately produce cell patterning in complex, vascularized constructs [11]. Ongoing research has focused on the development of printers that can switch more rapidly between ink cartridges and even mix ink formulations during printing, which can ultimately enable the generation of gradients in physical or biochemical properties within a single scaffold [141,142]. The usage of sacrificial inks, such as Pluronic F-127, can also provide structural support for architectures that would otherwise be susceptible to collapse during or after printing, and additionally can provide porous channels for nutrient and waste diffusion once the sacrificial material is removed [11]. Constructs thicker than 100−200 μm, which traditionally may have experienced cell death due to poor diffusion in the inner regions of the scaffold, can thus be printed with greater cell viability as a result of these porous channels [11]. These channels can furthermore be perfused with angiogenic factors or cells to produce vascularized tissue constructs with greatly enhanced viability [119]. The benefit of bioprinting and 3DP technologies is that the sacrificial materials can be deposited in highly defined distributions to produce well-organized vascular networks that resemble the distribution of vasculature in native tissue [119].

Another key component in developing complex, heterogeneous scaffolds is the patterning of growth factors and other biochemical cues by printing multiple inks within a single scaffold. For creating vascularized tissue constructs, it is important to have a stratified presentation of cues for angiogenesis and other tissue development [11]. For heterogeneous tissues, such as tendons, which contain transitions from bone to connective tissue to muscle, it is also important to generate spatial patterns of tissue-specific growth factors that mimic their organization in native tissue [11]. Growth factor patterning can be achieved by different means. One approach is to utilize multiple inks with different growth factor compositions and then to print the growth factors in their intended locations using the aforementioned multicartridge systems [11]. The growth factors themselves are usually loaded inside secondary vessels, such as poly(lactic-*co*-glycolic acid) (PLGA) microparticles, to allow for their sustained release kinetics after implantation of the scaffold [11]. Another approach is to print growth factor formulations at separate ends of a uniaxially oriented construct—for tissues such as nerves—and allow passive diffusion of the growth factors to generate growth factor gradients across the length of the construct [143]. In addition to spatial patterning, the temporal control of growth factor release is an ongoing area of research, as native tissue development involves different growth factor milieus at different timepoints of development [11]. While growth factor delivery from 3DP scaffolds has traditionally relied on the hydrolytic degradation of growth factor−containing microparticles, some research has now focused on methods to manually control growth factor release after scaffold implantation [11,144]. Plasmonic gold nanorods, for instance, maybe doped into PLGA microspheres so that spatiotemporally defined laser irradiation can be used after implantation to selectively heat nanorods and rupture biomolecule-containing microspheres [144]. Ultimately, it is of great interest for tissue engineers to continue developing new strategies for the spatiotemporal control of growth factor presentation so that these complex, 3DP scaffolds can more accurately recapitulate the dynamic biochemical environments seen in native tissue development.

Print resolution

Print resolution is a key parameter that determines not only the degree to which architectural components can be appropriately replicated but also to what degree growth factors or other biochemical cues can be patterned in the scaffold [104]. For the reconstruction of heterogeneous or vascularized tissues in particular, print resolution can determine the efficacy with which one can mimic the distinct physical and biochemical properties of different tissue types within a single construct [11]. The achievable resolution depends largely on the type of print technology and the associated limitations on droplet size, fiber diameter, etc., of the particular printer model. For extrusion-based printers the resolution is currently limited to about 200 μm and is effectively determined by the deposited fiber diameter, which in turn depends on needle/nozzle diameter [104]. In theory, smaller diameter needles will thus enable higher resolution printing, though the ability to achieve low enough viscosity to be printed through a small diameter needle depends on material/ink chemical composition and other properties such as molecular weight [145]. Thus the achievable resolution for an

extrusion-based system is determined by both the print system and the physical properties of the polymer ink itself. For inkjet systems, on the other hand, resolution is limited by the smallest physically achievable droplet size of approximately 1 pL, which results in an improved resolution compared to extrusion of about 20−100 μm [104]. LAB-printed droplets, on the other hand, can produce 80−100 μm resolution [105]. SLA and other light-based print methods, however, allow for the lowest achievable resolution of all the systems discussed so far, with SLA, in particular, being able to generate horizontal and vertical feature resolution as low as 1−2 μm [12]. Despite this the resolution of SLA-printed features can be compromised by shrinkage from residual cross-linking, and another notable drawback is that horizontal layers are necessarily uniform in material/ink composition due to spontaneous mixing of the preprint solutions—compromising any possibility of forming biochemical gradients in the same manner as extrusion- or inkjet-based techniques [12]. Overall, the granularity of growth factor and biomolecule patterning will depend on the resolution of print systems, which is an active an ongoing area of research for tissue engineers [104,146].

Porous architecture

The creation of interconnected porosity is an important output of 3DP, as tissue engineering scaffolds must allow for diffusion of waste and nutrients as well as cell migration during the regenerative process. Although 3DP can be used to create porous structures with high resolution, there are challenges associated with the maintenance of porous structures as printing progresses layer by layer. If the printed material is too soft or the fibers between subsequent vertical layers do not properly fuse, the resulting scaffold may experience poor structural integrity that leads to pore collapse [46]. These issues are typically exacerbated as the height and number of layers increase during the 3DP process, though they can sometimes be alleviated by coprinting rigid materials to support any soft materials susceptible to collapse. Cell-encapsulating hydrogels and natural polymers, such as gelatin, for instance, can be coprinted with rigid polyesters, such as PCL, so that the polyester provides maintenance of porous architecture [147]. Another potential issue is postprinting shrinkage or swelling of the material that changes pore size, which can particularly affect thermoresponsive polymers, such as gelatin [148]. Alternatively, sacrificial materials, such as Pluronic F-127 or carbohydrate glass, can be printed within hybrid scaffolds and subsequently removed to leave behind porous channels [118,119]. The benefit here is that channels with highly defined spatial organization can be created for the subsequent growth of vasculature or other tissue types within a heterogeneous construct [11]. Another method of introducing porosity is the usage of mesoporous materials that contain nanoscale pores within the material fibers themselves that are an order of magnitude smaller than the printed scaffold's macroporous network. These mesopores throughout the material fibers can be used as load bioactive molecules and enhance nutrient and waste diffusion in the printed construct [149]. Mesoporous bioactive glasses, in particular, have been 3D printed for the regeneration of bone tissue and present mesopores typically on the scale of 5−20 nm, compared to the main scaffold pores of several hundred microns in size [149,150].

Assessment of scaffold fidelity

During and after printing, it is important to assess the degree to which printed scaffolds resemble their digital models. Many 3D printers come equipped with camera systems that take top-down images of the scaffold in real time after each layer is printed [136]. These cameras are typically used in conjunction with laser-based distance sensors to automatically inform the printer of the location for the deposition of each layer and where to position the printhead. Essentially, the laser distance sensors scan the printed scaffold after each layer to attempt corrections for any misalignment of the printhead or discrepancies with the digital model. After the scaffold is printed the user can also assess any loss of fidelity from pore collapse or other issues by going through the images layer by layer and identifying any errors that propagate with layer deposition. The overall scaffold itself can be imaged and characterized by several means. First, SEM can be used to assess the surface morphology of printed scaffolds, as well as the fiber distribution and architecture at a very superficial level [12]. Before characterization, scaffolds are typically sputter coated with a thin layer of an electrically conductive material, such as gold, and then the scaffolds can be nondestructively imaged to produce high-quality images of scaffold surfaces. One of the primary limitations of SEM, however, is its limited depth of penetration. μCT instead can be used to generate full 3D images of high-density polymeric scaffolds—most often those incorporating metal or ceramic additives [149]. Another option is to incorporate fluorescent dyes within the inks, to allow for visualization of ink/material localization in the printed scaffold by fluorescent confocal microscopy [151]. Image analysis can then be used to quantify the spatial fidelity of material and dye deposition compared to the digital model. Regardless of the method used for scaffold visualization, it is essential for the user to verify the accuracy of both physical features as well as material localization for multimaterial scaffolds.

Printing applications: vascularized and complex, heterogeneous tissues

Using bioprinting techniques, tissue engineers have generated complex, heterogeneous scaffolds for various tissue types, ranging from osteochondral tissue [37] to skin [106], bladder tissue [152], liver tissue [153,154], heart valves [131], neural tissue [155], and more. For osteochondral tissue, some labs have printed gradients of osteogenic and chondrogenic biomolecules in order to mimic the spatial transition from bone to cartilage seen in native tissue. One study used a combinatorial approach of peptide gradients within a hydrogel that mimicked cell−cell or cell−matrix interactions seen in osteochondral tissue development and found that chondrogenesis varied spatially in these hydrogels based on the biochemical formulation [156]. To guide proper postprinting proliferation and differentiation, similar studies can serve as a blueprint for how to print biochemical factors in ways conducive to replicating native tissue complexity, which is one of the most difficult objectives of bioprinting [11]. Other strategies include the printing of gradients of osteogenic or chondrogenic growth factors in tandem with hydroxyapatite mineral gradients, in order to mimic the transition from bone-like to cartilage-like ECM [104,157]. For instance, the chondrogenic transforming growth factor beta 1 has been printed in an opposing gradient with hydroxyapatite, creating spatially gradated cues for chondrogenic and osteogenic development like that of the native osteochondral unit [157]. For neural tissue the bioprinting of neural stem cells and other progenitor cells has been combined with growth factor patterning to effect differentiation of delivered cells into glial cells, smooth muscle cells, and other relevant phenotypes [143,155,158]. For instance, axial gradients of neural growth factor and glial cell line−derived neurotrophic factor have been printed within silicon casts to provide directional cues for axons and Schwann cells, respectively, creating phenotypically appropriate tissue constructs for the repair of nerve gap injury [143]. To generate vascularized constructs, some groups have utilized sacrificial inks to generate vascular channels as discussed previously, while others have printed multiphasic scaffolds with vascular endothelial growth factor containing hydrogels dispersed throughout the construct [119,159].

Traditionally, printed scaffolds are cultured either in static conditions or in a perfusion bioreactor to produce some degree of cell attachment and/or differentiation prior to implantation. A few tissue engineers, however, have printed scaffolds in situ for intended application directly at the site of tissue defect, with notable examples, including skin [106] and meniscus [37]. The advantages of an in situ printing approach are that the scaffold can be implanted precisely at the site of defect with a minimized chance of infection, with adjustment to printing being made for the patient in real time, while the disadvantages are that scaffolds cannot be precultured for cells and that the conditions of printing are limited to those compatible with a physiological environment at material deposition.

Although significant progress has been made to address the biological functionality of 3DP scaffolds for specific tissues, several barriers remain for the implementation of 3DP strategies to human clinical applications. Regulatory approval is one critical prerequisite that can be challenging for tissue engineered products, especially those incorporating biological components such as cells [139]. The reader is encouraged to consult other chapters for a more in-depth discussion of the regulatory pathway. In addition, current technologies have yet to scale-up the output of these bioactive scaffolds in terms of sheer numbers. Further modification of the printing processes described in this chapter to allow for large-scale manufacturing will thus increase the potential for these technologies to address the high magnitude of clinical demand for implants.

Conclusion

3DP technologies, ranging from extrusion and inkjet printing to SLA and more, have enabled the creation of more highly biomimetic and complex scaffolds than those generated by traditional scaffold fabrication techniques. By selecting the appropriate design inputs, such as ink/material, cell type, and processing conditions, one can print scaffolds that recapitulate both the physical and biochemical cues of native tissue matrix. Thick, vascularized constructs and multiphenotype constructs, in particular, are now able to be fabricated more effectively due to advances in 3DP technology, and state-of-the-art custom printers have combined multiple processing techniques to print hydrogels, rigid synthetic polymers, and more, in tandem. As the field of bioprinting progresses, important considerations include the improvement of print resolution and handling of multiple inks, which maybe addressed by the development of even more powerful print systems across the techniques of inkjet printing, extrusion printing, SLA, and more. To improve biological activity of 3DP scaffolds, tissue engineers must also continue work on cytocompatible polymer-processing methods during printing, spatiotemporal control of biochemical cues, and the synthesis of novel bioactive and/or biocompatible scaffold materials. Furthermore, barriers remain for the implementation of these 3DP approaches in the clinic, including regulatory approval as well as the small scale in terms of scaffold numbers seen with current 3DP strategies. Tissue engineers will thus have to take these considerations in mind when developing new 3DP

systems and tissue applications. One important part of this process may be the translation of highly novel features seen in custom printers, such as multimaterial extrusion, to commercial printers in order to promote the utilization of these technological advances by more research groups within the field. Ultimately, 3DP and bioprinting, in particular, represent highly promising techniques for the fabrication of patient- and tissue-specific implants, and the development of new bioinks and innovative printer systems is ongoing.

Chapter 18

Biodegradable polymers

Julian Chesterman, Zheng Zhang, Ophir Ortiz, Ritu Goyal and Joachim Kohn
New Jersey Center for Biomaterials, Rutgers, The State University of New Jersey, Piscataway, NJ, United States

Introduction

The design and development of tissue-engineered products have benefited from the clinical utilization of a wide range of biodegradable polymers. Newly developed biodegradable polymers and modifications of previously developed biodegradable polymers have enhanced the tools available for tissue-engineering applications. Insights gained from studies of cell−matrix interactions, cell−cell signaling, and organization of cellular components are placing increased demands on medical implants to interact with the patient's tissues in a more biologically suitable fashion. Whereas, in the 20th century, biocompatibility was largely equated with eliciting no harmful response, the biomaterials of the 21st century will have to elicit tissue responses that support healing or regeneration of the patient's own tissues.

This chapter surveys the universe of biodegradable polymers that may be useful in the development of medical implants and tissue-engineered products. Here, we distinguish between biologically derived and synthetic polymers. The materials are described in terms of their chemical composition, breakdown products, mechanism of breakdown, mechanical properties, and clinical limitations. Also discussed are the product design considerations for processing biomaterials into a final form (e.g., gel, membrane, and matrix) that will induce the desired tissue response.

In this chapter, we follow the official polymer nomenclature conventions adopted by the International Union of Pure and Applied Chemistry (IUPAC). According to these rules, the correct naming of a polymer requires the simple addition of the prefix "poly" in front of the monomer name, if the monomer name consists of a single word. For example, the polymer made of ethylene is simply polyethylene. There is no space between poly and ethylene. When the monomer name consists of two or more words, the entire monomer name must be enclosed in parentheses in order to avoid ambiguity. For example, the polymer made from trimethylene carbonate (TMC) is correctly named as poly(trimethylene carbonate) (PTMC). Note the absence of a space between the prefix poly and the parenthesis. Polymers made of amino acids are sometimes referred to as peptides, proteins, or poly(amino acid)s. When referring to a polymer that is composed of a single type of amino acid, IUPAC rules require this material to be named as a poly(amino acid). When referring to several such polymers, the plural of poly(amino acid) is poly(amino acid)s. Note the placement of the plural "s" outside of the parenthesis. When a polymer is made of several different amino acids, then that polymer would be referred to as a poly(amino acids). Note the placement of the plural "s" inside the parenthesis, indicating that it is a single polymer that contains more than one type of amino acid as monomer. Unfortunately, these rules are often violated in the contemporary literature.

Biodegradable polymer selection criteria

The selection of biomaterials plays a key role in the design and development of medical implants and tissue-engineering products. While the classical selection criterion for a safe, stable implant dictated choosing a passive, inert material, it is now understood that any artificial material placed into the body of a patient will elicit a cellular response [1,2]. In fact, some of the least chemically reactive materials, such as polyethylene or polysiloxane, can cause significant inflammatory responses. Therefore it is now widely accepted that a biomaterial must interact with tissue in a biologically suitable manner rather than act simply as an inert body. Consequently, a major focus of biomaterials research is harnessing control over cellular interactions with biomaterials. Researchers now tend to explore ways to manipulate the cellular response by including biologically active components in the design of

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00019-8

biomaterials. Specific examples of such biologically active components include protein growth factors, antiinflammatory drugs, and gene delivery vectors [3].

While many biodegradable polymers have been developed for use as biomaterials, the selection of a polymer for a given application requires careful consideration of the specific cellular environment and interactions required. Such applications include

1. support for new tissue growth (wherein cell−cell communication and cells' access to nutrients, growth factors, and pharmaceutically active agents must be maximized);
2. prevention of cellular activity (where tissue growth, such as in surgically induced adhesions, is undesirable);
3. guided tissue response (enhancing a particular cellular response while inhibiting others);
4. enhancement of cell attachment and subsequent cellular activation [e.g., fibroblast attachment, proliferation, and extracellular matrix (ECM) production for dermis repair]; [4]
5. inhibition of cellular attachment and/or activation (e.g., platelet attachment to a vascular graft); and
6. prevention of a biological response (e.g., blocking antibodies against grafted cells used in organ replacement therapies).

Biodegradable polymers are applicable to those tissue-engineering products in which tissue repair or remodeling is the goal, but not where long-term material stability is required. Biodegradable polymers must also possess

1. manufacturing feasibility, including availability of sufficient commercial quantities of the bulk polymer;
2. the capability to be formed into the final product design;
3. mechanical properties that adequately address short-term function and do not interfere with long-term function;
4. low or negligible toxicity of degradation products, in terms of both local tissue response and systemic response; and
5. the capability to be formulated as a drug-delivery system in applications that call for prolonged release of pharmaceutically active compounds.

Biologically derived polymers

Biologically derived polymers are materials created by living organisms, as opposed to synthetic polymers, which are man-made. This distinction divides the universe of medically useful, biodegradable polymers into two large subgroups. However, the delineation between these groups is not always clear-cut. For example, glycolic acid is a natural metabolite and polyglycolide (PGA) is naturally produced by many organisms. However, glycolic acid can also be created synthetically from petroleum-derived starting materials. Currently, PGA is produced commercially by both fermentation and synthetic processes. Both production pathways result in the same final product, making PGA either a biologically derived or a synthetic polymer. A similar situation exists for polymers derived from hydroxybutyric and hydroxyvaleric acid. Commonly referred to as polyhydroxyalkanoates (PHAs), these polymers can be derived from either bacterial fermentation or purely synthetic processes. In this chapter, PHAs are included among the biologically derived polymers (since the most prevalent mode of commercial production is based on bacterial fermentation), while PGA and the closely related polylactide (PLA) are introduced to the reader as synthetic polymers (since the predominant mode of commercial production is currently based on petroleum-derived starting materials and synthetic polymerization reactions).

The biologically derived polymers can be further classified into peptides and proteins, polysaccharides, PHAs, and polynucleotides. Each of these subgroups will be discussed separately.

Peptides and proteins

Peptides and proteins are polymers derived from naturally occurring α-L-amino acids. Peptides are usually shorter chains (less than ∼100 amino acids), while proteins are longer chains (more than ∼100 amino acids). The amino acids are connected via hydrolytically stable amide bonds. Therefore these materials are usually degraded via enzymatic mechanisms. The major shortcoming of peptides and proteins as starting materials for the fabrication of any medical implant is their lack of processability. This term describes whether a polymer can be manufactured into a specific shape using any of the conventional polymer processing methods used in the plastics industry: compression molding, extrusion, injection molding, and fiber spinning. Another important limitation of peptides and proteins as biomaterials is their inherent immunogenicity. Any peptide or protein carries the risk of being recognized as foreign by the patient's immune system. For example, for many years, the safety of using bovine collagen was a hotly debated topic because of fears that the implantation of bovine collagen could provoke an immune response and predispose the patient to autoimmune diseases [5].

On the other hand, peptides and proteins can have outstanding biological properties and can facilitate designing biomaterials with desirable biological activity. This fact has been the driving force behind the long-standing interest in using peptides and proteins as starting materials for

TABLE 18.1 Proteins used as biodegradable biomaterials in medical implants.

Type of protein	Source	Function
Collagen	Isolated from cattle, fish, and other species	Key component of tissue architecture, which provides mechanical strength and supports cell attachment and growth. Used extensively as a tissue expander and bulking agent in cosmetic products
Gelatin	Partially hydrolyzed collagen	Used in the food industry, widely explored as a matrix for 3D cell culture and as a component of tissue-engineering scaffolds
Elastin	Isolated from cattle and birds	Key component of tissue architecture, which provides elasticity
Keratin	Isolated from skin, hair, and nails of sheep, cattle, and humans	Key structural component of outer skin, hair, and nails. Used as a matrix for cell growth and as a component in wound dressings and skin-care products
Silk	Isolated from insect larvae	Used in the textile industry because of its extraordinary strength. Also studied as a component of tissue-engineering scaffolds and as a cell culture substrate
Proteoglycans	Various tissue extracts	Used in research of cell–matrix interactions, matrix–matrix interactions, cell proliferation, and cell migration

medical implants or tissue-engineered products. Unfortunately, most peptides and proteins have mechanical properties that are not conducive for their use in medical implants, resulting in the usage of only a very small number of proteins as biomaterials (Table 18.1).

Collagen

Collagen is the major component of mammalian connective tissue, accounting for approximately 30% of all protein in the human body. It is found in every major tissue that requires strength and flexibility. Fourteen types of collagens have been identified; the most abundant being type I [6]. Because of its abundance and unique physical and biological properties, type I collagen has been used extensively in the formulation of biomedical materials [7]. Type I collagen is found in high concentrations in tendon, skin, bone, and fascia, which are consequently convenient and abundant sources for isolation of this natural polymer.

The structure, function, and synthesis of type I collagen have been thoroughly investigated [8]. Because of its phylogenetically well-conserved primary sequence and helical structure, collagen is only mildly immunoreactive [9]. However, many human recipients of medical or cosmetic products containing bovine collagen have antibovine collagen antibodies [10]. The clinical significance of this finding is not yet fully understood.

The individual collagen chains assemble into a triple α-helical structure known as procollagen, which can then be further modified to form larger organized structures. Collagen exists in tissue in the form of collagen fibers, fibrils, and macroscopic bundles [11]. For example, tendon and ligaments are comprised mainly of oriented type I collagen fibrils, which are extensively cross-linked in the extracellular space.

In vitro, collagen cross-linking can be enhanced after isolation through a number of well-described physical or chemical techniques [12]. Increasing the intermolecular cross-links

1. decreases biodegradation rate by reducing collagen's susceptibility to enzymatic degradation;
2. decreases the capacity of collagen to absorb water;
3. decreases collagen's solubility; and
4. increases the tensile strength of collagen fibers.

Collagen contains lysine residues with free amines, which can be used for cross-linking or modified to link or sequester active agents. These simple chemical modifications provide a variety of processing possibilities and consequently the potential for a wide range of tissue-engineering applications using type I collagen.

It has long been recognized that substrate attachment sites are necessary for growth, differentiation, replication, and metabolic activity of most cell types in culture. Collagen and its integrin-binding domains (e.g., Arg-Gly-Asp (RGD) sequences) assist in the maintenance of attachment-dependent cell types in culture [13]. For example, fibroblasts grown on collagen matrices appear to differentiate in ways that mimic in vivo cellular activity and to exhibit nearly identical morphology and metabolism [14]. Chondrocytes can also retain their phenotype and cellular activity when cultured on collagen [15]. Such results suggest that type I collagen can serve as tissue-regeneration scaffolds for any number of cellular constructs.

The recognition that collagen matrices could support new tissue growth was exploited to develop the original

formulations of artificial extracellular matrices for dermal replacements [1,2,16–18]. Yannas and Burke were the first to show that the rational design and construction of an artificial dermis could lead to the synthesis of a dermis-like structure whose physical properties "would resemble dermis more than they resembled scar" [18]. They created a collagen–chondroitin sulfate (CS) composite matrix with a well-described pore structure and cross-linking density that optimizes regrowth while minimizing scar formation [19]. The reported clinical evidence and its simplicity of concept make this device an important potential tool for the treatment of severely burned patients [20].

The advantageous properties of collagen for supporting tissue growth have been used in conjunction with the superior mechanical properties of synthetic biodegradable polymer systems to make hybrid tissue scaffolds for bone and cartilage [21,22]. These hybrid systems show good cell adhesion, interaction, and proliferation compared to the synthetic polymer system alone. Collagen has also been used to improve cell interactions with electrospun nanofibers of poly(hydroxy acids) such as PLA, PGA, poly(ε-caprolactone) (PCL), and their copolymers [21–25]. In addition, the combination of collagen scaffolds with biologically active entities, such as growth factors, platelet rich plasma [26], and various autologous or allogenic cell types [27], has provided significant opportunities for researchers to achieve tendon and ligament regeneration.

Gelatin

Gelatin is commonly used for pharmaceutical and medical applications because of its enzymatic biodegradability and biocompatibility in physiological environments [28–30]. Of the two types, acidic and alkaline gelatin, the former has an isoelectric point similar to collagen. The isoelectric point depends on its extraction procedure from collagen, and variations in it allow gelatin to bind with either positively or negatively charged therapeutic agents. Based on this fact, the acidic gelatin, with an isoelectric point of 5.0, could be used as a carrier for basic proteins in vivo, while basic gelatin, with an isoelectric point of 9.0, could be used for the sustained release of acidic proteins under physiological conditions. However, gelatin is liquid at temperatures above 30°C, so it must be cross-linked using compounds such as glutaraldehyde or genipin to generate hydrogels/scaffolds [31]. The advantage of gelatin as a carrier for controlled drug release is that the therapeutic agent can be loaded into the gelatin matrix under mild conditions. Gelatin hydrogels have been used as controlled release devices for a variety of growth factors known to enhance bone formation. For example, Yamada et al. successfully incorporated bFGF (basic fibroblast growth factor) into acidic gelatin hydrogels, which were implanted into a rabbit skull defect to allow for the localized release over 12 weeks [32,33]. In addition, gelatin scaffolds have been explored for cell culture and cell delivery [31].

Elastin

Elastin is an ECM protein and is most abundant in tissues where elasticity is of major importance, such as blood vessels (50% of dry weight), elastic ligaments (70% of dry weight), lungs (30% of dry weight) and skin (2%–4% of dry weight) [34,35]. It is important to note that elastin is not a single, well-defined molecule. Rather, elastin is used to describe a wide range of elastic peptide and protein sequences that exist in different lengths and with different compositions. A common feature of all elastin sequences is that they are rich in glycine, proline, and lysine. The basic structure–function–activity correlations of various elastin sequences were discovered by Urry et al. [36]. The elasticity and resilience of elastin stems from a combination of polymer chain recoil and a highly cross-linked structure [37].

In humans, elastin is synthesized early in life. By age 40 (approximately), elastin biosynthesis in humans slows down considerably. The appearance of skin wrinkles and other aging processes are directly related to the loss of elastin biosynthesis. This fact has been exploited as a marketing gimmick by cosmetic companies, who add elastin to a wide range of anti-aging products. However, there is overwhelming evidence that externally applied elastin is not able to pass through the skin and is not able to slow the loss of elastin from aging tissues [38].

Elastin is a highly versatile biomaterial that has inspired the imagination and curiosity of biomedical engineers. The ability of elastin to self-assemble into large supramolecular structures has been used to fabricate sponges, scaffolds, sheets, and tubes from human tropoelastin (elastin precursor) [39]. In addition, the use of solubilized elastin, tropoelastin, and elastin-derived peptides as surface coatings for synthetic polymers to improve the cellular response has been explored [37]. For example, poly(propylene fumarate) scaffolds coated with elastin had higher fibroblast and endothelial cell (EC) adhesion and proliferation than noncoated controls [40]. These elastin-based coatings adsorb onto a variety of synthetic polymers better than many other ECM proteins [41]. However, when elastin was used as a component in heart valve prosthetic devices, the deposition of calcium-rich precipitates was a significant problem. This process, often referred to as calcification, limited the utility of elastin-containing biomaterials in cardiovascular prosthetic implants [42]. This experience illustrates that the use of natural substances is not necessarily a guarantee for clinically successful device performance.

Keratin

Keratin is the name for a family of structural proteins that are abundant in the outer layer of human skin, in hair, and in nails. Keratin is rich in the amino acid cysteine and has the ability to self-assemble into bundles of fibers. Within these fiber bundles, individual strands are further cross-linked through disulfide (S−S) bonds involving the cysteine side chains. In this way, keratin forms particularly tough, insoluble structures that are among the strongest nonmineralized tissues found in nature. The only other nonmineralized tissue that resembles the toughness of keratin is chitin (the material found in the exoskeleton of insects and the outer shell of shellfish).

Since human hair is rich in keratin, this protein is added to many cosmetic (hair care) products. However, similar to the case of elastin-containing skin creams, keratin addition into hair-care products is primarily for marketing as externally applied keratin cannot penetrate into the hair shaft unless it has been hydrolyzed into short peptide sequences [43]. The exploration of keratin's properties also leads to the development of keratin-based biomaterials for use in biomedical applications. The unusual mechanical properties and strength of keratin and its ability to self-assemble were the driving force for these biomedical studies.

The history of keratin research illustrates another major challenge when using biologically derived polymers as biomaterials. There are a wide variety of keratins, which have been broadly categorized as hard and soft depending on their structure/function [44]. Thus depending on the animal/tissue source and extraction procedure used, the properties of the isolated keratin can vary dramatically [44]. The variability and irreproducibility of isolated protein samples is a general feature of most biologically derived polymers.

Early research focused on the preparation of protein films from keratin extracted from wool and human hair [45,46]. However, most laboratory-prepared keratin films were brittle and weak and did not share the outstanding strength of keratin formed in vivo [46]. Further research revealed that special preparation methods or the addition of glycerol as a plasticizer were required to form strong and flexible keratin films [45,47]. The feasibility of incorporating bioactive molecules, such as alkaline phosphatase into the keratin films for controlled release applications, has also been explored [46].

Keratin is also able to self-assemble into complex 3D architectures and induce cellular responses, which has been exploited to prepare scaffolds for tissue engineering. For example, keratin extracted from wool was used to form cell scaffolds for long-term cultivation [48]. Similarly, keratin extracted from human hair was used to generate hydrogels that facilitate nerve regeneration by enhancing Schwann cells attachment and proliferation and migration [49]. Finally, one of the most advanced biomaterial applications is the reported use of keratin extracted from human hair as a matrix for the regeneration of peripheral nerves [50].

Silk

On a weight basis, natural silk fibers can be stronger than high-grade steel. However, the strength of natural silk fibers is difficult to reproduce in the laboratory once pure silk has been extracted from the cocoons of silkworm larvae or from spiders' webs. Still, the unique mechanical properties of natural silk fibers have fascinated scientists for more than a century.

Consequently, researchers have explored its potential biomaterial applications and demonstrated that various silk protein preparations are biocompatible [51] and degradable [52]. In fact, the in vivo degradation rate of laboratory-made silk fibers can be tailored to be from months to years by modifying the processing procedure employed during the material's formation [52]. Silk can be thermally processed as it is stable below its degradation temperature (250°C or higher depending on processing method) [53]. In addition, silk biomaterials can withstand a variety of sterilization methods, such as ultraviolet (UV) and gamma irradiation, without altering their morphology or properties [54].

