While significant progress has been made toward our ability to fabricate tissue in the laboratory for the reconstruction of defects in the oral and maxillofacial skeleton, considerable challenges remain before these techniques are embraced as a feasible clinical modality. Some of the issues pertain to TE itself, such as the ability to identify and harvest a suitable population of cells capable of fulfilling the functions of the desired tissue, supporting cellular differentiation and reproduction through physiological levels of growth and attachment factors, promotion of vasculogenesis, and the development of matrices that fulfill the physical requirements of a skeletal site. Since many of the structures in the oral and maxillofacial region are composed of multiple tissue types, the ability to engineer composite structures is also important, as is consideration of the unique environment that tissue-engineered constructs are exposed to. Even as these demands are met, other factors must be considered before TE tissue can be adopted as part of a reconstructive surgeon's armamentarium. Existing reconstructive techniques were originally based on macroscopic concerns for restoring the shape and size of a missing structure. Since TE is essentially based upon cells, a microscopic appreciation of the function of a particular tissue type must first be derived. At this time, characterization of the function and pathological degradation of many of the structures in the oral and maxillofacial region is unfortunately deficient. In other words, before the replacement for a structure can be appropriately engineered, a better understanding of the function and local environment must first be achieved. This is particularly true of defects produced by on-going pathological processes where correction of the condition must precede replacement with yet another biological substrate. The future of oral and maxillofacial TE therefore lies in the hands of close collaborations between engineers and clinicians together.

Chapter 66

Periodontal tissue engineering and regeneration

Xiao-Tao He, Rui-Xin Wu and Fa-Ming Chen

State Key Laboratory of Military Stomatology and National Clinical Research Center for Oral Diseases, Department of Periodontology, School of Stomatology, Fourth Military Medical University, Xi'an, P.R. China

Introduction

Periodontitis is an infectious disease caused by pathogenic microorganisms in the subgingival biofilm, in combination with other risk factors, such as aging and cigarette smoking. Untreated periodontitis results in irreversible destruction of the tooth-supporting tissues, including periodontal ligament (PDL), alveolar bone, and cementum, and may lead to early tooth loss [1]. It has also been linked to many systemic disorders, such as diabetes, rheumatoid arthritis, neurodegenerative disorders, and cardiovascular complications, and has been associated with adverse pregnancy outcomes [2,3]. Consequently, periodontal disease significantly impacts a patient's quality of life and financially impacts both patients and the public healthcare system. Blocking the progression of periodontitis has been achieved by mechanically removing bacterial biofilm with scaling and root planning procedures. Although the elimination of periodontal pathogens may improve clinical attachment levels (CAL) of a tooth, reconstruction of the support and function of the affected tooth attachment apparatus represents an important therapeutic endpoint that has been an ongoing challenge in clinical periodontitis treatment [4]. Conventional treatment is generally unable to promote the regeneration of the damaged periodontal structures. Although numerous periodontal regenerative treatments have been established, such as techniques that use bone grafting, guided tissue/bone regeneration (GTR/GBR), enamel matrix derivative (EMD), and platelet-rich plasma (PRP), a positive outcome is difficult to predict, and in principle, these existing therapeutic paradigms fall short of reaching a consistent and complete regeneration of the periodontium, particularly in cases where the disease has caused large defects in the periodontal tissue [5].

The recognition that periodontal tissues possess the capacity, albeit in a very limited manner, to repair/regenerate has led to substantial efforts focused on understanding the biological basis for this activity and employing the accumulated knowledge to devise tissue-engineering technology that predictably promotes functional periodontal regeneration, that is, the restoration of all components of the periodontium and the reestablishment of their appropriate connections [6]. Tissue engineering, which is a term often used interchangeably with regenerative medicine, merges the fields of life sciences and engineering biotechnologies and aims to orchestrate body regeneration by specifically controlling the biological environment or developing biological substitutes to restore, maintain, or improve tissue function. The "engineering" of irreversibly damaged tissues is progressing toward reality by improvements in our understanding of wound repair and recent advancements in mysenchymal stem-cell (MSC) biology and biomaterials science. Such advancements help to target molecules and pathways in an effort to restore the regenerative capacity of tissue, and the periodontium could be considered a prime candidate for such endeavors [7]. Applied to periodontal therapy, tissue engineering offers the opportunity to improve periodontal regeneration in a more predictable and qualitative but possibly less invasive manner than currently available regenerative procedures [4,6].

It is an inherent belief in the current concept of periodontal tissue engineering that naturally occurring tissue regeneration can be reproduced in vitro. Clearly, a tissue-engineering approach to periodontal regeneration will need to utilize the regenerative capacity of stem cells residing within the periodontium (or other related tissues) and would involve the isolation of such cells and their

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00068-X

subsequent proliferation/differentiation within a three-dimensional (3D) framework followed by implantation into the defect [7]. The in vitro design of such therapeutics primarily considers the delivery of appropriate cells in sufficient quantity, the sustained release of chemical and mechanical signals that are often popularly termed growth factors (GFs) in a near-physiological level, and the engineering of extracellular matrix (ECM)-mimicking biomaterials with such desirable properties as macrostructures and microstructures, biodegradability, and biocompatibility [6]. The scaffold not only acts as a delivery vehicle for the cells to the site of regeneration, but it also plays an essential role in cell attachment, space retention, determination of morphological features, and recruitment of oxygen and nutrients [8]. After in vivo transplantation, blood supply, mechanical loading, and pathogen control will become the critical factors that influence the predictability of final outcome. New vascular networks promoted by angiogenic signals provide the nutritional base for periodontal tissue growth and homeostasis, while appropriate mechanical loading would be essential for the development of highly organized, functional PDL fibers [9]. Finally, because of the microbial load at the periodontal lesion, strategies to control infection and host response are required to optimize periodontal regeneration [4].

We must be aware that periodontal tissue engineering is now still in its early stage, with no current paradigm that takes all the aforementioned factors into proper consideration. If periodontal regeneration relies on the in vitro conditioning of a cell-seeded construct for implantation, the transplants should be designed to incorporate biochemical and biophysical signals that recreate important in vivo stimuli, albeit in simplified form, to create a tissue functionally equivalent to native periodontal tissue in terms of composition, biomechanical properties, and physiological performance [10,11]. Although in vitro periodontal tissue engineering has greatly increased our understanding of cellular behavior and cell-material interactions, this methodology is often unable to recreate tissue with the hierarchical organization and vascularization found within the native periodontium [12]. Thus most, if not all, efforts in this field are focusing on in vivo tissue-engineering strategies, in which the traditional triad (cells, regulatory signals, and scaffolds), or a combination thereof, is directly implanted at the damaged tissue site, or within ectopic sites capable of supporting neotissue formation, instead of attempting to recreate tissue replacements/constructs ex vivo [7]. In the broader scope of tissue engineering, cell-free methods can also be considered; nonetheless, it is widely accepted that most of the developing and established strategies rely on the use of cells of different origin. In vivo tissue engineering via cell transplantation or biomaterials design may offer a preferential route for regeneration of periodontal tissue with distinct advantages over in vitro methods that are based on the specific location of endogenous cultivation, recruitment of autologous cells, and patient-specific regenerated tissues [13]. In the future, these exciting developments are likely to help reconcile the clinical and commercial pressures on tissue engineering [12]. However, even if in vivo tissue-engineering strategies are to be used, many issues still that need to be addressed before such strategies become routine in periodontal practice. In particular, the events following cell transplantation are poorly understood. Furthermore, the efficacy and safety of prospective tissue-engineering-based therapies have not been fully evaluated, and the risks have already been underscored by several clinicians and researchers [14].

Approaches to the regeneration of periodontal tissue have made some progress recently, and these paradigms provide useful experimental models for the evaluation of future strategies for treating other connective tissue diseases. This chapter explores the potential cell types, signaling molecules, biomaterials, and various technologies based on the concept of tissue engineering for periodontal regeneration. In addition, possible new directions that need to be exploited to make periodontal tissue engineering a clinical success are highlighted.

Stem cells for periodontal bioengineering

Stem cells are the foundational cells for every organ and tissue, and they have a remarkable self-renewal ability, in that they can divide to replenish any other cell type, thus functioning as a part of a repaired tissue. The healthy PDL harbors stem-cell niches throughout adulthood and exhibits a limited regenerative capacity. However, in a diseased periodontal environment, the lack of robust stem cells renders the use of ex vivo expanded/manipulated stem cells a necessity [6,15]. In this context, periodontal cell therapy involves the treatment of periodontitis by transferring new cells into a defect site with the goal of improving the regeneration process [16]. The transplanted cells may participate in the repair of damaged periodontium, serving as building blocks by differentiating into multiple cell types, or regulate repair via secretion of growth or cellular signals, instead of, or in addition to, directly participating in regeneration of the tissue [17]. Both intraoral and extraoral MSCs have been evaluated for the treatment of periodontal disease and for the regeneration of damaged periodontium [4,14].

Intraoral mysenchymal stem cells

Of note, several cell populations with stem-cell properties have now been harvested from different tissues in and around a tooth and subjected to enrichment and expansion techniques (Fig. 66.1). These populations generally

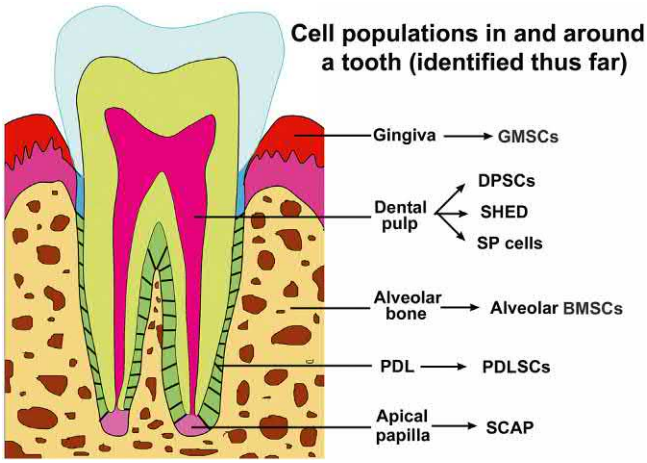

FIGURE 66.1 Selected stem/progenitor cells identified thus far in and around a tooth. PDLSCs, Periodontal ligament stem cells [18]; DPSCs, dental pulp stem cells from pulp of permanent teeth [19]; SP cells, side population cells isolated from dental pulp tissue [20]; SHED, stem cells from human exfoliated deciduous teeth [21]; SCAP, stem/progenitor cells from apical papilla [22,23]; GMSCs, mesenchymal stem cells from gingiva [24–26]; alveolar BMSCs, bone marrow stromal cells isolated from alveolar bone marrow [27,28].

include dental pulp stem cells (DPSCs) [19], stem cells from exfoliated deciduous teeth (SHED) [21], PDL stem cells (PDLSCs) [18], stem cells from apical papilla (SCAP) [22,23], dental follicle stem cells (DFSCs) [29,30], and MSCs from gingival tissues [24,25] and alveolar bone [27,28]. These stem/progenitor cells can be obtained with ease from medical waste, such as teeth extracted for orthodontic, impaction or irreversible periodontitis reasons, exfoliated deciduous teeth, or even gingiva that was removed for hyperplastic or esthetic reasons. The ease of access makes them an important source of autologous stem cells for use in the regeneration of PDL and bone lost in periodontal disease. These stem-cell populations have an advantage over other stem cells, such as bone marrow–derived MSCs (BMMSCs), because they can be obtained from patients in the dental clinic rather than requiring an invasive bone marrow aspiration procedure at a secondary clinic [8]. Because of their particular characteristics of proliferation, differentiation, and plasticity, dental stem cells have also enabled significant progress toward clinical orthopedics and oral maxillofacial bone reconstruction [31–33]. Thus, while not largely exploited, it can be seen that the humble tooth has an important role to play in the development of future regenerative therapies [34].

Periodontal tissue–derived stem cells

When considering application to periodontal regeneration, stem cells derived from the tissues surrounding the teeth, that is, the periodontium should be considered the first choice [14]. The PDL is a fibrous connective tissue that contains specialized cells located between the bone-like cementum and the inner wall of the alveolar bone socket. Just as PDL is essential for osteogenesis and cementogenesis during development and remodeling, cells derived from this tissue are supportive for the healing response to injury [35]. Early observations indicated that the PDL has a regenerative capacity and that a population of multipotent progenitor cells may exist within this tissue [36]. Transplantation of PDL-derived cells has shown the potential to regenerate bone and periodontal attachment apparatus in vivo [37–39]. PDLSCs were first isolated in 2004 and have been shown to give rise to adherent clonogenic clusters resembling fibroblasts [18]. They are positive for the stem-cell markers STRO-1 and CD146, and they are capable of developing into adipocytes, osteoblast-like cells, and cementoblast-like cells in vitro as well as producing cementum-like and PDL-like tissues in vivo [18,40]. In recent years, sources of stem cells from human [41], swine [42,43], and canine PDL tissues [44,45] are reported to be the most potent for periodontal tissue regeneration. Furthermore, in vitro studies have also found that PDLSCs were able to differentiate into mesodermal (i.e., adipocytes, osteoblasts, chondrocytes), ectodermal (i.e., neurons), and endodermal (i.e., hepatocytes) lineages [46]. Meanwhile, PDLSCs have also shown the capacity to differentiate into vascular cells, forming blood vessel-like structures in rats [47]. These findings suggest that the PDL constitutes an important stem-cell source, not only for the regeneration of periodontal tissues, but also for the regeneration of other tissues and organs, making them highly amenable for use in periodontal regeneration. The PDL is under constant strain from the forces of mastication, and thus PDLSCs are likely to play an endogenous role in maintaining PDL cell (PDLC) numbers. This might explain why they are better than other dental stem-cell populations at regenerating the complex structures of the periodontium [40,44,45]. Despite the considerable promise that the PDLSCs hold for periodontal regenerative medicine, outcomes obtained in animals have not been translated into the treatment of periodotitis in humans [48,49]. Hence, a need still exists for further characterization and validation of PDLSCs for clinical use [50].