Min et al. investigated the potential of electrospun silk matrices for accelerating the early stages of wound healing [55]. In another study, chitin was blended with silk fibroin to fabricate composite fibrous scaffolds for skin tissue engineering. The rationale of these experiments was to combine the good mechanical properties of silk fibers with the wound healing effects of chitin [56]. The chitin/silk fibroin blends were electrospun to form nanofibrous matrices and evaluated for initial cell attachment and spreading [57]. In vitro, increased adhesion of keratinocytes was observed on chitin/silk blend matrices compared to pure chitin matrices, but the significance of these results for wound healing in vivo has not yet been established.

Although silkworm silk has been used to make medical sutures for decades [58], other commercially available silk-based medical products have only recently begun to emerge. For example, Allergan obtained a 510(k) clearance from the Food and Drug Administration (FDA) for a silk surgical scaffold (Seri) for soft tissue reinforcement of defect sites [59] and Sofregen obtained 510(k) clearance from the FDA for a solubilized silk injection to treat vocal fold paralysis in 2019 [60].

Proteoglycans

Proteoglycans (PGs) are a major component of the ECM. They consist of one or more glycosaminoglycan (GAG) chains that are attached, via a tetrasaccharide link, to serine residues within a core protein [61,62]. GAGs are long chains of repeating disaccharide units that are variably sulfated. There are four main classes of GAGs—hyaluronic acid (HA), CS/dermatan sulfate (DS), heparin/heparan sulfate (HS), and keratan sulfate (KS). PGs exhibit great structural diversity because each type of PG may contain different kinds, numbers, and lengths of GAG chains. In addition, each type of PG can have a different core protein structure or sulfate modifications in the disaccharide repeating patterns. Finally, PGs can be present in either monomeric or aggregate form. Both the core protein and the GAG chains of PGs play key roles in tissue remodeling, intracellular signaling, uptake of proteins, cell migration, and many other crucial functions in native tissues [61,62]. The fact that PGs seem to be involved in so many crucial cell signaling pathways is the main reason for the intense interest of biomedical engineers in understanding their properties.

To replicate the biological functions of PGs in tissue scaffolds, PGs or their GAG chains have frequently been grafted to the polymers used in fabricating tissue scaffolds or onto the surface of tissue-engineering scaffolds. Most notably, CS GAGs have been used to create collagen−GAG hybrid materials that seem to be particularly effective in skin regeneration [63].

PGs are sometimes used alone or in combination with other matrix proteins, such as fibrin, collagen, or chitosan, to create hybrid materials [64−66]. The rationale for exploring such complex mixtures is usually an attempt to "mix and match" biological properties with appropriate mechanical properties. For example, a mixture of PGs and ECM proteins is part of the widely used Matrigel scaffold [67]. Among the various combinations, collagen−GAG scaffolds are often preferred for tissue-engineering applications, because collagen provides a very cell-friendly matrix environment and the specific GAG used can affect (and regulate) cell behavior. Collagen−GAG hybrids can be readily sterilized using heat and can be manufactured with a variety of pore structures and a wide range of degradation rates [68]. In addition, a collagen−GAG hybrid is used in the first commercial tissue-engineered product, which is an artificial skin scaffold developed by Integra LifeSciences, a New Jersey company.

Biomimetic materials

Biomimetic materials are synthetic (man-made) materials that mimic natural materials or that follow a design motif derived from nature. In the previous section, a number of peptides and proteins were discussed. In general, peptides and proteins are isolated from natural sources and are therefore listed among the biologically derived polymers. However, significant research breakthroughs were made when scientists started to create mimics of natural polymers by semisynthetic or totally synthetic means. An excellent example of this research approach is the work of Urry et al., who used peptide synthesis methods to create artificial variants of elastin [69,70]. Using a combination of solid-phase peptide chemistry and genetically engineered bacteria, they synthesized several polymers that contained homologies of the elastin repeat sequences valine−proline−glycine−valine−glycine. These biomimetic polymers had better engineering properties than their natural equivalents, which made it possible to create films and fibers that could be further modified by cross-linking. The resultant films had intriguing mechanical responses, such as a reverse phase transition, which resulted in contraction with increasing temperature [70]. The exact transition temperature could be controlled by varying the polymer's amino acid composition [70]. Several medical applications are under consideration for this system, including musculoskeletal repair, ophthalmic devices, and mechanically/electrically stimulated drug delivery.

Other investigators, notably Tirrell and Cappello, have combined techniques from molecular and fermentation biology to create novel protein-based biomaterials [71−74]. These researchers had the innovative idea to create genetically engineered microorganisms that would produce the polymers that they wanted to study. In this way, completely new variations of biologically derived peptides and proteins could be prepared. These protein polymers were based on repeat oligomeric peptide units, which were controlled via the genetic information inserted into the producing bacteria. It has been shown that the mechanical properties and the biological activities of these protein polymers can be preprogrammed, which suggests a large number of potential biomedical applications [75].

Another approach to elicit an appropriate cellular response to a biomaterial is to graft active peptides to the surface of a biodegradable polymer. For example, peptides containing the RGD sequence have been grafted to various biodegradable polymers to provide active cell-binding surfaces [76]. Similarly, Panitch et al. incorporated oligopeptides containing the Arg-Glu-Asp-Val (REDV) sequence to stimulate EC binding for vascular grafts [77].

Polysaccharides

Polysaccharides are polymers made of various sugar (saccharide) units. The most common monosaccharides are

glucose and fructose. Sucrose is the chemical name of the widely used table sugar. Sucrose is a disaccharide composed of glucose and fructose. Scientists who are not experts in sugar chemistry are often unaware of the exquisite structural variability of these molecules. For example, the important human food, starch, and the structural polymer of all plants, cellulose, are both polymers of glucose. The only difference between starch and cellulose is the way in which the individual glucose units are linked together. When the many different saccharide isomers are combined using a variety of chemical bonds, the result is an extremely large number of structurally different polysaccharides. In fact, the chemistry of polysaccharides is as rich in diversity and variability as protein chemistry. It is therefore not surprising that various saccharides and polysaccharides play an important role in fine-tuning the responses of cells to their environment (Table 18.2).

As previously described, disaccharide and tetrasaccharide-linked polymers, such as GAGs and PGs, are critical in regulating key cell functions. In contrast, the industrially used polysaccharides (such as starch and cellulose) are polymers comprising exclusively various sugar (saccharide) units as monomers. These polysaccharides can be extremely large polymers containing millions of monomers and are mostly used in nature for cellular energy storage or as a structural material. As a general rule, most natural polysaccharides are not biodegradable when implanted in mammalian species due to a lack of digestive enzymes. Therefore without further chemical modification, most polysaccharides are not obvious material choices for use in biomedical applications.

Cellulose

Cellulose is the most abundant polymeric material in nature. In its most common form, it is a fibrous, tough, water-insoluble material that is mostly found in the cell walls of plants, mainly in stalks, stems, or trunks. Cellulose is the major component of wood. Cellulose is composed of D-glucose units that are linked together by β-(1→4) glycosidic bonds. In nature, cellulose is formed by a simple polymerization of glucose residues from a substrate such as Uridine diphosphate glucose [78]. Cellulose possesses high strength in the wet state [79]. The major commercial applications of cellulose are in the paper, wood, and textile industries [80] where millions of tons of cellulose are processed annually worldwide.

The major limitation of cellulose as a biomaterial is that it is not biodegradable, due to the lack of digestive enzymes for cellulose in humans [81,82]. However, a number of cellulose derivatives, such as methylcellulose, hydroxypropyl cellulose, and carboxymethyl cellulose, have been explored as biomaterials due to the useful material properties exhibited by these synthetically created derivatives [83]. The potential applications include drug-delivery implants, barriers for the prevention of surgical adhesions, or scaffolds in cartilage tissue engineering [84,85]. In vivo studies have been performed to assess the biocompatibility of a bacterial cellulose scaffold by subcutaneous implantation in rats [85]. While there were no macroscopic or microscopic signs of inflammation around the implants and no fibrotic capsule or giant cells were observed, the limited biodegradability of cellulose will most probably prevent the use of this material in most biomedical applications [85].

Starch

Whereas cellulose is composed of D-glucose units that are linked together by β-(1→4) glycosidic bonds, starch is composed of D-glucose units that are linked together by α-(1→4) glycosidic bonds. This change makes starch

TABLE 18.2 Widely investigated polysaccharides.

Type of polysaccharide	Source	Function
Cellulose	Cell walls of green plants	Main structural component of plants which keeps the stems, stalks, and trunks rigid
Starch (amylose and amylopectin)	Present in all staple foods	Important in plant energy storage
Alginate	Cell walls of bacteria	Protects bacteria from engulfment by predatory protozoa or white blood cells (phagocytes)
Glycosaminoglycans	Widely distributed	Cell–matrix interactions, matrix–matrix interactions, cell proliferation, and cell migration
Chitin/chitosan	Exoskeleton of insects, shells of crustaceans, cell walls of fungi	Structural component

digestible, thereby allowing its use as a major human nutrient. The chemistry of starch is complicated by the fact that starch consists of linear and branched chains, referred to as amylose and amylopectin, respectively [86]. The relative abundance of these two natural ingredients can significantly influence the material properties of starch. Consequently, hundreds of different starches exist, each with its own particular composition of amylose and amylopectin.

Starch can be totally water insoluble or partially soluble at room temperature, depending on the proportions of amylose and amylopectin present. Water-soluble starches can be dispersed in water and form clear solutions upon heating. Upon cooling, soluble starch forms a highly viscous solution at low concentrations and a stiff hydrogel at higher concentrations. This phenomenon is the basis of the thickening action of soluble corn starch, which is used extensively in the food industry.

Although enzymes present in the human gut can digest starch, it is not readily biodegradable when implanted into human tissues. The cellular energy storage polymer in humans is glycogen and not starch. Consequently, starch is not an obvious choice for biomedical applications. However, some starch-based polymers are biodegradable in human tissues and biocompatible, so several potential applications have been explored. Starch-based polymers were used to prepare scaffolds for cartilage regeneration, which did not perform better than other types of scaffolds [87]. Starch was also used for the design of implantable drug-delivery systems [88]. In spite of the research conducted by several laboratories worldwide, starch-based polymers are not likely to find major biomedical applications in the near future.

Alginate

Alginate is a natural anionic polysaccharide found in seaweed, which is composed of β-(1−4) linked D-mannuronic acid and α-L-guluronic acid units. Along its polymer chain, alginate has regions rich in sequential mannuronic acid units or guluronic acid units and regions, in which both monomers are equally prevalent.

The most important use of alginate in biomedicine is as a cell-compatible hydrogel. Alginate can form strong hydrogels in the presence of divalent cations (such as Ca^{2+} or Ba^{2+}) that interact with the carboxyl groups present along the alginate backbone to form ionic cross-links. In a typical procedure a solution of alginate is added to cells suspended in physiologic buffer solution. This mixture is then dropped slowly into a solution of calcium chloride. As each drop of the cell suspension touches the calcium chloride solution, the alginate forms a hydrogel that encapsulates and captures the suspended cells. This process has been used in vitro to encapsulate human articular chondrocytes in the presence of recombinant human bone morphogenetic protein 2 [89].

Alginate has a well-characterized structure, which allows for a range of comparative studies to be performed. Cells do not readily attach and grow on or within alginate hydrogels [90], which is a common feature of most unmodified polysaccharides. However, the carboxyl groups in its guluronic acid residues provide an easy handle for the chemical modification of alginate [91]. This feature makes it possible to attach biologically active ligands (such as the important RGD peptide) to the alginate backbone [91].

Alginate's major disadvantage is the difficulty of its isolation from contaminated seaweed, which leads to the presence of mitogenic, cytotoxic, and apoptosis-inducing impurities in the final processed material. Although such molecules can be removed by further purification steps, it is a time consuming and costly process [92].

Gellan gum

Gellan gum is another anionic polysaccharide, similar in utility profile to alginate. It can be easily processed into transparent gels that are resistant to heat. Gellan gum is not cytotoxic [93] and can be injected into tissues. It has been used in vivo in humans as an ocular drug-delivery vehicle [4]. Gellan gum is still relatively unknown in the biomedical community and only a few studies have explored this material for tissue engineering [94]. Like alginate, gellan gum can be used for the encapsulation and in vitro culture of cells [93]. Gellan gum hydrogels were able to support the development of nasal chondrocytes and injectable gellan gum hydrogels were efficient in the encapsulation and support of human articular chondrocytes while also enabling active synthesis of ECM components.

Glycosaminoglycans

GAGs, which consist of repeating disaccharide units in linear arrangement, usually include an uronic acid component (such as glucuronic acid) and a hexosamine component (such as *N*-acetyl-D-glucosamine). The predominant types of GAGs attached to naturally occurring core proteins of PGs include CS, DS, KS, and HS [95,96]. The GAGs are attached to the core protein by specific carbohydrate sequences containing three or four monosaccharides.

The largest GAG, HA (hyaluronan), is an anionic polysaccharide with repeating disaccharide units of *N*-acetylglucosamine and glucuronic acid, with many unbranched units ranging from several hundred to several thousand. HA can be isolated from natural sources (e.g., rooster combs) or via microbial fermentation [97].

Because of its water-binding capacity, dilute solutions of HA form viscous solutions.

Like collagen, HA can be easily chemically modified, for instance by esterification of the carboxyl moieties, which reduces its water solubility and increases its viscosity [97,98]. HA can be cross-linked to form molecular weight complexes in the range $(8-24)\times10^6$ g/mol or to form an infinite molecular network (gel). In one method, HA is cross-linked using aldehydes and small proteins to form bonds between the hydroxyl groups of the polysaccharide and the amino or imino groups of the protein, thus yielding high molecular weight complexes [99]. Other cross-linking techniques include the use of vinyl sulfone, which reacts to form an infinite network through sulfonyl-bis-ethyl cross-links [100]. The resultant infinite network gels can be formed into sheaths, membranes, tubes, sleeves, and particles of various shapes and sizes. Only minor cross-species variations have been found in the chemical and physical structure of HA [101]. In addition, it is biocompatible and elicits minimal inflammation, which makes it desirable as a biomaterial [102]. Its main drawbacks in this respect are its residence time and the limited range of its mechanical properties.

Because of its relative ease of isolation and modification and its superior ability in forming solid structures, HA has become the preferred GAG in medical device development. It has been used as a viscoelastic substance during eye surgeries since 1979 [103] and has undergone clinical testing as a means of relieving arthritic joints [104]. In addition, gels and films made from HA have shown clinical utility in preventing the formation of post-surgical adhesions [105–107]. The benzyl ester of HA, sold under the trade name HYAFF-11, has been studied for use in vascular grafts [108–113]. Finally, HA has recently seen widespread usage as a 3D printable bioink [114].

Chitosan

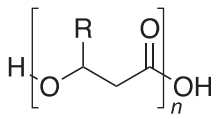
Chitosan is a biosynthetic polysaccharide that is the deacylated derivative of chitin. Chitin is a naturally occurring polysaccharide that can be extracted from crustacean exoskeletons or generated via fungal fermentation processes. Chitosan is a β-1,4-linked polymer of 2-amino-2-deoxy-D-glucose; thus it carries a positive charge from amine groups [115]. It is hypothesized that the major path for chitin and chitosan breakdown in vivo is through lysozyme, which acts slowly to depolymerize the polysaccharide [116]. The biodegradation rate of the polymer is determined by the amount of residual acetyl content, a parameter that can easily be varied. Chemical modification of chitosan produces materials with a variety of physical and mechanical properties [117–119]. For example, chitosan films and fibers can be formed using cross-linking chemistries adapted from techniques for altering other polysaccharides, such as treatment of amylose with epichlorohydrin [120]. Like HA, chitosan is not antigenic and is well-tolerated when implanted [121].

Chitosan has been formed into membranes and matrices suitable for several tissue-engineering applications [122–124] as well as conduits for guided nerve regeneration [125,126]. Chitosan matrix manipulation can be accomplished using the inherent electrostatic properties of the molecule. At low ionic strength, the chitosan chains are extended via the electrostatic interaction between amine groups, whereupon orientation occurs. As ionic strength increases and chain–chain spacing diminishes, the consequent increases in the junction zone and stiffness of the matrix results in increased average pore size. Chitosan gels, powders, films, and fibers have been formed and tested for such applications as encapsulation, membrane barriers, contact lens materials, cell culture, and inhibitors of blood coagulation [127].

Polyhydroxyalkanoates

PHAs are polyesters composed of β-hydroxy fatty acids such as of 3-hydroxybutyric acid and 3-hydroxyvaleric acid. These linear polymers provide intracellular energy storage by acting as a reserve of carbon and energy [128] in certain microorganisms. These polyesters are slowly biodegradable, biocompatible, thermoplastic materials [129,130]. Depending on growth conditions, bacterial strain and carbon source, the molecular weights of these polyesters can range from tens into the hundreds of thousands. Although the structures of PHA can contain a variety of *n*-alkyl side chain substituents (Structure 18.1), the most extensively studied PHA is the simplest: poly(3-hydroxybutyrate) (PHB).

Imperial Chemical Industries developed a biosynthetic process for the manufacture of PHB, based on the fermentation of sugars by the bacterium *Alcaligenes eutrophus* [131]. PHB homopolymer, like all other PHA homopolymers, is highly crystalline, extremely brittle, and relatively hydrophobic. Consequently, the PHA homopolymers have degradation times in vivo on the order of years [129,132]. Copolymers of PHB with 3-hydroxyvaleric acid are less crystalline, more flexible, tougher, and more readily processable [133]. However, they are still too hydrolytically stable to be useful in short-term applications where resorption of the degradable



STRUCTURE 18.1 General structure of poly(3-hydroxyalkanoate)s where R is an *n*-alkyl chain.

polymer within 1 year is desirable. PHB and its copolymers with up to 30% of 3-hydroxyvaleric acid are now commercially available under the trade name Biopol [133] and are mostly used as environment-friendly polymers that degrade slowly when disposed of in a landfill.

PHB has been found to have low toxicity, in part due to the fact that it degrades in vivo to D-3-hydroxybutyric acid, which is a normal constituent of human blood [134]. Applications of these previously tested polymers and others now under development include controlled drug release, artificial skin, and heart valves, along with industrial applications such as paramedical disposables [135–137]. Among the biomedical applications, sutures are the main product where PHAs are used, although a number of clinical trials for other applications may still be ongoing [138].

Polynucleotides

Gene delivery from the surfaces of tissue scaffolds represents a new approach to manipulating the local environment of cells [139]. Gene-therapy approaches can be employed to increase the expression of tissue inductive factors or block the expression of factors that would inhibit tissue formation [140]. A biomaterial can enhance gene transfer by localized expression of the genetic material and by protecting the genetic material against degradation by nucleases and proteases. Sustained delivery of DNA from a polymer matrix may transfect large numbers of cells at a localized site and lead to the production of a therapeutic protein that could enhance tissue development. For example, Yao investigated the potential of chitosan/collagen scaffolds with pEGFP-TGFβ1 as a gene vector candidate in cartilage tissue engineering [141].

Synthetic polymers

The concept of a polymer evolved from the study and commercial development of biologically derived macromolecules such as cellulose derivatives (celluloid, cellulose acetate) and vulcanized rubber in the 19th century. In 1907 the first totally synthetic polymer, Bakelite, was invented [142]. At that time the macromolecular structure of Bakelite and all other polymers was still not understood. It was only in 1922 that Hermann Staudinger proposed that the properties of polymers can be best explained by assuming that they consist of long chains of monomers linked together via regularly repeating bonds. The shortage of natural materials (in particular rubber) during World War II was the driving force behind the development of totally synthetic polymers. During World War II, nylon, Teflon, various polyesters, and synthetic rubber emerged. The tremendous improvements in virtually all consumer products since 1945 would not have been possible without the development of hundreds of specialized polymers.

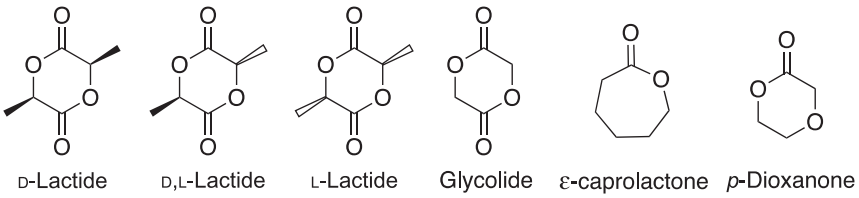
World War II left an additional legacy: the medical needs of millions of injured warfighters across the globe stimulated the development of new surgical procedures and innovative medical devices. Often, advances in the material sciences produced and enabled commensurate advances in medical practice. A new polymer, referred to as Vinyon N, was developed during World War II for use in parachutes. In 1952 vascular surgeons noticed the stretchiness and elasticity of this material and developed the first vascular graft using Vinyon N [143]. This effort became the starting point for the development of polymer-based medical implants and devices.

The systematic development of polymers for medical implants started with a focus on inert, biostable materials to be used in implants that lasted for the lifetime of the patient. It was only in 1969 that a biodegradable polymer, PGA, was used to create the first synthetic degradable suture line [144]—a breakthrough that ultimately ended the use of suture lines made from the intestines of animals. Due to the efforts of many research groups, a number of different polymeric structures and compositions have been explored as degradable biomaterials. However, commercial efforts to develop these new materials for specific medical applications have been limited. Thus detailed toxicological studies in vivo, investigations of degradation rate and mechanism, and careful evaluations of their physicomechanical properties have only been published for a very small fraction of those polymers. The following section is focused on a review of the most commonly investigated classes of biodegradable, synthetic polymers.

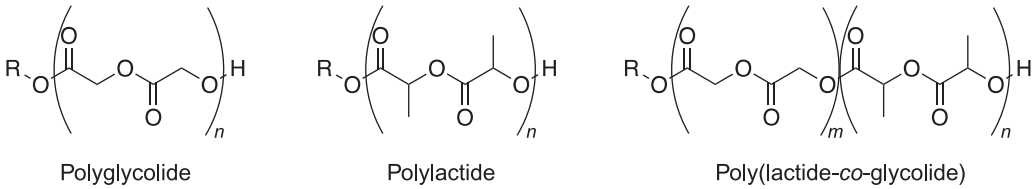
Aliphatic polyesters

Aliphatic polyesters made of hydroxy acids, such as glycolic acid, lactic acid, and ε-hydroxycaproic acid, have been used for a variety of medical product applications. As an example, bioresorbable surgical sutures made from poly(α-hydroxy acids) have been in clinical use since 1969 [144–146]. Other implantable devices made from these versatile polymers (e.g., internal fixation devices for orthopedic repair) are now part of standard surgical protocols [76,147,148].

Although polyesters can be synthesized by the polycondensation of hydroxy acids, such as lactic acid [149], it is difficult to achieve high molecular weights and control the molecular weight, molecular weight distribution, and architecture of the polymer using this process. In most cases, biodegradable polyesters are synthesized in a two-step procedure: first, the hydroxy acids are transformed into intramolecular lactones (Structure 18.2),



STRUCTURE 18.2 Cyclic esters used in ring-opening polymerizations.



STRUCTURE 18.3 Polyglycolide, polylactide, and their copolymer poly(lactide-*co*-glycolide).

which are then used as monomers in ring-opening polymerizations.

Aliphatic polyesters degrade via hydrolysis of the ester bonds, which results in a decrease in the polymer molecular weight of the implant [150]. This initial degradation occurs until the molecular weight of the resulting oligomers is less than 5000 g/mol, at which point the oligomers become water soluble and the degrading implant starts to lose mass as well. The final degradation and resorption of the polyester implants may also involve inflammatory cells, such as macrophages, lymphocytes, and neutrophils. Although this late-stage inflammatory response can have a deleterious effect on some healing events, these polymers have been successfully employed as matrices for cell transplantation and tissue regeneration [151,152]. The useful lifetime of implants made from these polymers is determined by the initial molecular weight, exposed surface area, crystallinity, and (in the case of copolymers) by the ratio of the monomers.

Aliphatic polyesters have a modest range of thermal and mechanical properties and a correspondingly modest range of processing conditions. The polymers can generally be formed into films, tubes, and matrices using such standard processing techniques as molding, extrusion, solvent casting, spin casting, and fused deposition modeling (3D melt printing). Ordered fibers, meshes, and open-cell foams have been formed to fulfill the surface area and cellular requirements of a variety of tissue-engineering constructs [76,147,153]. The aliphatic polyesters have also been combined with other components, for example, poly(ethylene glycol), to modify the cellular response elicited by the implant and its degradation products [154].

Polyglycolide, polylactide, and their copolymers

PGA, PLA, and their copolymer poly(lactide-*co*-glycolide) (PLGA) are the most widely used synthetic degradable polymers in medicine (Structure 18.3). Of this family of linear aliphatic polyesters, PGA has the simplest structure and is more hydrophilic than PLA. Since PGA is highly crystalline, it has a high melting point and low solubility in organic solvents. PGA was used in the development of the first totally synthetic absorbable suture [144]. The crystallinity of PGA in surgical sutures is typically in the range of 46%−52% [155]. Due to the hydrophilic nature and quick water uptake, surgical sutures made of PGA typically lose their mechanical strength over a period of 2−4 weeks postimplantation [156].

In order to adapt the materials properties of PGA to a wider range of possible applications, researchers undertook an intensive investigation of copolymers of PGA with PLA (Structure 18.3). Alternative sutures composed of PLGA are currently marketed under the trade name Vicryl [157]. Due to the presence of pendant methyl groups, PLA is more hydrophobic than PGA. High molecular weight PLA limits the water uptake of thin films to about 2% [155] and results in a rate of backbone hydrolysis lower than that of PGA [156]. In addition, PLA is more soluble in organic solvents than PGA.

It is noteworthy that there is no linear relationship between the ratio of glycolide to lactide and the physicomechanical properties of their copolymers. Whereas PGA is highly crystalline, crystallinity is rapidly lost in PLGA copolymers [158]. These morphological changes lead to an increase in the rates of hydration and hydrolysis. Thus copolymers tend to degrade more rapidly than either PGA or PLA [155,156].

Since lactic acid is a chiral molecule, it exists in two stereoisomeric forms that give rise to four morphologically distinct polymers. D-PLA (PDLA) and L-PLA (PLLA) are the two stereoregular polymers, D,L-PLA (PDLLA) is the racemic polymer obtained from a mixture of D- and L-lactic acid, and meso-PLA can be obtained from D,L-lactide. The polymers derived from the optically

active D and L monomers are semicrystalline materials, while the optically inactive PDLLA is always amorphous.

The differences in the crystallinity of PDLLA and PLLA have important practical ramifications. Since PDLLA is an amorphous polymer, it is usually considered for applications, such as drug delivery, where it is important to have a homogeneous dispersion of the active species within a monophasic matrix. On the other hand, the semicrystalline PLLA is preferred in applications where high mechanical strength and toughness are required, such as sutures and orthopedic devices [159–161].

PLLA and PDLA are semicrystalline polymers with a glass transition temperature (T_g) of approximately 60°C, and a peak melting temperature (T_m) of approximately 180°C [162,163]. PDLLA is amorphous with a T_g of 57°C [162]. Both semicrystalline PLLA and amorphous PDLLA polymers are rigid materials. Their Young's modulus and stress at break values are close to 3.5 GPa and 65 MPa, respectively. However, these polymers are relatively brittle with an elongation at break of less than 6% [164–166].

PLAs degrade by hydrolysis to form naturally occurring lactic acid. Degradation of the polymers starts with water uptake, followed by random cleavage of the ester bonds in the polymer chain. The degradation is throughout the bulk of the material [167]. Upon degradation the number of carboxylic end groups increases, which leads to a decrease in pH and an autocatalytic acceleration of the rate of degradation [168]. During the degradation of semicrystalline PLLA, crystallinity of the residual material increases as hydrolysis preferentially takes place in the amorphous domains [169]. In general, the rate of degradation and erosion of amorphous PDLLA is faster than that of PLLA [170].

Ikada et al. were the first to report on the stereocomplexation of enantiomeric PLLA and PDLA polymers during coprecipitation of mixed polymer solutions in nonsolvents [171]. Since then, they have shown that stereocomplexation of PLLA and PDLA can take place in dilute and concentrated solutions, during solvent evaporation and spinning, and during annealing of their mixtures prepared in the melt [172]. Other groups have also reported the formation of PLA stereocomplexes [173,174].

Upon stereocomplexation the melting temperature of the PLA stereocomplexes increases to about 230°C, which is 50°C higher than the enantiomeric PLLA and PDLA polymers. Stereocomplexation influences the mechanical properties of PLA films [167]. When stereocomplexes were formed from PLLA and PDLA, their films were stiffer, stronger, and tougher than films prepared from the enantiomeric polymers. In addition, under hydrolytic degradation conditions, the degradation of thin films of stereocomplexes of PLLA and PDLA is slower than that of the enantiomeric PLLA and PDLA homopolymers [175]. These findings are of great interest to biomedical engineers as they provide a simple way to increase the mechanical strength of these polymers with a concomitant increase in hydrolytic stability.

In addition, PLA, PGA, and their copolymers have been combined with bioactive ceramics, such as bioglass particles or hydroxyapatite, that stimulate bone regeneration while greatly improving the mechanical strength of the composite material [176]. It was also reported that composites of these polymers and bioglass are angiogenic (e.g., they supported the growth of blood vessels), thereby suggesting a novel approach for providing a vascular supply to implanted devices [177].

Some controversy surrounds the use of these materials for orthopedic applications. According to one review of the clinical outcomes for over 500 patients treated with resorbable pins made from either PGA or PLGA, 1.2% required reoperation due to device failure, 1.7% suffered from bacterial infection of the operative wound, and 7.9% developed a late noninfectious inflammatory response that warranted operative drainage [178]. This delayed inflammatory reaction represents the most serious complication of the use of PGA or PLA in orthopedic applications. The mean interval between device implantation and the clinical manifestation of this reaction is 12 weeks for PGA and can be as long as 3 years for the more slowly degrading PLA [178]. Whether avoiding reoperation to remove a metal implant outweighs an approximately 8% risk of severe inflammatory reaction is a difficult question; in any event an increasing number of trauma centers have suspended the use of these degradable fixation devices. It has been suggested that the release of acidic degradation products [glycolic acid for PGA, lactic acid for PLA, and glyoxylic acid for poly(*p*-dioxanone) (PDS)] contributes to the observed inflammatory reaction. Thus the late inflammatory response appears to be a direct consequence of the chemical composition of the polymer degradation products [178]. The incorporation of alkaline salts or antibodies to inflammatory mediators may diminish the risk of a late inflammatory response [179]. A more desirable solution to these problems for orthopedic (and perhaps other) applications requires the development of new polymers that do not release acidic degradation products upon hydrolysis.

Using biodegradable PGA mesh scaffolds and a biomimetic perfusion system, Niklason et al. successfully engineered small-diameter vessel grafts using either ECs and smooth muscle cells obtained from vessels in various species, or mesenchymal stem cells derived from adult human bone marrow [180,181]. In this approach, ex vivo culture resulted in the formation of a tissue-engineered vascular structure composed of cells and ECM, while the PGA degraded during the same period. Cellular material

was removed with detergents to render the grafts nonimmunogenic. Tested in a dog model, grafts demonstrated excellent patency and resisted dilatation, calcification, and intimal hyperplasia [182]. Finally, the semicrystalline character of PLLA means that it is well suited for the use in fused deposition modeling (3D melt printing) and it has been employed to generate a variety of complex architectures and 3D scaffolds for regenerative medicine [183].

Poly(ε-caprolactone)

PCL (Structure 18.4) is an aliphatic polyester that has been intensively investigated as a biomaterial. The discovery that PCL can be degraded by microorganisms led to the evaluation of PCL as a biodegradable packaging material; later, it was discovered that PCL can also be degraded hydrolytically under physiological conditions [184–186]. Under certain circumstances, cross-linked PCL can be degraded enzymatically, leading to what can be called enzymatic surface erosion [184,185]. Low molecular weight fragments of PCL are reportedly taken up by macrophages and degraded intracellularly, with a tissue reaction similar to that of the other poly(hydroxy acids) [186]. Compared with PGA or PLA, the degradation of PCL is significantly slower. PCL is therefore most suitable for the design of long-term, implantable systems, such as Capronor, a 1-year implantable contraceptive device [187].

PCL exhibits several unusual properties not found among the other aliphatic polyesters. Most noteworthy are its exceptionally low glass transition temperature of about −60°C and its low melting temperature of 57°C. Another unusual property is its high thermal stability. Whereas other tested aliphatic polyesters had decomposition temperatures (T_d) of 235°C–255°C, PCL has a T_d of 350°C, which is more typical of poly(ortho esters) than aliphatic polyesters [188]. Similar to PLLA, these thermal characteristics mean that PCL is well suited for fused deposition modeling (3D melt printing) and it has been used to prepare a variety of 3D scaffolds for tissue engineering [189,190].

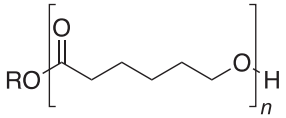
A useful property of PCL is its propensity to form compatible blends with a wide range of other polymers [191]. In addition, ε-caprolactone can be copolymerized with numerous other monomers (e.g., ethylene oxide, chloroprene, tetrahydrofuran, δ-valerolactone, 4-vinylanisole, styrene, methyl methacrylate, and vinyl acetate). Particularly noteworthy are copolymers of ε-caprolactone and the various lactide monomers, which have been studied extensively [185,192]. PCL and copolymers with PLA have been electrospun to create nanofibrous tissue-engineered scaffolds that show promise for vascular applications [23–25,193]. The toxicology of PCL has been extensively studied as part of the evaluation of Capronor. Based on a large number of tests, the monomer (ε-caprolactone) and the polymer (PCL) are currently regarded as nontoxic and tissue compatible materials. Early clinical studies [194] of the Capronor system were started around the year 2000 and resulted in a commercial implant used in Europe, but not in the United States.

Poly(p-dioxanone)

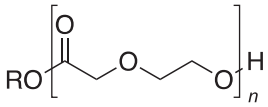
PDS is prepared by the ring-opening polymerization of *p*-dioxanone (Structure 18.5). It is a rapidly biodegrading polymer that was first commercialized by Ethicon in 1981 as a suture material [195]. When compared on a weight basis (e.g., per 1 g of implant), PDS releases degradation products that are less acidic than those released by PGA or PLA. The reduced acidity is a potential advantage for orthopedic applications, which led to the development of small bone pins (marketed as Orthosorb in the United States and Ethipin in Europe) for the fixation of fractures in nonload bearing bones [196,197]. However, PDS is softer, more flexible, and weaker than PLA/PGA, so it is better suited for soft tissue applications than for most orthopedic applications [195]. Thus it has been fabricated into rings for pediatric heart valve repair [198] and stents, such as the Ella stent, for use in the esophagus [199], trachea [200], and intestine [201]. In addition, PDS exhibits shape memory, so it is a promising material for tissue-engineering scaffolds for vascular grafts where it would provide kink resistance and rebound [195]. Finally, several academic laboratories have investigated PDS microparticles [202], micelles [block copolymer with poly(ethylene glycol)] [203], and electrospun nanofibers [204] for drug-delivery applications.

Poly(ortho esters)

Poly(ortho esters) are a family of synthetic degradable polymers that have been under development since 1970 [205,206]. Devices made of poly(ortho esters) can be formulated in such a way that the device undergoes surface erosion, which means that the polymeric device degrades at its surface only and thus tends to become thinner over



STRUCTURE 18.4 Poly(ε-caprolactone).



STRUCTURE 18.5 Poly(*p*-dioxanone).

time rather than crumbling into pieces. Since surface-eroding, slab-like devices tend to release drugs embedded within the polymer at a constant rate, poly(ortho esters) appear to be particularly useful for controlled release drug delivery [207]; this interest is reflected by the many descriptions of these applications in the literature [208].

There are two major types of poly(ortho esters). Originally, poly(ortho esters) were prepared by the condensation of 2,2-diethoxytetrahydrofuran and a diol [209] and marketed under the trade names Chronomer and Alzamer. Upon hydrolysis, these polymers release acidic by-products that autocatalyze the degradation process, resulting in degradation rates that increase with time. Therefore Heller et al [210] synthesized a new type of poly(ortho ester) based on the reaction of 3,9-bis(ethylidene 2,4,8,10-tetraoxaspiro {5,5} undecane) with various diols (Structure 18.6), which do not release acidic by-products upon hydrolysis and thus do not exhibit autocatalytically increasing degradation rates. By selecting diols having different degrees of chain flexibility, polymers can be obtained that range from hard, brittle materials to materials that have a gel-like consistency. A drug release system for mepivacaine (a treatment for postoperative pain) was tested in Phase 2 clinical trials between 2000 and 2005 [206]. Finally, in 2016 the FDA-approved Sustol, which uses a fourth-generation poly(ortho ester)-based drug-delivery system (Biochronomer) to provide extended release (>5 days) of granisetron to prevent chemotherapy-induced nausea and vomiting [211,212].

Aliphatic polycarbonates

Aliphatic polycarbonates (Structure 18.7) are biodegradable polymers that are promising biomaterials due to their nonacidic degradation products [213]. Similar to aliphatic polyesters, most aliphatic polycarbonates are prepared by the ring-opening polymerization of cyclic monomers [213,214]. By selecting appropriate monomers the hydrophobicity, degradability, viscoelasticity, and other properties of polycarbonates can be easily tailored [215,216]. Commercially available cyclic carbonate monomers include TMC, neopentylene carbonate, and 5-benzyloxytrimethylene carbonate, while numerous other carbonate monomers (>100) have been synthesized for specific applications [213,215]. The relative ease of preparing custom carbonate monomers makes them attractive candidates for introducing specific functionality into polyesters and polycarbonates [217]. For example, cyclic carbonate monomers with pendant functional groups, such as alkyls [218], alkynes [219], azides [220], coumarins [217], halides [221], protected hydroxyls [222], carbamates [223], carbohydrates [224], and dithiocarbonates [225], have been prepared and polymerized.

Aliphatic polycarbonates are typically amorphous with relatively low glass transition temperatures (T_g); the T_g for PTMC ranges from −17°C to −20°C depending on the molecular weight [226]. However, a few are semicrystalline, such as poly(neopentylene carbonate), which has a melting point of 107°C [227]. Notably, aliphatic polycarbonates, such as PTMC and poly(ethylene carbonate), have been observed to degrade by surface erosion in vivo [226,228] as opposed to the bulk degradation behavior observed for polyesters. The surface erosion in vivo is a result of macrophage-mediated enzymatic or oxidative degradation [229,230]. In addition, the in vivo degradation behavior of PTMC is dependent on the molecular weight with higher molecular weight polymers (>100 kg/mol) degrading faster than lower molecular weight polymers (<70 kg/mol) [226,231]. Consequently, high molecular weight PTMC has been explored for a variety of biomaterial applications including soft tissue regeneration [232–234], sutures [235,236], and drug delivery [237–239].

STRUCTURE 18.7 Aliphatic polycarbonate initiated by an alcohol with alkyl chain, R_i, from a cyclic carbonate where R is an alkyl chain with optional pendant functionality.

Biodegradable polyurethanes

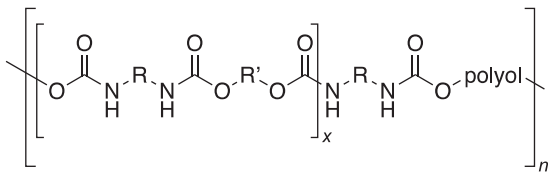
Polyurethanes contain a urethane moiety in their repeating unit and were first produced by Bayer in 1937. These polymers are typically produced through the reaction of a diisocyanate with a polyol. Conventional polyols are polyethers or polyesters. The resulting polymers are segmented block copolymers with the polyol providing a low glass transition temperature (i.e., <25°C) soft segment and the diisocyanate component, often combined with a hydrocarbon chain extender, providing the hard segment (Structure 18.8). A wide range of physical and mechanical properties have been realized with commercial polyurethanes.

Polyurethanes have been used in biomedical applications since the 1960s, particularly as a blood-contacting material in cardiovascular devices [240,241]. Intended as nonbiodegradable coatings, polyurethanes fell out of favor

with the failure of pacemaker leads and breast implant coatings. Subsequent studies, as reviewed by Santerre et al., have clarified much about the behavior of polyurethanes in biological systems [242]. Elucidation of the biodegradation mechanism and its dependence on the polyurethane structure and composition have led to the development of biodegradable polyurethanes for a variety of tissue-engineering applications such as meniscal reconstruction [243], myocardial repair [244], and vascular tissues [245]. The design of biodegradable polyurethanes has required alternative diisocyanate compounds since traditional aromatic diisocyanates are toxic and suspected carcinogens. Biodegradable polymers are made from biocompatible diisocyanates, such as lysine-diisocyanate or hexamethylene diisocyanate, that release nontoxic degradation products.

The urethane bond is essentially nondegradable under physiological conditions. Therefore biodegradable polyurethanes can only be obtained when the employed soft polyol segments are degradable [242]. As an example, aliphatic poly(ester urethane)s containing random 50/50 ε-caprolactone/L-lactide copolymer segments, 1,4-butanediol and 1,4-butanediisocyanate were synthesized and used to prepare porous structures for meniscus reconstruction [246]. In these polymers the biodegradation mechanism involves the hydrolytic cleavage of the ester bonds in the ε-caprolactone/L-lactide copolymer segments to form low molecular weight blocks of the nondegradable hard segments, which are ultimately excreted from the body via the liver and/or kidney.

An interesting application of polyurethanes was developed by Santerre et al. where fluoroquinolone antimicrobial drugs were incorporated into the polymer as hard-segment monomers [242]. This innovation led to the design of drug polymers (trade name: Epidel) that release the drug when degraded by enzymes generated by an inflammatory response. These polymers are an example of a "smart" system in that antibacterial agents are released only when inflammation is present. Once healing occurs, the enzyme level drops and the release of drug diminishes.



STRUCTURE 18.8 Segmented polyurethane prepared from a diisocyanate, OCN-R-NCO; a chain extender, HO-R′-OH; and a polyol building block.

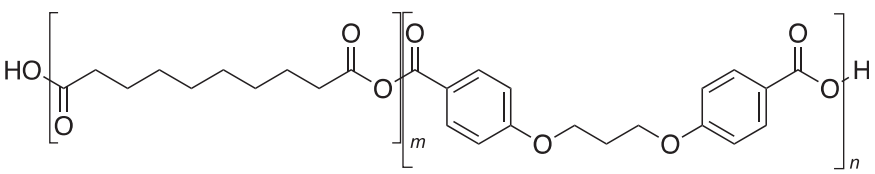
Polyanhydrides

Polyanhydrides (Structure 18.9) were first investigated in detail by Hill and Carothers [247] and were considered in the 1950s for possible applications as textile fibers [248]. Their low hydrolytic stability, the major limitation for their industrial applications, was later recognized as a potential advantage by Langer et al. [249], who suggested the use of polyanhydrides as degradable biomaterials. A study of the synthesis of high molecular weight polyanhydrides has been published by Domb et al. [250].

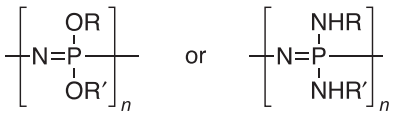
A comprehensive evaluation of the toxicity of the polyanhydrides showed that, in general, they possess excellent in vivo biocompatibility [251]. Their most immediate applications are in the field of drug delivery, although tissue-engineering applications are also being developed. Drug loaded devices are best prepared by compression molding or microencapsulation [252]. A wide variety of drugs and proteins, including insulin, bovine growth factors, angiogenesis inhibitors (e.g., heparin and cortisone), enzymes (e.g., alkaline phosphatase and β-galactosidase), and anesthetics have been incorporated into polyanhydride matrices, and their in vitro and in vivo release characteristics have been evaluated [253]. One of the most aggressively investigated uses of the polyanhydrides is for the delivery of chemotherapeutic agents. An example of this application is the delivery of BCNU (bis-chloroethylnitrosourea) to the brain for the treatment of glioblastoma multiforme, a universally fatal brain cancer [254]. For this application, polyanhydrides derived from 1,3-bis(4-carboxyphenoxy)propane and sebacic acid received FDA regulatory clearance in the fall of 1996 and are currently being marketed under the name Gliadel.

Polyphosphazenes

Polyphosphazenes (Structure 18.10) consist of an inorganic phosphorous-nitrogen backbone, in contrast to the commonly employed hydrocarbon-based polymers [255]. Consequently, the phosphazene backbone undergoes hydrolysis to phosphate and ammonium salts, with the concomitant release of the side group. Of the numerous



STRUCTURE 18.9 Example of a clinically relevant polyanhydride formed from two diacids, specifically sebacic acid and 1,3-bis(4-carboxyphenoxy)propane (repeating units *m* and *n*, respectively).



STRUCTURE 18.10 General structures for oxide and amine functionalized polyphosphazenes.

polyphosphazenes that have been synthesized, those that have potential for use in medical products are substituted with either amines of low p*K*a or activated alcohol moieties [256–258]. Singh et al. have modified the side groups to tune properties, such as the glass transition temperature, degradation rate, surface wettability, tensile strength, and elastic modulus, thereby enabling these polymers to be considered for a wider range of biomedical applications [259]. The most extensively studied polyphosphazenes are hydrophobic with fluoroalkoxy side groups [260]. In part, these materials are of interest because of their expected minimal tissue interaction, which is similar to Teflon.

Polymers of aryloxyphosphazenes and closely related derivatives have also been extensively studied. One such polymer can be cross-linked with dissolved cations, such as calcium, to form a hydrogel matrix because of its polyelectrolytic nature [261]. Using methods similar to alginate encapsulation, microspheres of this polymer have been used to encapsulate hybridoma cells without affecting their viability or their capacity to produce antibodies [262]. Interaction of these microspheres with poly(L-lysine) resulted in a semipermeable membrane that was capable of retaining the secreted antibodies [262].

Biodegradable polyphosphazenes have been explored for a range of biomedical applications, including nerve regeneration [263], tendon regeneration [264], and hard tissue-engineering scaffolds [265]. The delivery of drugs such as doxorubicin using polyphosphazenes has also been investigated [266]. Finally, an in vivo study of subcutaneously implanted samples of alanine-modified polyphosphazenes in a rat model demonstrated their biodegradability and resulted in a moderate inflammatory response after 2 weeks that had decreased to a mild inflammatory response after 12 weeks [267].

Poly(amino acids) and pseudo-poly(amino acids)

Since proteins are composed of amino acids, many researchers have tried to develop synthetic polymers derived from amino acids to serve as models for structural, biological, and immunological studies. In addition, many different types of poly(amino acids) have been investigated for use in biomedical applications [268]. Poly(amino acids) are usually prepared by the ring-opening polymerization of the corresponding *N*-carboxy anhydrides, which are in turn obtained by reaction of the amino acid with phosgene [269].

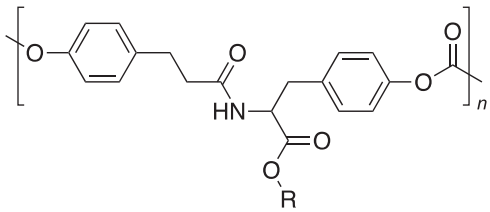
Poly(amino acids) have several potential advantages as biomaterials. The variety of amino acid structures allows a large number of polymers and copolymers to be prepared. In addition, amino acid side chains offer sites for the attachment of small peptides, drugs, cross-linking agents, or pendant groups to modify the physicomechanical properties of the polymer. Since these polymers release naturally occurring amino acids as the primary products of polymer backbone cleavage, their degradation products are expected to show a low level of systemic toxicity.

Poly(amino acids) have been investigated as suture materials [257], as artificial skin substitutes [270] and as drug-delivery systems [271]. Various drugs have been attached to the side chains of poly(amino acids), usually via a spacer unit that distances the drug from the backbone. Combinations of poly(amino acid)s and drugs that have been investigated include poly(L-lysine) with methotrexate and pepstatin [272] and poly(glutamic acid) with adriamycin and norethindrone [273]. Short amino acid sequences, such as RGD and Arg-Gly-Asp-Ser (RGDS), which are strong promotors of specific cell adhesion, have been linked to the polymer backbone to promote cell growth in tissue-engineering applications [274,275].

Despite their apparent potential as biomaterials, poly(amino acids) have actually found few practical applications. *N*-Carboxy anhydrides, the starting materials, are expensive to make and difficult to handle because of their high reactivity and moisture sensitivity. Also, most poly(amino acids) are highly insoluble and nonprocessable materials. Furthermore, the antigenicity of poly(amino acids) containing three or more amino acids limits their use in biomedical applications [268]. Finally, poly(amino acids) degrade via enzymatic hydrolysis of the amide bond, so it is difficult to reproduce and control their degradation in vivo, because the level of relevant enzymatic activity varies from person to person. Consequently, only a few poly(amino acids), usually derivatives of poly(glutamic acid) carrying various pendent chains at the γ-carboxylic acid group, have been identified as promising implant materials [276].

As an alternative approach, Kohn et al. replaced the peptide bonds in the backbone of synthetic poly(amino acids) by a variety of "nonamide" linkages such as ester, iminocarbonate, urethane, and carbonate bonds [277,278]. The term pseudo-poly(amino acid) is used to denote this new family of polymers, in which naturally occurring amino acids are linked together by nonamide bonds (Structure 18.11).

The use of such backbone-modified pseudo-poly(amino acids) as biomaterials was first suggested in 1984 [279]. The first pseudo-poly(amino acids) investigated



STRUCTURE 18.11 A poly(amide carbonate) derived from desaminotyrosyl tyrosine alkyl esters. This structure is an example of a new family of amino acid–derived polymers.

were a polyester from *N*-protected trans-4-hydroxy-L-proline and a poly(iminocarbonate) from tyrosine dipeptide [280,281]. Several studies indicate that the backbone modification of conventional poly(amino acids) generally improves their physicomechanical properties [277,282,283]. This approach is applicable to, among other materials, serine, hydroxyproline, threonine, tyrosine, cysteine, glutamic acid, and lysine; it is only limited by the requirement that the nonamide backbone linkages give rise to polymers with desirable material properties. Additional pseudo-poly(amino acids) can be obtained by considering dipeptides as monomeric starting materials. Hydroxyproline-derived polyesters [281,284], serine-derived polyesters [285], and tyrosine-derived polyiminocarbonates [286] and polycarbonates [287] represent specific embodiments of these synthetic concepts.

Combinations (hybrids) of synthetic and biologically derived polymers

Biologically derived polymers have important advantages over synthetic materials, which often include reduced toxicity and improved bioactivity. The reduced toxicity is typically due to the polymers deriving from molecules that naturally occur in the body [288]. The improved bioactivity refers to the ability of many biologically derived to elicit specific cellular responses. Collagen, for example, is a bioactive material because of its ability to support cell attachment, growth, and differentiation. However, the usefulness of biologically derived polymers is often limited by their poor engineering properties. Important disadvantages of biologically derived polymers are

1. high batch-to-batch variability due to complex isolation procedures from inconsistent sources;
2. poor solubility and processability, preventing the use of industrial manufacturing processes;
3. risk of contamination by pyrogens or pathogens;
4. poor or limited materials properties such as strength, ductility, elasticity, or shelf life; and
5. high cost.

In overall terms, synthetic materials offer a wider range of useful engineering properties (polymer composition, architecture, mechanical properties, etc.), but they generally fail to promote cell growth and differentiation to the same degree as some of the biologically derived polymers [289]. To address these shortcomings an obvious approach is to combine biologically derived polymers with synthetic materials. As a general rule, the purpose of such hybrid materials is to combine the bioactivity of biologically derived polymers with the superior engineering properties of synthetic materials.

As an example, a clinically useful cornea replacement material was obtained when collagen was incorporated into a synthetic, polyacrylate-based hydrogel [290]. Another example of this approach is provided by a hybrid material derived from silk fibroin (as the hydrophobic, bioactive material) and poly(vinyl alcohol) (PVA) (as the hydrophilic, synthetic component) [291]. PVA can be cross-linked under mild conditions by exposure to UV radiation. This cross-linking method allows PVA and fibroin to form a highly biocompatible hydrogel with adjustable engineering properties [291].

A final example of this approach is provided by a hybrid material composed of poly(*N*-isopropylacrylamide) (pNIPAM) as the synthetic component and various natural polysaccharides as the biologically derived component [292]. pNIPAM undergoes a thermally induced phase transition around 32°C that causes the soluble material to precipitate. The resulting product is liquid and injectable at room temperature and precipitates to form a hydrogel at body temperature, thereby facilitating the formation of a solid implant while eliminating the need for surgical insertion. Disadvantages of pNIPAM as a biomaterial include its inability to support cell growth and its lack of biodegradability. These disadvantages can be overcome by cross-linking pNIPAM with natural polysaccharide precursors, leading to cell-permissive formulations that will biodegrade in vivo.

Using polymers to create tissue-engineered products

The medical implant of the future will not be an artificial prosthetic device that replaces tissue lost due to trauma, disease, or aging, but a tissue scaffold that integrates with the surrounding healthy tissue and assists in the regeneration of lost or damaged tissue. As one possible implementation of this concept, the biomedical literature envisions porous sponge-like tissue scaffolds composed of bioactive polymers. These tissue scaffolds could either be preseeded with specific cell populations prior to implantation into the patient or be implanted first and then colonized by the patient's own cells, thereby leading to the regeneration of the desired tissue. In either case, one can formulate several design criteria to guide the biomedical engineer in

the process of selecting an appropriate biomaterial for the intended application.

First and foremost, one must be concerned with the bulk polymer properties. The biomaterial must have an appropriate range of physicomechanical properties, biodegradation rates, and biocompatibility appropriate for the intended application. Next, it must be possible to create the desired tissue scaffold shape and architecture using cost-effective fabrication methods. For example, electrospinning may be the preferred fabrication method to create an ECM-like scaffold that consists of nano-sized fibers. Since electrospinning requires that the biomaterial is soluble in nontoxic solvents, any insoluble biomaterial would not meet a key design requirement. Finally, it is important to consider the biological properties of the biomaterial. Tissue-engineering products require specific cellular responses. For example, in a bone regeneration scaffold, the ability to support the attachment and growth of osteoblasts in combination with the ability to adsorb and concentrate endogenous bone morphogenic protein on the polymer surface may be important design requirements. There are many additional requirements that impose further limitations on the selection of the biomaterial and/or the architecture of the implant. For example, whenever functional tissue has to form within the tissue-engineering scaffold, a lack of proper vascularization will impede a favorable tissue response. Details, such as pore size, pore structure, and pore connectivity, are often critical for promoting angiogenesis and hence vascularization of the scaffold [293].

Once an appropriately shaped tissue scaffold has been conceptualized, it is time to consider a wide range of secondary design criteria relating to the device's shelf life, ability to be sterilized and packaged for clinical use, and overall cost. Here, being able to create a terminally sterilized device is a factor often overlooked by academic researchers, who fail to consider the fact that most FDA-recognized sterilization methods cannot be applied to products that contain living cells. Thus the requirement to ensure device sterility has been a major hurdle in translating research concepts from the laboratory to clinical practice.

Barriers: membranes and tubes

Design formats requiring cell activity on one surface of a device while precluding transverse movement of surrounding cells onto that surface call for a barrier material. For example, peripheral nerve regeneration must allow for axonal growth, while at the same time precluding fibroblast activity that could produce neural-inhibiting connective tissue. Structures, such as collagen tubes, can be fabricated to yield a structure dense enough to inhibit connective tissue formation along the path of repair while allowing axonal growth through the lumen [294]. Subsequently, conduits composed of a silk fibroin scaffold coupled with biologics have shown improved performance [295]. Similarly, collagen membranes for periodontal repair provide an environment for periodontal ligament regrowth and attachment while preventing epithelial ingrowth into the healing site [296]. Antiadhesion formulations using HA, which prevent ingrowth of connective tissue at a surgically repaired site, also work in this way [105].

Gels

Gels are used to generate a specialized environment for cells by either providing a hydrogel scaffold on which they can grow or encapsulating them in a protective isolated environment. For example, collagen gels for tissue engineering were first used to maintain fibroblasts, which were the basis of a living skin equivalent [297]. Gels have also been used for the maintenance and immunoprotection of xenograft and homograft cells, such as hepatocytes, chondrocytes, and islets of Langerhans, used for transplantation [298–300]. Semipermeable gels have been created to limit cell–cell communication and interaction with surrounding tissue, and to minimize the movement of peptide factors and nutrients through the implant. Injectable biodegradable gel materials that form through cross-linking in situ show promise for the regeneration of bone and cartilage [301]. The use of biodegradable polyester dendrimers (highly branched, synthetic polymers with layered architectures) to form hydrogels for tissue-engineering applications such as corneal wound sealants has also been discussed [302]. In general, nondegradable materials are used for cell encapsulation to maximize the long-term stability of the implant. In the future, however, it may be possible to formulate novel "smart" gels, in which biodegradation is triggered by a specific cellular response instead of simple hydrolysis.

Matrices

It has been recognized since the mid-1970s that 3D structures are an important component of engineered tissue development [16,17]. Yannas et al. were the first to show that pore size, pore orientation, and fiber structure are important characteristics in the design of cell scaffolds. Several techniques have subsequently been developed to form well-defined matrices from synthetic and biologically derived polymers, and the physical characteristics of these matrices are routinely varied to maximize cellular and tissue responses [303–306]. Examples of engineered matrices that have led to several resorbable templates are oriented pore structures designed for regeneration of trabecular bone [307,308].

Conclusion

Research using currently available biomaterials and research aimed at developing novel biodegradable polymers have both helped to advance the field of tissue engineering. Throughout most of the 20th century, research and development efforts focused on a small number of biodegradable polymers with a history of regulatory approval, thereby making PLA the most widely used biodegradable polymer. Research in the 21st century aims to develop advanced biodegradable polymers that elicit predictable and useful cellular responses. To achieve this goal, current research efforts focus on creating bioactive materials that combine the superior engineering properties of synthetic polymers with the superior biological properties of natural materials. The extremely complex material requirements of tissue scaffolds pose significant challenges and require a continued research effort toward the development of new bioresorbable polymers.

Chapter 19

Three-dimensional scaffolds

Ying Luo
Lyndra Therapeutics, Watertown, MA, United States

Introduction

A key concept in tissue engineering (TE) is using material-based porous three-dimensional (3D) scaffolds to provide physical and structural support and deliver micro-environmental cues to cells to enable or facilitate tissue formation [1]. Through decades of investigations, 3D scaffolds have evolved to serve complex functions with dynamic and programmable features at nano-, micro- to macro-scales in various TE applications. Scaffolds can be seeded with different types of cells, including stem cells, progenitors, mature differentiated cells, or cocultures of cells for de novo tissue construction in vitro; scaffolds can also be directly implanted in vivo to deliver soluble/insoluble and temporal/spatial cues to guide the regeneration of defected tissue in situ. While their functions vary with specific TE approaches and clinical needs, scaffolds may potentially coordinate biological events on time and length scales ranging from seconds to weeks and nanometers to centimeters, respectively [2]. One important theme in the research of 3D scaffolds is to advance the material synthesis and fabrication techniques to enable the construction or regeneration of functional tissue. On the other hand, efforts should be directed to understanding the correlations between scaffold properties and its biological functions in directing cell and tissue responses, which constitute the important foundation for deriving design principles for 3D scaffolds.

During the biological processes of tissue development, cells constantly decode and release different morphogenetic factors into their surroundings. In response, cells make decisions on how to divide, differentiate, migrate, degrade/produce extracellular matrix (ECM), and orient themselves. Based on our understanding of reciprocal cell−ECM interactions in native tissues, it should theoretically be possible to design scaffolds to mimic the regulatory function of the natural ECM and promote tissue formation via programing one or more chemical/physical properties in scaffolds. Living cells and tissues, however, are not simple, linear systems. The complex roles that ECM structures play in orchestrating cellular and tissue processes are exhibited with spatial and temporal dynamics and precision. Complexity may also come from the context of an in vivo physiological condition, which generates variables not only from mechanical or electrical processes but also local/systemic pathological responses. Indeed, the dynamic superposition of environmental factors with the function of scaffolds can profoundly impact the outcome of the tissue-formation process. Nevertheless, correlations between individual scaffold properties and certain aspects of the tissue-formation process (e.g., cellular phenotype/organization, ECM production, emergence of tissue structure, and recovery of tissue function) can be derived and applied to the optimization of scaffold designs [3−6].

In this chapter, based on our current understanding of the correlation between scaffold properties and functions in promoting tissue formation, we summarize basic scaffold design approaches and essential principles that may guide the rational multifunctional design of scaffolds for TE (Fig. 19.1A). Design variables are decoupled and analyzed in terms of how they have been controlled using different materials and fabrication techniques, and what implications they have in regulating the tissue-formation process. From an engineering standpoint, it is desirable that scaffold properties and functions can be reproducibly integrated within a scaffold construct through standardized and customizable fabrication process, such that different types of cellular and tissue events can be coordinated/controlled and patient-specific variations and needs can be addressed.