The alveolar bone is a main part of the tooth-supporting apparatus, functioning as an anchorage of the tooth root to the alveoli and resorbing the forces generated by the function of mastication. Progenitor cells responsible for alveolar bone formation lay in the periosteal region, the PDL, or around the blood vessels. Alveolar bone marrow is considered to be a useful and easily accessible source of bone-related progenitor cells; alveolar MSCs have an osteogenic potential that is similar to, or even more responsive than, cells derived from the iliac crest,

although alveolar MSCs show poor chondrogenic or adipogenic potential [27]. Recently, putative stem cells from human PDL on the alveolar bone surface were isolated, characterized, and provisionally named as "alveolar PDLSCs." Interestingly, these "alveolar PDLSCs" exhibited a strong proliferative capability, expressed high percentages of MSC markers, and were found to have a higher osteogenic/adipogenic differentiation potential than those from the PDL of the root surface [28]. However, further studies need to be carried out to demonstrate that the reported "alveolar PDLSCs" are PDL-derived.

The periosteum is also considered to be a suitable cell source for periodontal regeneration [51]. Mizuno et al. [52] grafted autologous cultured cell membrane that was derived from periosteum peeled from the mandibular body into a mechanically created class III furcation defect in dogs. Proper regeneration of multiple periodontal tissues was observed 3 months after the surgery. In addition, a treatment for human periodontal disease using periosteum-derived cells has already been conducted. It was shown that cultured periosteum combined with PRP and porous hydroxyapatite (HA) granules induced significantly more favorable clinical improvement in infrabony periodontal defects, when compared with the control group (PRP with HA) [53].

The cementum is a specialized calcified substance with ultrastructural similarity to bone that covers the root surface. It is excreted by cementoblast cells within the root of the tooth and is thickest at the root apex. These cementoblasts develop from undifferentiated mesenchymal cells in the connective tissue of the dental follicle at the interface between the dentinal tissue and the PDL, and they contribute to periodontal repair/regeneration after damage. The organic ECM of cementum contains proteins that selectively enhance the attachment and proliferation of cell populations residing within the PDL space [54]. In 1998, human cementum−derived cells were isolated, cloned, and characterized in vitro and in vivo. These cells are capable of differentiating and forming mineralized tissue that exhibits several features identical to cementum when transplanted into immunodeficient mice, although different from the mineralized matrix produced by human BMMSCs [55]. In a proof-of-concept investigation, cementoblasts showed a marked ability to induce mineralization in periodontal wounds in a rodent periodontal fenestration model when delivered to the defects via biodegradable polymer sponges. However, the implanted dental follicle cells seemed to inhibit periodontal healing [56]. These results confirm the selective behaviors of different cell types in vivo and support the role of cementoblasts as a tool to better understand periodontal regeneration and cementogenesis.

The human gingiva is the oral mucosal tissue that surrounds the teeth and forms a mucoperiosteum covering the alveolar bone. Since the epithelial layer shows a unique fetal-like scarless healing process after wounding and has the capacity for continuous renewal, it is anticipated that this tissue could also be a source of stem cells. Recently, cells with MSC properties have been isolated from gingival tissues (GMSCs) and characterized [25,26,57]. GMSCs are easy to isolate and homogeneous, and they proliferate more quickly than BMMSCs in the absence of GFs. GMSCs display a stable morphology and do not lose MSC characteristics at higher passages. In addition, they maintain normal karyotype and telomerase activity in long-term cultures and are not tumorigenic, suggesting that they are superior to BMMSCs for cell therapy in regenerative medicine [24]. Very recently, the in vivo efficacy of utilizing GMSCs in bone regeneration was demonstrated in a mandibular defect as well as a critical-sized calvarial defect model in rats [58]. Furthermore, these cells gave rise to high-quality iPS cells, which suggests that gingival tissue is also a promising cell source for investigating the basis of cellular reprograming and pluripotency for future clinical applications [59].

Stem cells from apical papilla

The apical papilla tissue is only present during root development before the tooth erupts into the oral cavity [60]. A unique population of dental stem cells known as SCAP is located at the tips of growing tooth roots. These cells form adherent clonogenic clusters, and similar to other MSC populations, they are capable of differentiating into adipocytes and odontoblasts/osteoblasts in vitro [23]. By cotransplanting SCAP cells, to form a root, and PDLSC, to form a PDL, into tooth sockets of mini pigs, dentine and PDL were formed [22]. These findings provide support for the use of combined MSC populations in root and periodontal regeneration. Most human tissues from early in their development are not clinically available for stem-cell isolation; however, because roots develop postnatally, the root apical papilla is accessible in dental clinical practice from extracted wisdom teeth. Thus a very active source of stem cells with embryonic-like properties can be readily obtained. Further experiments on the properties of these cells obtained from human teeth following expansion in culture are needed.

Dental follicle stem cells

The dental follicle is a loose mesenchymal tissue surrounding the developing tooth germ that participates in the formation of periodontal progenitor cells. It is believed that this tissue contains stem cells and lineage-committed progenitor cells or precursor cells for cementoblasts, PDLCs, and osteoblasts [61]. The presence of stem

cells in the dental follicle (DFSCs) of human third molar teeth was demonstrated in 2005 [30], suggesting an alternative population of dental stem cells capable of differentiating into cells of the periodontium [62]. These fibroblast-like, colony-forming, and plastic-adherent cells express stem-cell markers (STRO-1 and nestin) and can be maintained in culture for at least 15 passages. STRO-1-positive dental follicular progenitors have been shown to differentiate into cementoblasts in vitro [62] and to form cementum in vivo [29]. Current evidence has shown that immortalized DFSCs were able to recreate PDL-like tissues that expressed periostin, Scx, and type XII collagen, as well as the fibrillar assembly of type I collagen when transplanted into immunodeficient mice [63], while EMD [64] or dentin noncollagenous proteins extracted from dentin [65] could stimulate DFSCs to differentiate into cementoblast lineages. Similar to SCAP, DFSCs represent cells from a developing tissue and might therefore exhibit a greater plasticity than other dental stem cells. However, further research is needed to explore the properties and potential uses of both SCAP and DFSCs.

Hertwig's epithelial root sheath

Considering the difficulty of regenerating functional cementum in periodontal tissue engineering by common practice, some researchers recently have tried to take inspiration from the process of normal tooth root development [66]. Hertwig's epithelial root sheath (HERS) is a bilayer epithelial sheath located at the cervical loop of the enamel organ, which separates dental follicle from dental papilla. Emerging evidence has shown that HERS cells can differentiate into cementum-forming cells via epithelial−mesenchymal transition and induce odontoblast differentiation of dental papilla via epithelial−mesenchymal interaction [67]. As the epithelial remnants of HERS, epithelial cell rests of Malassez are the only odontogenic epithelial cells in mature PDL tissues. Accumulative studies suggested that Malassez play essential roles in maintaining PDL homeostasis, such as prevent ankyloses and root resorption. More importantly, some of its subpopulations harbor features of stem cells, which show the ability to form calcium in osteoinductive microenvironment [68]. Although the study of HERS and Malassez is still at initial stage, these researches can broaden our knowledge on the interactions between tooth development and regeneration.

Stem cells from dental pulp or exfoliated deciduous teeth

The first human dental stem cells were isolated from dental pulp tissue of extracted third molar teeth (DPSCs) and were characterized relative to BMMSCs [19]. DPSCs were found to be highly proliferative, clonogenic cells capable of differentiating into odontoblast-like cells and forming dentin/pulp-like complex when implanted into immunocompromised mice. Subsequently, human MSCs were isolated from exfoliated deciduous teeth and were observed to induce bone and dentin formation in vivo. Furthermore, compared with DPSCs or BMMSCs, SHED grow and proliferate more rapidly and have a higher number of population doublings [21]. Further data demonstrate that pulp side population cells maintain self-renewal and multipotency for dentinogenesis, chondrogenesis, adipogenesis, and neurogenesis [20]. Although there is no evidence that supports the use of DPSCs to regenerate PDL, they showed the highest osteogenic potential among BMMSCs, PDLSCs, and periosteal cells, indicating that they may form a useful cell source for bone reconstruction around teeth and dental implants [69,70]. In 2009, the clinical trial of alveolar bone reconstruction using DPSCs was successfully carried out, and the data suggest that a DPSC/collagen sponge biocomplex can completely restore human mandible bone defects [31]. Interestingly, the implantation of autologous SHED has been applied to regenerated whole dental pulp in human teeth with injured pulp necrosis [71]. Taken together, these results suggest a potential role for DPSCs in bone and dentin regeneration; however, significant further work is required in this area.

Extraoral mysenchymal stem cells

Extraoral MSCs, that is, nondental stem cells, such as BMMSCs and adipose-derived stem cells (ASCs), have also been investigated as alternative cell sources for periodontal regeneration and bioengineering [72−75].

Bone marrow−derived mysenchymal stem cells

BMMSCs are the most widely investigated MSCs in tissue engineering and regenerative medicine because they are easily accessible, their isolation is straightforward, they can be biopreserved with minimal loss of potency, and they have shown no adverse reactions to allogenic versus autologous MSCs transplants. These cells are clonogenic and have demonstrated the ability to form bone and cartilage in vivo. Because of their differentiation potential, BMMSCs have been used in various phases of clinical application, particularly in orthopedics [76]. Indeed, BMMSCs can efficiently regenerate not only bone tissue but also periodontal tissue in various animal models [77]. Recent data have shown that bone marrow progenitor cells can communicate with dental tissues and become tissue-specific mesenchymal progenitor cells to maintain tissue homeostasis [78]. Animal experiments have demonstrated that autotransplantation of BMMSCs

induced periodontal regeneration in experimental class III furcation defects, and that the defects were regenerated with cementum, PDL, and alveolar bone in the MSC-atelocollagen groups. Less periodontal tissue regeneration was observed in the control group than in the MSC-atelocollagen groups [72]. In addition, transplanted BMMSCs labeled with green fluorescent protein (GFP) were detectable by immunohistochemical analysis 4 weeks after transplantation. The periodontal defects were almost regenerated with periodontal tissue. Cementoblasts, osteoblasts, osteocytes, and fibroblasts of the regenerated periodontal tissue were positive for GFP, which suggested that transplanted BMMSCs could survive and differentiate into periodontal tissue cells, resulting in an enhancement of periodontal tissue regeneration [79]. Moreover, clinical evidence indicated that periodontal tissue could be successfully regenerated using autologous BMMSCs combined with PRP [32]. Significantly, when evaluated in periodontal defects in dogs, cryopreserved MSCs showed no altered regenerative capacity compared with freshly isolated MSCs when applied to periodontal regeneration [80]. Notably, a few clinical cases showed the successful treatment of challenging periodontal defects with a novel cellular allograft that contains native MSCs and osteoprogenitor cells [81]. These data suggest that bone marrow is an excellent candidate source of MSCs for periodontal regeneration. Nonetheless, the established shortcomings in relation to the isolation of BMMSCs, that is, pain and morbidity associated with bone marrow harvest, complicated procedures, as well as low harvested cell number, all mean that the use of this cell population in periodontal regeneration in the clinical setting will be a significant challenge in the future. Consequently, researchers have shifted their efforts on assessing alternative sources of MSCs for periodontal therapies [8].

Adipose-derived stem cells

Adipose tissue is an abundant source of MSCs. ASCs can be readily harvested in large quantities and can be obtained with relative ease with low donor site morbidity. ASCs have adipogenic, myogenic, osteogenic, and chondrogenic potential, and they are very angiogenic in nature. These multipotent cells can be utilized in regenerating diseased or damaged tissue throughout the body, including the periodontium. More importantly, the safety and efficacy of ASCs have been demonstrated in numerous preclinical studies, supporting the use of these cells in curing human disease. Although ASCs originate from mesodermal lineages, recent preclinical studies have demonstrated that the use of ASCs in regenerative medicine is not limited to mesodermal tissue but can also extend to both exodermal and endodermal tissues and organs [74]. Advances in ASCs in regenerative medicine during the past 10 years have paved the way to improved periodontal regeneration. For example, 8 weeks after the transplantation of ASCs mixed with PRP into rat periodontal defects, new PDL-like and alveolar bone−like structures were formed, which implies that ASCs could promote periodontal regeneration in situ [75]. In a canine model of periodontal tissue regeneration, ASCs were transplanted with PRP into dental root bifurcation defects. ASC and PRP transplantation were found to prevent epithelial invasion into the defect area after 4 weeks, while newly induced bone was observed at the site of implantation after 8 weeks [74]. Recently, freshly isolated, uncultured stromal vascular fraction of adipose tissue [82], syngeneic or allogeneic adipose−derived cells [83,84] all have been suggested as a source of autologous progenitor/stem cells, offering a practical, promising candidate for future periodontal tissue engineering or cell-based periodontal therapy.

Selection of cell types

Although both dental and nondental MSCs for periodontal regeneration are promising (Table 66.1), we must be aware that mesenchymal cell populations from different tissues display distinct biological properties [14]. Even if they carry common genetic markers, they are likely to be conditioned by their specific microenvironment and to be committed toward a specific differentiation pathway. Dental stem cells are isolated from specialized tissue with potent capacities to differentiate into odontogenic cells. However, they also have the ability to give rise to other cell lineages similar to, but different in potency from, that of BMMSCs [60]. When comparing different tissue-derived stem-cell sheets for periodontal regeneration in a canine 1-wall defect model, PDLSCs resulted in more newly formed cementum and well-oriented PDL fibers than other cells (BMMSCs and alveolar periosteal cells). In addition, nerve filament was observed in the regenerated PDL tissue only in the PDLC group. The amount of alveolar bone regeneration was highest in the PDLC group, although it did not reach statistical significance among the groups. These results indicate that PDLSCs combined with a β-tricalcium phosphate (β-TCP)/collagen scaffold serve as a promising tool for periodontal regeneration [45]. In another dog model with advanced periodontitis, PDLSCs were also demonstrated to be the most favorable candidate for cell therapy when compared to DPSCs and DFSCs. Autologous PDLSCs showed the best regenerative capacity of PDL, alveolar bone, and cementum as well as peripheral nerve and blood vessel [44]. Except for PDLSCs, it remains to be determined which source of MSCs will be most suitable for regenerative periodontal therapy. The use of dental follicular cells is

likely to be limited by the availability of tooth germs, and nondental stem cells may require the transfer of genes to enhance their odontogenic potential. Although the best stem-cell source is yet to be identified, the prospect of using these cells for regeneration represents a step forward in the development of more predictable biologically based therapies for the periodontium [77].

Signaling molecules

GFs mediate crosstalk between cells and their microenvironment via their autocrine and paracrine effects [87]. They initiate their action by binding to specific receptors on the surface of target cells and their chemical identity, concentration, duration, and context contain information that dictate cell fate for safe and effective regeneration of functional tissue. Hence, the importance of GFs in tissue engineering is unsurprising, considering their importance for tissue regeneration [88]. Accordingly, stimulation of osteogenesis, cementogenesis, and connective tissue formation via presentation of various signaling molecules is necessary for periodontal tissue engineering. A number of recombinant human GFs, biological agents (e.g., EMD), and a patient's own biologically active products (e.g., PRP) are now used clinically or are currently under extensive investigation, and some of them have been examined by controlled clinical studies or randomized controlled clinical trials.

Types of signals

Bone morphogenetic proteins

The bone-healing process initiated by a single molecular species of bone morphogenetic proteins (BMPs), members of the transforming GF (TGF)-beta superfamily such as BMP-2 or BMP-7, sets in motion a cascade of cellular events resulting in differentiation of progenitor cells into phenotypes involved in periodontal regeneration [89]. Current data suggest that BMP-2, BMP-4, BMP-7 (i.e., osteogenic protein-1, OP-1) and BMP-12 are potent inducers of bone formation during mandibular reconstruction, with OP-1 (occasionally BMP-2) inducing substantial cementogenesis. In this context, BMP-12 supports the reestablishment of the PDL, including regeneration of cementum and functionally oriented fibers, and prevents ankylosis and root resorption following replantation of teeth (reviewed in [89,90]). There is mounting evidence that recombinant human BMPs stimulate periodontal regeneration if applied with suitable carriers [91,92]. However, the optimal effects are modulated by a range of factors that need careful evaluation in clinical studies. Furthermore, we must be aware that severe side effects, such as ankylosis and root resorption, have also been reported [93], although these were not always in accordance with outcomes obtained by other groups [94]. Considering the results of studies indicating that the application of recombinant human BMP-2 around a periodontal defect induces bone formation but not cementum formation [95], the combined use of BMP-2 and BMP-7 might be suitable for regenerating two hard tissues: bone and cementum [96]. In addition, BMP-2 has also been used in combination with other GFs, such as insulin-like GF (IGF)-1, to synergistically enhance differentiation of PDLCs [86,97] or recombinant human β-nerve GF [98] to improve the quality and quantity of regenerated bone. Of note, the absorbable collagen sponge (ACS) carrier containing recombinant human BMP-2 is now commercially available as InFuse Bone Graft (Medtronic, Minneapolis, MN, United States) and has been applied for sinus floor augmentation and for localized alveolar ridge augmentation following tooth extraction in patients.

Platelet-derived growth factors

Platelet-derived GF (PDGF), as a serum GF for fibroblasts, has five isoforms (AA, AB, BB, CC, and DD); of these, PDGF-BB was found to be more potent than the other isoforms in promoting mitogenesis of PDLCs [99]. At concentrations of 10−20 ng/mL, in vitro studies suggested that PDGF-BB stimulated the proliferation of fibroblasts and osteoblasts [100,101], whereas a higher concentration (≥50 ng/mL) is required for the adhesion of PDL fibroblasts to diseased roots; concentrations of 5−20 ng/mL were not effective [102]. PDGF has also been shown to be effective when combined with either IGF, as shown by significant bone fill upon reentry into the defects in animal models [103] and in patients with periodontal disease [104], or with dexamethasone [105], the latter being a well-known osteogenic differentiation factor. PDGF and IGF-1 had additive effects on calvarial DNA synthesis, but PDGF opposed the stimulatory effect of IGF-1 on collagen synthesis, and IGF-1 prevented the PDGF effect on collagen degradation [100]. In further research, IGF-1 alone at a dose of 10 μg did not significantly alter periodontal wound healing, while PDGF-BB alone at the same dose significantly stimulated new attachment, with trends of effect on other parameters. For example, the PDGF-BB/IGF-1 combination resulted in significant increases in new attachment and osseous defect fill above vehicle at both 4 and 12 weeks [106]. In humans, the use of purified rhPDGF-BB mixed with bone allograft resulted in robust periodontal regeneration in both class II furcations [107] and interproximal intrabony defects [108]. Based on those preclinical and clinical studies, recombinant human PDGF-BB homodimer in β-TCP is approved for the treatment of intrabony and furcation defects, as well as gingival recession in periodontal disease and is commercially available as Gem-21 (Osteohealth Co., Shirley, NY, United States). Furthermore, a large multicenter randomized controlled trial study of PDGF-BB homodimer, together with β-TCP, in the surgical treatment of a 4 mm or greater intrabony periodontal defect demonstrated significant increases in CAL reduced gingival recession at 3 months postsurgery and improved bone fill when compared with those of β-TCP alone at 6 months [108]. The safety and effectiveness of this product was further demonstrated recently in a double-blind, prospective, parallel, active-controlled, randomized, multicenter clinical trial involving 54 patients with periodontal osseous defects [109]. Further longitudinal clinical data are still needed to confirm the long-term effect of this product [110]. Although far from ideal for meeting the needs of complex periodontal therapy, the road from basic research to clinical applications of PDGF-BB or BMP-2 suggests a potential use of protein-based therapeutics for stimulating and accelerating periodontal tissue healing and bone regeneration [111].

Fibroblast growth factor-2

Fibroblast GF (FGF)-2 is a heparin-binding protein that regulates cellular functions including migration, proliferation, and modulation of ECM production, in the wound healing cascade [112]. In periodontal regenerative therapies the in vivo effectiveness of FGF-2 has been evaluated in beagle dogs as well as in nonhuman primates

(reviewed in [113]). The results of these studies suggest that FGF-2 induces significant periodontal tissue regeneration with new cementum and new alveolar bone formation. Recently, a double-blind, placebo-controlled clinical trial (Phase II) was conducted in 253 adult patients at 30 Japanese dental facilities. The data obtained demonstrated that FGF-2 was efficacious in regenerating periodontal tissue without clinical safety problems [114]. Further clinical trials (Phase III) are still needed to establish the clinical efficiency and value of FGF-2 products [115].

Growth/differentiation factor-5

Growth/differentiation factor (GDF)-5 is a member of the TGF-β superfamily, which shows a close structural relationship to BMPs and plays critical roles in skeletal, tendon, and ligament morphogenesis [116]. In the periodontal field, it has been reported that cells involved in root- and PDL-forming stages exhibit significantly stronger signals of GDF-5 in comparison to those in more mature, well-established tissues [117]. In vitro studies have shown that recombinant human GDF-5 at concentrations of 10−1000 ng/mL inhibits alkaline phosphatase activity in human PDLCs [118]. Recently, the effect of recombinant human GDF-5 on periodontal repair was demonstrated in animal models by using various biomaterials as vehicles for delivery, such as ACS, β-TCP or an injectable poly-lactide-*co*-glycolide acid (PLGA) composite (reviewed in Ref. [119]). The combined results suggest that recombinant human GDF-5 appears to safely and effectively support periodontal wound healing/regeneration in intrabony periodontal defects without complications, while in a dose-dependent order. Recently, a Phase IIa randomized controlled clinical and histological pilot study evaluated recombinant human GDF-5/β-TCP for periodontal regeneration in 20 chronic periodontitis patients [120].

Platelet-rich plasma

The use of PRP, a platelet concentrate from autologous blood, is one of the strategies available for modulating and enhancing periodontal wound healing and regeneration [5]. PRP includes a pool of GFs such as TGF-β, vascular endothelial GF, PDGF, IGF-1, epidermal GF, and FGFs. For this reason, it has been suggested that the use of PRP might increase the rate of bone deposition and bone quality in such dental treatments as sinus lifts, placement of autogenous mandibular bone grafts, implants, and periodontal surgery. Both preclinical and clinical studies demonstrate the effectiveness of PRP in bone and periodontal augmentation when used in conjunction with bone graft materials (reviewed in Ref. [5]). Unfortunately, the literature on the topic is contradictory and the published data are difficult to sort and interpret. For example, in a series of clinical studies performed by Döri et al. on the healing of intrabony defects, the addition of PRP failed to improve the total outcomes in terms of probing depth reductions and CAL gains [121]. Furthermore, PRP may not provide any additional effect when associated with GBR around dental implants [122]. Although data published thus far suggest that PRP does not always exert additional effects, a systematic review of literature does find evidence for beneficial effects of PRP in the treatment of periodontal defects. Nonetheless, evidence for beneficial effects of PRP in sinus elevation appeared to be weak [123]. While PRP has been somewhat beneficial when used in periodontal or implant regeneration, it has fallen out of favor recently because of the lack of controlled clinical trials providing strong evidence of its efficiency [124]. However, the use of a patient's own biologically active proteins, GFs and biomaterial scaffolds for therapeutic purposes has opened a new way of understanding regenerative medicine. These simple and cost-effective procedures may have a potential impact in reducing the economic costs for standard medical treatments, soon achieving a "golden age" by the development of user-friendly platelet concentrate procedures and the definition of new and efficient concepts and clinical protocols [5].

Enamel matrix derivative

EMD, an extract of porcine immature enamel matrix, is regarded as a candidate protein mixture that is thought to be the induction of proliferation, migration, adhesion, mineralization, and differentiation of cells in periodontal tissue [125]. EMD contains over 95% amelogenin with small amounts of enamelin and other proteins. In 2000, a randomized, double-blind, placebo-controlled, split-mouth study was designed to compare the clinical and radiographical effects of EMD treatment with that of placebo-controlled treatment for intrabony defects. The results demonstrated that treatment with flap surgery and EMD, compared to flap surgery with placebo, produced a significantly more favorable clinical improvement in intrabony periodontal defects [126]. A commercial EMD, marketed as Emdogain (Institut Straumann AG, Basel, Switzerland), received US Food and Drug Administration (FDA) approval and has been available for clinical application for over 10 years, leading to a number of clinical trials performed to evaluate the clinical effects of Emdogain (reviewed in Ref. [5]). In principle, EMD, which seems to be safe, was able to regenerate lost periodontal tissues in previously diseased sites based on clinical parameters and was better than open flap debridement (OFD) alone or GTR. A systematic review indicates that a combination of EMD and PDGF-BB together with β-TCP can improve the treatment efficacy of intrabony

defects [127]. Combined with allograft materials, EMD may be of additional benefit, but it needs to be further investigated [128]. Thus far, however, no evidence indicates that more teeth could be saved, and no evidence points to any important differences between EMD and GTR [129]. Of interest, a 10-year investigation following treatment of intrabony defects with EMD, GTR, EMD plus GTR, or OFD indicated that the three regenerative treatments showed a statistically significant higher CAL gain, compared with that of OFD at both one and 10 years [130]. However, another double-blind randomized clinical evaluation of EMD for the treatment of proximal class II furcation involvements showed that the use of EMD did not promote a superior reduction in probing pocket depths or a gain in clinical and osseous attachment levels, but only resulted in a higher rate of class II to class I furcation conversion [131]. It seems that the clinical application of EMD for periodontal therapy still requires additional well-controlled clinical trials. EMD is applied not only for periodontal surgery but also for tooth transplantation [132] and management of periimplantitis [133]. However, the clinical predictability of such treatments remains to be determined.