Three-dimensional scaffold design and engineering

An understanding of the fundamental scaffold properties and functions involves hierarchal design of temporal and/or

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00020-4

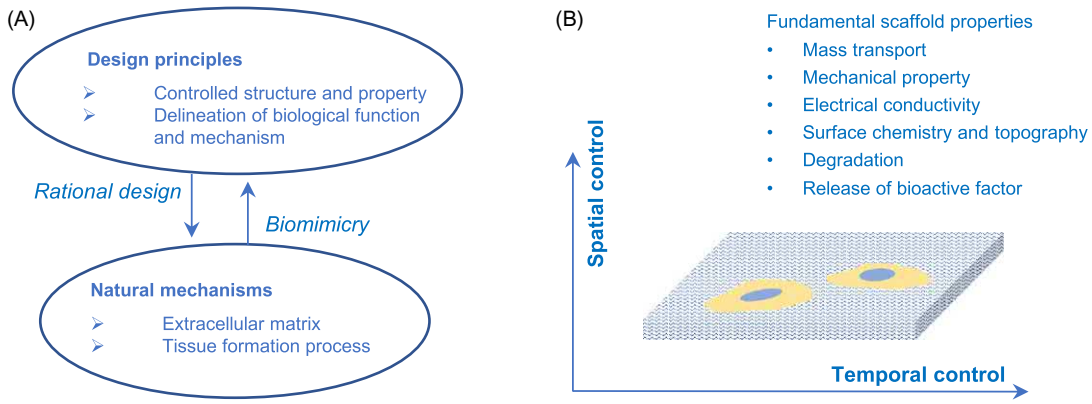

FIGURE 19.1 **A)** Design of TE scaffolds involves the rational approach through elucidation of structure-property-function relationships in scaffolds and the biomimicry approach through emulating natural mechanisms of ECM during tissue formation process. **B)** A TE scaffold holds fundamental properties that are essential to its function—spatial as well as temporal control of these properties in 3D environment enables building scaffolds with dynamic and instructive functions.

spatial parameters in scaffolds at multiple length scales and investigation of cellular and tissue responses under different conditions (Fig. 19.1B). At any given time point the scaffold properties will provide an initial set of environmental conditions for cells and tissues at the onset of in vitro seeding (i.e., time zero) or during the acute phase of the host response following direct implantation in vivo. These fundamental material properties are basic scaffold variables for mediating cell behavior and tissue responses and they typically include mass transport (pore architecture), mechanics, electrical conductivity, and surface chemistry and topology (Fig. 19.1B). TE involves dynamic processes in 3D space. On the temporal and spatial axes, the scaffold properties may be varied, patterned, or programed. Temporally, the initial scaffold properties and associated functions would evolve over time in response to the seeded or infiltrating cells in an in vitro/in vivo environment. The degradation of scaffold and release of bioactive factors are two active scaffold properties that can modulate the construct and local microenvironment over time and will be discussed under the "Temporal control" section. Spatially, all properties of fundamental materials can be generated with anisotropic patterns and constraints to guide cell orientation, cell−cell interaction, and tissue morphogenesis. Designing and enabling spatial control therefore presents a major challenge in TE given the complicated hierarchal organization of cells, ECM and functional units in all tissue types. As all the fundamental scaffold properties and functions act in an interdependent way, the investigation and fabrication of 3D scaffolds entail decoupling of variables and understanding how each aspects of a scaffold correlate with the biological function. These scaffold properties can then be integrated to yield optimized constructs for different TE applications.

Mass transport and pore architectures

As a porous 3D substrate, the scaffold provides conditions that determine how fluids, solutes, and cells move in and out of the tissue construct. The mass transport processes are correlated with the scaffold chemical compositions and the geometrical parameters of its pores or voids—characterized mainly by pore size, porosity, pore interconnectivity/tortuosity, and surface area. The pore architecture of a scaffold may also change due to chemical disruption [e.g., pH dependence of the hydrolysis of poly (lactic-*co*-glycolic acid) (PLGA) scaffolds] and modulation by biological components. These factors interdependently affect the diffusive or convective behavior of soluble nutrients, growth factors, and cytokines. Compared to the vascularized tissues containing convective flows, diffusion is often the primary mass transport mechanism in engineered tissue constructs cultivated in vitro and prior to inosculation with the host vasculature following implantation in vivo. In the environment with fluidic dynamics, permeability has been used as an effective parameter to characterize the property of a scaffold to transport water, small molecules, and proteins [7,8]. Permeability of a scaffold can be measured through experiments combined with computational methods to derive the permeability coefficients that reflect the hindered movement of solutes and permeation of fluids through porous scaffolds [9].

The structural characteristics of the pores and void spaces in scaffolds are also the primary variables that govern the initial cell distribution and organization in scaffold. Once a scaffold is impregnated with cells, the solute diffusion and distribution profiles are influenced by the cellular environment as well as the pore architecture of the scaffold. In metabolically active tissues in vivo,

most cells reside within 100 μm of a capillary. In engineered tissue constructs cultivated in static culture without medium perfusion, neo-tissue formation is generally limited to the peripheral 100−200 μm of the scaffold due to diffusion limitations [10−12]. Subsequently, the organization and density of cells in this peripheral region can further influence the distribution and availability of nutrients to cells within the scaffold interior [13]. Although certain types of cells may tolerate nutrient deficiency to some extent (such as chondrocytes under hypoxia), the induction of rapid vascularization following implantation is considered essential for establishing nutrient exchange and retaining a viable cell population within the construct.

One main parameter that affects the efficiency of initial cell impregnation is the pore size of the scaffold. The resulting geometries and spatial characteristics of individual cells or cell aggregates within the void space of scaffolds direct the subsequent cell proliferation, differentiation, and tissue formation events. As observed in the nonwoven fibrous scaffolds made of poly(ethylene terephthalate) and seeded with human placenta trophoblast cells in vitro, the size of cell aggregates increased with larger pore volumes between fibers, but larger cell aggregates exhibited attenuated differentiation and suppressed proliferation activities compared to smaller ones [14,15]. In another study, in the genipin-cross-linked gelatin scaffolds, chondrocytes demonstrated dedifferentiation in pores smaller than 200 μm but better proliferation and ECM production in the scaffolds with pore size between 250 and 500 μm [16].

Cell transport and vascularization as a result of scaffold pore size can also affect the tissue types and tissue-formation process in scaffolds. When bone morphogenetic proteins were loaded into honeycomb-shaped hydroxyapatite scaffolds to induce osteogenesis, it was found that smaller diameters (90−120 μm) induced cartilage followed by bone formation, whereas those with larger diameters (350 μm) induced bone formation directly [17]. The difference was likely caused by the different onset time of vascularization and cell differentiation.

Optimal scaffold pore sizes have been suggested for regenerating various types of tissues in vivo. For example, the critical pore size was found to be above 500 μm for rapid fibro-vascularization in poly(L-lactic acid) (PLLA) scaffolds with cylindrical pores [18]. In the ECM analog scaffolds made of cross-linked collagen and glycosaminoglycans (GAGs), the average pore diameters required to induce dermis and peripheral nerve regeneration were within 20−120 and 5−10 μm, respectively [19]. In bone engineering, early studies by Hulbert et al. showed that a minimum pore size of 100 μm was required to allow bone tissue ingrowth in ceramic scaffolds [20]. Further investigations found that larger pore sizes (e.g., > 100 μm) may favor higher alkaline phosphatase activity and more bone formation [21,22]. In recent years, mesenchymal stromal cells (MSCs) from animal and human sources have been intensively investigated for tissue regeneration applications through different scaffolds. The pore size may also range from tens to hundreds of micrometers depending on the specific cell type and scaffolds. A summarization that may suggest optimal pore size and porosity in different TE scenarios can be found in the review by Loh and Choong [23].

In addition to pore size, cell transport behavior such as diffusion, attachment, and migration are also affected by a number of other basic geometrical parameters of scaffolds, including porosity (the fraction of pore volume), pore shape, pore interconnectivity, and surface area [24]. It is therefore pivotal to elucidate how the architecture of pores relates to the biological response of cells and tissues. Rapid prototyping or solid free-form fabrication allows the generation of highly controlled scaffold structures through 3D printing, or additive manufacturing techniques. Macroscopic geometry and local topologies in scaffolds can be custom-designed by computational algorithms to control the permeability and mechanical properties [4]. In the study on seeding chondrocytes in scaffolds made through 3D fiber deposition and particle leaching, a significantly higher GAG content was observed in the fibrous scaffolds compared to the porous foams (Fig. 19.2A and B) [25]. Besides the fibrous morphology, the more uniform porous structure via controlled fiber deposition was suggested relevant to the better scaffold function.

In the recent decade, scaffolds have been fabricated toward mimicking the anisotropic natural tissue, which often contains pore size gradients, layered structures, and hierarchical pores at different length scales. Scaffolds showing gradient in pore size were generated through conventional fabrication methods or computational-aided prototyping [26,27]. For example, in the gradient scaffold fabricated through an additive manufacturing process and seeded with human MSCs, a gradual increase in chondrogenic markers was observed within the gradient structures with decreasing pore size (Fig. 19.2C) [26]. In other studies, scaffolds showing dual or multiple architectural features were also designed. For example, scaffolds were fabricated to contain both macroscale and microscale pores to serve respective functions to support cell attachment and promote nutrient permeation ([28−30]). As shown in a composite cardiac scaffold in Fig. 19.2D [29], the scaffold was fabricated to contain microchannels, an interface, and grids in different layers, and all structures were simultaneously fabricated with microscale pores to

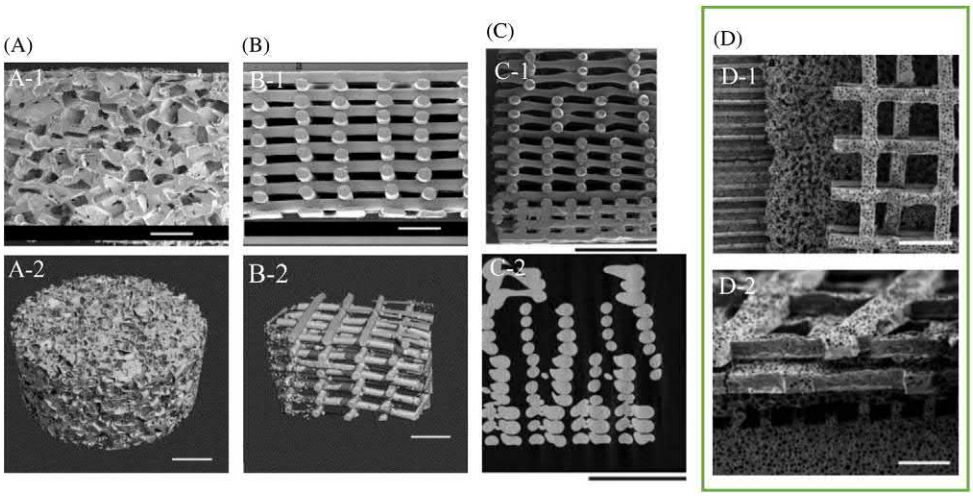

FIGURE 19.2 Evolving structures of porous scaffolds fabricated for cartilage tissue engineering: from **A** to **C**, scaffolds containing random pores, homogenous structures and graded structures. promote the transport of molecules. These new trends in pore design highlight the needs for scaffolds with multifaceted and biomimetic functions in order to achieve optimal tissue growth.

Mechanics

The mechanical properties of the natural ECM are of paramount importance in dictating macroscopic tissue functions (e.g., bearing load) and regulating cellular behavior via mechanotransduction signaling. In designing tissue constructs, scaffold mechanical properties are often sought that resemble native tissue properties. Foremost, in the acute phase following implantation, the scaffold must fulfill the key mechanical functions of the tissue that is being replaced. For example, the earliest TE blood vessels based on cell-contracted collagen gels were not strong enough to withstand physiologic blood pressures and thus had to be reinforced by a tubular synthetic polymer mesh to ensure structural integrity [31]. TE blood vessels based on relatively strong nonwoven poly(glycolic acid) (PGA) scaffolds exhibited burst pressures exceeding physiological requirements upon implantation ($>$ 2000 mmHg) [32]. In addition to appropriately matching gross tissue mechanical properties, the scaffold must also provide an internal micromechanical environment conducive toward the de novo synthesis and organization of ECM. For example, while nonwoven PGA scaffolds have been successfully employed in blood vessel [32] and heart valve TE [33], their application to myocardial tissue has been comparatively challenging [34]. In contrast to the predominant load-bearing functions of vessels and valves, the primary function of myocardial tissue is cyclic contraction. While the out-of-plane compressive modulus of a typical nonwoven PGA scaffold is relatively low ($\sim 6.7 \pm 0.5$ kPa [35]), the in-plane tensile and compressive moduli resisting cardiomyocyte-mediated contraction are comparable at $\sim 284 \pm 34$ kPa [36].

The mechanical properties of TE scaffolds are determined in part by the bulk properties of their constituent materials (e.g., modulus of elasticity, degradation rate). For example, most hydrogel materials exhibit much lower strength and stiffness as compared to hydrophobic polyester materials. As traditional PLGA-based scaffolds have a limited subset of mechanical properties, new biodegradable materials have been developed, such as poly(hydroxyalkanoates) and poly(glycerol sebacate) to improve scaffold's toughness and elasticity [37,38]. Because of the high porosity and concomitant low material content, the mechanical properties of TE scaffolds are very often primarily dictated by the structural arrangement of their constituent materials (e.g., pore size, fiber diameter and orientation; Table 19.1) and associated modes of structural degeneration (e.g., fiber fragmentation, bond disruption). For example, the effective stiffness (E) (equivalent to initial tensile modulus) of nonwoven PGA scaffolds was predictably modulated by tuning the fiber diameter via NaOH-mediated hydrolysis [36]. Inhomogeneity is another important characteristic of natural tissues, which contain microdomains of distinct morphology and mechanical property to define tissue mechanics and mechanotransduction. The scaffolds generated containing

TABLE 19.1 Dependence of a scaffold mechanical property (initial tensile modulus) on the bulk material mechanical property and scaffold structure.

Material	Initial tensile modulus (MPa)		
	Fibrous scaffold	Foam scaffold	Bulk material
PGA	0.284 ± 0.034 (nonwoven) [36]	0.919 ± 0.067[a] (salt leach) [189]	18,780 ± 3430 (fiber) [36]
PEUU	8 ± 2 (electrospun) [190]	~1.4[b] (TIPS[c]) [191]	60 ± 10 (film) [190]
PGS	N/A	0.004052 ± 0.0013 (salt leach) [192]	0.282 ± 0.0250 (film) [193]

Several order-of-magnitude differences in modulus can be realized by starting with different bulk materials and/or by converting the bulk material into different porous scaffold structures (e.g., foam or fibrous). For comparison, the initial tensile modulus of a typical passive muscle tissue was reported to be 0.012 ± 0.004 MPa [45]. *PEUU*, Poly(ester urethane) urea; *PGA*, poly(glycolic acid); *PGS*, poly(glycerol sebacate).

[c]*Thermally induced phase separation.*

fibers and proteoglycan-rich microdomains provided a paradigm showing the mechanics of a scaffold could also be designed with microstructure- and domain-dependent properties [39].

In addition to the initial structure imparted during the fabrication of the TE scaffold, the dynamic degeneration, modulation, and alteration of mechanical properties need to be studied. For example, while 50:50 blend PGA/PLLA scaffolds do not undergo significant mechanical degeneration over a period of 3 weeks [40], scaffolds dip-coated with the biologically derived thermoplastic poly(4-hydroxybutyrate) (P4HB) incur rapid loss of rigidity with cyclic flexural mechanical loading as the P4HB bonds between fibers are disrupted [41]. Depending on the kinetics of scaffold hydrolysis, structural degeneration may be more pronounced and thus represents a more important consideration in scaffold design.

With the evolving tissue-formation process, the effective mechanical properties of scaffold will be determined by the combined effects of the cells, ECM, scaffold, and their unique micromechanical interactions. The appropriate formulation and validation of a mathematical model to simulate and/or predict the mechanical properties of a scaffold is critical to monitor the scaffold system and understand the dynamics in the tissue scaffolds. While standard phenomenological models are useful in characterizing the gross mechanical behavior of a scaffold or an engineered tissue construct (i.e., for meeting organ and tissue-level functional requirements), recent formulated structural-based models have been developed to investigate the micromechanical environment presented at the cell level. Structural-based models can either be computationally driven, as in the work of Hollister et al. [4,42], or purely analytical [36,43] to bridge the gap between the disparate length scales of cells, tissues, and scaffolds. For example, contrary to traditional rule of mixtures theories [44], higher order reinforcement effects were observed via the structural-based modeling of commercial nonwoven PGA and PLLA scaffolds as a result of the deposition of ECM molecules. The scaffolds were effectively stiffened due to extensive fiber–fiber crossover points that also imparted changes in fiber geometry and micromechanical properties, highlighting the importance of an accurate micromechanical representation of the TE scaffold [36,43].

The effects and associated mechanisms of how mechanical properties of the scaffolds instruct the cell behavior have also been studied using hydrogel matrices. To understand the role of material elasticity on cell behavior, myoblasts were cultured on collagen strips attached to glass or polymer gels of varied elasticity [45]. Cells were found to differentiate into a striated, contractile phenotype only on substrates within a very narrow range of muscle-like stiffness (i.e., 8–11 kPa) (Fig. 19.3A) [45]. In another study, it was further demonstrated that the matrix stiffness regulates stem cell differentiation independently of protein tethering and porosity [46]. More recent studies reported that the stiffness of hydrogel matrices generate essential microenvironmental cues to regulate stem cell behaviors, including phenotype, self-renewal, and differentiation, suggesting mechanical property as an important factor in driving the scaffold function [47–49]. In addition to stiffness, the viscoelastic property of hydrogel matrices was investigated, and it was found that in gels of faster relaxation, cell spreading/proliferation, osteogenic differentiation in MSCs, and cartilage matrix formation by chondrocytes could all be enhanced (Fig. 19.3B) [50,51]. The mechanical sensing and mechanotransduction that may involve cellular traction force and the stress-stiffening-mediated mechanism [52] highlight how the reciprocal remodeling process between cells and matrices should be considered in the design of scaffolds.

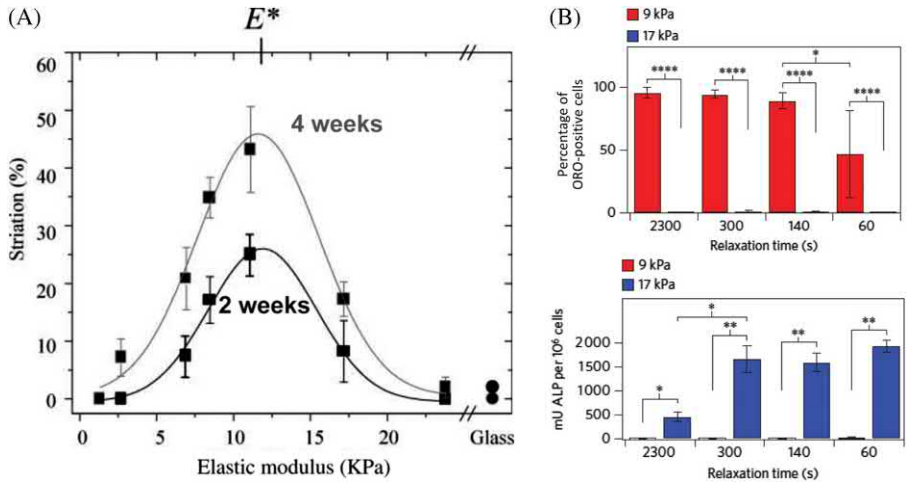

FIGURE 19.3 Cell differentiation exhibits sensitivity to local micromechanial properties of scaffolds. **A)** Substrate stiffness had a profound influence on myocyte differentiation, with optimal differentiation (as assessed by striation) occurring within a very narrow range of muscle-like stiffnesses (i.e. 8-11 kPa) (reproduced from *Engler, Griffin et al. 2004*, with permission by Rockefeller University Press). **B)** Quantification of the percentage of cells positive for oil red O (upper image) and a quantitative assay for alkaline phosphatase activity (lower image) showing MSCs increased osteogenic differentiation in gels with faster stress relaxation (reproduced from *Chaudhuri, Gu et al. 2016*, with permission by Nature Spring).

Because the foremost role of the scaffold following implantation is to temporarily fulfill the key mechanical functions of the replaced tissue, it is also essential to consider the physiological loading state of the native tissue and tissue remodeling of scaffolds from human recipient. While the physiological loading state may be highly complex, certain mechanical testing configurations are applicable. For example, the physiological loading state of a semilunar heart valve leaflet includes multiaxial flexural, tensile, and fluid shear stress components. In light of the strong planar anisotropy and tri-layered structures exhibited by native leaflet tissues, biaxial tensile testing [53] and flexural testing [54] have been employed to characterize their behavior. In another study of heart valve TE using PGA meshes, computational modeling based on mechanically induced tissue remodeling predicted leaflet compression and subsequent shortening as a result of physiological loading pressures [55]. More physiologically relevant geometry was designed to counteract the leaflet retraction, and the long-term functionality study demonstrated the potential of computational simulations to guide the design of TE constructs [56,57].

Electrical conductivity

Electrical conduction is an important mechanism that enables cellular signaling and function in many types of tissues. The cardiac electrical conduction system is essential to maintaining synchronous beats that pump blood in an ordered fashion. In the process of bone regeneration, naturally occurring piezoelectric properties of the apatite crystal are hypothesized to generate electric fields involved in bone remodeling. The nervous system possesses the well-known system of electrochemical signaling. Much research has been carried out using materials to record from and influence bioelectric fields. In making tissue scaffolds, electrically conductive biomaterials have been studied to understand their abilities to interface with bioelectrical fields in cells and tissues to replicate normal electrophysiology. Notably, most of these conductive scaffolds have been investigated for engineering and repair of cardiac and neural tissues.

A wide variety of electrically conductive polymers have been incorporated and developed into scaffolds, and they can be generally categorized into polymeric and carbon-based materials. Due to the ease of fabrication and the demonstrated biocompatibility, poly(pyrrole) (PPy), poly(aniline), and polythiophene derivatives are the most studied conductive polymers [58,59]. In contrast to static charge seen in conductive materials such as PPy, piezoelectric materials, including poly(vinylidene fluoride) and poly(tetrafluoroethylene), display transient charge in response to mechanical deformation [60]. There are also efforts to synthesize biodegradable conductive polymers, for example, through the incorporation of 3-substituted hydrolysable side groups [61], connecting degradable ester linkages with oligomers of pyrrole, aniline, and oligothiophene [58,62,63], and emulsion/precipitation of PPy in poly(D,L-lactide) [64]. In recent years, carbon-based nanomaterials, including carbon nanotubes and graphene, have emerged in biomedical studies due to their exceptional electrical conductivity [65]. While methods have been established to blend the carbons into traditional scaffolds or hydrogels, foams or fibrous scaffolds mainly based on carbon nanotube or graphene were also fabricated through methods such as vapor deposition and sacrificial template [66,67].

Electrical stimulation was found to promote cellular response and integration of cells dispersed in scaffolds. Neonatal cardiomyocytes cultured on collagen sponges

and matrigel show synchronized contraction in response to applied electric fields [68,69]. Electrical stimulation also promoted the maturation of stem cell–derived cardiomyocytes [70]. The beneficial effects of rendering the scaffold materials conductive were then often demonstrated in synergy with electrical stimulation in a variety of cells. In an early study, applied potentials were applied change surface properties of conductive polymers, resulting in altering the shape and function of bovine endothelial cells, including DNA synthesis and extension [71]. Later the electrical stimulation also promoted neurite outgrowth on the oxidized polypyrrole films [72]. More recently, human neural stem/progenitor cells were cultured in a 3D hydrogel construct containing nanocarbon tubes and PPy, and the incorporation of conductive materials and electrical stimulation upregulated the calcium channel expression and intracellular calcium influx in differentiated stem cells [73]. In another study the carbon-based 3D graphene foam promoted the differentiation of neural stem cells toward astrocytes and neurons and in the meantime showed good coupling with cells under electrical stimulation [67]. The carbon nanotube was also observed to act as electrical nanobridges between cardiomyocytes and promoted electrical coupling, synchronous beating, and cardiomyocyte function [74].

A number of conductive scaffolds have been investigated in vivo to evaluate their function to promote cardiac and neural tissue repair. For example, in the study on a PPy–chitosan hydrogel, the conductive material was found to improve the cardiac function following an myocardial infarction by accelerating transverse conduction velocities compared to nonconductive controls [75]. Besides the early polypyrrole-based neural prosthetics [76,77], conduits were recently fabricated containing single-layer or multilayer graphene, and the electrically conductive scaffolds exhibited the function to promote axonal regrowth and remyelination after the peripheral nerve injury [78].

Over the years, the mechanistic basis for each of these electrical–material–tissue interactions is still not fully understood and will continue to be an important area for future study. Some hypotheses can be found in the literature. This enhanced function of engineered cardiac tissues may be due to greater ultrastructural organization in response to electric fields [68]. Increased neurite outgrowth with electrical stimulation may be caused by better ECM protein adsorption [79] rather than direct effects on the cell itself although there is ample evidence of the latter. Electrophoretic redistribution of cell surface receptors likely governs the galvanotropic response of neurons to a horizontally oriented two-dimensional (2D) applied field [80]. Such mechanisms do not fully explain altered cell function in response to stimulation applied to the substrate or material relative to the medium or a distant ground. For such depolarization, signaling through voltage-gated calcium channels can activate ubiquitous second messengers such as cyclic adenosine monophosphate (cAMP) and alter gene transcription affecting learning, memory, survival, and growth [81]. Such secreted gene products might be used to enhance survival of host cells surrounding an implanted scaffold. Lately, in the study in which electrical preconditioning of human neural progenitor cells on PPy scaffolds enhanced the stroke recovery, it was shown that the electrical stimulation may have improved the functional outcome through regulating the angiogenesis-relevant vascular endothelial growth factor-A (VEGF-A) and hypoxia-inducible factor-1α (HIF-1α) pathways [82]. Given that applied electric fields can so profoundly affect the cell function, conductive 3D scaffolds will be important tools for harnessing this interaction to create functional tissues.

Surface properties

Cells interact with scaffolds primarily through the material surface, which is dominated by the surface chemical and topological features. The surface chemistry here refers to the insoluble chemical environment that the scaffold surface presents to cells, which can be directly from the biochemical compositions of the bulk, and/or the substances derived from surface adsorption or chemical reactions. Besides mediating cell behavior and functions inside scaffolds, controlled surface properties are of central importance in directing the inflammatory and immunological response. Controlled surface properties may be useful for ameliorating the foreign body reaction at the host–scaffold interface in vivo [83,84].

Surface chemistry

Each type of synthetic, natural, or composite scaffold gives rise to a set of distinct surface chemical characteristics governed by the material chemistry and its physical form (such as crystallinity, charge, and topology). Although numerous efforts have been made to tailor the scaffold surface, the chemical environment can exhibit extremely complicated patterns within the biological milieu. Complex processes such as the spontaneous adsorption of a diversity of proteins from biological fluids to the scaffold surface, and the protein surface conformation are difficult to analyze, which however exert profound effects on the scaffold performance. To tailor the scaffold chemical properties, the interactions of scaffolds with different environmental factors need to be considered.

Scaffolds derived from natural ECM materials such as collagen, fibrin, hyaluronic acid (HA), proteoglycans, or their composites have the advantage of directly containing

innate biological ligands that cells can recognize and provide natural mechanisms for tissue remodeling. ECM analogs have been created to emulate an appropriate tissue regeneration environment. For example, as an essential ECM component in natural cartilage tissue, collagen type II scaffolds may have better biochemical properties to maintain chondrocyte phenotype and enhance the biosynthesis of GAGs compared to collagen type I [85]. Fibrin, the native provisional matrix of blood clots, can provide ligands to initiate cell attachment and ECM remodeling [86]. HA plays a role in morphogenesis, inflammation, and wound repair, and the cell−ECM interactions mediated through receptors such as CD44 and the receptor for hyaluronan mediated motility (RHAMM) can be activated in scaffolds with HA constituents [86]. Recently, scaffolds directly derived from decellularized ECM have attracted great interests due to the possibility to preserve and recapitulate the native tissue components and functions. Decellularized ECM can be processed directly into various forms, including patches, scaffolds, powders as well as hydrogels, and has provided a versatile platform for TE applications [87−89]. The tissue regenerative functions of decellularized matrices are associated with mechanisms involving modulation of the immune response, release or exposure of growth factors and cryptic peptides, and recruitment of progenitor cells [88]. Recently, arrays of 2D and 3D tissue ECM substrates were fabricated and the tissue-specific cellular responses were studied [90]. The methodology may be useful for understanding the microenvironment and function of natural ECM-based materials.

Synthetic scaffolds offer a variety of mechanisms to modulate cell behavior. Chemical reactions with biological fluid remodel the scaffold surface and affect tissue growth through both reaction dynamics and kinetics. Studies have shown that bioactive glasses (Class A Bioglass composed of 45%−52% SiO_2, 20%−24% CaO, 20%−24% Na_2O, and 6% P_2O_5) have superior osteoproductive properties than either bioactive hydroxyapatite or bioinert metals and plastics. The difference was found to be due to the surface reaction kinetics in physiological fluid. The rapid reaction rate that converts amorphous silicate to polycrystalline hydroxyl-carbonate apatite on the bioglass surface is the key to positively regulating the cell cycle and bone formation [91]. Physical processes also play active roles in controlling the material−cell interface. Because of the adsorbed protein moieties from serum or body fluid, many polyester-based scaffolds, such as those made from poly(α-hydoxy esters), exhibit adequate adhesion to support cell attachment and tissue growth in some in vitro and in vivo applications. Methods that alter the surface hydrophobicity, for example, by changing monomer compositions or by chemical surface treatment, can potentially improve the scaffold performance [92−94]. For example, biodegradable foams of hydrophobic polymers (e.g., PLLA and PLGA) can be efficiently wet by two-step immersion in ethanol and water. This surface treatment could overcome the hindered entry of water into air-filled pores to facilitate cell seeding [92].

Surface modifications of scaffolds have been developed to generate surface chemical specificity and recognition. The surface chemistry can be created by either incorporating bioactive moieties directly in the scaffold bulk or modifying the surface. These moieties bound to scaffolds trigger desired specific intracellular signaling. In particular, many synthetic and natural hydrogel materials [e.g., poly(ethylene glycol) (PEG), poly(vinyl alcohol) (PVA), alginate, and dextran] are protein-repellent, and immobilizing biomolecules to such hydrogel scaffolds may be especially useful in tailoring the surface chemistry for cell−material interactions at the molecular level.

Cell adhesion mediated through extracellular adhesive proteins is involved in many intracellular signaling pathways that regulate most fundamental cell behaviors, including differentiation, proliferation, and migration. Enriching scaffold surfaces with specific ECM-derived adhesion proteins has been widely applied to scaffold modification. PLGA-based scaffolds have been coated with fibronectin by physical adsorption for supporting growth and differentiation of human embryonic stem cells in 3D [95]. Fibronectin was covalently attached to PVA hydrogels for improved cell adhesion, proliferation, and migration [96]. Fibrinogen was also denatured and fused into the backbone of a PEG hydrogel material [97] to elicit cellular responses. Elucidating the underlying molecular mechanisms on scaffold surface however is not a trivial task. Fundamental studies have been carried out to understand how the adsorption and denaturing of proteins can lead to different cellular responses at the material surface and may provide a molecular basis to control cell−material interaction and specificity for rational scaffold design [84].