Stem cell–derived exosomes

Exosomes are nanosized extracellular vesicles (40–150 nm) secreted by almost all kinds of cells and play key roles in intercellular communication by transferring their cargos containing mRNAs, miRNAs, and proteins to the recipient cells. The contents of exosome cargos are largely determined by the origin and functional status of their parental cells. Therefore stem cell–derived exosomes can bear the therapeutic effects and can be used as the substitutes of stem cells to promote the regeneration of various tissues. Accumulative studies have demonstrated that exosomes are immune-tolerant and can exert various positive effects on the cellular behaviors of stem cells, such as cell migration, proliferation, and differentiation [134]. Moreover, emerging evidence has indicated that exosome can also speed up angiogenesis and prevent the fibrosis to improve wound healing [135]. In addition, the contents of exosomes can be conveniently enriched by packing exosomes with miRNA, genetic material, and other small bioactive ingredients due to their highly efficient delivery of cargos [134]; hence stem cell–derived exosomes have great potentials for tissue repair and regeneration. In periodontal regenerative therapies the in vivo effectiveness and safety of exosomes has been evaluated in ligature-induced rat periodontitis. The results have indicated that exosomes secreted by adipose-derived stem/stromal cells resulted in significantly higher area of newly formed periodontal tissues than adipose-derived stem/stromal cells [136]. Of note, the mechanisms underlying the therapeutic effects of stem cell–derived exosomes have not been illuminated yet. Further clinical trials are also required to confirm the efficiency and safety of clinical utilization of exosomes.

Crucial delivery barriers to progress

The biological basis of using GFs in periodontal tissue engineering stems from their inherent property of inducing chemotaxis and/or mitogenesis of mesenchymal and somatic cell populations, initiating a cascade of events that ultimately lead to proliferation and differentiation of these cells. BMP-2/-7, GDF-5, FGF-2, and PDGF have been intensively investigated in preclinical and clinical trials and the results appear promising [89,90,111,113,119]. However, at this point in time, it appears very difficult, if not impossible, to translate knowledge about the functions of GFs in embryonic development, tissue formation/homeostasis, and bone healing into clinically applicable solutions that address the loss of periodontal tissue. First, GF therapy is currently hampered by the lack of a safe and efficient delivery system that can provide a sustained therapeutic effect without cytotoxicity or unwanted side effects as a result of using very high doses of GFs [137]. Second, enormous costs are associated with recombinant human GFs in relation to the relatively small and non-life-threatening periodontal defects for which other treatment options (e.g., implants) exist. Of note, the delivery strategies commonly used today in periodontology are bolus injection or physical combination of GFs with prefabricated biomaterials. The rapid degradation, hence low local availability of GFs, suggests that these delivery strategies do not meet the physiological requirements of periodontal tissue repair processes [138]. Thus in spite of the many recombinant GFs and cytokines now available for research purposes and the testing of some in humans, the clinical experience has, so far, been disappointing. Consequently, sophisticated approaches must be developed to deliver GFs that allow for the controlled, sustained, and localized delivery of proteins [88]. New drug delivery systems that regulate the biological presentation of GFs represent an attractive new generation of therapeutic agents for the treatment of a wide variety of diseases. Such devices essentially allow the loaded GF(s) to be released at a desired rate and concentration and to remain at injury sites for a sufficient time to recruit progenitors and stimulate the tissue healing processes [138] (Fig. 66.2). In addition, drug delivery systems, termed cell scaffolds, can be formulated to have particular structures that facilitate cellular infiltration and growth. To improve their properties, many drug delivery systems serve dual purposes. In addition to providing cell support, cutting-edge scaffolds biologically interact with adhering and invading cells and effectively guide cellular

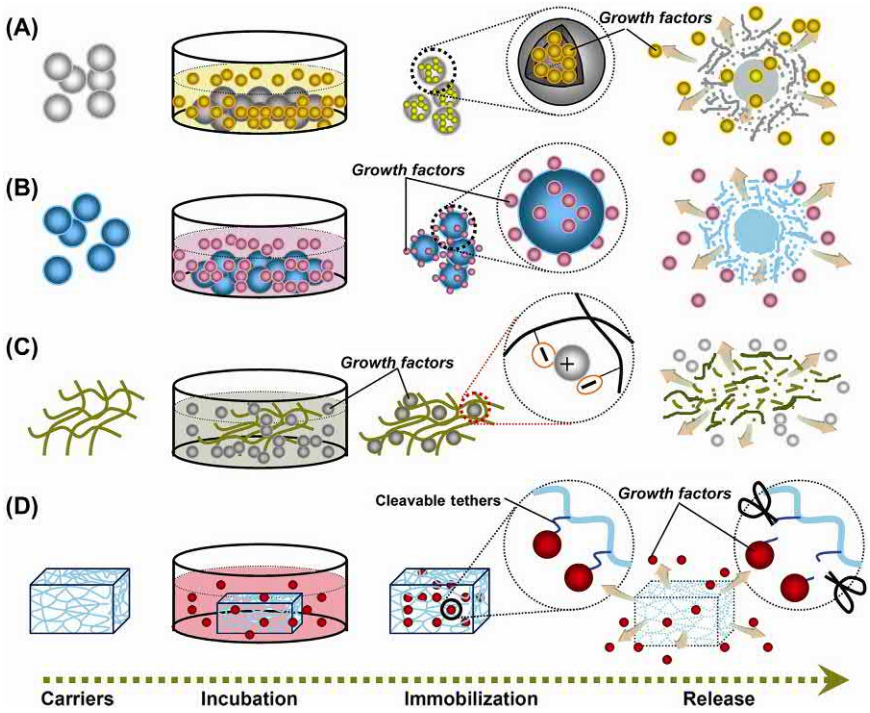

FIGURE 66.2 Schematic illustrations of the frequently investigated methods for immobilization of GFs and their primary release mechanisms (illustration is not to scale). (A–C) Noncovalent immobilization: GFs are directly entrapped into (A) or adsorbed onto (B) the carriers, or immobilized via the formation of ionic complexes with polymer matrices (C). (D) Covalent immobilization: GFs are modified and thereafter covalently crosslinked to the hydrogels via crosslinkable and cleavable bonds that can be liberated once the tethers are degraded hydrolytically or enzymatically. *GFs*, Growth factors. *Reproduced from Chen FM, Wu LA, Zhang M, Zhang R, Sun HH. Homing of endogenous stem/pregenitor cells for in situ tissue regeneration: promises, strategies, and translational perspectives. Biomaterials 2011;32:3189–209 with the permission of Elsevier Inc.*

growth and development by releasing bioactive proteins. To design controlled release systems for specific applications, it is important to understand the basic principles of protein delivery and the stability of each applied biomolecule [140].

Many biological and engineering challenges in the use of GFs for tissue regeneration remain to be solved. It is certain that these signaling molecules promote periodontal tissue and bone formation, but the ideal concentrations still need to be determined, and safety issues currently remain. In addition, understanding when to manipulate the cell's differentiation pathway with the application of single or multiple doses of GFs at the appropriate concentration is required to optimize the effect of these agents in periodontal wound healing. It also seems that any treatment aiming to mimic the natural tissue regeneration processes should not be limited to the provision of a single GF but should deliver multiple agents at an optimized ratio in a specific spatiotemporal pattern [87]. Therefore different release profiles from the same carrier may be particularly important in tissues with mixed cell populations, such as those found in the periodontium, where similar tissues, like bone and cementum, grow at different rates [140]. Furthermore, treatment of intrabony defects with GFs is likely to require both appropriate temporal release of the agents and a carrier that can serve as a template for new tissue formation, providing space maintenance and supporting the mucoperiosteal flap. Many of these issues have not been adequately addressed, at least from a periodontal standpoint; elucidation of these factors is essential prior to conducting expensive human clinical trials.

Gene delivery as an alternative to growth factor delivery

Because of the short half-life of topically administered GFs in vivo, usually ranging from several hours to several days, researchers have tried to extend protein activity using gene delivery strategies that involve converting cells into protein-producing factories. This is achieved by delivering plasmid DNA encoding the GF(s) of interest into cells/tissues either directly or via gene delivery vehicles or vectors [141]. This therapeutic concept has emerged as a promising strategy for the modulation of the host response triggered by periodontal microbe and the regeneration of periodontium during disease progression [4].

Using viral vector transduction, cells can be manipulated in vitro and when transplanted into patients, these cells might restore normal tissue function. One of the most promising gene therapy approaches for periodontal regeneration, however, is based on the combination of naked DNA with a biodegradable carrier. Using this approach, collagen or other biomaterials are used to engineer a so-called gene-activated matrix that can carry and deliver naked DNA that directs an individual's own cells to produce a therapeutic effect [142]. A gene therapy product does not need to carry and deliver manipulated

stem/progenitor cells; rather, it is able to signal the available cells to differentiate into a phenotype more favorable to the regenerative process [143].

Viral vector genes can be expressed in vivo from weeks to years, thereby having greater sustainability than that of a single protein or compound application. A unique advantage of gene therapy is the possibility of delivering more than one regenerative factor by employing two or more DNAs [144]. This combinatorial approach has shown significant regenerative potential compared to individual gene delivery, offering strong potential in regenerating tissues in three dimensions at the tooth−ligament−bone interface. In addition, gene therapy has also been investigated for the possibility of modulating periodontal disease progression via delivery of either antimicrobial or host modulators, considering that the host response against pathogenic bacteria is a major cause of periodontal tissue destruction [145]. Based on this concept, gene delivery, in combination with tissue engineering, is the only possible strategy that may mimic critical aspects of the natural biological processes occurring in periodontal development and repair [4,10,11,146−148]. The genes of interest in periodontal therapy include, but are not limited to, BMPs, PDGF, FGF-2, IGF-1, and TGF-β (reviewed in [141]). Of interest, the adenovirus encoding the PDGF-B gene delivered in a collagen matrix exhibits acceptable safety profiles for possible use in human clinical studies [149]. Although hundreds of gene therapy clinical trials have taken place in the past 20 years, much work still needs to be done to ensure an ideal safety profile for each gene and delivery method combination. With further efforts in this field, it is expected that gene therapy may augment current protein-based strategies and potentially allow for tissue-specific targeting and delivery of multiple signals in a spatially controlled and bioavailable fashion with the goal of regenerating natural tissue replacement in the craniofacial and periodontal region [143].

Scaffolding and biomaterials science

The management of periodontal defects began with the introduction of a "filler" material that aimed to induce bone regeneration. Various types of bone grafts, such as synthetic filler materials (alloplastic materials), autografts, allografts, and xenografts, have been investigated for this purpose. Although utilization of such grafting materials for periodontal defects may result in some gain in CAL and radiographic evidence of bone fill, careful histological assessment usually reveals that these materials have little osteoinductive capacity and generally become encased in dense fibrous connective tissue [7]. Frequently, these treatments serve to ease the symptoms, not cure the disease. Tissue engineering offers clear merits over conventional replacement therapies that suffer from a host of drawbacks, such as scarcity of donor source, donor site morbidity, risk of lateral transmission of pathogens, and graft-versus-host rejection. A major unmet challenge in tissue engineering today has been the synthesis of complex constructs that are principally comprised of biomaterials and multiple cell types. This development is also true in periodontal tissue engineering. With the possibility of therapeutic cell cloning becoming a reality, there is an urgency to develop technologies that can precisely control the behavior of stem cells in culture. Central to these technologies would be the probable inclusion of biomaterials as an important component because the scaffold plays a vital role in converting isolated cells into functional tissues. Advances in biomaterial research will undoubtedly facilitate the transformation of this concept into reality. Factors of great importance in the selection of a suitable scaffold material include such properties as porosity, tissue conductivity, biocompatibility, and resorption rate. An appropriate scaffold has several design criteria that ensure not only the precise delivery of therapeutic cells to the site of injury but also the rigorous control of their fates in vitro and in vivo toward regeneration.

Requirements of cell scaffolds

The implantation of cells in the afflicted area could be a direct approach in regenerative strategies, but the requirement for a support material to promote regeneration, especially in large sized defects, is a critical consideration. Periodontal tissue and bone are expected to grow into an adjacent defect only when the space is maintained and soft tissue ingrowth is prevented. Thus the scaffold should act in a manner consistent with the established principles of GTR. To maintain the space for a sufficient time, the scaffold needs to feature such properties as ease of clinical handling and shaping and sufficient rigidity to withstand soft tissue collapse into the defect [7]. In addition, the scaffold should be biocompatible with no biological hazards, and it should assist tissue functionality by promoting the easy diffusion of nutrients, GFs, and cellular waste products. Furthermore, its biodegradability should be adjustable to the time required for tissue regeneration, thus avoiding interference with the physiological healing process. When considering the compatibility of internal structure with cell attachment and colonization and the compatibility of ingrowth tissues with those to be regenerated, the amount of porosity and the pore size of the supporting 3D structure are important features in the design of tissue-engineering scaffolds [150]. ECM components organized in the PDL not only reflect the functional requirements of this matrix, such as mechanical stress and storage of signaling molecules, but also regulate the tissue framework during development and regeneration.

This idea is inspired in nature itself because most cells in the body subsist in a 3D world and are anchored onto a network of ECM, which the scaffolding design proposes to recreate. With this in mind, scaffold characteristics should mimic the complex and demanding environment to which cells are exposed and should be able to define a local biochemical and mechanical niche with complex and dynamic regulation that cells may sense, while, at the same time, not inducing an overexpression of inflammatory response [151]. Moreover, biosafety and bioactivity are of great importance. Although no guidelines have yet been established for assessing the safety and efficacy of a biological transplant, clearly the materials should be free from transmittable disease and immunologically inert [7].

Biomaterial-based immune modulation

Although a set of newly designed parameters (e.g., geometries, architectures, and mechanical properties) used for finely tuning the cellular behaviors of stem cells has been introduced into the field of biomaterials, limited success is achieved when the in vitro studies were translated into the in vivo experiments [12]. The reason might be lie in that findings based on certain stem-cell types cannot genuinely reflect the in vivo cell milieu, where multiple cell types are involved in the process of periodontal tissue engineering. Besides stem cells, immune cells have received considerable attention as modulators of disease pathogenesis and tissue remodeling following injury [152,153]. Macrophages can exert either positive or negative influences on the outcomes of the implanted biomaterials depend on their polarization states. Classically, the polarization states of Mφs can be divided into two categories, M1 and M2 Mφs: M1 Mφs can exaggerate proinflammatory responses by producing toxic reactive oxygen intermediates and proinflammatory cytokines, whereas M2 Mφs secrete antiinflammatory cytokines to promote tissue remodeling and healing (reviewed in Ref. [154]). Emerging evidence has shown that finely tuning Mφs toward the M2 phenotype could not only prevent bone loss caused by periodontitis but also exploit the power of stem cells to promote periodontal tissue regeneration [153,155]. These finding suggested that the design of biomaterial phytochemical modifications should also utilize the host immune response to ameliorate the outcomes of medical implants and periodontal tissue engineering therapies [156,157].

Classes of biomaterials

For regeneration, biomaterials are intensively utilized, as a scaffold for cell delivery, a template for cell proliferation and differentiation, or as a capsule/filter to maintain the cell's viability and to deliver the synthesized biomolecules. The resorption, mechanical strength, and efficacy of these materials can be manipulated through structural and chemical design parameters. Biomaterials used in periodontal tissue engineering include natural or synthetic polymers, ceramics, and composites. Each material offers a unique chemistry, composition and structure, degradation profile, and possibility for modification.

Naturally derived polymers

Natural biomaterials serve as a cornerstone in the development of matrix-based regenerative therapies that aim to accelerate clinical application due to their excellent biocompatibility, biodegradability, affinity for biomolecules, and wound healing activity [158]. Collagen, hyaluronic acid, alginate, and chitosan scaffolds have been used in periodontal regenerative research for more than two decades. The natural origin of these materials allows the design and engineering of biomaterial systems that function at the molecular level, often minimizing chronic inflammation. They can also be easily modified, both chemically and physically, to form desired structures, possess optimal properties, and perform specific functions for various applications. The use of natural polymers in the form of hydrogels allows for the incorporation of biological agents by promoting crosslinking when the GF is dispersed in the polymer solution. Because natural polymers are often soluble in water, the creation of hydrogels may occur under mild fabrication conditions that are relatively harmless to the bioactivity of the GFs. Normally, these hydrogels are degraded by enzymes and/or acid hydrolysis at a rate depending on the degree of crosslinking or the molecular weight [158]. In addition, natural polymers can also be modified to become 3D scaffolding materials, such as porous sponges, particles, films, and rods, and for the formulation of stimuli-responsive biomaterials.

Purification of the major component of the ECM has been the subject of many potential tissue engineering strategies (reviewed in Ref. [159]). Collagen is regarded as one of the most useful biomaterials owing to its excellent biocompatibility and safety associated with its biological characteristics, such as biodegradability and weak antigenicity. While collagen hydrogel fits well with injectable cell delivery, highly porous collagen lattice sponges with crosslinking provide mechanical stability that has been used to support the in vitro growth of many types of tissues and to deliver multiple GFs. Following the clinical use of collagen carriers delivering BMPs for tibial shaft fractures [160], spine fusions, and long-bone nonunions [161], collagen is currently being evaluated for widespread clinical periodontal regeneration. Particularly, collagen is used clinically as a composite with ceramics [162]. Commercially available collagen composite scaffolds include Formagraft (Nuvasive, San Diego, CA,

United States) and OssiMend (Collagen Matrix, Franklin lakes, NJ, United States). Apart from InFuse Bone Graft, ACS has been used as a carrier and/or scaffold for periodontal regeneration in animal studies [163] and clinical trials [41].

As a deacetyled derivative of chitin, chitosan is structurally very similar to naturally occurring glycosaminoglycans and is biodegradable in mammals. Chitosan has several merits for use as a cell vehicle material, including its ability to be molded into various geometries (e.g., porous structures) and forms (e.g., gels), ease of chemical modification, high affinity for in vivo macromolecules, and minimal foreign body reaction [164]. While chitosan can support cell attachment for cell delivery purposes, it is not strongly supportive of tissue regeneration, as demonstrated by its effect on the width of keratinized gingiva in dogs [165]. Accordingly, chitosan needs to be either modified chemically or conjugated with other molecules or peptides to enhance its biocompatibility for cell attachment and capability for tissue regrowth [7]. For example, the addition of HA beads to chitosan gels produced a novel scaffold in which the pore sizes and interconnectivity were preserved. When loaded with FGF-2, this scaffold may provide a suitable 3D environment supporting cellular structure, proliferation, and mineralization [166]. Chitosan has also been widely used in combination with collagen [146,167], coral [148], HA [147], and β-TCP [168] to develop new scaffolds for periodontal tissue-engineering applications.

Alginate hydrogels bearing cell adhesion ligands have been used as scaffolds for cell encapsulation and transplantation, and they have yielded promising results in experiments aimed at engineering bone tissue capable of growth from small numbers of implanted precursor cells. An alternative to alginate hydrogels as a cell carrier is the incorporation of cells into beads of alginate to prevent immune cells and soluble complexes from killing the transplanted cells; this property negates the need for immunosuppressant use [169]. As a result of the semipermeable nature of the beads, the soluble factors made by the entrapped cells can be released at the implantation site to guide regenerated tissues [7]. However, these developments have not yet been used in periodontal bioengineering. Of interest, calcium alginate film was found to be more effective for GTR and GBR use than the collagen membrane [170].

Synthetic polymers

Numerous synthetic polymers have been widely used for scaffolding applications. Although synthetic matrices in their native forms lack cellular recognition sites, they have well-controlled and reproducible chemical and physical properties [171]. Synthetic polymers have many advantages. For example, they offer the ability to provide controllable and reproducible structural properties, they are biocompatible, and their biodegradation rates can be tailored for the intended application through specific chemical manipulation. Synthetic scaffolds are produced by a variety of fabrication techniques, and these materials can be easily manufactured into preformed sizes and shapes according to clinical requirements. Synthetic matrices are typically processed into the form of solid scaffolds, small particles, or hydrogels, depending on the mechanical and degradation properties for the particular application [171].

Hydrolytically degradable polymers are widely used materials for scaffold manufacture. The US FDA has approved the use of poly(α-hydroxyester)s, such as poly (glycolic acid) (PGA), poly(L-lactic acid) (PLA), and their copolymers, PLGA and polycaprolactone (PCL), for a variety of clinical applications. Solid scaffolds are typically porous matrices fabricated by techniques such as solvent casting, gas foaming, particulate leaching, and electrospinning [171]. Normally, these materials do not elicit a permanent foreign body response as they are gradually degraded into natural metabolites and eventually replaced by natural tissue. The physical properties of these polymers can be readily altered by varying the ratio of lactide/glycolide, the molecular weight, and the crystallinity, or by combining them with other materials [150]. In some cases, synthetic polymers can be used as additions to natural biomaterials. For example, the rapid degradation of fibrin, a biopolymer critical to hemostasis and wound healing, can be decelerated by modification with poly(ethylene glycol) (PEG), thus creating a hybrid material for cell delivery [172].

PLA is one of the most promising biopolymers, because it is a naturally occurring organic acid, and the monomers may be produced from nontoxic renewable feedstocks [173]. Other degradable polymers include PEG [174], polylactide and polyglycolide [175], and polylactide acetyltributyl citrate and polydioxanon [176], and these polymers have also been explored and tested for guiding periodontal tissue regeneration. Amorphous poly (D,L-lactic acid) is one of the most popular materials considered for scaffold production, and it is used in combination with bioactive glasses because it can be combined with such biomolecules as GFs and antibiotics to establish a locally acting drug delivery system [150]. By this modification, the creation of a macroporous structure within the bioceramic materials is possible. For example, when PLGA microparticles are incorporated into calcium phosphates (CaP) cement, a macroporous CaP cement scaffold is formed after PLGA hydrolysis in vivo [177]. Although synthetic scaffolds have excellent mechanical properties and processing ability, their lack of natural biological cues can be a potential weakness. Furthermore, some

polymers suffer from shortcomings, such as eliciting persistent inflammatory reactions and eroding or being incapable of integrating with host tissues [13]. These issues need to be addressed prior to clinical application.

Ceramic-based materials

Ceramic-based materials have been widely used for bone and periodontal regeneration. Commercially available products include CaPs (e.g., HA and TCP), calcium sulfate, and bioactive glass [178]. Clinically used forms of HA and β-TCP include injectable formulations that harden at body temperature, such as β-BSM (Etex, Cambridge, MA, United States) and BoneSource HA Cement (Stryker, Kalamazoo, MI, United States). These materials exhibit a range of degradation rates that span from weeks to years. Their biocompatibility and high protein-binding affinity make them good vehicles for drug delivery [109]. Recently, several porous ceramic scaffolds have also been examined for their utilization as cell delivery materials [7].

Both synthetic and coral-derived porous HA have been shown to support significant clinical improvements in periodontal measures following implantation in intrabony defects [15]. The porosity and degree of sintering of synthetic HA ceramics primarily determine the rate of biodegradation.

The degradation rate of β-TCP, a porous form of CaP, can be controlled by changing the Ca/P ratio. Because of its degradation characteristics and its similar proportions of calcium and phosphate to cancellous bone, β-TCP is regarded as an ideal material for bone substitutes for periodontal repair [119,179]. Owing to the rapid degradation of β-TCP and its associated poor mechanical properties, research has focused on mixed CaPs, such as mixtures of β-TCP and HA or β-TCP and polymers. These hybrid materials appear to be reliable vehicles for cell delivery, with studies showing good tissue formation associated with the implanted cells [7]. The treatment of periodontal intrabony defects with a combination of two ceramics (calcium sulfate in combination with β-TCP) led to a favorable clinical outcome after two years [180]. The alloplastic material Osteon (Genoss, Suwon, Korea) has an HA surface coated with β-TCP (70% HA and 30% β-TCP). The pore size of Osteon is 300−500 μm, and its volumetric porosity is approximately 77%. It has recently been reported that it is suitable for use in sinus graft applications [181]. For periodontal regeneration in periodontitis models, HA/TCP composite is demonstrated to be effective, both as vehicles for cell delivery [42] and as supporting biomaterials for cell sheet implantation [43].

Biomaterial redesign for periodontal application

The selection of the specific biomaterial is a key variable in the design and development of scaffolding systems. It has recently been proposed that a combination of several materials may offer the best opportunity for beneficial clinical outcomes [137]. For example, a porous chitosan/collagen scaffold [167] and a glycidyl methacrylate derivatized dextran/gelatin scaffold prepared through a freeze-drying process were developed specifically for periodontal tissue engineering. Furthermore, natural polymers can be strengthened mechanically by combining them with ceramics, such as HA [147,166], β-TCP [168] or polylactide (blends, copolymers, and interpenetrated networks) [182]. Thus for periodontal regeneration, one promising direction is the formation of hybrid materials that take advantage of both natural and synthetic materials by combining excellent mechanical properties and an intrinsic structure highly compatible with tissue ingrowth. However, in nearly every case, these materials were adopted from other areas of science and technology without substantial redesign [13]. Although a number of biomaterials, such as ASC and β-TCP, have had a long history of clinical use in periodontal therapy, very few interact with their surrounding host environment or promote regeneration of functional periodontal tissue such that a seamless integration with host tissue is created in an intelligent and proactive fashion. Alongside the rapid advances in stem-cell biology, progress in biomaterials design and engineering is now converging to enable a new generation of instructive materials to emerge as candidates for periodontal regenerative medicine.

In terms of shape and geometry, preformed scaffolds are suitable for defects requiring mechanical strength or a predefined shape, such as one-walled bone defects, whereas injectable scaffolds may facilitate clinical use in two- or three-walled intrabony defects. Injectable types of scaffolds are expected to form the shape of any cavity or repair site but must solidify within a clinically acceptable timescale in situ. Of note, such devices will shorten surgical operation time, minimize damaging effects of large gingival retraction and lessen postoperative pain. One critical disadvantage of injectable biomaterials is their poor mechanical strength and porosity; however, pores can be generated in scaffolds with rapidly degrading particles or gaseous bubbles as porogens to promote cell attachment, migration, proliferation, mass transfer, vascularization, and material resorption [183]. These modified hydrogels are promising delivery systems for therapeutic cells.