Immobilizing peptide ligands derived from the active domains of ECM adhesion proteins to scaffolds is another major approach to generate specific surface-bound biological signals. For example, integrins, the principal adhesion receptor mediating cell−ECM attachment, comprise a family of more than 20 subtypes of heterodimeric transmembrane proteins. Each of them recognizes and interacts with certain types of ECM adhesion proteins to activate a cascade of signaling pathways to regulate essential cell activities and functions [98]. Integrins can be activated by short peptides in similar ways, for example, arginine-glycine-aspartate (RGD) from fibronectin and tyrosin−isoleucine−glycine−serine−arginine (YIGSR) from laminin. As these short peptides are relatively stable and economical to use, incorporating them into scaffolds

represents an important way to generate surface biomimicry and has been widely investigated for TE scaffolds [99–102]. Recent studies were also carried out to improve the specificity of RGD-based sequence to bind and activate integrin subtypes. Recombinant fragments derived from fibronectin were shown to enhance the osteogenic differentiation of MSCs through specifically engaging the $\alpha_5\beta_1$ integrin versus $\alpha_v\beta_3$ [103]. The importance to improve the molecular specificity was also demonstrated in the experiment comparing the ligands specifically binding to $\alpha_3/\alpha_5\beta_1$ and $\alpha_v\beta_3$, in which the $\alpha_3/\alpha_5\beta_1$-specific scaffolds showed the superior function to modulate the vascular patterning and support the formation of mature and nonleaky vasculature [104].

Like most biomolecules in natural ECM, the functions of immobilized bioactive ligands are influenced by their spatial characteristics in modulating membrane receptors and activating intracellular signaling. In modified fibrin gels, 3D neurite migration demonstrated a biphasic dependence on the RGD concentration, with the intermediate adhesion site densities (between 0.2 and 1.7 mol of peptide/mol of fibrinogen) yielding maximal neurite extension compared with the higher densities, which inhibited the neurite outgrowth [105]. In another study, integrin clustering, a prerequisite to many integrin-mediated signaling pathways, was recapitulated by the RGD nanoclusters immobilized on a comb-polymer substrate [106]. More studies through nanotechnologies identified the spacing requirement of RGD ligands at 70 nm on 2D surface to trigger cellular response [107,108]. In solutions the clustering of adhesive ligands was also investigated through dendrimer constructs for the purpose of promoting cellular response [109].

Surface topography

The material–cell interactions mediated through topographical features have traditionally been studied through planar substrates. Surface modification techniques, including photolithography, contact printing, and chemical treatments, have been developed to generate micro- and nanoscale surface topographical features. Surface topographical features such as ridges, steps, and grooves were found to guide cytoskeletal assembly and cell orientation. Compared to smooth surfaces, surfaces with textures such as nodes, pores, or random patterns are often associated with marked changes of cell morphology, cell activities, and the production of autocrine/paracrine regulatory factors [110,111]. In general, surface roughness increases cell adhesion, migration, and the production of ECM. Cells sense and respond to topographical features in a scale-dependent way [112]. As demonstrated on titanium surfaces, while microtextures increased osteoblast attachment and growth, only the presence of nanoscale roughness led to enhanced cell differentiation in connection with elevated growth-factor production [113].

Current fabrication techniques can be used to generate a wide variety of topographical features in scaffolds. Scaffolds can be randomly packed with regular or irregular geometries and shapes (e.g., particles, pellets, and fibers), or condensed with amorphous structures (e.g., foam and sponge), or fabricated with specifically designed architectures. Surface topography can also be generated and varied through coating nanoparticles of different shapes onto scaffolds [114]. Depending on the topographical feature size and the scaffold geometry, scaffolds provide a variety of topographical properties at different length scales. In 3D scaffolds, cells may dwell on or be surrounded by curved surfaces provided by fibers or walls of pores [110]. The topography may pertain to the gross contact area or subcellular interface between cell and scaffold, generating different cell responses that must be correlated with a specific scale and cell–scaffold interaction. The cellular responses can be investigated at multicellular, cellular, and molecular levels. In the studies on MSCs seeded onto polymeric fabrics containing microscale fibers, increased fiber diameter favored cell attachment and mature cell adhesion and promoted the MSC differentiation into osteoblast-like cells, with the optimal fiber diameter found at 9 μm [115]. Mechanistically, it was found that the fibrous topography triggered RhoA/ROCKII signaling in concert with Myosin IIa activation, which accounted for subsequent cell tension and osteogenic differentiation of osteoprogenitors grown on poly(methyl methacrylate) fibers [116]. In another study the electrospun fibrous scaffolds also enhanced the paracrine function of MSCs compared to the planar substrate and benefited skin tissue repair as a result of the upregulated expression of proangiogenesis and immunomodulatory factors [117].

The size scale of most natural ECM components, for example, fibrous elastin and collagen, falls into the range of several to tens of nanometers. The extracellular environment is dominated by nanoscale topographical features, such as nanopores, ridges, fibers, ligand clusters, and high surface area-to-volume ratios in 3D. Such native topographies can be recapitulated to a degree in scaffolds made of natural ECM polymers such as collagen and elastin. As synthetic materials have the advantage of greater control over scaffold properties, interest is growing in developing techniques to generate nanoscale topography. Surface treatment techniques such as sodium hydroxide etching have been used to generate nanoscale roughness to increase cell adhesion, growth, and ECM production [118]. 3D PLLA-based scaffolds containing nanofibers have been produced by thermally induced phase separation processes [119,120], and selective surface adsorption of adhesion proteins was observed. In a more versatile method, electrospinning techniques have been used to

fabricate a variety of synthetic and natural materials with different hydrophobicities into fibers with diameters ranging from a few to hundreds of nanometers [121]. Another important approach involves building scaffolds from the bottom up. Polypeptides made of 12−16 amino acids have been designed to form hydrogel scaffolds through β-sheet assembling [122]. Amphiphilic molecules consisting of a hydrophilic peptide head and a hydrophobic alkyl tail self-assemble into nanocylinders to form interwoven scaffolds [123,124].

Nanofibrous scaffolds have demonstrated abilities to support nanoscale-specific cell activities. For example, on TiO_2 nanotubes, human MSCs demonstrated adhesion or differentiation into osteoblast-like cells with the tube diameter at 30 or 70−100 nm, respectively [125]. When cardiomyocytes were cultured in meshes made of electrospun poly(ε-caprolactone) nanofibers, they expressed cardiac-specific markers and were contractile in 3D scaffolds [126]. In a scaffold based on self-assembled peptide amphiphilic molecules containing the laminin epitope isoleucine-lysine-valine-alanine-valine (IKVAV), neural progenitor cells selectively differentiated into neurons [123]. Some possible mechanisms associated with nanotopography in scaffolds may be related to cell receptor regulation (clustering, density, and ligand-binding affinity) on nanofibers, nutrient gradients in nanoporous matrices, mechanotransduction induced by the unique matrix mechanics, and the conformation of adhered proteins for cellular recognition sites. As it is likely that topographical cues are in close relationship with cell stiffness and adhesion, the mechanical properties of scaffolds should be considered as an important parameter in conjunction with topography to understand the combinatorial effects of scaffolds on triggering specific cell response.

Temporal control

Scaffold degradation

Unlike permanent or slowly degrading implants that may serve to augment or replace organ function (e.g., hip implants, artificial hearts, or craniofacial plates), TE scaffolds serve as temporary devices to facilitate tissue healing and regeneration process. The regeneration of a fully functional tissue ideally coincides in time with complete scaffold degradation and resorption. Controlling degradation mechanisms allows scaffolds to temporally cooperate with cell and tissue events via changes in scaffold properties and functions. Tuning the scaffold degradation rate to make it kinetically match with the evolving environment during tissue healing and regeneration is an important design criterion.

During scaffold degradation, some scaffold properties and functions may weaken or diminish with time. In general, there exist lower and upper limits on the optimal degradation rate that may vary with different cellular or tissue processes, scaffold chemical compositions, and scaffold functions. For example, scaffolds often need to serve mechanical functions, such as in bone implants to support compressive loading while maintaining an environment permissive to new bone formation. If a material degrades prior to transferring mechanical load to the new tissue, the therapy would fail [127]. Alternatively, materials in bone implants that degrade too slowly may cause stress shielding, thereby impeding the regeneration process and potentially endangering surrounding tissues [128]. In skin wound models, healing can be compromised when the scaffold degradation occurs too quickly, whereas scar tissue occurs when the degradation is too slow [19]. The optimal skin synthesis and prevention of scar formation could be achieved when the template was replaced by new tissue in a synchronous way, that is, the time constant for scaffold degradation (t_d) and the time constant for new tissue synthesis during wound healing (t_h) were approximately equal [19]. Matching tissue formation with material degradation thus requires coupling of specific temporal aspects of tissue-formation processes with chemical properties of the scaffold.

Scaffold degradation can occur through mechanisms that involve physical or chemical processes, and/or biolological processes that are mediated by biological agents such as enzymes in tissue remodeling. Degradation results in scaffold dismantling and material dissolution/resorption through the scaffold bulk and/or surface. In the passive degradation mode the degradation is often triggered by reactions that cleave the polymer backbone or cross-links within the polymer network. Many polyester scaffolds made of lactic acid and glycolic acid, for example, PLLA and PLGA, undergo bulk backbone degradation due to their wettability and water penetration through the surface. Hydrophilic scaffolds such as hydrogels made of natural or synthetic materials cross-linked by hydrolysable bonds (e.g., ester, carbonate, or hydrazone bonds) also convert to soluble degradation products predominantly through the bulk [129,130]. Chemical degradation can be conveniently varied through scaffold physical and chemical properties such as the backbone hydrophobicity, crystallinity, glass transition temperature, and cross-link density. Because of this flexibility, the degradation rate can principally be engineered for optimal tissue regeneration [127,131].

Scaffolds degrading through passive mechanisms exhibit limited capabilities to match with tissue growth and wound healing. In bulk degradation the accumulation of degradation products may exert adverse effects on tissue, for example, acidic products from PLGA degradation. It is also difficult to tailor the degradation to match the healing rate, which may vary with wound conditions

such as age of the patient, severity of the defect, and presence of other diseases. In order to exert more control over the degradation properties of a scaffold and to attempt to tailor the degradation of the scaffolds, consideration of pertinent wound healing and tissue regeneration mechanisms is required. For example, would healing is a highly complex, yet orchestrated cascade of events controlled by a vast array of cytokines and growth factors that generally involves three phases, including inflammation, granulation tissue formation, and remodeling of the ECM. Scaffolds should be designed to degrade in vivo during the formation of granulation tissue and/or during the remodeling process. Ideally these materials should withstand uncontrolled dissolution or degradation at physiologic conditions while being resorbed by natural cell−mediated processes. Many inorganic scaffolds for bone TE demonstrate biodegradable and bioresorbable characteristics to facilitate new tissue formation [132−134].

While scaffolds derived from naturally derived materials such as collagen and decellularized matrix are capable of incurring biological degradation, protease-mediated degradation mechanism can be designed in scaffolds so that the scaffolds are dismantled through cellular proteolytic activities [135,136]. In one of the early studies a PEG hydrogel modified with adhesion ligands was cross-linked with molecules containing matrix metalloproteinase (MMP) peptide substrates. Human primary fibroblasts inside the gel migrated inside the gel matrix via secreting MMP to break down the polymer chain. The protease-degradable materials allow cells to remodel the surrounding environment, providing an important biomimetic strategy to design scaffolds with controlled degradable mechanism. The MMP-sensitive hydrogels have been investigated for different tissue regeneration scenarios such as bone regeneration and cardiac differentiation by supporting 3D cell culture and cell invasion in vivo [137]. The MMP-sensitive substrates were also later introduced into a number of hydrogel-based scaffolds, including polysaccharides networks [138,139], self-assembling peptides [140,141], and the electrospinning fibrous structure [142]. The approach demonstrated how scaffold degradation can be engineered to synchronize with wound healing and new tissue synthesis via natural mechanisms. MMP-sensitive matrices have not only been tested in vivo applications but also used to discover degradation-associated cell−matrix interactions [143−145]. In particular, degradation was found to be a parameter separated from matrix mechanics and mediated the cellular traction in MSCs to drive osteogenesis, providing an important insight into how cell would sense and respond to microenvironment cues from TE scaffolds [144].

Delivery of soluble bioactive factors

The incorporation of delivery systems in 3D scaffolds offers an indispensable platform for enabling temporal and spatial control in tissue constructs. The release of bioactive factors can provide direct instructive and regenerative signals while limiting side effects at unwanted body locations [146]. Although numerous material-based controlled release systems are at the disposal of tissue engineers, most of them need to be adapted when applied to tissue scaffolds. The release of soluble factors from scaffolds can be mediated through single or multiple mechanisms, for example, by diffusion, dissolution, scaffold or carrier degradation, or external stimuli. In particular, delivery of growth factors has been studied for various tissues, due to their important roles in instructing cell behavior.

Built upon established particle-based delivery systems, one common method for controlling the release from a scaffold involves prefabricating biofactor-loaded particles and embedding them into a scaffold matrix [147,148]. The release of biofactors in these systems can be delayed with a minimized burst effect, compared to the systems made of particles alone. Typical particle carriers include PLGA and hydrogel microspheres. This method takes advantage of established systems but involves composite matrices that influence the release profile. Alternatively, soluble factors may be incorporated directly into the scaffold itself without a secondary carrier/matrix. This often requires the scaffold to be fabricated under mild physiological conditions to preserve the bioactivity of proteins or other biofactors. Growth factors and proteins have been incorporated in scaffolds through surface coating [149], emulsion-freezing drying [150], gas-foaming/particulate leaching [151,152], and nanofiber electrospinning [121,153]. Different delivery profiles of growth factors or DNA plasmids were achieved. Fibrous scaffolds obtained via electrospinning were investigated widely in recent years. The release function can be introduced into the synthetic and natural electrospun fibers via surface processing such as adsorption, immobilization of particles, and conjugation of biofactors. Coaxial electrospinning process can give core−shell structures, which allow encapsulation of biomolecules and deliver them with reduced burst effect and prolonged duration [154]. Due to their hydrophilic and biocompatible nature, hydrogel scaffolds are amenable to incorporating proteins and plasmid DNA, yielding both higher loading efficiencies and bioactivity compared to PLGA-based materials. Biofactors have been immobilized in hydrogel matrices via physical interactions and/or covalent chemical bonds for prolonging retention time and controlling release via designed mechanisms [155,156]. Heparin has in particular been used in hydrogels to bind to growth factors and sustain

their release and inspired the design of other types of affinity-based systems, which have also been developed [157].

Scaffolds that integrate controlled release methods have been used in conjunction with scaffolds for a variety of purposes, including enhancing tissue formation, stimulating angiogenesis, guiding cell differentiation, and facilitating wound healing [156,158]. Delivering growth factors from scaffolds has demonstrated advantages over using the free form directly [159]. Synergistic effects on accelerating tissue regeneration have been observed when scaffolds, cells, and growth factors are combined. For example, autologous bone marrow–derived cells transplanted with scaffolds containing bone morphogenetic protein-7 resulted in the greatest bone formation compared to constructs without either growth factor or cells [160].

A major challenge in delivering biofactors involves achieving meaningful pharmacokinetic delivery. The dosage, release kinetics, and duration time should be optimized and tailored to tissue growth/healing processes. For example, the uncontrolled release of BMP-2 may have led to unwanted outcome of Infuse, which is used clinically to promote bone repair. Scaffolds have been investigated toward releasing a low dose of BMP-2 [161]. Scaffolds capable of biomimetic delivering of biological factors also provide attractive strategies in TE. Many growth factors are tightly sequestered in the ECM as inactive precursors and get released through the interaction with cells via specific protease-mediated mechanisms. Based on affinity or protease-sensitive mechanisms, hydrogel matrices containing immobilized growth factors allowed for the release of growth factors through plasmin activity [162,163].

Sequential delivery adds a new layer of temporal control in scaffolds integrated with release functions and has been investigated for angiogenesis, cardiac tissue, bone engineering/regeneration, etc. [146]. In one study, to simulate the temporal pattern of VEGF and platelet-derived growth factor (PDGF) in angiogenesis, PLGA-based scaffolds have been developed to deliver these two angiogenic factors with distinctive kinetics for rapid formation of a mature vascular network [164]. In the study on knee meniscus repair, nanofibrous scaffolds were designed to first release collagenase to generate ECM porosity and then PDGF to attract angiogenic cells, showing a delivery paradigm of temporal and functional coordination [165].

Spatial control

The hierarchically ordered organization of cells and ECM in 2D and 3D spaces is a basic yet most important characteristic of tissue structure. The ordered structures at meso- and microscales give rise to specific geometry and function of tissue and organ and are prerequisites to provide signals to guide cell activities, including localization, alignment, and formation of conjunction to induce tissue morphogenesis in 3D space. Spatial control in 3D scaffold therefore not only pertains to generation of anatomically relevant structures but also involves manipulation of appropriate spatial cues at multicellular levels to enable ordered cellular arrangement and tissue formation.

Recapitulation of the spatial characteristics of a natural tissue in scaffolds is a process dependent on the choice of materials and fabrication techniques. The mechanical, physical, and chemical properties determine how the material should be processed, while different material modification and fabrication methods may configure the shape and microstructure at a certain length scale or have precision limitation. The use of conduit scaffolds has been investigated widely for promoting nerve tissue repair or replacing small-diameter blood vessel. For example, PLGA conduit devices facilitated and guided Schwann cell attachment for peripheral nerve regeneration [166] and multiple-channel, biodegradable scaffolds were fabricated to transplant Schwann cells and guide directional growth of axons for treating spinal cord injury [167] Similar studies illustrate how defined shape and void spaces in scaffolds can provide spatial guidance in vitro or at the defect site to define cell localization/distribution to promote tissue growth. However, many tissues contain complex anatomical and microarchitecture that would be hard to replicate through one fabrication process such as molding or templated synthesis. Recent investigations therefore have been focused on how to improve the processability/shape fidelity of materials and versatility/precision of fabrication methods, so that scaffolds can be generated to contain 3D microanatomical structures and support functions with physiological relevance.

In terms of spatial cues, anisotropic characteristics of pore architectures, mechanics, surface properties, degradation, and delivery can all potentially generate signals recapitulating haptotaxis and chemotaxis for guided tissue growth. The most studied approaches in particular involve topographical structures and chemical patterning to provide contact guidance. Planar materials/substrates have been developed containing aligned longitudinal regions such as ridges, grooves, wrinkles, and chemical heterogeneities to induce cell orientation and organized aggregation [110,168]. As to applications, cells with geometrical patterns obtained from 2D or "2.5D" topographical systems may be used directly for transplantation. For example, in the study of endothelial cell cords molded from microgooves, the strand-like microtissues could also define neovessel architecture *in vivo* and improve angiogenesis [169]. In another study, the human umbilical vein endothelial cells and human mesenchymal stem cells patterned on a polyester urethane urea were investigated as a

cardiac patch that outperformed the control patch without cellular patterns [170]. Nonetheless, given the numerous studies conducted on 2D systems, accelerating the translation of spatial guidance and geometric control of cells to 3D is of great importance.

To induce cell alignments in 3D, orientation of fibers was generated in scaffolds. Collagen and fibrin aligned using magnetic fields [171,172] increased the rate and depth of axonal elongation in vitro and improved sciatic nerve regeneration in vivo as compared to scaffolds with random fiber orientations [171]. In the electrospun scaffolds, two layers of orthogonally oriented nanofibers made of poly(3-caprolactone) was subcutaneously implanted. The cell alignment inside the scaffold was found to be maintained by the oriented fibers, exhibiting histological similarity to intestinal circular and longitudinal smooth muscle [173]. More complex 3D structures may be created through templated synthesis and was effective to orchestrate the assembly of multiple cell types. This was shown in the study in which hydrogel matrices were fabricated to contain interconnected microchannels lined with endothelium as well as the interstitial zone with matrix and other types of cells [174]. 3D structure and anisotropy can also be created through stacking of thin sheets/laminates [175–178]. In particular, the recent techniques allowed the tissues assembled on 2D to be constructed to further build anisotropic architectures to combine cells and tissue components. Direct printing of materials with cells opened another important avenue to generate tissues with heterogeneous architecture. Different 3D printing processes demonstrated well-defined cellular patterns with high resolution, but the effects of spatial guidance on tissue morphogenesis in the holistic construction remain to be understood [179,180].

Due to the wide application of hydrogel materials in TE, creating heterogeneous chemistry in hydrogel matrices is an important approach to achieve spatial control for tissue guidance. Patterned photoimmobilization of adhesive RGD ligands was first demonstrated in the agarose matrix [181]. The patterns of adhesive and nonadhesive regions induced oriented axonal elongation from dorsal root ganglion cell aggregates in vitro. By developing photocleavage and photocaging chemistry in hydrogels, temporospatial control was further achieved through lithographical techniques and allowed for the generation of topographical and biochemical patterning with high precision and resolution [182–184]. Studies have also been carried out to incorporate chemical gradients in scaffolds. Gradients of proteins play important roles in tissue formation/remodeling during embryogenesis and wound healing. Concentration gradients of peptides and proteins in hydrogels were generated for the study of cell and tissue guidance. For example, the entrapment of nerve growth factor in a poly(2-hydroxyethyl methacrylate) hydrogel induced directional axonal growth from PC12 cells in vitro [185]. The gradient of VEGF-165 guided the migration of endothelial cells into the porous collagen scaffolds while showed no influence on the cell proliferation [186]. In a modified electrospinning process through dual syringes with varied velocities, the gradient of adhesive RGD peptides facilitated the cell infiltration into the fibrous HA scaffold [187]. Recently, combinatorial hydrogels were fabricated with gradient peptides that mimic cell–cell or cell–matrix interactions and biochemical formulations were screened in a high-throughput way for optimal chondrogenesis conditions [188]. Hydrogels providing patterned and tailored physical/chemical microenvironment may find broad applications in understanding cell–matrix interactions to advance the scaffold design.

Conclusion

Major challenges in 3D scaffold design involve the systematic understanding of how fundamental scaffold properties are interrelated in affecting cell behavior, and how these properties can be rationally programed—spatially and temporally—to provide the necessary signals to aid tissue formation/regeneration. Advanced fabrication methods and 3D scaffolds became available in the past to control the microenvironment with precision and resolution to study cell and tissue responses. New mechanisms and functions of 3D scaffolds were discovered and delineated, laying foundations for designing the new generation of TE scaffolds.

Part Five

Transplantation of engineered cells and tissues

Chapter 20

Targeting the host immune response for tissue engineering and regenerative medicine applications

Jenna L. Dziki[1,2] and Stephen F Badylak[1,2,3]

[1]McGowan Institute for Regenerative Medicine, University of Pittsburgh, Pittsburgh, PA, United States, [2]Department of Surgery, University of Pittsburgh School of Medicine, Pittsburgh, PA, United States, [3]Department of Bioengineering, University of Pittsburgh, Pittsburgh, PA, United States

Introduction

The field of tissue engineering/regenerative medicine (TE/RM) evolved as an alternative to conventional methods for the functional replacement and repair of injured or missing tissues and organs. While the field is no longer in its infancy and significant progress has been made, the task of building new tissue is obviously nontrivial. In addition to providing or recruiting stem/progenitor cells, and providing for an adequate vascular supply, the role of the immune system in tissue development and maintenance and the host immune response to TE/RM interventions is now recognized as critical for clinical success.

The typical approach of avoiding the immune response to an implanted biomaterial and/or TE/RM construct through either immunosuppression or development of "inert" biomaterials has been marginally successful. Insights derived from developmental biology and immunology, among other fields, have clearly shown the critical role of the immune response in the reconstruction of functional tissue, and that the constructive and regulatory signals of the immune system should be harnessed and embraced rather than avoided and suppressed. The present chapter will review specialized immune cell function in the context of tissue repair, how such cell types accomplish these feats, and novel TE/RM strategies that are now positioned as immune-stimulatory therapies rather than immune-avoidant therapies through purposeful targeting of the immune response.

Immune cells and their roles in building tissues after injury

Early attempts to engineer new tissues typically involved implantation of biomaterials, cells, or biomaterial-cell composites that avoided what was then considered to be the primary barrier to success: a foreign body reaction (FBR) [1]. With any implanted foreign object a series of immune cell actions leads to distinctive host response. In brief, recognition of a foreign body consists of adsorption of proteins on the implant surface, acute inflammation followed by chronic inflammation at the implant site, macrophage infiltration and frustrated phagocytosis with the formation of multinucleate foreign body giant cells, and eventual fibrous connective tissue within and/or around the implant. As a result, there is a barrier to the restitution of functional, innervated, and vascularized site-specific tissue [2,3].

Characterization of each of the different immune cell types and their signaling mechanisms that mediate the above processes is prerequisite to the identification of pivotal moments at which the immune response can be modulated and therefore contribute to improved outcomes. However, the complexity of such immune cell activities is significant. Any immune response, let alone a response to biomaterials or cell-biomaterial constructs, inevitably involves coordinated networks of signaling molecules combined with specific spatiotemporal roles and both direct and indirect signaling mechanisms by each immune

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00021-6

cell type. An attempt to briefly summarize the known contributions to date of different immune cells to implanted materials and how they impact outcomes is described herein.

Neutrophils

Identified as the most rapid responders, neutrophils infiltrate the implant site and play a major role in phagocytosis of bacteria or cell debris. These cells dominate in number between minutes and days after implantation of the biomaterial or TE construct. Though much of the focus in the field to date has been upon other, less transient cell types, neutrophils play a clear role in the divergent immune responses commonly seen between synthetic versus biologic materials. For example, synthetic materials are associated with increased neutrophil recruitment compared to biologic materials, and this may be linked to disparate long-term outcomes [4]. Neutrophils themselves have been characterized as plastic cell types, with the ability to participate in both proinflammatory and antiinflammatory activities including generation of reactive oxygen species, in protease release, and the secretion of chemokines and cytokines that selectively recruit reparative macrophages allowing for matrix deposition and angiogenesis [5]. Recent work, however, has shown that selective depletion of neutrophils after synthetic versus biologic material implantation modulates myeloid cell phenotype and number. Neutrophil depletion did not have a significant impact upon the host response to biologic or synthetic materials, suggesting that neutrophil activity may be associated with, but not a causative player in FBRs to implanted constructs [4].

Eosinophils

The identified role of eosinophils in TE/RM outcomes has likewise been considered associative rather than causative in the FBR or tissue-integration outcomes. However, an emergent role for eosinophils in normal wound healing and in response to injury has prompted a more in-depth investigation into their role in biomaterial-mediated tissue remodeling. In muscle injury, for example, eosinophils are rapidly recruited to the injury site in large numbers. These cells secrete IL-4 during degranulation, which facilitates a regenerative response to acute muscle injury. Moreover, recent work using eosinophil-deficient mice has demonstrated that eosinophils are not only associated with but also are required for muscle regeneration as they are responsible for the majority of the IL-4 secreted at the muscle injury site [6]. Eosinophils also play a critical role in mediating cross-talk between other immune cells of both the innate and adaptive systems [7,8]. The emergent role of eosinophils in propagating the seemingly disparate processes of allergic reactions and maintenance of immune homeostasis makes them potentially attractive targets for immunotherapy and immunomodulatory biomaterials.

Macrophages

Macrophages have been the primary focus of TE/RM researchers due to their relative abundance in the early days following implantation of a biomaterial or cell construct. Findings of the past 20 years have dramatically changed the understanding of macrophage biology. Macrophages, such as T cells, can exist as either a proinflammatory, type 1 (M1), or antiinflammatory, type 2 (M2) cell based upon their differential metabolism of L-arginine [9], resulting in either nitric oxide (NO) generation or arginase generation, respectively. These metabolic profiles are associated with either proinflammatory or proremodeling effects. These two phenotypes play an essential role in normal wound healing [10], development [11], and tissue homeostasis [12]; physiological roles that implicate their potential as a target for RM therapies. Moreover, the ability of exogenously delivered stem/progenitor cells to exert beneficial in vivo effects may be due in part to their proclivity to promote immunomodulation that facilitates downstream constructive tissue remodeling [13–15]. In the context of implanted biomaterials an early macrophage transition from an M1-like phenotype to an M2-like phenotype has been shown to be predictive of host tissue integration at later time points [16]. Macrophages and their ability to contribute to a microenvironment that is either prohibitive or beneficial for tissue remodeling are now thought of as important determinants of TE outcomes, rather than merely antigen-presenting phagocytes.

Dendritic cells

Dendritic cells have not been considered as primary determinants of success or failure of a biomaterial in clinical applications. However, dendritic cells directly interact with implanted constructs and play a significant role in facilitating proregenerative cross-talk among other immune cells, namely between macrophages and cells of the adaptive immune system. For example, dendritic cells can respond directly to biomaterial-associated molecules such as extracellular matrix (ECM) components and the degradation products of degradable, synthetic scaffolds following macrophage-mediated degradation of such materials [17]. Since these materials degrade upon implantation, macrophages secrete effector molecules such as IL-6, IL-1B, TNFa, TGFB, and IL-10, which bind dendritic cell receptors and can drive differential responses. For example, it has been shown that

macrophage secretion of IL-6 can maintain a dendritic cell in an immature state via STAT3 activation [18]. In contrast, TGFB secretion from macrophages can promote dendritic cell signaling to T cells, promoting a regulatory T cell phenotype [19]. In other words, dendritic cells are a required mediator between the innate and adaptive arms of the immune response, both of which contribute to the clinical outcome when biomaterials are used. Direct modulation of dendritic cell responses is an emerging field in biomaterial and pharmacologic development.

T and B cells

Though the innate immune system is the first responder to any implanted material, the adaptive immune system has been shown to play a critical role in the determination of outcomes and in facilitating proregenerative cross-talk with cells of the innate immune system. Though historically T and B cells have been associated with tissue and organ graft acceptance or rejection, antibody formation, and immunologic memory, these cell types are now recognized to play a role in resolving inflammation and promoting wound healing. Th1 and Th2 type T cells have been shown to propagate M1- and M2-like macrophage phenotypes through the secretion of cytokine networks. T cells also play a role in activating other cells of the immune response, particularly eosinophils [20]. Particular biomaterials and their degradation products have specific effects upon T and B cells. For example, polymers with cationic properties have been shown to activate a Th1 type adaptive immune response [21]. Regulatory T cells (T_{regs}) have been shown to play a role in skin wound healing [22] and myocardial infarction [23] by promoting a tolerant immune cell microenvironment and activating proremodeling phenotypes in other effector T cells and macrophages. T and B cells can secrete cytokines that in some cases promote tissue remodeling and in others propagate fibrosis or tumorigenesis [24]. These disparate phenotypes highlight the importance in identifying the signaling molecules, including cytokines, and their associated mechanisms rather than categorizing immune response types simply as type 1 or type 2, since such cytokines can cause paradoxical effects in different microenvironments.