The functional significance of the ECM has generally been defined in terms of the provision of a structural support for cell adhesion and the establishment of tissue physical integrity. Recent evidence has, however, led to a paradigm shift where the ECM is increasingly recognized as exerting a profound influence on cell behavior. Therefore biomaterials are required to act as the temporary ECM in the regeneration of a new tissue. To this

end, a scaffold is not simply a mechanical support and initial cell anchorage site, but it must be "informative" to the cells. That is, the scaffold should be capable of stimulating specific cellular response at the molecular level [184]. It follows that the design of new cell seeding scaffolds must take into account microenvironment design features that induce the appropriate gene expression in cells forming new tissues [185]. The complexity of this design process is exemplified by the dynamic states of the cells and tissues, which are regulated by the spatial and temporal coordination of multiple cell processes, each of which is regulated by multiple reciprocal interactions between cells and their ECM [185]. Biomaterial modification can take on different levels of complexity to produce increasing levels of physiological "mimicry" and functionality. Their interactions with cells and tissues may be improved or fine-tuned by adequate chemical modifications, such as grafting with cell adhesion peptide Arg-Gly-Asp (RGD) or by surface treatments (e.g., surface plasma modification or surface chemistry modification through grafting with other polymers) [158,186]. The incorporation of RGD peptides in hydrogel matrices has been found to significantly enhance the attachment, spreading, survival, and mineralization of encapsulated dental follicle progenitors, suggesting that RGD additives may promote the use of hydrogels for periodontal mineralized tissue engineering. The incorporation of peptide motifs recognized by cell receptors and the use of recombinant DNA technology have enabled the creation of naturally derived tissue-engineering scaffolds with new levels of biofunctionality [17]. Typical surface modifications include, but are not limited to, changes in hydrophilicity, functionalization with charged groups, the incorporation of insoluble ligands and peptide cell recognition sequences (e.g., RGD), the attachment of larger proteins, supramolecular self-assembly, and the development of materials that bind and release soluble factors [187]. The wettability of the material surface, particularly in synthetic polymers, can be effectively regulated by physical treatments, for example, by irradiation with ions, plasma, or ultraviolet light. The irradiation-activated material surface can be functionalized by various biomolecules and nanoparticles. This characteristic further enhances its attractiveness for cells and its effectiveness in regulating cell functions [188]. Strategies based on physical cues include the reproduction of nanoscale topology, superposition of mechanical cues, and control of degradation. Designing biological recognition into a biomaterial may also obviate the need for therapies based on the delivery of cells or recombinant GFs, which are subject to regulatory constraints [185]. To this end, scientists are creating new materials, including those with improved biocompatibility, stealth properties, responsiveness (smart materials), specificity, and other critical properties.

We must be aware that sites of injury or diseased organs are characterized by heightened immunological surveillance and a high concentration of inflammatory cytokines. As such, these sites often present environments hostile to healthy cells attempting to establish and repopulate. This is extremely important in the management of periodontal disease. Therefore to eliminate the need to promote a harsh immunosuppressive regime, an additional role for scaffolds needs take into account the insulation of their cellular cargos from the host immune system to, in turn, promote the survival of transplants [4]. Finally, to engineer functional periodontal tissues, the correct mechanical stimuli will need to be conveyed to the developing tissues within the scaffold, although very few studies have addressed this issue [7]. To date, biomaterials are rapidly being developed to display and deliver stem-cell regulatory signals in a precise and near-physiological fashion within the tissue defect, fostering the regeneration of the missing tissue [87]. The transplant must participate in the regenerative process, considering the specific properties of each tissue interface, which can only be achieved through the design of scaffold materials accommodating the specific characteristics of periodontal hard and soft tissues, and providing stem cells with the necessary cues to satisfy cellular needs of both tissue types. Further synergism of cell biological and biomaterials technologies promises to have a profound impact on stem-cell biology and to provide insights that will advance stem cell−based clinical approaches to tissue regeneration [189].

Periodontal bioengineering strategies

Periodontal tissue-engineering strategies typically involve harvesting of suitable autologous donor tissues (e.g., the PDL) from which cells are isolated and expanded in a good manufacturing practice facility. Expanded cells are then seeded onto a matrix and surgically implanted into the host's periodontal defects. Alternatively, the cell/matrix may be further incubated in a bioreactor, or other such system prior to implantation, in which the cells may be exposed to biological, chemical, or physical stimuli that promote the formation of the appropriate tissue [6]. Considerable preclinical data and some clinical successes support the applicability of these cell-based approaches [44,72,74]. However, the process is very complex and not cost-effective. In addition, the scarcity of the cell source is an issue. Although allogenic cell transplantation has shown success [43], the potential risks associated with transplanting exogenous (foreign) cells remain to be addressed. Even without any therapeutic intervention, living periodontal tissues can have a staggering capacity for regeneration. As such, a biomaterials/protein-based strategy that avoids the use of ex vivo cultured stem cells to facilitate endogenous repair is a novel approach to periodontal tissue engineering.

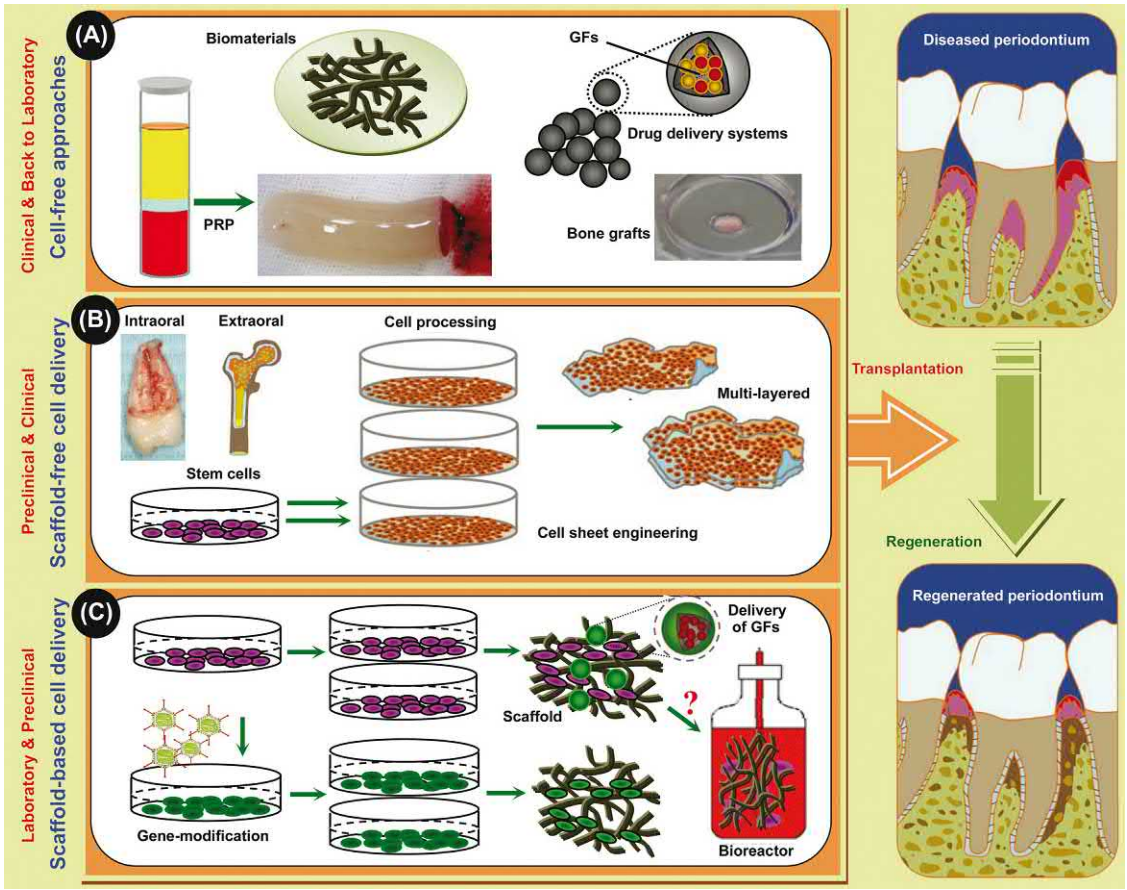

FIGURE 66.3 Cell-free (A) and cell-based (B and C) technologies for periodontal tissue engineering. (A) Cell-free approaches aim at achieving endogenous periodontal regeneration with the use of GFs, well-designed biomaterials, PRP, and its associated formulations, and maybe other commercially available products, alone, or in combination. In this regard, periodontal defects are likely to be restored by endogenously recruited cells and without the need of delivery of ex vivo manipulated cells. This concept has been employed in clinic for several decades and feedback based on clinical practice has led to new insights into and novel applications of such endogenous mechanisms for tissue regeneration [137,139]. Besides, both extraoral and intraoral stem cells represent a viable and accessible "tool" for regeneration. Adequate cell density could be reached in vitro under a controlled environment and made readily available for reimplantation into a periodontal defect site via either scaffold-free (i.e., cell sheet engineering) (B) or scaffold-based delivery (C). Although the time is now ripe to move stem-cell therapy from preclinical studies to clinical trials, there are a number of biological, technical, and translational hurdles that remain unresolved. For scaffold-based delivery the expanded cells are seeded into a 3D scaffold (normally containing GFs), and immediately implant into periodontal defects (in vivo) or to create tissue-like constructs in bioreactor before transplanting into patients (in vitro). In both cases, gene of interest may be incorporated into a therapeutic cell because a therapeutic gene has been shown to increase the regenerative potential and enhance the availability of therapeutic cells. *3D*, Three-dimensional; *GFs*, growth factors; *PRP*, platelet-rich plasma.

Based on current understanding of periodontal tissue engineering, both cell-free and cell-based approaches have their own advantages and disadvantages, and both warrant further investigation (Fig. 66.3).

Cell-free approaches

As noted in the Introduction section, recent advances in periodontal bioengineering have shifted the focus from the attempt to recreate tissue replacements ex vivo (in vitro paradigm) to the development of an in vivo paradigm to achieve in situ periodontal regeneration [6,12]. However, a daunting question for the in vivo paradigm involves the requirement for transplanted cells, as this has been viewed as a core component for in vivo tissue engineering. Interestingly, but not surprisingly, cell-free in vivo tissue engineering has shown that appropriate stimuli can activate local cellular populations and direct their trafficking, leading them to contribute to endogenous tissue formation [5] (Fig. 66.4). The design of cell-free approaches for periodontal regeneration is based on the concept that relies on harnessing the intrinsic regenerative potential of endogenous tissues using a conductive/inductive scaffold, either alone or in combination with such molecular stimuli as GF or genes, to initiate reparative processes in situ [12,139,190,191]

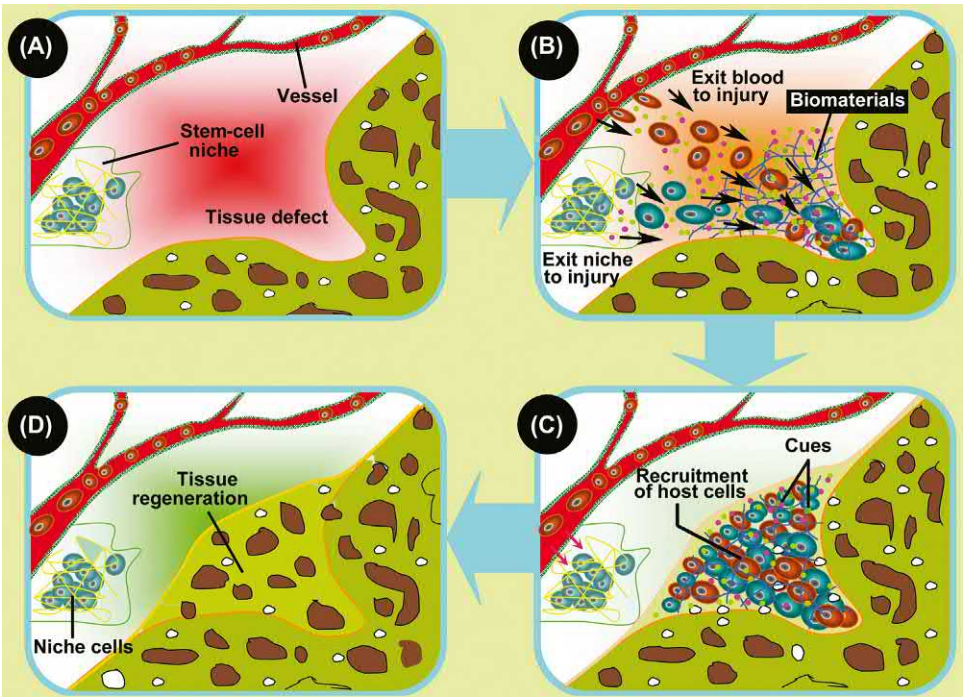

FIGURE 66.4 Schematic representation of the recruitment of host cells for endogenous tissue regeneration. (A) Tissue defect; (B) cell trafficking in response to implantated biomaterials and growth factors; (C) sufficient cell populations recruited to the defect; (D) defect restoration via endogenous tissue regeneration. The use of well-designed biomaterials in combination with molecular stimuli (growth factors or genes) may harness the body's innate ability to restore small or moderate tissue defects without the need of ex vivo cell delivery. This concept is generally termed cell-free tissue-engineering strategy. *Modified from Chen FM, Zhao YM, Jin Y, Shi S. Prospects for translational regenerative medicine. Biotech Adv 2012;30:658–72.*

In carefully selected cases, upon implantation, a conductive scaffold may guide the regeneration of the periodontal tissue by passively allowing the attachment and growth of vascular elements and progenitor/stem cells that reside in the tissue defect. Nevertheless, its regenerative potential is limited by the lack of biologically active factors and sufficient progenitor cells within the defect site. On the other hand, an inductive scaffold may guide the regeneration of the periodontal tissue by carrying one or more biologically active factors, such as stromal cell–derived factor-1, BMP-2, PDGF-BB, and/or FGF-2, which recruit vascular events and progenitor/stem cells from the immediate vicinity to the tissue defect (reviewed in Ref. [13]). The regenerative potential of an inductive scaffold is higher than that of conductive biomaterial, because more progenitor cells can repopulate the tissue defect [192]. Trafficking of stem/progenitor cells requires the complex processes of mobilization of MSCs from their niche, recruitment to the desired target tissue or site, and integration and maturation at the target site. For cell-free tissue engineering to be successful, identification of specific cues that steer stem cells to their niche and increase the efficiency of the homing process is of critical importance [157,193]. For stem cells to be recruited by injured tissues, implanted biomaterials must initiate a sequence of coordinated interactions between the cells and their environment and provide the signals and signposts that guide the cells along their journey [139,156,194]. Therefore artificial biomaterial niches would need to incorporate appropriate navigation cues that could attract endogenous stem cells and have ECM-mimicking components and structures that could localize and accommodate the cells within the destination [6,156].

The use of PRP and EMD in periodontal reconstructive surgery provides evidence that cell-free approaches are useful in various experimental and clinical models, yet the outcomes have frequently been inconsistent or conflicting between studies [6]. If we just consider the current endogenous technique for routine clinical periodontal regeneration, it clearly needs to be improved and refined [195]. One pivotal aspect in the development of PRP technology, for example, has been the deep platelet characterization that has been developed to determine the most important GFs and cytokines contained within these cells, and the protocols that facilitate their safe manipulation and concentration [196]. Cell-free tissue engineering is still in its infancy. New insights from developmental biology and other biological disciplines are actively guiding the development of biofunctonalized materials that work with nature's own mechanisms of repair, where the scaffold should be considered as both a biochemical and biophysical signaling device, modulating and orchestrating cellular activity in the defective microenvironment to harness and direct a patient's own regenerative potential [194]. Although the cell-free approach offers a preferential route for tissue-engineering therapies to be utilized within clinical settings, much remains to be done to illustrate how to administer chemicals that direct stem cells for targeted movement and how to recreate a local

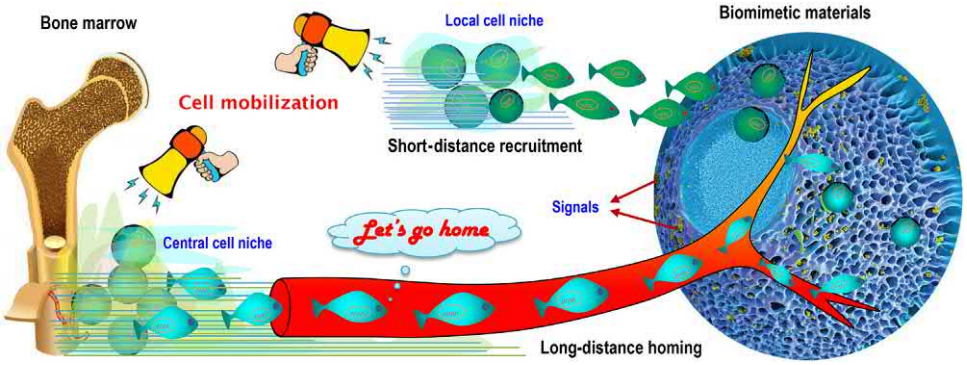

FIGURE 66.5 Schematic representation of how to coax stem-cell homing and recreate a local microenvironment for stem-cell accommodation. The administration of chemicals and growth factors can mobilize resident stem cells from their niche (e.g., the bone marrow) and importantly direct stem cells to move and be recruited to site of injury, wherein biomimetic materials are normally applied to recreate a local microenvironment favoring the recruited cells to live and hence facilitate the cells to regenerate new tissues. *Modified from Wu RX, Xu XY, Wang J, He XT, Sun HH, Chen FM. Biomaterials for endogenous regenerative medicine: coaxing stem cell homing and beyond. Appl Mater Today. 2018;11:144–65.*

microenvironment using biomaterials linked to the immune system to stimulate cell to carry out repairs [156,157,194] (Fig. 66.5).

Cell-based approaches

If an existing degree of periodontal dysfunction already exists and cannot be restored by endogenous mechanisms alone, stem-cell implantation to enhance a regenerative outcome could be pursued as an alternative (Table 66.2). In addition to promoting tissue repair directly, MSCs have also been shown to modulate the immune system and attenuate tissue damage caused by excessive inflammation [6]. This immune modulation has been found to be an active process that renders stem cell therapy.

Scaffold-free cell delivery

Without the use of scaffolds, cells can either be injected directly to the defect or form sheets/microtissues for surgical implantation (reviewed in Ref. [14]). The main drawback of single-cell injection is the high cell loss caused by washout and the low level of integration of the transplanted cells, in addition to the risk of unwanted neoplastic growth if the cells eventually settle in nontarget sites. The development of advanced scaffold-free delivery systems is an emerging subdiscipline of regenerative medicine with broad applications and significant impact in orthopedics and reconstructive surgery. For example, cell sheets/microtissues allow for the generation of functional cell transplants in which cells can survive, grow, and recapitulate native tissue characteristics. In this concept, fibroblasts, or other cell types that secrete significant amounts of ECM proteins, are cultured for a prolonged period to create sheet/tissue-like structures for therapeutic use [115]. Based on the presence of deposited ECM produced during in vitro incubation, the cell transplants can be easily transferred and attached to other surfaces, such as tooth root and host bone tissues. The resulting cell sheets/pellets retain their original ECM and cell–cell contacts to facilitate cell integration and tissue formation.

Because cell sheet engineering can produce functional layers of cells, various types of cell sheet transplantations without scaffolds have been tested for periodontal regeneration, and these have shown significant potential to induce the reformation of the PDL and cementum [39,43,45]. Thus the application of cell sheets may be an effective clinical strategy, and the safety and efficacy were evaluated, both in vitro and in vivo, and presented no evidence of malignant transformation [50,197]. Very impressively, this concept has also been tested in a feasibility/pilot study in which autologous PDLCs were utilized in the treatment of human periodontitis [41]. Recently, a randomized clinical trial in which autologous PDLSC sheets in combination with Bio-Oss was used to treat periodontal intrabony defects has already been performed [48,49]. Although the use of PDLSC sheets in combination with bone graft materials did not produce satisfying therapeutic outcomes, this preliminary study confirmed the safety and feasibility of translation of stem cell sheets utilized in clinical practice. Considering the complex microenvironment of periodontal defects (e.g., oral microorganism, inflammatory, and mechanical stimuli) and the complex structure of periodontium (alveolar–PDL–cementum) to be regenerated, future clinical trials can focus more on ingenious designing of cell sheets, for example, multiple-layered cells sheets with inflammatory or hypoxic pretreatments.

Cell pellets or microtissues are groups of cells (cell reaggregates) normally ranging in size between 100 and 500 μm in diameter. These cell aggregates gain structure and functionality resembling the native tissue when dispersed cells are grown under certain culture conditions [200]. Keeping this in mind, ex vivo expanded dental

stem cells were grafted to the periodontal defect without the need of a scaffold, where the cellular pellets could cover the denuded root surface thoroughly and fill the defect [44]. Furthermore, bilayered cell pellet constructs comprising calcified bone-forming cell pellets (i.e., BMMSCs) and cementum/PDL-forming cell pellets (i.e., PDLSCs) can be fabricated in vitro via the intrinsic capacity of monodispersed cells to self-assemble into a

microtissue (e.g., 3D spheroid). This strategy may provide an alternative to reconstruct extensive periodontal defects and achieve a predictable and complete regeneration of the periodontium. However, the possibility of microtissues turning into tumors based on their structural similarity is a great concern, especially when undifferentiated cell types are used [201].

Scaffold-based cell delivery

From an engineering standpoint, current approaches to periodontal regeneration via scaffold-based cell transplants can be summarized into four possible strategies [14]:

- Stem cells are amplified by ex vivo expansion and differentiated into the target cell type before being seeded into scaffolds to constitute the transplants;
- Stem cells are amplified and differentiated directly in the scaffold before implantation, which is a strategy more suited to adult stem cells, but instructive signals need to be incorporated into the scaffolds to effect direct cell proliferation/differentiation in situ within the scaffolds;
- Stem cells are partially differentiated into progenitor cells, either before or after seeding into scaffolds, to give rise to proto-tissues; following implantation, these constructs transiently release progenitors that migrate into surrounding regions where they undergo terminal differentiation, integrate and contribute to regeneration of the lesion areas (prolonged release of stem/progenitor cells may be achieved when a suitable scaffold is used to maintain them in a partially differentiated state).
- Injectable transplants composed of pristine or stimulated stem cells encapsulated in biodegradable hydrogels; this strategy is attractive for soft tissue repair or treatment of solid tissues with critical size defects that are too fragile for surgical intervention.

All four strategies have been tested in periodontal tissue engineering. Injectable materials are considered to be the ideal delivery vehicles for cells and bioactive factors, because they can be delivered by a minimally invasive process and can fill irregular spaces of the defect. The injectable system can offer early mechanical stabilization by in situ polymerization, such as fibrin and alginate [85]. The rapid degradation of fibrin can be decelerated by modification with PEG, thus creating a hybrid material for robust cell delivery [172]. It is known that PRP may enhance new bone formation and accelerate existing wound healing process. Therefore autologous injectable scaffold was used to deliver BMMSCs to the periodontium [32]. Although cell transplantation via injectable matrices into sites of articular defects has been successful, it has not been tested in either preclinical or clinical studies to demonstrate whether injections of stem cells into periodontal defects can achieve significant improvement.

In contrast, hydrogel sponges as vehicles for cell and drug delivery for periodontal regeneration have been tested in various animal models and in clinical practice with success [158,198]. In terms of synthetic biomaterials, a pilot study has demonstrated that cementoblasts have a marked ability to induce mineralization in periodontal wounds when delivered via PLGA polymer sponges [56]. Impressively, a collagen sponge scaffold has been shown to be an effective cell delivery vehicle for oromaxillofacial bone tissue repair in patients [31].

Solid scaffold-cell transplants may stimulate the repair of damaged/diseased tissue while maintaining adequate integrity, where HA/TCP can be used directly as a cell delivery scaffold [42,43]. The requirements and design of scaffold systems for cell delivery have been discussed previously in this chapter. Many promising strategies for functional tissue engineering aim to replicate components of the natural cellular microenvironment by providing a synthetic ECM and by delivery of GFs [137]. A major clinical challenge in the reconstruction of large oral and craniofacial defects is the neogenesis of osseous and ligamentous interfacial structures where the natural 3D shape of the tissue needs to be recreated. In this regard the multiscale computational design and fabrication of composite hybrid polymeric scaffolds (PCL-PGA) to carry genetically modified human cells to regenerate human tooth dentin−ligament−bone complexes have been tested in vivo. This approach offers potential for the clinical implementation of customized periodontal scaffolds that may enable regeneration of multitissue interfaces required for oral, dental, and craniofacial engineering applications [10,11]. Recently, cell-based research has focused on the geometric design of scaffolds for tissue engineering. However, the orchestration of multiple tissue formation, spatial fibrous tissue organization, and endpoint functional restoration using a single in vivo scaffold system remains a significant challenge.

Stem cells can potentially be expanded on microcarrier beads in spin culture for direct transplantation into tissue defects. The process of encapsulation physically isolates cells from the outside environment and aims to maintain cellular physiology within a selectively permeable membrane [199,202]. By mechanically blocking the cells from immune attack, this technology significantly reduces posttransplantation cell apoptosis and offers a solution to the shortage of donors for functional cell transplantation, particularly since it allows xenobiotic or allogenic cells to be used. However, this therapy has not yet been introduced to periodontics, and it still faces many challenges, such as materials choice and design, before it can be moved into clinical reality [203].

In prospect, shape memory materials are potentially useful for periodontal regeneration, although they remain to be tested. These materials can deliver bulky scaffolds via minimally invasive surgery to the periodontal defects. Using these smart materials, future scaffolds may be fabricated in a condensed state before transplantation and then later acquire the desired shape in vivo [200]. Self-shaped hydrogels can be structurally collapsed into smaller, temporary shapes that permit their minimally invasive delivery in vivo. Scaffolds are rehydrated in situ with a suspension of cells or cell-free medium and delivered through the same catheter. The rapid recovery of the scaffold properties facilitates efficient cell seeding in vivo and permits neotissue formation in the desired geometries [203]. Improved delivery platforms coupled with enhanced understanding of the mechanistic/biological regulators of tissue formation should lead to better and more predictable therapeutics within the next decades [148].