Specialized immune cell functions beyond host defense

Beyond their ubiquitous role in responding to a foreign body, such as a biomaterial or a tissue engineered construct, immune cells play specialized roles in nearly all body systems. For example, alternatively activated macrophages have been shown to contribute to thermogenesis in adipose tissue via IL-4 signaling [25]. Macrophages contribute to iron recycling and delivery to hepatocytes in the liver [26]. Brain resident macrophages, microglia, are required to maintain synaptic health and contribute to normal neuronal development [27]. Macrophages also regulate cardiac conduction in the AV node [28]. Immune cells, such as macrophages, eosinophils, and T cells, can create coordinated cytokine networks that are powerful determinants of tissue remodeling after injury. For example, prostaglandin E2 secretion into the stem cell niche is required for efficient myogenesis via myoblasts and satellite cells [29]. Cytokines that are categorized as alarmins, such as IL-33, play diverse roles in tissue homeostasis, disease progression, fibrosis resolution, and allergic reactions [30]. Many alarmins are considered double agents, as their signaling mechanisms can promote both proinflammatory and proremodeling effects dependent on their localization and the signaling pathways they activate [31].

Recent work has revealed that immune cell signaling both with other immune cells and with stem/progenitor cell populations goes beyond cytokine networks and proteolytic enzyme release and includes the release of a wide variety of extracellular vesicles (EV). Much of the research surrounding the release of EV focuses on stem-cell EV release. However, not only do stem-cell associated EV send potent signals to immune cells but also immune cells may release specialized EV of their own. EV are known to contain potent bioactive signaling molecules, including microRNA, proteins, lipids, and nucleic acids [32]. The role that EV plays in disease pathogenesis, tissue homeostasis, and potentially disease resolution is becoming more clear, and a better understanding of how EV interact with immune cells could provide new insights to tailoring TE and RM therapies. For example, tumor-associated macrophages have been shown to release the EV that are enriched with certain microRNA that potentiate breast cancer cell invasion [33]. Conversely, delivery of EV to macrophages can selectively prompt their release of proinflammatory or proremodeling cytokines [34]. In fact, the renewed interest in studying EV and their signaling mechanisms, particularly exosomes, stems from important findings showing exosome release from antigen-presenting cells, B-lymphocytes, in particular, which can induce MHC-class II specific responses [35]. These findings, among other recent findings, suggest that natural processes, such as the secretion of EV, that can be manipulated for promoting constructive and functional tissue remodeling outcomes.

Tissue engineering/regenerative medicine strategies as immunotherapy

The increasing complexity of immune cell function and interactions with other cell types has shifted the

perspective with which tissue engineers evaluate and analyze the immune response to their constructs. Instead of focusing on circumvention of an FBR through the development of "inert" biomaterials, a term that is arguably self-contradictory, TE strategies can now be considered as immunotherapies, specifically designed to manipulate immune cell function.

The FBR has been considered a limiting factor to implanted materials [36]. It is now well established that biologic materials derived from mammalian ECM, when properly prepared, can mitigate the FBR and promote improved tissue remodeling outcomes. In contrast, synthetic biomaterials are typically associated with a robust FBR [37]. Research over the past decade has uncovered clues as to why such divergent results occur. As previously mentioned, biomaterials derived from ECM promote a favorable macrophage response at early time points that is predictive of downstream constructive remodeling, but the specific component(s) responsible for these effects is unknown. The answer is slowly emerging through the understanding of how external factors, including material processing and patient-related factors, can affect the host response. For example, cross-linking ECM bioscaffolds negatively affects the macrophage response [38]. Though this less favorable response could be a direct result of the chemicals used for cross-linking, studies have shown that a lack of scaffold degradation and associated absence of release of bioactive degradation products may be the real culprit [39,40]. Other factors, such as source tissue [41], source animal age [42], and terminal sterilization [43], have also been shown to play a role in dictating both the macrophage response and downstream outcomes to ECM-based materials. External factors, such as incorporation of site-appropriate mechanical loading at the biomaterial implant site [44], can markedly change the macrophage and remodeling response. Taken together, tissue engineers can tailor the design and processing methods for superior outcomes as a first step to positioning biomaterials as immunotherapies. The choice of scaffold material utilized can also have profound effects upon the immune response.

One example of biomaterials designed to modify the immune response involves cytokine signaling to promote better host tissue integration. IL-4-coated polypropylene mesh materials can shift the early macrophage response following implantation toward an M2-like phenotype and diminish downstream fibrosis [45]. The use of polyethylene glycol hydrogels to deliver cytokines, such as TGF-B or IL-10, has been developed to modulate dendritic cell activation states [46]. Other groups have evaluated combinatorial approaches delivering more than one small molecule, cytokine, or pharmacologic agents to promote tissue remodeling processes such as angiogenesis [47]. Such approaches highlight the feasibility and proof-of-concept in modulating the immune response to promote better outcomes.

Future considerations for immune cell targeting tissue engineering/regenerative medicine therapies

Targeting immune cells and their associated signaling is an attractive and potentially powerful approach for the field of TE. There is now convincing evidence of the constructive cross-talk that exists between stem cells and the immune system. However, effective methods of utilizing this phenomenon to promote functional tissue formation have yet to be identified. However, as the understanding of how immune cells work in concert with tissue building efforts, and as the toolkit with which to identify, manipulate, and evaluate those roles expands, TE technologies are primed for clinical translation to treat a variety of disease states.

Chapter 21

Tissue engineering and transplantation in the fetus

Christopher D. Porada, Anthony Atala and Graça Almeida-Porada
Wake Forest Institute for Regenerative Medicine, Wake Forest University, Winston-Salem, NC, United States

Introduction

The first successful interventional procedure performed on a fetal patient took place in 1963, when Sir William Liley transfused red blood cells into the peritoneal cavity of a fetus suffering from erythroblastosis fetalis [1–3]. It was not until nearly 20 years later, in 1982, that Dr. Michael Harrison and his colleagues at the University of California, San Francisco (UCSF) performed the first successful in utero surgical procedure [4] to correct a patient with congenital hydronephrosis. It was this landmark achievement that ushered in a whole new era of prenatal medicine. Since that time, tremendous progress has been made in both open fetal surgery procedures and in fetoscopic intervention, due in large part to Dr. Harrison's remarkable drive and spotless integrity, which led him to establish an international fetal-treatment registry, in which he urged physicians to report all outcomes of any attempted fetal procedures, with the goal of establishing "the benefits and liabilities of fetal therapy as soon as possible" [5]. As a direct result of these efforts, physicians are now able to treat/correct a variety of anatomic anomalies that would previously have been fatal or sentenced the unborn child to a lifetime of disability [6,7].

To provide a few examples, a great deal of progress has made in the in utero surgical correction of lower urinary tract obstruction, which is a common congenital abnormality occurring in up to 1% all fetuses [8–16], surgical correction of congenital diaphragmatic hernia [3,16–23], surgical debulking of very dangerous and often prenatally fatal sacrococcygeal teratoma [3,16,18,23–28], both "open" and fetoscopic-based approaches to correct congenital cystic adenomatoid malformation and congenital pulmonary airway malformations [24,29–32], and even efforts to surgically correct neural tube defects such as myelomeningocele (MMC/spina bifida aperta) [33–40]. Looking specifically at MMC, recent exciting results in animal models have highlighted the potential of novel tissue engineering-based approaches using injectable scaffolds, either alone or seeded with stem cells to create so-called stem-cell patches [41–46]. These new noninvasive approaches to treating MMC are particularly appealing, because they could achieve the watertight tissue closure that is needed to prevent damage to the spinal cord much earlier in gestation than the current open surgery-based methods can be performed. As such, the potential benefit to the patient is greatly enhanced [16].

Despite the remarkable differences, such advances have made for these patients and their families, it is important to note that, even when using approaches such as fetoscopy that are considered to be relatively noninvasive, these surgery-based methods still carry a high risk of premature rupture of membranes (PROM)/preterm prelabor rupture of membranes (PPROM), with resultant preterm birth and fetal demise [16,18,23]. A joint endeavor undertaken by investigators at UCSF, UC Berkeley, and Caltech recently led to the development of a highly promising biocompatible adhesive called Amnioseal, which is injected prior to performing fetal surgical procedures to preseal the amniotic membranes and thereby prevent PROM/PPROM [47], which would be a true game-changer in the field of fetal surgery.

Importantly, however, even if this new biomaterial proves completely effective at preventing PROM/PPROM, fetal treatments that are based on surgical intervention will still be intrinsically limited to the treatment of disorders involving/caused by structural abnormalities [16,23,48,49]. In contrast, in utero transplantation (IUTx) and in utero gene therapy (IUGT) offer the possibility of

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00022-8

treating, and ideally curing, a wide range of genetic disorders. With the advent of high-resolution ultrasonography and exquisitely sensitive, high-throughput molecular techniques, the vast majority of congenital conditions can now be diagnosed early in gestation using fetal cells or even trace amounts of cell-free fetal DNA that are present in the maternal blood [50]. As such, diagnoses can now be made with vanishingly small risks to the fetus and the mother.

Of note, these remarkable advances in prenatal imaging, molecular diagnostics, and fetal surgical techniques have not only improved the ability to identify diseases early in development, they have also made it possible to safely deliver stem cells and/or gene therapy vectors to precise anatomic sites within the early-gestation fetus. Preemptive treatment of the fetus by IUTx or IUGT would completely transform the paradigm for treating genetic disorders [6], allowing physicians to intervene prior to clinical manifestations of disease, an approach that could promise the birth of a healthy infant who required no further treatment. In addition to the obvious psychological benefits of curing a disease in utero, the elimination of the need for lifelong, noncurative treatment would have a profound impact on the quality of life (QoL) of the patient, and his/her family, as well as dramatically reducing the cost burden for society. It is critical to note that there are also several biological advantages unique to fetal development, which provide compelling reasons to believe that stem-cell transplantation and/or gene therapy would be far more efficient and effective if administered during fetal life rather than postnatally.

In this chapter, we present the therapeutic rationale for the use of IUTx and IUGT, and we review key experimental evidence to support their use. We discuss some of the unforeseen biological barriers that have thus far precluded more widespread clinical application/success of IUTx, and we provide an overview of IUGT, illustrating some of the unique advantages it offers as a treatment modality, as well as some of the potential risks to be addressed prior to clinical implementation. We showcase the hemophilias as a prime example of a genetic disease that could be corrected via IUTx and/or IUGT, and we finish the chapter by highlighting several recent breakthroughs that promise to move these exciting therapeutic approaches into the clinic in the near future.

Rationale for in utero therapies

Long before scientists even considered performing in utero treatments, a naturally occurring phenomenon established critical proof-of-concept for the potential of IUTx by providing irrefutable evidence that introducing foreign cells early during fetal development could lead to lifelong engraftment and induce durable immune tolerance to the cellular donor. This remarkable discovery was made in 1945 by Owen [51], who perceptively observed that the shared placental circulation present in monochorionic dizygotic cattle enabled intrauterine exchange of circulating hematopoietic stem cells (HSC) and that this produced life-long hematopoietic chimerism, which resulted in donor-specific tolerance to the sibling twin [51–53]. This extraordinary finding in cattle was of tremendous interest from a biological standpoint. However, it was the subsequent observation that natural chimerism also occurs in both nonhuman primate (NHP) and human twins [54–59] and that this chimerism, just as Owen observed in cattle, led to a lack of alloreactivity between the two siblings [54,59], which established the clinical relevance of this intriguing natural phenomenon. Even more striking was the finding that, in the case of dizygotic human twins, the levels of chimerism that have been observed have often been high enough that they would be predicted to exert a therapeutic effect in most hematologic diseases [60]. Collectively, these exciting findings in nature have long provided the scientific basis for the promised therapeutic potential of IUTx, and for its ability to induce donor-specific immune tolerance and have fueled efforts to bring this therapy to clinical fruition.

While these "experiments of nature" provided proof-of-concept for IUTx, why would such an approach be clinically useful or offer benefits over existing postnatal approaches to therapy? To answer these questions, we must first consider the fact that many genetic diseases exert a significant amount of irreversible damage during embryonic and fetal development. For example, substantial neuronal damage is associated with inherited metabolic diseases such as Gaucher's, Lesch–Nyhan, and Tay Sachs. In these patients, even state-of-the-art treatment given postnatally only mediates a limited therapeutic benefit, since it cannot reverse the damage that the disease has exerted during development. By far, the most compelling rationale for IUTx (and IUGT, as we discuss later) is the ability to treat these diseases early enough in development to prevent disease onset and thereby evade the devastating manifestations that would otherwise occur before birth. It is important to note that, even in patients with diseases that can be treated postnatally, compelling psychological and financial benefits exist to correct such diseases in utero, since prenatal intervention would allow the birth of a healthy infant, who, ideally, would require no further treatments.

There are also several indisputable physiological/biological reasons to believe that treating in utero would be easier and produce a more pronounced effect than waiting until after birth to intervene. It has long been appreciated that normal developmental events that occur within the nascent hematopoietic/immune system create several unique opportunities that may facilitate the engraftment

of foreign cells and eliminate the need for the myeloablative conditioning required with postnatal hematopoietic transplantation, thereby avoiding the complications and significant risks inherent to this toxic procedure [61–64] (reviewed in [60]). We will, therefore, begin our dialogue about in utero therapies by providing a brief history of the origins of IUTx, highlighting some of the key experimental advances that have been made in recent years, and summarizing the clinical IUTx studies that have been performed.

In utero transplantation

Although several cell types have been considered and explored in the context of IUTx, this chapter will focus predominantly on HSC, which represent the prototype stem cell within the body. HSC are multipotent stem cells that undergo self-renewal and multilineage differentiation to generate all of the mature hematopoietic lineages and thereby maintain functional hematopoiesis throughout fetal and adult life [65,66]. As such, they are well suited for treating a broad range of hematopoietic disorders, and the successful transplantation of HSC can result in lifelong disease correction. Since their discovery, HSC have been the focus of intensive research and have proven clinically invaluable to restore hematopoiesis following inadvertent radiation exposure and following radio/chemotherapy to eliminate hematologic tumors. HSC are the most extensively characterized stem cells in the body, and much of what we know about the biology and behavior of stem cells in general is based upon the paradigm established with studies on HSC. In light of their remarkable properties, it is not surprising that HSC were the first cell type tested in IUTx, and they are the cells that have been used in the vast majority of both experimental and clinical IUTx studies to-date.

Postnatal HSC transplantation is a lifesaving procedure that can cure numerous malignant and benign hematologic disorders. Unfortunately, however, its execution is not without problems and significant risks to the patient, as a suitable, immunologically compatible donor must be found (which is often not possible), and the pretransplant conditioning regimen and the posttransplant period of leukopenia, during which the patient is severely immunocompromised, often result is serious morbidities that can prove fatal, even in the hands of an experienced transplant team. The developing fetus provides a unique opportunity to overcome these issues, due to the large-scale migration of stem cells that occurs to seed tissue compartments during ontogeny. Definitive hematopoiesis commences in the yolk sac and/or aorta–gonad–mesonephros region, migrates to the fetal liver, and finally shifts to the bone marrow (BM), where it then resides for the remainder of life [67–69]. Much of the initial rationale for attempting HSC transplantation in utero was based on the hope that it might be possible to "piggyback" on these naturally occurring migrations and exploit the nascent hematopoietic niches arising during development to achieve efficient engraftment, differentiation, and expansion of donor HSC without the need for myeloablation. If this supposition proved correct, IUTx would enable donor reconstitution of the defective hematopoietic compartment and correction of the disease while eliminating one of the primary causes of the marked morbidity and mortality associated with postnatal HSC transplantation.

Unfortunately, experiments over the last 20 years have made it clear that this expectation was naively optimistic. Once it became apparent that the endogenous circulating fetal HSC are present in relatively large numbers and that they possess higher proliferative and repopulating capacity than their adult (donor) counterparts [70–72], scientists came to appreciate that the fetal hematopoietic system is, in fact, highly competitive, and therefore poses a formidable obstacle to engraftment of transplanted adult HSC. However, it was still hoped that, with better understanding, it might one day be possible to manipulate the regulatory signals controlling the migrations of HSC and their seeding of nascent marrow niches to tip the scale in favor of the donor cells [73].

Looking beyond the unique biological characteristics of the fetal recipient, the very small size of the fetus also offers a distinct logistical/technical advantage compared to an adult or even a pediatric patient in the context of an HSC transplantation. IUTx would ideally take place at about 12 weeks of gestation, at which point the human fetus weighs roughly 35 g [6,7,50,60,74,75]. By virtue of its extremely small size/mass, a much larger cell dose can be transplanted on a per kilogram basis than could ever be achieved after birth. Another major advantage of the fetal environment is the isolation of the fetus within the sterile environment that exists within the uterus. This is particularly important if one considers treating an immunodeficiency, since performing the transplant in utero would enable the maternal womb to serve as a sterile isolette, sheltering the fetus from pathogens while its immune system is reconstituted from the transplanted HSC [6].

As discussed in the preceding section, Owen's experiments of nature highlighted another aspect of fetal biology that provides what is perhaps the most compelling reason to perform transplantation or gene therapy in utero: the ability to induce immune tolerance to the cell donor or the vector-encoded transgene product(s) [61]. Early in gestation, the nascent immune system undergoes a course of self-education that occurs primarily in the fetal thymus. This process consists of both a positive selection of prelymphocytes that recognize "self"-major histocompatibility complex (MHC) and the deletion of any prelymphocytes that recognize, with high-affinity, any of the innumerable

fetal self-antigens in association with self-MHC [76,77]. Ideally, this process creates an immune system that is devoid of self-reactive lymphocytes and yet retains the diversity required to recognize any foreign antigens in association with self-MHC [60,77]. It stands to reason that, if allogeneic cells were introduced during this time via IUTx, donor antigens should be presented in the thymus along with the host's own self-antigens as part of this naturally occurring education process, leading to the deletion of any alloreactive T-cells, and thereby creating donor-specific immune tolerance. The induction of tolerance following IUTx is important for two reasons. First, the presence of tolerance should facilitate the maintenance of the donor hematopoietic cells. Perhaps even more importantly, a growing body of data supports the exciting possibility that, even if the levels of donor cell engraftment following IUTx are not sufficient to be curative/therapeutic, the antigen-specific tolerance induced by IUTx may enable the administration of postnatal "booster" transplants of same-donor HSC to achieve therapeutic levels of engraftment without the need for toxic myeloablation. It has also been suggested that this state of immune tolerance to the HSC donor might even make it possible to later perform transplants of same-donor solid organs (should it prove necessary) without fear of rejection [78–83].

Early murine experiments with in utero transplantation

Billingham et al. [61] performed groundbreaking studies in mice in the 1950s that provided the first experimental evidence that IUTx of allogeneic cells induced donor-specific tolerance that was robust enough to enable successful postnatal skin grafting. After this pivotal demonstration, work over the next two decades was largely focused on naturally occurring chimeras and better defining the potential for in utero chimerism to produce immune tolerance, and the fledgling field of IUTx would have to wait until the end of the 1970s before Fleischman and Mintz would publish the first report of successful hematopoietic chimerism following IUTx, and provide the first exciting experimental proof that IUTx could reverse a genetic disorder. To accomplish this remarkable achievement, Fleischman and Mintz used a line of mice with genetic anemia caused by c-Kit deficiency to make three important observations: (1) transplanting adult allogeneic BM stem cells into the placenta of these mice at E11 reversed the genetic anemia; (2) the degree of erythroid replacement correlated with the degree of underlying anemia; and (3) erythroid reconstitution could remarkably be achieved in this model following the transplantation of just a single HSC [84,85]. It was these early studies asking questions about basic stem-cell biology that identified host cell competition as a barrier to donor cell engraftment after IUTx. As we will discuss in detail shortly, this unexpected phenomenon was to prove critical to the clinical implementation of IUTx.

Almost another two decades would pass before Blazar's team [86] would confirm the ability of IUTx to achieve multilineage chimerism in stem cell–deficient recipients. However, in contrast to the erythroid-specific defect studied by Fleischman and Mitz, Blazar's group demonstrated that when mice with a T-cell proliferation and survival defect due to severe combined immunodeficiency (SCID) were treated by IUTx, the engraftment of the transplanted donor cells was restricted to the lymphoid lineage, a phenomenon termed "split chimerism" [87,88]. These studies thus provided the first evidence that host cell competition could limit donor cell engraftment following IUTx, and further solidified the concept that, when a lineage-specific deficiency is present, IUTx can yield nearly complete reconstitution of the defective lineage yet contribute only negligibly to the other hematopoietic lineages. These findings thus hinted that achieving clinically meaningful levels of donor cell engraftment after IUTx in recipients with a competitive hematopoietic compartment was likely going to be far more difficult that had been assumed. This notion was strengthened by subsequent studies showing that IUTx in immunocompetent, wild-type mice often led to very low engraftment rates, while studies in immunodeficient recipients uniformly yielded far more encouraging results [84,86,87,89].

In utero transplantation experiments in large preclinical animal models

Since these initial trailblazing murine studies were performed over three decades ago, a great deal of progress has been made in the field, not only in mice, but in larger preclinical/ translational animal models as well. Sheep was the first large animal model in which successful engraftment of allogeneic cells was demonstrated following IUTx [90]. Of the available animal models, sheep have been a particularly valuable preclinical tool for the study of IUTx. Fetal sheep provide a natural, unperturbed environment in which to study IUTx. Moreover, since even xenogeneic cells are not rejected if IUTx is performed early enough in gestation, it is possible to study the engraftment and differentiation capacity of a variety of human stem cells in this system [91–100]. Sheep share many important physiological and developmental characteristics with humans. As a result, they have been used extensively in the study of mammalian fetal physiology, and the results obtained with this model have been directly applicable to the understanding of human fetal growth and development [101].

Like humans, sheep typically give birth to only one or two offspring in each pregnancy. This is in marked contrast to dogs, cats, pigs, and many other large animals that have large litters of offspring. A major complication that arises with translating approaches that prove successful in mice and even more modestly sized animal models to humans is the issue of accurate scale-up of cell/vector dosage per kg body weight. A typical human patient is roughly 2500 times larger than a mouse [102], making linear scale-up of dosage based on body-weight challenging, if not impossible. Importantly, sheep are similar in size/weight to humans, both at birth (7−9 lb) and as adults (150−200 lb), making it possible to develop and test clinically relevant doses of cells/gene therapy vectors directly in this model prior to translating to the clinic. In addition, the development of the ovine hematopoietic and immune systems during fetal ontogeny has been delineated in great detail, and it has proven to be quite similar to that of humans [103−109], making this model ideal for investigating the immune facets of IUTx (and IUGT). The long lifespan of sheep (>10 years in captivity) allows the important issues of long-term efficacy and safety to be addressed with far greater rigor than could ever be accomplished in short-lived animals such as mice.

The fetal sheep model has also played a critical role in defining the phenotype of long-term engrafting human HSC, enabling the identification of several novel human stem-cell markers/phenotypes (e.g., CD34 + CD38 −, HLA-DR −, Thy-1 +, CD133, KDR, and CD34 −) [110−119], many of which are now in clinical use, attesting to the high translational value of data obtained with this preclinical model. This system has also proven invaluable for defining the role the various hematopoietic niches within the recipient marrow play in the engraftment of HSC following IUTx [101,120−122], and it has proven itself as a preclinical model for studying the process of HSC mobilization, since engrafted human hematopoietic cells respond to mobilizing human cytokines in a manner that is similar to their native counterparts [100,123−126]. These collective data provide strong support for the value of the fetal sheep model for developing/testing IUTx/IUGT approaches and obtaining results of high clinical relevance [75,127,128].

Like sheep, dogs are also receptive to fetal transplants of xenogeneic cells, and low-level multilineage hematopoietic engraftment has been achieved following IUTx in hematologically normal dogs [80]. Flake's group used the canine model to provide compelling evidence of the therapeutic potential of IUTx by showing that the levels of hematopoietic engraftment following IUTx are sufficient to (1) correct the clinical phenotype of the canine analog of human leukocyte adhesion deficiency; and (2) induce donor-specific tolerance (in some animals) that permitted postnatal "boosting" of chimerism using a mild conditioning regimen, followed by transplantation of same donor T cell−depleted marrow [64,80,129,130]. In addition to studies in mice, sheep, and dogs, IUTx has also been successfully performed in goats [131,132], pigs [80], and NHPs, although the levels of engraftment achieved in the NHP model were relatively low [132−138]. Subsequent studies in the porcine model provided compelling evidence that inducing immune tolerance in the fetus is highly beneficial for postnatal solid organ transplantation, as IUTx of adult BM−derived HSC in fetal pigs prolonged the survival of a kidney allograft [139]. These studies thus provide important experimental support for the possibility of using this strategy in fetuses with congenital abnormalities that require postnatal organ transplantation.

Despite the undeniable advantages of performing translational research in large animal models that more closely mimic human patients, there are important questions that are just not feasible to attempt to answer in large outbred animals. Due to the ease and exquisite precision with which they can be genetically manipulated, murine models have been used to interrogate various aspects of the immune system to gain an understanding of the mechanism(s) of tolerance induction following IUTx. Data from Flake, MacKenzie, Peranteau, Shaaban, Nijagal, et al. published over the last decade have collectively provided compelling evidence that clonal deletion, anergy, and induction of donor-specific Tregs all appear to play critical roles in the establishment of chimerism and the induction of immune tolerance [79,81,83,140−145]. Interestingly, these studies in mice have demonstrated that stable engraftment of even low levels of allogeneic HSC (1%−2% engraftment) can lead to postnatal tolerance across full MHC barriers, and have revealed that tolerance induction depends upon achieving a threshold level of engraftment and on maintaining chimerism in the host [146]. Elegant recent work from Shaaban et al. has indicated that Natural Killer (NK) cell tolerance appears to play a key part in establishing this engraftment threshold [147−150].

While similar mechanistic studies are clearly needed in preclinical large animal models, as the human immune system may well present its own set of unique challenges, these collective results demonstrate the technical feasibility of IUTx, confirm its ability to induce donor-specific immune tolerance, and shed light on some of the requisite pathways to tolerance induction, establishing an essential foundation for ultimate clinical application of IUTx.

Barriers to in utero transplantation success

An improving understanding of the ontogeny of the fetal immune system combined with the evidence provided by the preceding studies led to the seemingly sound premise

that a so-called "window of opportunity" [62] should exist, prior to the appearance of mature T-cells in the fetal thymus and circulation (~12–14 weeks of gestation in the human fetus) [77], during which the fetus should be "preimmune" and receptive to allogeneic (or even xenogeneic) cells/tissues. However, as the interest in IUTx grew, experimental evidence began accumulating that made it clear that significant barriers existed that prevented successful engraftment after IUTx if the recipient did not possess a lineage-specific defect, such anemia or SCID, that bestowed a competitive advantage to the donor cells [62,143,151–154]. In 2007 Peranteau et al. [155] performed critical studies that toppled the long-standing belief that the fetus is truly "preimmune." In this report, it was shown that when cells from congenic donors were used for IUTx, mice could more consistently be engrafted, and at higher levels, compared to when IUTx was performed with phenotypically identical cells from allogeneic donors. Moreover, when allogeneic cells were used, only ~30% of the recipients consistently exhibited chimerism. These surprising findings thus suggested that the fetal immune system represents one of the major barriers that limit HSC engraftment following IUTx. The authors went on to perform elegant tracking studies that demonstrated that although 100% of allogeneic and congenic recipients maintained high levels of engraftment up to 3 weeks after IUTx, between 3 and 5 weeks post-IUTx, 70% of allogeneic animals lost their engraftment, while 100% of congenic animals remained chimeric [155].

The authors then demonstrated that both cellular and humoral adaptive alloresponses were present in nonchimeric animals, which led to the conclusion that the host (fetal) immune response was responsible for limiting donor cell engraftment. This report was troubling, as it was in seeming contradiction with a wealth of prior data, from multiple groups, including these authors, which had demonstrated that IUTx, in both mice and other animal models, led to successful long-term chimerism in a percentage of recipients and often led to deletional tolerance to donor antigens. A possible explanation for these differing findings came from the intriguing observation that if pups that received IUTx were placed with surrogate mothers that had not been exposed to donor alloantigens, all recipients maintained their chimerism [140,156]. These findings thus provided evidence that an immune barrier to IUTx existed not only as a result of the nascent fetal immune system but also that of the mother and suggested that IUTx may have the potential to trigger maternal alloimmunization. The authors went on to theorize that this maternal alloimmunization led to the subsequent transfer of allo-antibodies (Abs) to the pup via breast milk, which induced an adaptive alloresponse in the pup with a subsequent loss of chimerism. Perhaps most importantly, this study confirmed that in the absence of a maternal immune response, either via foster nursing or through the use of maternal donor cells, engraftment and tolerance were uniformly present via a mechanism of partial deletion of donor-reactive T-cells and the induction of a potent T-regulatory cell response.

An independent series of murine IUTx studies, performed at around this same time by Nijagal, MacKenzie, et al., corroborated the finding of maternal alloimmunization as a result of the fetal intervention but found that subsequent maternal–fetal T-cell trafficking was the main factor responsible for the loss of chimerism [141,142,157–159]. Obviously, placentation, maternal–fetal trafficking of Abs and cells, and the time course of events after IUTx are considerably different in mice when compared to large animal models or during human pregnancy. Nonetheless, these findings raise the important question of whether maternal immunization is an issue in large animal models and clinical circumstances, and whether it is a limitation to hematopoietic engraftment following IUTx. Until this question is addressed, these findings have led to the informal consensus in the field that it may be prudent to use maternal cells in any clinical application of IUTx to remove the possibility of triggering a maternal immune response.

While the data from these studies are certainly compelling, and the methods used were unassailable, Shaaban et al. astutely noted that the maternal immune system has been intact in all human patients who have thus far undergone IUTx for a variety of diseases, despite the nature of the clinical outcome (success or failure); data which they feel supports the conclusion that the maternal immune response cannot be a key determinant in IUTx-related engraftment failure [147,148]. In an effort to resolve/explain this incongruity between mouse data and clinical outcomes, this group has spent many years investigating the ontogeny of the fetal immune system to define the immune cells and pathways present at the time of IUTx that could serve as a barrier to engraftment of allogeneic cells. These authors have identified a subset of early NK cells within the fetal liver that express adult levels of alloreactive receptors, suggesting that NK cells may pose a barrier to engraftment of transplanted cells as early as the end of the first trimester in humans. Indeed, depleting NK cells from the fetus, but not from the mother, enabled reliable engraftment of allogeneic cells following IUTx [147,148,150]. Interestingly, the levels of early chimerism required to induce NK cell tolerance (1%–2%) agree exactly with the threshold levels discussed earlier, likely due to a mechanistic link that exists between the induction of prenatal NK cell tolerance and the process of trogocytosis [149]. While these important findings will have to be reproduced in large animal models of IUTx, these elegant and highly mechanistic studies collectively provide a very persuasive argument for the importance of fetal NK cells in the ability to achieve engraftment of

allogeneic cells following IUTx, just as has been seen in postnatal HSC transplantation [160].

To further complicate the already perplexing issue of the role of the fetal and maternal immune systems in acceptance of hematopoietic allografts following IUTx, recent work from the Peranteau lab has now added to the compelling evidence for the importance of the maternal immune system in the ultimate fate of hematopoietic cells following IUTx. In these studies, the authors showed that the presence of preexisting maternal Abs to antigens present on the transplanted cells leads to very rapid (within 4 hours) prenatal rejection of allotransplants following IUTx in a murine model system [161].

In addition to the fetal and/or maternal immune response, perhaps the most important perceived barrier to engraftment of allogeneic HSC is host cell competition. In the setting of postnatal HSC transplantation, the recipient receives myeloablative conditioning prior to donor cell infusion, to suppress endogenous hematopoiesis and, perhaps, free spaces within the hematopoietic niches of the BM. In marked contrast, following IUTx, the donor cells must compete against the robust fetal hematopoietic compartment. The idea that donor (adult) cells may have a competitive disadvantage in the fetal environment is supported by the ease with which high levels of donor hematopoiesis can be achieved in c-Kit-deficient mice, in which as few as one or two normal HSC can fully reconstitute the hematopoietic compartment after IUTx [84]. Studies of IUTx performed in SCID mice also illustrate the importance of host cell competition [87,162]. In this model, in which donor lymphoid cells have a survival and proliferative advantage, IUTx results in complete reconstitution of the lymphoid compartment with minimal engraftment of other unaffected lineages.

These preceding experimental data illustrate just how effective this competitive advantage can be in the setting of a proliferative defect in one or more lineages. However, when no defect in host hematopoietic vigor is present, the scale tips in favor of the endogenous fetal HSC, which have a marked competitive advantage over their adult-derived counterparts [70,163–166], due to their accelerated/enhanced cycling and expansion kinetics. Data from the congenic mouse model of IUTx provide a striking example of the degree to which this competition limits long-term donor cell engraftment. Even in this setting, in which no immune barriers exist, long-term donor cell engraftment levels remained below 10% following the delivery of mega-doses of donor cells (2×10^{11} donor cells/kg) [155].

The limited number of available niches and the proliferative capacity of the fetal environment have also been implicated as a barrier to success with IUTx [82]. Favorable competition of transplanted HSC with the host cells for available hematopoietic niches is essential for successful engraftment, as evidenced by the enhanced success of IUTx when more competitive fetal donor cells or larger doses of adult cells are used [73,167]. Improved competition for available host niches would obviously be predicted to lead to higher levels of early chimerism, as is seen in adult mice, in which selective depletion of host HSC before BM transplant results in high rates of engraftment [168]. However, no direct evidence exists to support the existence of quantitative or qualitative differences in the number of HSC or available niches between recipients with SCID and those with sickle cell disease or β-thalassemia (reviewed in Refs. [169,170]), or any of the range of other disorders that have proven refractory to correction by IUTx. As such, it is hard to envision how a competitive niche model could explain the conflicting observations for immunodeficient versus nonimmunodeficient recipients, with respect to the success of donor cell engraftment following IUTx [148]. Nevertheless, the possibility that there are a finite number of available hematopoietic niches for donor cell engraftment following IUTx is supported by the finding that increasing the dose of donor cells results in an eventual plateau of engraftment efficiency in an allogeneic and xenogeneic fetal sheep model [171].

Using sheep as a large animal model of IUTx, we demonstrated that administering allogeneic adult BM–derived mesenchymal (CD146 + CXCL12 + VEGFR2 −) or endothelial (CD146 + CXCL12 + VEGFR2 +) cells prior to, or in combination with, HSC, resulted in robust CXCL12 production within the fetal marrow environment, and significantly increased the levels of hematopoietic engraftment. Moreover, the increased expression of VEGFR2 in the microvasculature of CD146 + CXCL12 + VEGFR2 + transplanted animals enhanced the levels of donor-derived hematopoietic cells in circulation. These studies provide important insights into IUTx biology and demonstrate the feasibility of modulating/enhancing the resident marrow niches to enhance HSC engraftment to levels that would likely be therapeutic in many candidate diseases for IUTx [172].

In other studies, maternal administration of busulfan 6 days prior to IUTx was shown to significantly increase engraftment in fetal sheep [173]. While informative, it is not clear whether the toxicities associated with the use of a myeloablative agent during pregnancy would be clinically acceptable. However, recent studies from MacKenzie et al. demonstrated that selective in utero depletion of host HSC using an Ab against the c-Kit receptor (ACK2) results in therapeutic levels of engraftment after neonatal transplantation [174], without any of the cytotoxic effects of an agent like busulfan.

Collectively, these studies support the notion that augmenting host stem-cell niches or inducing resident HSC to vacate the existing niches may both represent viable means of improving chimerism after IUTx. Clearly,

however, further studies are needed to better understand this important issue and develop methods of optimizing the benefits on donor HSC engraftment while ensuring the safety of the fetus and mother.

Clinical experience with in utero transplantation

The early experimental success of IUTx in various animal models generated a great deal of excitement and led to many clinical attempts around the world to treat various hematologic disorders with IUTx. In humans, the first successful IUTx was performed for bare lymphocyte syndrome [175]. Following this seminal case, successful transplantation of fetuses with SCID was also achieved in a number of centers [176–179]. In these cases, fetal liver, paternal BM, or maternal BM–derived CD34 + cells were transplanted between 16 and 26 weeks of gestation and resulted in engraftment of donor cells at birth, and clinical improvement. To date, IUTx has been performed on 48 human patients for 14 different genetic disorders, including hemoglobinopathies, chronic granulomatous disease (CGD), Chediak–Higashi syndrome, and inborn errors of metabolism [62,75,180–183] (reviewed in Ref. [50]). These studies have collectively provided irrefutable proof that the early human fetus can safely be accessed multiple times, assuming that a minimally invasive, ultrasound-guided approach is employed [62,75,156,176,180,181,184].

Unfortunately, with the notable exception of patients with SCID, the clinical experience thus far with IUTx has been largely disappointing. However, SCID is a unique disorder that provides a survival and proliferative advantage for donor T-cells, and the engraftment achieved in these patients has only been documented to reconstitute the T-cell lineage (split chimerism) [75], just as Blazar et al. observed in their early experimental work in mice [87,162]. The results of the 48 clinical IUTx cases performed to-date have clearly demonstrated that IUTx, using currently employed methods, is unable to establish therapeutic levels of donor cell engraftment in recipients whose hematopoietic system exhibits a normal level of competitiveness. Regrettably, the large number of variables and inherent inconsistencies among these reported clinical cases have made it impossible to identify a common factor(s) responsible for the observed poor engraftment and lack of clinical success. As a result, investigators have been forced to perform the previously detailed, rigorous experiments in animal models to gain insight into the barriers that limit engraftment after IUTx.

Since the majority of the anticipated target disorders to be treated via IUTx, such as the hemoglobinopathies and the lysosomal storage diseases, are competitively normal in fetal life, methods must be developed in clinically relevant animal models to overcome host cell competition to improve clinical success with IUTx. A recent study performed in the canine model by Flake's group [64] showed that administering large numbers of highly enriched HSC via an ultrasound-guided intravascular (intracardiac) route resulted in significantly higher levels of engraftment than the intraperitoneal (IP) route that has been used in most clinical studies. Of note, the levels obtained via this new route would be predicted to be therapeutic in most candidate diseases, which has generated a great deal of enthusiasm in the field [185,186]. However, other studies in sheep have produced contradictory results, showing that the intravascular route is no better than the IP route, leading the authors of this other study to conclude that the markedly greater safety afforded by the IP route will likely make this the clinical route of choice [187].

One area that has shown great promise is the notion that the best clinical application for IUTx in the near future may be to use IUTx to induce prenatal tolerance to facilitate nontoxic postnatal BMT [7,60]. This approach significantly lowers the threshold of chimerism required for clinical success, since, as previously discussed, stable engraftment levels of only 1%–2% should reliably induce donor-specific immune tolerance. Unequivocal proof for the therapeutic merit of this approach was recently provided by Peranteau, Flake, et al., who used IUTx to achieve low-level hematopoietic engraftment to induce tolerance, and then performed a postnatal, nonablative "boost" transplantation with same-donor HSC. This tactic yielded sufficient levels of donor cell engraftment to phenotypically correct both β-thalassemia and sickle cell disease in the murine system [188]. These exciting results led the authors to conclude, "if adequate engraftment can be achieved to consistently induce donor-specific tolerance without graft versus host disease (GVHD) in a preclinical model, then clinical trials of IUTx for treating genetic disorders that can be prenatally diagnosed and treated by mixed hematopoietic chimerism, such as the hemoglobinopathies and selected immunodeficiency disorders should be initiated" [188]. This conclusion likely played a key role in the recently commenced clinical trial at UCSF to treat α-thalassemia via IUTx [ClinicalTrials.gov Identifier: NCT02986698].

Rationale for in utero gene therapy

When considering the best way to treat genetic diseases, it is critical to realize that a significant amount of irreversible damage often occurs during embryonic and fetal development. Considering inherited metabolic diseases such as Gaucher's, Lesch–Nyhan, and Tay Sachs as examples, these disorders produce marked irreversible neuronal damage during fetal life, making postnatal treatment of only limited therapeutic benefit, since it cannot reverse the damage that the gene defect exerted during development. Even in patients with diseases that can be

cured postnatally, compelling psychological and financial benefits exist to argue for performing correction in utero, since it would allow the birth of a healthy infant, who, ideally, would require no further treatments. While IUTx can potentially treat many disorders, some genetic diseases may not be amenable to correction by the transplantation of "healthy" stem cells, and for some, it may be preferable to correct the genetic abnormality in situ.

Setting aside the obvious clinical and financial advantages of curing a disease prior to birth, the fetus has many unique properties that make it a far better gene therapy recipient than the adult or even pediatric patient. For example, due to their ability to integrate into the genome of the host cell, γ-retroviruses and lentiviruses have received a great deal of attention as gene delivery vectors, since transduction of a long-lived cell could provide lifelong therapeutic benefit following a single administration. However, one of the main limiting factors to the successful application of these integrating vectors to in vivo gene therapy is the low level of initial transduction and the limited degree of expansion of transduced cells that occurs following gene therapy, since the majority of stem-cell populations in the adult are relatively quiescent and may be inaccessible due to anatomic barriers. During specific periods of development, however, stem and progenitor cell populations are present at relatively high frequencies, and they are accessible to gene transfer, providing a unique window of opportunity to achieve efficient gene transfer to these nascent stem-cell populations, which will be unreachable later in life [7,60]. In the fetus, cells that comprise each of the major tissues/organs are actively cycling to support the continuous growth occurring throughout gestation. Thus most cell types that are largely quiescent in the adult are mitotically active in the fetus, making them amenable to genetic correction with vectors requiring cell division. Furthermore, the active cycling should result in expansion of the gene-corrected cells during the remainder of gestation, allowing even low levels of initial transduction to yield significant levels of gene-corrected cells by birth.

In addition to the ability to access nascent stem-cell populations, just as with IUTx, the immaturity of the fetal immune system should enable delivery of immunogenic transgenes and/or viral vectors that would be rejected by the fully developed postnatal immune system. Many patients suffer from the genetic diseases currently being targeted with postnatal gene therapy because they have never produced a specific protein. As a result, their immune system has never "seen" this protein, and, following postnatal gene therapy, the cells of the immune system identify and destroy any cells in the body expressing the very protein that could cure the patient's disease. Performing IUGT should induce a state of tolerance to the transgene and the viral vector itself, which would not only ensure long-term, stable transduction and expression but should also make it possible to administer postnatal "booster" treatments (if required) with the same vector and transgene without eliciting an immune response.

Furthermore, in similarity to our discussion on IUTx, the extremely small size of the fetus at the proposed time of intervention offers distinct advantages, as it is possible to achieve much higher vector-to-cell ratios than would be possible later in life, which should greatly enhance the efficiency of transduction. In addition, the ability to administer a small volume of vector and achieve the desired rate of transduction is of additional benefit from a technical/logistical standpoint, since the large-scale production of certain vectors under good manufacturing practice (GMP) conditions is often quite challenging.

Hemophilia A as a model genetic disease for correction by in utero gene therapy

Gene transfer using viral vectors exploits the natural ability of the parent virus to efficiently attach to a target cell and transfer its genetic material to the host cell nucleus. To maximize safety, these viral-based vectors are engineered to be devoid of most, if not all, viral genes, which renders the viral vector incapable of replication or expression of potentially immunogenic and/or toxic viral genes. Because the vector is ultimately responsible for the transfer of genes to the fetus, the choice of vector is of utmost importance in fetal gene therapy. Without delving into a complete discussion of viral vectorology, which is well beyond the scope of this chapter, it is important to note that the specific vector to be used for a given IUGT application will depend largely upon one's goals and the disease and/or cell type being targeted. This vector should be selected after careful consideration of such factors as the ability to integrate into host genomic DNA, tissue tropism, packaging capacity, and potential immunogenicity. Most investigators in the field would likely agree that an ideal vector for curing a genetic disease via IUGT (or postnatal gene delivery, for that matter) would selectively target a specific cell type/organ and be able to mediate sufficient levels of gene transfer to produce therapeutic effect with only a single application.

To consider initial target diseases for exploring the therapeutic potential of IUGT, it goes without saying that testing for the target disease must be in place to allow accurate diagnosis before birth, and there must be compelling reasons to pursue prenatal treatment rather than waiting until after birth. Using a variety of animal model systems and rodent models of human genetic diseases and a wide range of transduction methods, IUGT has been targeted to multiple organs [128,181,184,189–208], and in several disease models, phenotypic rescue has been

accomplished [128,181,184,194–196,199–201,209–225]. In the interest of space, and to illustrate the profound therapeutic potential of IUGT, and the ease with which it could be implemented clinically to cure disease, the next section of this Chapter will focus on hemophilia A (HA), presenting HA as an archetype for the host of genetic diseases that could be corrected by IUGT, the rationale for pursuing its treatment prior to birth, the feasibility of doing such, and clinical, societal, and financial advantages IUGT could offer over existing treatments for this disease.

The need for better hemophilia A treatments

HA is the most frequent inheritable coagulation deficiency [226]. The clinical severity of HA is determined by the patient's FVIII plasma levels, but up to 70% of patients with HA present with a severe (<1% of normal FVIII levels in plasma), life-threatening phenotype [227–229]. These patients suffer frequent spontaneous hemorrhaging, which leads to hematomas, chronic painful and debilitating arthropathies, and potentially life-threatening internal bleeding [227]. The current HA standard of care is 2–3 prophylactic intravenous infusions of recombinant or plasma-derived FVIII per week to maintain hemostasis. This "protein-replacement therapy" has greatly improved QoL and extended the life expectancy for many patients with HA. However, it is far from ideal, as it sentences patients to a lifetime of intravenous infusions multiple times each week, and saddles patients with treatment costs that can exceed $300,000/year. Even among the ~25% of HA patients worldwide who are fortunate enough to have access to FVIII prophylaxis, approximately 30% will mount an immune response (inhibitors) to the infused FVIII [230]. In the best-case scenario, these inhibitors reduce the effectiveness of subsequent FVIII infusions; in the worst-case scenario, they cause treatment failure, putting the patient at risk of a life-threatening bleed. These significant shortcomings highlight the need for novel therapies that can provide longer lasting correction, or permanent cure, of HA.

In contrast to current protein-based therapeutics, a single successful gene therapy treatment could promise lifelong correction of HA; indeed, several aspects of HA make it a unique and ideal target disease to correct with gene therapy [206,231–239]. First, although the liver is thought to be the major site of FVIII production within the body [240], FVIII need not be expressed in either a specific tissue or cell type to produce a therapeutic effect. As long as it is produced by cells that have access to the circulation, FVIII can exert its appropriate clotting activity. Second, even if FVIII levels could be restored to only 3%–5% of normal, this seemingly minimal change would exert a marked clinical effect and greatly improve the QoL of patients with severe HA, converting these patients to a moderate/mild phenotype. Conversely, even supraphysiologic FVIII levels are predicted to be safe, creating a wide therapeutic window for HA gene therapy [229]. Armed with this knowledge, the hemophilias were listed among the most promising, "Target 10" diseases in the roadmap that the American Society of Gene and Cell Therapy (ASGCT) (www.ASGCT.org) provided to NIH director, Dr. Francis Collins.

Preclinical animal models for hemophilia A and recent clinical successes

A number of animal models have been developed to evaluate new methods of not only treatment of coagulation disorders but also the prevention and treatment of inhibitor formation. Fortunately, colonies of HA dogs in which spontaneous mutations occurred within the FVIII gene [241,242] and FVIII-deficient mouse models produced via gene targeting and knockout technologies [243] are both available to study the basic biology and function of FVIII and to explore/develop gene therapy–based approaches for treating HA. Pronounced therapeutic benefit has been demonstrated in multiple studies postnatal gene therapy studies in murine models [234,236,244–250]. Phenotypic correction has also been achieved with postnatal gene therapy in dogs with HA, but correction in this more clinically predictive model has proven far more difficult than in mice [251,252].

Despite the promising results obtained in both these models, however, until recently, no therapeutic benefit had been seen in any of the postnatal clinical gene therapy trials conducted for HA, which was in marked contrast to successes that had been reported in clinical gene therapy trials treating patients with hemophilia B (HB) [253]. The past 2 years, however, have seen unprecedented progress in the successful clinical use of postnatal gene therapy to treat HA. Spark Therapeutics recently presented [254] results of a Phase 1/2 Trial [ClinicalTrials.gov Identifier: NCT03003533] testing the efficacy of their proprietary AAV-based gene therapeutic, Spk-8011, in 12 adult HA patients. The results of this trial thus far have been highly promising, demonstrating durable FVIII expression, a 94% reduction in bleeds, and a 95% reduction in FVIII infusions. However, two of the patients developed a significant immune response to the AAV capsid, one of which required hospitalization. This anticapsid response, and the steroid therapy administered to counter it, led to a drop in FVIII levels to below 5% in these patients [254].

Bayer also recently initiated a Phase 1/2 open-label safety and dose-finding study of their AAV therapeutic,

BAY2599023 (DTX201), which has the hu.37 capsid, in adults with severe HA [ClinicalTrials.gov Identifier: NCT03588299]. This trial will have 18 participants but began enrolling in November 2018, so no results have yet been reported.

The most exciting clinical findings in an HA gene therapy trial, however, have come from BioMarin [ClinicalTrials.gov Identifier: NCT02576795]. Patients were administered a single IV injection of either a low dose (4×10^{13} vg/kg) or high dose (6×10^{13} vg/kg) of BioMarin's AAV-based HA gene therapy vector, valoctocogene roxaparvovec (BMN 270), and some have now been followed for over 2 years. In the high-dose cohort, patients experienced a 97% reduction in mean annualized bleed rate (ABR), a 96% reduction in mean FVIII usage, no spontaneous bleeds, and elimination of all bleeds in target joints. QoL as measured by the six-domain Haemo-QoL-A instrument rapidly improved across all domains. Throughout the nearly 2-year follow-up in this high-dose cohort, mean FVIII activity levels have been consistently within the normal or near-normal range in all patients, and the mean FVIII activity level of this cohort as a whole is 59%. The low-dose cohort also showed a 92% reduction in ABR, and a 98% decrease in mean FVIII usage. Consistent with the reduction in ABR and FVIII usage, QoL in this low-dose cohort was also markedly improved. At 1-year postvector infusion, the mean FVIII activity level of the low-dose cohort as a whole was 32%.

Overall, this ongoing trial has demonstrated BMN 270 to be fairly well tolerated at all tested doses. Importantly, no participants developed inhibitors to FVIII, and no participants withdrew from the study. The most common adverse events (AEs) across all dose cohorts were as follows, listed with percentage of participants experiencing each AE: alanine aminotransferase (ALT) elevation (73%); arthralgia (60%); aspartate aminotransferase elevation (53%); headache (47%); back pain and upper respiratory tract infection (40%); and fatigue, insomnia, and pain in extremities (33%) [255]. In the high-dose cohort ($n = 7$), the first treated subject exhibited a 1.5-fold increase in ALT over baseline at 4–7 weeks postvector infusion. This was presumed to be due to mounting of an anticapsid immune response, and the patient was placed on steroids. All subsequent patients in the high-dose cohort were treated prophylactically with steroids. Interestingly, this prophylactic steroid therapy did not halt ALT elevation in four of the seven patients in this high-dose cohort, yet no capsid-directed T-cell response was seen in any of these subjects, raising the possibility that the observed ALT elevation may not, in fact, be due to an immune response, but rather to direct hepatotoxicity or other unknown effects, perhaps arising from the use of an insect-line/baculovirus-based manufacturing process. It is also possible that this manufacturing process somehow causes the immune response to AAV-5 to differ from that of other AAV vectors, which are produced in mammalian cells via plasmid transfection [256].

Given these recent successes, gene delivery strategies using AAV vectors are likely to become more mainstream treatment options for HA (and other diseases as well). Despite these successes, however, a major barrier exists to prevent the widespread adoption of AAV-based gene therapy: the high seroprevalence of neutralizing Abs (NAbs) to AAV that exists in the general population. Recent studies suggest that 30%–70% of patients have NAbs to specific serotypes [257–259]. As such, these patients will not be candidates for gene therapy treatments using AAV vectors. Numerous attempts have been made to eliminate preexisting Nabs, including the use of immunosuppression [260,261], plasmapheresis [262], the inclusion of empty capsids to serve as "decoys" [263], novel bioengineered capsids, or localized vector infusion [264]. Sadly, however, these approaches have only modestly decreased titers and have not succeeded in eliminating the NAbs. Performing gene therapy in utero would eliminate this problem, as the fetus lacks Abs to AAV. Moreover, a stable level of FVIII early in life would prevent the onset of joint bleeds and the development of arthropathy.

Sheep as a preclinical model of hemophilia A

To develop and test the efficacy and safety of IUGT approaches to treating HA and ensure that the data generated are predictive of clinical outcome when these therapies are translated to human patients, it is essential to employ a preclinical animal model that both precisely mimics the disease process of HA, and closely parallels normal human immunology and physiology. To this end, we used a variety of reproductive technologies to successfully reestablish, and then clinically characterize, a line of sheep [265–269] that possess a spontaneous frameshift mutation [267,268] that results in severe HA, which, if not treated at birth, is fatal within the first hours/days of life [270–272]. All affected animals born thus far have experienced multiple spontaneous episodes of severe bleeding, including muscle hematomas, hematuria, and hemarthroses, all of which have promptly responded to infusion of human FVIII. Importantly, chromogenic assays performed independently at the Blood Center of Wisconsin and Emory University revealed undetectable FVIII activity in the circulation of these sheep, explaining their severe phenotype. Importantly, just like human patients with severe HA, these sheep experience frequent spontaneous bleeds into their "knees," which, over time, produce crippling arthropathies that ultimately lead to decreased movement, difficulties walking, and eventually symptoms of pain even just to stand up. These recurring spontaneous

joint bleeds make this line of sheep unique among animal models of HA. Also in similarity to human patients, some of these sheep developed inhibitors following FVIII administration. However, since we had not yet cloned and sequenced ovine FVIII, we were restricted to treatment with human FVIII, leaving unanswered the question of whether these animals will also make inhibitors to the ovine protein. An ongoing collaboration with Drs. Spencer and Doering at Emory University has resulted in the successful cloning and large scale production of recombinant B domain−deleted ovine FVIII [273], making it possible to address this important question and to construct gene therapy vectors encoding ovine FVIII for testing in this valuable model.

As discussed in detail in the section on In utero transplantation experiments in large preclinical animal models, sheep possess many characteristics that make them an ideal preclinical model for IUGT. An additional unique advantage to using sheep in the context of HA treatment is that, like humans, the majority of the FVIII carrier protein, vWF, is stored/located within their platelets. This is in contrast to dog, in which vWF circulates free in plasma [274,275]. This key difference makes the sheep the most clinically relevant large animal model in which to test the efficacy of platelet-targeted gene therapy approaches for treating HA [239,276−278]. In addition, we also reported that sheep naturally harbor Abs to many of the serotypes of AAV being employed as gene delivery vectors [279], suggesting they may also represent a unique preclinical model in which to explore means of circumventing this significant clinical hurdle. For these collective reasons, we feel that sheep are an especially fitting model in which to develop and test gene therapy treatments for HA.

In addition to carefully defining the clinical picture of these animals, we also sequenced the entire coding region of the ovine FVIII gene to determine the molecular basis for their disease. In similarity to mutations seen in many human patients [280], these animals possess a premature stop codon with a frameshift mutation. This is the only animal model of HA with this clinically relevant mutation-type, providing a unique opportunity to study therapies in this context. Armed with this genome sequence data, we next developed a polymerase chain reaction (PCR)-based test to enable us to screen for the disease-causing mutation and thereby identify affected animals at birth and even in utero, using amniotic fluid-derived cells [265−269]. We have also recently shown, by immunohistochemical staining of tissue sections with Abs to various epitopes of the FVIII molecule, which these sheep are completely devoid of any FVIII antigens. As such, they are an excellent model of severe, cross-reacting material-negative HA patients and thus represent a highly stringent preclinical system to study the ability of in utero interventions to induce tolerance to FVIII.

Beyond the value of another large animal model of HA and the uniqueness of the mutation, sheep possess many characteristics that make them an ideal preclinical model for gene therapy, especially in the context of HA. First, sheep share many important physiological and developmental characteristics with humans, they have been used extensively in the study of mammalian fetal physiology, and the results obtained with this model have been directly applicable to the understanding of human fetal growth and development. In contrast to other large animal models such as dog and pig, sheep, like humans, typically have singleton or twin pregnancies, rather than large litters of offspring. Second, sheep are fairly close in size to humans, both at birth and as adults, which would likely eliminate the need for scale-up of vector dose to move from experiments in sheep to trials in humans. Third, the development of the sheep immune system has been investigated in detail [103−109], making sheep well suited for studying the immunological aspects of gene therapy for HA. An additional unique advantage to using sheep to study HA treatment is that in sheep, like human, a large percentage of the vWF is found within platelets rather than free in plasma (*Robert Montgomery and Qizhen Shi, personal communication*). This is in contrast to dog, in which vWF circulates free in plasma [274,275], making the sheep an ideal large animal model in which to explore the use of platelet-targeted gene therapy for HA [239,276−278,281−283]. For these reasons, we feel sheep are a particularly relevant model for developing and testing gene-based HA treatments.

Feasibility and justification for treating hemophilia A prior to birth

Even if FVIII costs were reduced to the point that most HA patients could afford prophylaxis, these patients would still require recurrent, intravenous infusions throughout their lives, be plagued by subclinical microbleeds resulting from the troughs in circulating FVIII levels that occur between infusions, and still have a significant risk of treatment failure due to inhibitor induction. These problems, as well as many of the obstacles that have dogged clinical gene therapy trials to-date, could likely be overcome/eliminated by performing gene therapy prior to birth. For individuals with a family history of HA (~75% of HA cases), prenatal diagnosis for HA is feasible, available, and is both encouraged and cost-effective, even when considering developing third-world countries [284−295]. Moreover, recent studies have proven the feasibility of diagnosing HA in utero via digital PCR on the small number of fetal cells present within the mother's blood, enabling prenatal diagnosis of HA with effectively zero risk to the fetus or mother [294,296].

Although most individuals with a family history of HA are encouraged to have prenatal screening, however, parents currently have only two choices following prenatal diagnosis of HA: pregnancy termination or the birth of a child with HA. The availability of a safe and effective in utero treatment would provide parents with a much needed third option, which would certainly provide the needed impetus for much more widespread prenatal HA screening. While in vitro embryo screening and selection has been proposed as a possible solution in families with a history of HA and other genetic diseases, such an approach is very expensive and requires highly skilled personnel and specialized equipment/facilities, which would not likely be available in much of the world. In contrast, IUGT does not require any sophisticated equipment that would not already be in place for prenatal diagnosis, and it should not be prohibitively expensive.

Since parents currently have no therapeutic options for treating a child diagnosed in utero with HA, ~1 in 5000 boys born each year worldwide is affected with HA [226], despite the availability of prenatal screening. In the United States alone, correcting this disease prior to birth could benefit the ~240 patients/year born into families with a history of HA. IUGT could promise the birth of a healthy infant who required no further treatments, removing the heavy physical, psychological, and monetary burden on the patients, their families, and the health care system. The current estimate for the lifetime cost of prophylactic treatment for one HA patient is $20 million. Curative IUGT would thus save ~$48 billion over the lifetime of the HA patients born just this year in the United States. Such a treatment, if successful, would also clearly represent a major advance with respect to the QoL of the patient, as the patient would receive a single treatment rather than a lifetime of expensive and potentially dangerous infusions several times each week.

When considering a prenatal treatment, especially for a disease involving abnormal coagulation, safety of the fetal patient is paramount. Importantly, the fetus possesses unique hemostatic properties that make it an ideal patient. During early fetal life, activation of FX occurs predominantly via tissue factor activity, making it largely independent of the FIXa/FVIIIa phospholipid complex [297]. As a result, the fetus develops without hemorrhage, despite having little or no expression of FVIII and FIX [297–299]. The unique hemostasis of the fetus should thus allow IUGT to be performed safely for HA; indeed, one of the 48 human patients that has thus far received IUTx [181,182] was transplanted in the hopes of correcting HA, or at least inducing immunological tolerance to FVIII [180,183,300]. While only this one HA patient was treated, he suffered no untoward effects as a result of the in utero intervention, he has thus far exhibited reduced severity of disease compared to his siblings, and he (in contrast to his siblings) has not developed inhibitors with FVIII treatment (*J.L. Touraine, personal communication* and [300]). This remarkable case thus provides clinical validation for prior experimental studies demonstrating that exposure to vector-encoded proteins (including coagulation factors) during early immunologic development induces stable immune tolerance [203,204,301,302]. The lifelong tolerance to FVIII induced by an IUGT-based HA treatment should therefore prevent the development of FVIII inhibitors that plague patients treated with replacement therapy [230,303–306]. In this one clinical case, Dr. Touraine relied on the ability of unpurified fetal liver cells to endogenously produce sufficient levels of FVIII, after transplant, to mediate correction. The only partial correction observed in this patient supports the approach of using gene transfer to ensure adequate levels of FVIII are obtained for full phenotypic correction.

Although the clinical and financial advantages of IUGT are compelling, in and of themselves, it is important to acknowledge that there are also features of the fetus that make it a far better gene therapy recipient than the adult [128,307,308]. For instance, cell populations that are quiescent in the adult, and largely refractory to transduction with many commonly employed viral vectors, are actively cycling in the fetus and amenable to transduction at relatively high efficiencies. For example, we showed that by administering a single IP injection of a small volume of a γ-retroviral vector at the optimal stage of gestation (which we determined experimentally), it is possible to achieve gene transfer levels within the hematopoietic system of 5%–6% [196,222,309], levels that would undoubtedly be beneficial in HA. Further studies involving Ab selection of CD34 + cells and serial transplantation/repopulation [196,222,310], provided compelling evidence that this approach successfully modified bona fide HSC, indicating this method could provide lifelong disease correction.

Our results also demonstrated that this approach successfully transduced hepatocytes and hepatic endothelium at levels that could well be therapeutic in HA, and defined the temporal window during gestation for optimal transduction of these cells [194]. Concurrently, fetal gene delivery experiments conducted in sheep, rodent, and NHP models, by other investigators who employed a variety of viral-based vectors, produced similar results [128,181,184,189–208]. The collective results of these studies clearly support the ability of this method to deliver an FVIII transgene to the nascent liver with sufficient efficiency to convert severe HA patients to a moderate or, perhaps, even mild phenotype [194].

While the active cell cycling in the fetus enables efficient transduction with vectors that require mitosis, it is important to note that this ongoing proliferation in all of

the fetal organs is also of benefit when using vectors that do not have an absolute requirement for mitosis. Gene delivery early in gestation, regardless of the vector employed, also makes it possible to achieve subsequent expansion of these gene-corrected cells throughout the rest of gestation. As such, even if the initial gene transfer only transduces a small number of the desired target cells, this subsequent expansion could produce clinically useful levels of gene-correction by birth.

As mentioned earlier, one of the biggest obstacles/drawbacks to treating severe HA by repeated protein infusion is the formation of inhibitory Abs in ~30% of patients. It is important to note that the distinct immunologic benefits to performing IUTx (which we discussed at length earlier in this chapter) also apply to IUGT. We have spent the last two decades performing IUGT studies in the sheep model [128,194–197,222,280,301,309,311–313], and have shown that it is possible to take advantage of this unique temporal window of relative immuno-naïveté to efficiently deliver exogenous genes a variety of fetal tissues and induce durable tolerance to the vector-encoded gene product [301]. This tolerance induction appears to involve both cellular and humoral mechanisms, since Ab and cellular responses to the transgene product were both significantly diminished in these animals, even several years after IUGT. Further mechanistic studies demonstrated that IUGT early in fetal development exploits both central and peripheral tolerogenic avenues in the fetus [302]. These results strongly imply that IUGT, even if it not curative, would still be an ideal treatment modality for HA, since the induced immune tolerance would ensure that postnatal therapy, be it protein- or gene-based, could proceed safely without any of the immune-related problems that currently plague HA treatment.

Interestingly, although the incidence of HA is ~7 times that of HB, to-date, the only experimental studies to directly investigate IUGT for treating the hemophilias have targeted HB [factor IX (FIX) deficiency] [189,190,202–204,206–208,314,315]. The choice to target HB rather than A most likely results from the greater ease with which FIX can be cloned into a variety of viral vectors, and efficiently expressed upon transduction of appropriate target cells; this is in marked contrast to the difficulties that were initially seen when attempting to express FVIII in the context of viral vectors [316]. The treatment of HB by IUGT has been extensively studied in murine models with gene transfer performed at various gestational ages, via different routes of injection, and using different vector types. Schneider et al. compared IP, intramuscular, and intravenous injections of human FIX carried by adenovectors and AAV-2 into mouse fetuses and found that adenovectors resulted in initially higher levels of FIX. Interestingly, given their episomal nature, adenovector-injected mice maintained therapeutic levels of FIX for 6 months, and no Abs developed against either vector or transgene [208]. In other studies, Sabatino et al. reported low-level human FIX expression following intramuscular injection of fetal and neonatal mice with either AAV-1 or AAV-2. Curiously, the injection of AAV-1 induced tolerance and allowed the postnatal readministration of the FIX-encoding AAV-1 vector, increasing FIX levels sufficiently to reach the therapeutic range, while injection of AAV-2 did not induce immune tolerance [317].

Without a doubt, the most impressive and clinically promising results of IUGT in hemophiliac mice were achieved by Waddington et al., who injected a FIX-encoding lentiviral vector into E15 mouse fetuses and demonstrated therapeutic levels of FIX (9%–16% of normal) and improved coagulation for 14 months post-IUGT. Furthermore, no immune response developed to FIX, even when the protein was repeatedly injected postnatally [204].

Collectively, these murine studies have provided compelling evidence that IUGT can result in expression of FIX at levels that not only have therapeutic significance, but are often sufficient to induce tolerance, thus allowing postnatal administration of the same vector or the FIX protein without eliciting an immune response. Because HA patients have at least a 10-fold higher likelihood of developing inhibitors than HB patients [318,319], these studies, while encouraging, leave unanswered the critical question of whether fetal gene delivery's ability to induce immune tolerance to marker gene products and FIX will hold true for the induction of tolerance to FVIII, given FVIII's higher inherent immunogenicity. What we are currently addressing is an important question in the sheep model.

All of the afore-referenced studies demonstrated that the direct injection of viral vectors into the developing fetus can be an effective way of delivering an exogenous gene and achieving long-term expression in multiple tissues and confirmed the therapeutic potential of an in utero approach to gene therapy. However, for this technology to move forward into the clinical arena will likely require the development of vectors that can target specific cell types following in vivo administration, to eliminate the risk of inadvertently modifying nontarget cells, like those of the germline [192,193,280], following a direct vector injection approach to IUGT. In an effort to develop safer means of correcting HA and other diseases prior to birth, we have been exploring the possibility of using mesenchymal stromal cells (MSC) as vehicles to deliver exogenous genes to the developing fetus. In the next section of this Chapter, we discuss our rationale for using these cells as therapeutics for HA and summarize our promising results using FVIII-expressing MSC to treat pediatric HA sheep.

Mesenchymal stromal cells as hemophilia A therapeutics

Decades after the groundbreaking studies that Friedenstein performed to better understand the marrow microenvironment [320,321], results from various labs around the world have revealed that MSC possess a very broad differentiation potential, both in vitro and in vivo and exhibit properties that suggest at least a subset of this population may be true stem cells [93–95,322–331]. MSC are very rare, only comprising roughly 0.001%–0.01% of cells within the marrow [332]. However, they can be passaged extensively in vitro without a loss of differentiative potential, making it possible to extensively expand these cells in vitro to easily obtain sufficient numbers for clinical use [333]. Since MSC were first discovered within the BM, much of the work to-date has focused on MSC isolated from this tissue. However, we and others have now shown that cells with the phenotype and functionality of MSC can also readily be isolated from numerous tissues, including brain, liver, lung, fetal blood, umbilical cord blood, kidney, and even liposuction material [92,334–340]. Importantly from the standpoint of in utero therapies, MSC have also been isolated from the amniotic fluid and the chorionic villi, raising the exciting possibility that autologous MSC could be used as cellular therapeutics or gene delivery vehicles for in utero therapy [341–346].

As discussed earlier, the liver is believed to be the primary anatomic site of FVIII synthesis/production. Studies from our group and others over the past decade have provided compelling evidence that MSC from various sources can generate, in vitro and in vivo, cells which are indistinguishable from native hepatocytes, and have shown that transplantation of MSC in a range of model systems results in fairly robust formation of hepatocytes which repair a variety of inborn genetic defects and injuries [93,94,97,98,100,327,347–371]. Of direct relevance to HA treatment, we have found that, after transplantation into fetal sheep, human MSC engraft at levels of up to 12% within the recipient liver [93,98,100,323,324,372–375] and contribute to both the parenchyma and the perivascular zones of the engrafted organs, positioning them ideally to deliver FVIII into the circulation. Since FVIII levels of 3%–5% of normal would convert a patient with severe HA to a moderate or mild phenotype, it seems reasonable to conclude that these levels of engraftment produce a therapeutic benefit. In other recent studies, we have demonstrated that MSC from various tissues throughout the body endogenously produce and secrete biologically active FVIII [376]. Collectively, these results suggest that MSC are ideally suited for treating HA.

However, upon further analysis, we found that, although MSC engrafted at significant levels within the natural sites of FVIII synthesis, the levels of FVIII production were too low to provide an effective means of treating HA. By using gene therapy to engineer MSC to express FVIII, however, it is likely that the levels of engrafted MSC we have thus far achieved in utero could provide therapeutic benefit in HA, especially if newer, expression-optimized FVIII variants were employed [233,250,377,378]. Importantly, MSC are efficiently transduced with all of the major clinically prevalent viral vector systems including adenovirus [379–381], murine retroviruses [381–385], lentiviruses [386–391], and AAV [392,393]. Furthermore, in contrast to studies with hematopoietic stem cells [394–396], human MSC are stable in culture, do not form tumors in vivo (unlike murine MSC [397]), and there is no evidence that human MSC transform or progress to clonal dominance following transduction. In fact, even following intentional induction of genomic instability, human MSC have been shown to undergo terminal differentiation rather than transformation [398], with very rare transformants only arising after very extended in vitro propagation, and being easily identifiable (and removable) based on their altered cell surface marker profile [399]. As such, MSC appear to represent very safe cellular vehicles for delivering a therapeutic gene.

Looking specifically at using MSC to treat HA, multiple studies have already proven that MSC can be efficiently transduced with murine retroviral and lentiviral vectors with gene cassettes encoding FVIII from a variety of species and secrete high levels of functional FVIII protein. Importantly, FVIII purified from the conditioned medium of the transduced MSC had a specific activity, electrophoretic mobility, and proteolytic activation pattern that was identical to commercially produced FVIII [400]. Given the widespread distribution and engraftment of MSC following transplantation, the ability of MSC to give rise, in vivo, to cells of numerous tissue types, and their ability to efficiently process and secrete high amounts of biologically active FVIII, it is not surprising that we and others feel that MSC represent ideal vehicles for delivering an FVIII transgene throughout the body, and thereby providing long-term/permanent correction of HA [400–403].

In addition to their widespread engraftment and their ability to serve as delivery vehicles for the FVIII gene, MSC have rather unique immunological properties that may further increase their utility for treating HA. MSC do not normally express MHC class II or the costimulatory molecules CD80 and CD82, and as such, they do not provoke the proliferation of allogeneic lymphocytes or serve as very effective targets for cytotoxic T- or NK cells. In fact, a large body of evidence is now accumulating that MSC can be transplanted across allogeneic barriers without eliciting a pronounced immune response [404,405]. Thus off-the-shelf MSC from an unrelated donor could

theoretically be used to treat HA, greatly increasing the feasibility of obtaining and using these cells for therapy. MSC also possess the clinically valuable ability to selectively migrate to sites of injury and/or inflammation within the body, whereupon the MSC then mediate repair both by engrafting and generating tissue-specific cells within the injured tissue [406–408], and by releasing trophic factors that blunt the inflammatory response and often promote healing by activating the tissue's own endogenous repair mechanisms. This property raises the exciting possibility that, following infusion, FVIII-expressing MSC might have the ability to selectively migrate to sites of active bleeding/injury, thereby focusing the therapy where it is most needed.

Preclinical success with mesenchymal stromal cell–based hemophilia A treatment

Despite the many physiological and clinical advantages to intervening prior to birth, there are already ~16,000 people in the United States alone with HA, who obviously would not benefit from the development of an in utero therapy. Furthermore, over 25% of HA-causing mutations arise de novo, making it unlikely this patient population would be screened prenatally. We therefore began investigating, in two pediatric HA lambs, whether the many advantages of MSC as a cellular vehicle for delivering an FVIII gene can still be realized if these FVIII-expressing MSC are transplanted during early childhood. During the first 3–5 months of life, both these animals had received frequent, on-demand infusions of human FVIII for multiple hematomas and chronic, progressive, debilitating hemarthroses that had resulted in severe defects in posture and gait and rendered them nearly immobile. Given the severe, life-threatening phenotype of the HA sheep, we elected to utilize haploidentical allogeneic cells from the ram that had sired the two HA lambs, rather than attempting to collect marrow to isolate autologous MSC.

Based on our prior in utero studies, we knew that MSC should engraft throughout all of the major organs [93,94,98,409–411] and durably express the vector-encoded genes [94,410,412] following IP injection. The IP route also enabled the MSC to enter the circulation in an almost time-release fashion, as they were absorbed through the peritoneal lymphatics. The IP route also allowed us to avoid the extensive lung-trapping which occurs following IV administration of MSC, promising more efficient delivery of the MSC to the desired target tissues and eliminating the clinical risk of emboli formation [413,414].

MSC were simultaneously transduced with two lentivectors: the first encoded an expression/secretion optimized porcine FVIII (pFVIII) transgene [415] and the second encoded an eGFP reporter to facilitate tracking of donor cells in vivo. Because the pFVIII transgene had previously been shown to be expressed/secreted from human cells at 10–100 times higher levels than hFVIII [233,234,378], we reasoned that even low levels of engraftment of the transduced MSC should exert a therapeutic benefit. Once the transduced MSC were sufficiently expanded, they were transplanted via IP injection, under ultrasound guidance, in the absence of any preconditioning.

Following transplantation, a highly sensitive chromogenic assay was unable to detect any FVIII activity in the circulation, but the clinical picture improved dramatically in both animals. All spontaneous bleeding events ceased, and they enjoyed an event-free clinical course, devoid of spontaneous bleeds, obviating the need for hFVIII infusions. Even more remarkably, existing hemarthroses resolved, their joints recovered fully, and they regained normal posture and gait, resuming a normal activity level. To our knowledge, was the first report of phenotypic correction of severe HA in a large animal model following transplantation of cells modified to express FVIII, and the first time that reversal of chronic debilitating hemarthroses was achieved in any setting.

Upon euthanasia, PCR analysis demonstrated MSC engraftment in nearly all tissues analyzed, including liver, lymph nodes, intestine, lung, kidney, omentum, and thymus. Subsequent confocal analysis on frozen tissue sections revealed large numbers of FVIII-expressing MSC within the synovium of the joints which exhibited hemarthrosis at the time of transplant, confirming the intrinsic ability of transplanted MSC to home to and persist within sites of ongoing injury/inflammation, releasing FVIII locally within the joint, and providing an explanation for the dramatic improvement we observed in the animals' joints. Collectively, the results of the PCR and confocal analyses strongly support the conclusion that widespread durable engraftment of MSC can be achieved in a large animal model following transplantation in a postnatal setting, without the need for preconditioning/ablation. However, the levels of engraftment seen in these pediatric animals were substantially lower than those obtained in our prior in utero studies. Moreover, despite the marked clinical improvement and the widespread engraftment of the transplanted MSC, both animals mounted a fairly robust immune response to pFVIII, in similarity to prior studies performed with HA mice [378]. These inhibitors exhibited cross-reactivity to hFVIII, which was surprising, given the well-established ability to use pFVIII products in human patients with existing anti-hFVIII inhibitors [416–419].

Therefore this postnatal study proved that MSC can serve as cellular vehicles to deliver FVIII and produce a therapeutic benefit, and we posit that administering this

same treatment in utero would have a more pronounced and more durable effect, since higher levels of donor MSC engraftment could be achieved, and because inhibitor formation could be avoided due to the induction of immune tolerance to the FVIII transgene.

Risks of in utero gene therapy

Despite the great promise IUGT holds for the treatment of HA and the myriad other genetic diseases that can be diagnosed prenatally, several important safety concerns must be addressed prior to its clinical application. While the risks of postnatal gene therapy have been recognized and extensively discussed, specific risks may be higher for the fetus than for the postnatal recipient. There are two sets of potential safety concerns associated with IUGT: those associated with fetal intervention, and those due to the gene transfer itself. As with any fetal intervention, infection, preterm labor, and fetal loss are all theoretically possible. In reality, however, a wealth of clinical data exist that provide unassailable proof that the early human fetus can be accessed multiple times with an extremely low procedure-related risk, assuming that a minimally invasive, ultrasound-guided approach is employed [62,75,156,176,180,181,184].

The risks that cause the most concern regarding the use of IUGT include disruption of normal organ development, insertional mutagenesis, and germline transmission [420]. Although IUGT holds great potential for restoring normal function, manipulating the fetus has the potential to alter normal organ development, and the possibility for deleterious effects due to the injection and from any inherent toxicity of the vector itself both need to be considered and carefully evaluated. NHPs injected with lentiviral vectors in utero via either the intrapulmonary or intracardiac route showed no adverse effects on postnatal heart and lung development [200]. In contrast, studies performed by Gonzaga et al. found that expression of FGF-10 in the developing rat lung following IUGT leads to cystic adenomatoid malformations illustrating how the forced expression of a specific transgene can lead to malformation [421]. These findings suggest that strategies involving expression of growth factors, transcription factors, or other regulatory molecules will need to be carefully examined, as they may have significant potential to alter normal organ development, particularly early in gestation.

Genomic integration–associated insertional mutagenesis

Insertional mutagenesis is a major concern with all of the integrating viral vectors and has been the subject of intense investigation since the clinical observation of four cases of T-cell leukemia, diagnosed 31–68 months after postnatal γ-retroviral-mediated gene transfer to autologous HSC to correct children with X-linked SCID. This concern was further heightened when linker-mediated PCR analysis of lymphocytes from these patients revealed that insertional mutagenesis had occurred in all four cases, and was at least partially responsible for the observed leukemogenesis [422–424]. Importantly, in our long-term IUGT studies in fetal sheep, we also employed γ–retroviral vectors and achieved significant levels of gene transfer to hematopoietic cells, which persisted in these sheep throughout the 5-year course of study [196,222,309]. Moreover, transgene-positive CD34 + cells could be detected in the marrow of these animals several years post IUGT [310], and gene-marked BM cells isolated from these IUGT recipients were able to serially engraft secondary fetal sheep recipients. These three pieces of data demonstrate that this approach resulted in gene transfer to *bona fide* HSC, yet we never observed leukemogenesis in any of these animals. Given that sheep have a lifespan of roughly 10 years, this study should more or less approximate a 35-year follow-up in "human years". The difference between our study and the clinical trial (aside from the obvious species difference) that likely explains the differing outcome is the differing transgene. In our experimental proof-of-concept studies, we employed marker genes to facilitate tracking and quantitation of gene-marking in various tissues. In the clinical trial for X-SCID, the vector encoded the therapeutic common gamma chain (γc) gene (IL-2RG), as this was the gene defect causing X-SCID. Subsequent studies revealed that the observed leukemogenic event in these patients was likely the result of a combinatorial effect of both the insertion of the vector in close proximity to the LMO-2 gene (which has, itself, been associated with T-cell leukemias) and a growth advantage conferred on the transduced cells by the high expression levels of the therapeutic γc gene [425–428]. Further adding to the concerns regarding insertional mutagenesis is a study recently presented at the 2019 ASGCT meeting in which the authors describe the occurrence of oncogenesis in an X-linked CGD patient treated with γ-retroviral-modified HSC [429]. This study represents the first report of the occurrence of G to A hypermutation occurring during the processes of reverse transcription and integration leading to altered expression of a neighboring cellular gene and oncogenesis. This most recent report provides a sobering lesson in the complexities of gene therapy risk assessment, which is still a relatively new and rapidly evolving field.

Looking specifically at IUGT, to-date there has been only one report of oncogenesis after prenatal gene delivery. In their study, Themis et al. reported a high incidence of postnatal liver tumors in mice following prenatal

injection with a third-generation equine infectious anemia virus (a lentivirus) vector. These tumors were not seen in mice that received a very similar vector constructed on an HIV backbone [430]. The authors did not identify the genomic insertion sites in these animals, so it remains unclear whether insertional mutagenesis was the cause of the observed tumor formation. Nevertheless, this important study demonstrates that the fetus may be particularly sensitive to tumorigenesis induced by certain vectors.

In another recent study, Chan et al. made the surprising finding that long-term expression of vector-encoded coagulation factors IX and X following liver-directed IUGT with AAV-5 or AAV-8 vectors in NHP fetuses at ~0.4 gestation was largely due to the genomic integration of the AAV vectors within the genome of the recipients' hepatocytes. Specifically, 57%–88% of AAV sequences that were retrieved from recipient hepatocytes exhibited random genomic integration of the AAV genome [431]. Despite several reports to the contrary [432,433], it has long been the accepted dogma that AAV vectors integrate only very rarely, if at all, into the host genome following transduction [434,435]. As such, these findings are particularly surprising and troubling from a safety standpoint, as they suggest that insertional mutagenesis may also be a possibility with AAV vectors. Indeed, two studies in murine models have provided evidence that AAV integration in hepatocytes can, under the right conditions, lead to oncogenesis [436,437]. Collectively, these experimental and clinical findings suggest that preclinical assessment of the risk of insertional mutagenesis following IUGT will require very carefully designed studies with the actual vector to be employed for the pending clinical trial, in an animal model that has been thoroughly validated in the setting of the target disease.

Potential risk to fetal germline

While gene transfer to the vast majority of the fetal tissues would be desirable for correcting diseases, such as the hemophilias, that would benefit from widespread systemic release of a secreted transgene product, PCR analyses of sheep that had received IUGT also revealed that the fetal reproductive tissues often contained the vector sequences, raising the troubling possibility that the vector may have reached the developing germline [196]. In the human fetus the primordial germ cells (PGC) are compartmentalized in the gonads at 7 weeks of gestation [438]. As such, the germline should only be accessible through the vascular system, and targeted gene therapy that is administered after this time period should not affect the germline. Nevertheless, the possibility of inadvertent germline gene transfer is clearly a major safety concern and a bioethical issue, and as such, this critical issue needed to be examined in greater detail.

Since prior studies had demonstrated that both the embryonic germline [439–442] and isolated PGC [443] can readily be infected with γ-retroviral vectors and pass the vector genetic material to subsequent generations in a Mendelian fashion as part of the permanent genome, we employed a three-tiered approach to scrutinize this important issue in detail in the sheep model of IUGT: (1) tissue sections prepared from the in utero treated animals were examined by immunohistochemical staining; (2) we performed genetic analysis on isolated sperm cells from the treated males; and (3) we conducted breeding experiments in a limited number of animals and analyzed the resultant offspring [193,195,196,222]. These studies indicated that although the fetal ovaries appeared to be unaffected by this approach to IUGT, numerous cells within the developing fetal testes were modified, including interstitial cells, Sertoli cells, and small numbers of both immature germ cells within the forming sex cords and the resultant sperm cells.

Importantly, however, gene-modified germ cells were only observed in two of the six animals examined in our studies, and, in these two animals, the incidence of germ cell modification was well below the theoretical level of spontaneous mutation within the human genome [444]. This low frequency of modification coupled with observations that genetic alterations to the germ cells may produce deleterious effects, placing them at a disadvantage during fertilization, suggest that the likelihood of any genetic alterations present being passed to subsequent offspring would be extremely unlikely. In agreement with this supposition, we did not observe transfer of the vector sequences in any of the 10 offspring we studied, even when both the parents had received IUGT. This is clearly an issue that will need to be addressed in greater detail, nevertheless, prior to moving IUGT into clinical trials. This need for further investigation is underscored by the fact that, in other studies employing lentiviral vectors in NHPs, Tarantal et al. observed modification of the female germline, but no effect upon the male germ cells [192]. Thus the issue of germline safety will likely have to be investigated in more than one preclinical model, employing the specific vector being considered for clinical use, in order to obtain an accurate assessment of the risk posed by the procedure.

While these studies in different animal models both suggest that the frequency of germline transduction is low and related to gestational age and mode of vector administration, they also suggest that low-level transduction of germ cells after systemic administration of integrating vector to the fetus may not be entirely avoidable. As such, when contemplating ultimate clinical application of IUGT, careful consideration may need to be given to

determining what frequency of potential germline transduction is considered acceptable in the context of treating a severe, perhaps life-threatening genetic disorder.

Conclusion and future directions

Although great progress has been made, there are many remaining hurdles for IUTx and IUGT to overcome before they become mainstream clinical modalities. Challenges for IUTx are primarily related to overcoming the competitive barriers to engraftment in the fetus, and better defining the innate and adaptive immune limitations to engraftment in large animals and humans. As our understanding of stem-cell biology and the ontogeny of hematopoiesis and the hematopoietic niche ontogeny advance, the therapeutic applications of IUTx will likely expand from their current narrow focus to include the treatment of nonhematopoietic diseases. While the strategy of prenatal tolerance induction for facilitation of postnatal HSC transplantation is nearing clinical application and has great potential to benefit many patients, the development of an IUTx strategy that allowed a single-step treatment to achieve therapeutic levels of engraftment would be ideal, and it would likely propel this promising therapy into the clinic.

IUGT holds even greater promise for treating/curing essentially any inherited genetic disease. From our findings in the sheep model and those of other groups exploring IUGT in sheep, mice, and NHPs, it is clear that the direct injection of viral vectors into the developing fetus can be an effective way of delivering an exogenous gene and achieving long-term expression in multiple tissues, suggesting IUGT may one day be a viable therapeutic option for diseases affecting any of the major organ systems. Moreover, even if not curative, IUGT would be ideal for a disease like HA, since lifelong immunologic tolerance could be induced to FVIII, thus overcoming the immune-related hurdles that currently hinder postnatal treatment of this disease.

Given its great potential, the International Fetal Transplantation and Immunology Society recently facilitated a panel discussion of international experts to consider the scientific, clinical, and ethical issues related to prenatal gene transfer for the treatment of genetic diseases. The goal of the session was to revisit the 1999 NIH Recombinant DNA Advisory Committee Policy Conference recommendations [445], examine the current status of IUGT, identify gaps in knowledge in need of resolution, achieve an agreement among the members of the international scientific community regarding target diseases, procedural- and vector-related safety considerations, and define a roadmap (which was recently published [446]) for developing clinically translatable IUGT therapeutic approaches. This discussion was prompted, in part, by two recent preclinical studies that have shown the remarkable therapeutic potential of IUGT and have validated the advantages to correction prior to birth. In the first of these studies [447], Massaro et al. demonstrated the first successful application of IUGT in a mouse model of acute neuronopathic Gaucher disease (nGD). nGD is a human genetic disease in which marked irreversible neurological pathology already manifests in utero. The acute childhood form of nGD is lethal and is untreatable, since enzyme cannot cross the blood–brain barrier. In this remarkable study, the authors showed that IUGT with an AAV vector encoding glucocerebrosidase (GC) reconstituted neuronal GC expression, abolished neurodegeneration and neuroinflammation, and enabled the mice to be fertile, fully mobile, and to live for up to at least 18 weeks. In a second recent landmark study [448], Chan et al. reported that in utero delivery of AAV-5 or -8 vectors encoding human coagulation factor IX (hFIX) or X (hFX) under the control of a liver-specific promoter into NHP fetuses at $\sim$0.4 gestation resulted in sustained curative levels of hFIX and hFX and induced durable immune tolerance to the coagulation factors, in the absence of clinical toxicity, supporting IUGT's therapeutic potential for early-onset monogenic disorders.

After extensive deliberation the panel agreed that IUGT, using an ex vivo or in vivo direct approach, remains the best therapeutic strategy for treating, and ideally curing, a wide range of genetic disorders early in gestation, such as hemophilia, lysosomal storage disorders, and spinal muscle atrophy. The panel also set forth several criteria they felt should be met in order for IUGT to be considered. The first of these was that reliable prenatal enzymatic [449] or genetic diagnosis, and a strong genotype/phenotype correlation impacting clinical prognosis must exist for the disease being considered. Second, it was stressed that there must be a compelling reason to use IUGT, based on a need to (1) intervene during development to prevent damage caused by the disease; (2) make use of unique physiologic characteristics of the fetus, such as the more permissive blood–brain barrier, which make possible successful delivery to otherwise difficult-to-access tissues; or (3) exploit the immunologic environment at the time of treatment to prevent pre- or postnatal immune reaction to the transgene-encoded protein. It was agreed that to be considered as a good candidate for treatment by IUGT, said disease should (1) result in severe fetal morbidity and/or mortality either in utero or postnatally; (2) exhibit poor clinical outcome with existing postnatal therapies, be limited by huge economic burden, or be hindered by immunologic responses/rejection; or (3) not be associated with other serious abnormalities or disorders that are not corrected by the therapeutic gene.

The panel also acknowledged that, as with any fetal intervention, infection, preterm labor, and fetal loss are all

theoretically possible. However, a considerable amount of clinical data exist that provide unassailable proof that the human fetus can be accessed multiple times with an extremely low procedure-related risk. Indeed, the technical aspects pertaining to systemic injections using fetal umbilical vein access or IP injection are safe, straightforward, mainstream procedures [450]. Maternal safety was recognized to be a critical consideration for IUGT, particularly with respect to possible exposure to the viral vectors or gene products infused into the fetus. Although the procedure has proven to pose minimal risk to the mother, it was stressed that infection and impairment of future ability of the mother to reproduce should be considered, as should the possible immunological consequences/risks to the mother as a result of exposure to a viral vector and/or its encoded protein.

It was agreed that many of the concerns and/or limitations that were identified may well be solved in the future with new technologies that allow nonviral delivery, and/or specific cell targeting and gene-editing to minimize the risk of off-target events, or by the use of an ex vivo approach to IUGT.

Brief mention was also made of how the development of gene-editing technologies such as zinc-finger nucleases, TAL effector nucleases, and Clustered Regularly Interspaced Short Palindromic Repeats/CRISPR associated protein (CRISPR/Cas) [451,452] has the potential to revolutionize the whole way in which gene therapy is conceptualized. The ability to modify a chosen sequence in its native genomic locus offers incredible advantages, in terms of both safety and efficacy, over current "gene-addition," and would completely eliminate existing concerns related to random genomic integration, inappropriate levels or tissue distribution of transgene expression, and inadvertent germline alteration. As such, these newer technologies are likely to be a key component of future IUGT studies/trials. Indeed, recent work from the Peranteau group has provided compelling proof-of-principle for the ability to effectively use genome-editing technology to correct mutations in metabolic genes and in genes related to monogenic lung disease prior to birth in mice [453,454]. These groundbreaking studies thus provide a glimpse into the exciting future of IUGT and its vast potential to correct genetic diseases.

In closing, IUTx and IUGT hold great promise for treating/curing many inherited genetic diseases. At the present time, these in utero interventions stand at a critical juncture [186] and have vast potential for dramatically improving human healthcare. Many of the most daunting obstacles have recently been overcome in animal models, or are at least better understood, which has reinvigorated this exciting field. Looking specifically at IUGT, gene delivery technologies have evolved significantly in the last decade, such that many of the most daunting obstacles have now better been identified and this exciting field has been reinvigorated. There is no doubt that surpassing the few remaining hurdles to allow clinical implementation of these therapies will dramatically change the whole paradigm for the way we perceive and treat many genetic disorders.