Challenges and future directions

The currently available treatments, which are based on the "damage to heal approaches," have had only limited success in periodontal medicine. With an increasing aging population, tissue-engineering strategies provide important cures and hope for the treatment of periodontal disease, and they have set the stage for successful regeneration of many other tissues. The development of biological transplants for reconstructive therapies has considerably improved the currently available treatment options for periodontal repair. Particularly, the accelerated pace of research in the stem-cell field and the accumulated body of knowledge has spurred interest in the potential clinical use of stem cells [17]. This developing area is attracting increasing attention from both the private and government sectors because of its considerable economic and therapeutic potential. However, there are critical steps in moving the field toward human clinical utility [204]. In particular, the events following cell transplantation are poorly understood, underscoring the considerable need for robust preclinical modeling for the evaluation of the safety and efficacy of stem cells. Although the clinical application of stem cells to the regeneration of periodontal tissue has begun, the risks of stem-cell therapies should not be ignored or underestimated by clinicians and researchers [14].

There are two main criteria for successful tissue engineering [7]. First, there are the engineering principles, which relate to biomechanical properties of the scaffold, architectural geometry, and space maintenance. In this regard, biomaterials are increasingly being developed as in vitro microenvironments mimicking in vivo stem-cell niches. Future successful periodontal bioengineering may very well rest on the ability to effectively utilize these biomaterials as delivery platforms for appropriate cells and/or factors [148]. However, current macroscale methodologies to produce these niche models fail to capture the spatial and temporal characteristics of the complex native stem-cell regulatory systems. The second criterion relates to the biological functions of the engineered construct, including cell recruitment, proliferation, and survival in culture, and at the site of implantation, neovascularization and delivery of GFs necessary for successful differentiation and tissue regeneration. However, control over stem-cell fates within a complex in vivo milieu is extremely difficult and represents the most challenging issue faced by current periodontal bioengineering.

Tissue engineering is making an important impact on the concept of periodontal therapy, and several clinical trials involving transplantation of stem cells into human patients have already begun or are in preparation (reviewed in Refs. [14,204]). The use of protein- or cell-based therapy to enhance and direct periodontal wound healing into a more predictable regenerative path is being exploited in bioengineering efforts that aim at developing a new therapeutic paradigm for clinical application. As tissue engineering becomes more of a clinical reality through the ongoing bench-to-bedside transition, research in this field must focus on addressing relevant clinical situations [204]. Acknowledging that tissue regeneration alone is not the only answer to predictably securing a long-term stable treatment for the patient with a history of periodontal disease, host modulation therapies are therefore rising as an important aspect in the control of periodontal diseases and tissue reengineering [4]. Although most in vivo work in the area of periodontal tissue engineering focuses on tissue regeneration within sterile, surgically created defects, there is a growing need for the investigation of engineering approaches within contaminated or infectious wound beds, such as those that may be encountered following tissue damage by periodontitis. As discussed within the context of this chapter, there are a number of developing systems that have the potential to optimize tissue healing biology. A major obstacle that remains today is how to maximize the utility of therapeutics delivered to a passive or permissive environment where there is a context for the type of cell needed but in which very few biological signals are given to encourage normal cell function [4]. In addition, the tissue-engineering field still needs to confront other hurdles, such as identifying the best cell sources, clinically relevant cell numbers, an effective mode of administration, the integration of new cells into existing tissue matrices, and the achievement of functional properties of tissue equivalents using an expanded repertoire of biomaterials. Finally, major constraints to the tissue-engineering fields remain in the context of practical, safety, and regulatory concerns related to the application of these technologies in the clinical arena [4].

Closing remarks

Regenerative therapies for periodontal disease that use patients' cells to repair the periodontal defect have been proposed in a number of preclinical and clinical studies. Periodontal tissue–derived stem cells, such as PDLSCs, are committed toward all of the periodontal developmental lineages that contribute to cell turnover in the steady-state and would thus be useful cell sources for treating periodontally destructive diseases, such as periodontitis. Treatments that partially regenerate damaged periodontal tissue through the localized administration of GFs have now been established. Although the clinical practice is not very successful, such regenerative therapies have provided very useful and feasible clinical study models for the future design of tissue engineering and stem-cell therapies. Using currently available clinical strategies, partial regeneration of the periodontal tissue is becoming possible; however, methods to achieve the functional regeneration of large defects caused by severe periodontal disease are still lacking. To address this, it is essential to better understand the cellular and molecular mechanisms underlying periodontal development and, thereby, identify the appropriate functional molecules that induce the differentiation of stem cells into periodontal lineage cells for the successful reconstruction of periodontal tissue. The field of periodontal bioengineering has entered an exciting new developmental phase that will make increasingly important contributions to the patient. Particularly, a number of biological technologies are being aggressively explored for clinical translation, signifying a veritable "coming of age" of the field. However, such issues as appropriate delivery devices, immunogenicity, autologous cells versus allogenic cells, identifying tissues that provide the most appropriate donor source, control of the whole process, and cost-effectiveness are all important considerations that should not be overlooked. The future of periodontal bioengineering is undoubtedly driven by technology. New applications and improvement upon current designs will depend heavily on innovations in biomaterials engineering. Progress in stem-cell biology will be imperative in dictating advances in stem cell–based regeneration. A better understanding of the molecular mechanisms by which substrate interactions impact stem-cell self-renewal and differentiation is of paramount importance for targeted design of biomaterials. Discoveries in the fields of developmental biology and functional genomics should also be exploited for broadening the repertoire of biological molecules that can be incorporated into biomaterials for fine-tuning stem-cell activities. With the merger between the two powerful disciplines—biomaterials engineering and stem-cell biology—a new drawing board now lies before us to develop therapies that promise to revolutionize periodontal tissue engineering.

Respiratory system

Chapter 67

Cell- and tissue-based therapies for lung disease

Jeffrey A. Whitsett, William Zacharias, Daniel Swarr and Vladimir V. Kalinichenko

Division of Neonatology, Perinatal and Pulmonary Biology, Cincinnati Children's Hospital Medical Center, Perinatal Institute, University of Cincinnati College of Medicine, Cincinnati, OH, United States

Introduction: challenges facing cell and tissue-based therapy for the treatment of lung disease

The lung is a remarkably complex organ that evolved for the adaptation of vertebrates to terrestrial life. While embryonic development proceeds normally in the absence of lungs, life after birth requires respiration, a process that is dependent upon the structure and function of the lung. The respiratory tract consists of distinct anatomic regions from the nasal passages, pharynx, larynx, trachea, bronchi, lobar bronchi, bronchioles, and peripheral airways that direct inhaled gases to the alveoli. The distinct architecture of these regions is populated by a great diversity of cell types with distinct functions, (Fig. 67.1) [1].

Lung function is entirely dependent on its remarkable structure that exchanges millions of liters of environmental gases throughout our lifetime. Unlike other organs, for example, endocrine organs that synthesize and secrete hormones critical for the growth and metabolism of many target organs, respiration is an intrinsic property defined by lung structure and mechanics. Acute and chronic pulmonary disorders causing respiratory failure are major causes of morbidity and mortality. There are limited curative therapies for respiratory failure caused by pulmonary disorders, for example, congenital malformations, diffuse interstitial lung diseases (ILD), emphysema, chronic obstructive pulmonary disease (COPD), pulmonary fibrosis, and pulmonary hypertension, other than lung transplantation with its accompanying clinical challenges. Regeneration or replacement of functional respiratory tissues remains a long-term goal for ventilatory failure whether related to airway or alveolar disorders. A number of reviews summarize progress in tissue engineering and regenerative medicine relevant to pulmonary diseases [2–4]. New therapies will depend on protecting lung structures that bring environmental gases to an extensive alveolar surface across which oxygen and carbon dioxide are exchanged with the pulmonary vascular bed. Since the pathogenesis in many pulmonary disorders is complicated by defects in mucociliary clearance, and innate, acquired immunity, cell-based therapies will need to account for the highly inflammatory tissue environments characteristic of acute and chronic pulmonary diseases. Achieving tissue or cell-based treatments must overcome formidable technical challenges for regenerative medicine, especially considering the extensive tissue remodeling and inflammation associated with life-threatening pulmonary disorders. Repair/regeneration of tissues in conducting airways (e.g., the repair or replacement of the larynx, trachea, or bronchial cartilage) or the delivery of therapeutic cells or cellular products to the lung parenchyma is also the target of regenerative medicine. This chapter will consider issues regarding the application of cell and tissue-based therapies for the prevention and treatment of lung disease. The development of new therapeutic strategies, for example, the use of endogenous lung stem cells, mesenchymal stem cells (MSCs) or their products, and induced pluripotent stem (iPS) cell-based treatments using tissue engineering will depend upon knowledge of pulmonary morphogenesis and repair of lung structures (Fig. 67.2).

Understanding these processes will be useful in guiding studies in which the principles of lung cell–developmental biology are applied to enhance the treatment of life-threatening pulmonary disorders.

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00069-1

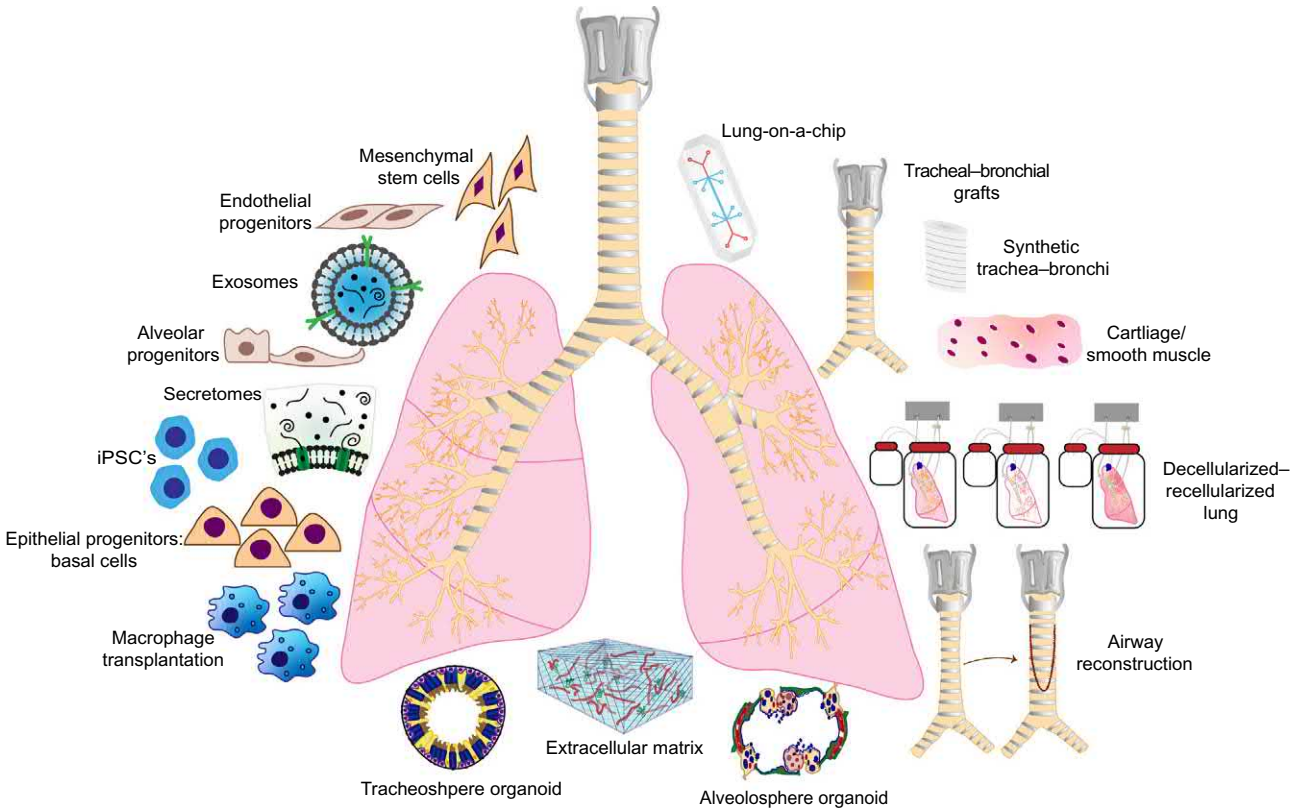

FIGURE 67.1 Strategies for cell and tissue-based therapies for lung diseases. Advances in cell and molecular biology and engineering are being applied to enhance normal lung regeneration or replace cells and tissues for the treatment of life-threatening pulmonary diseases. Research strategies include the delivery of cells, for example, mesenchymal stem cells, lung endothelial, and epithelial progenitors, induced pluripotent stem cells, macrophages or their cellular products, via the airways or the circulatory system. Lung progenitors are seeded on biomatrices, decellularized, and recellularized lung tissues and are being studied at air–liquid interface in perfused and ventilated devices. Tissue engineering and cell-based therapies are being used to produce tracheal–bronchial grafts for the prevention of airway scarring after surgery.

Lung morphogenesis informs the process of regeneration

The lung is a highly complex organ formed by the intricate interplay of dozens of cell types, with contributions from each of the three germ layers. Lung morphogenesis begins as evagination of a small cluster of endoderm-derived cells within the anterior foregut (Fig. 67.3). Epithelial cells of the lung primordia proliferate and migrate into the splanchnic mesenchyme. During, and perhaps even prior to this initial outgrowth of the nascent lung, a complex series of signals are exchanged between the epithelium and mesenchyme which are essential for the proper patterning, differentiation, and outgrowth of each cellular compartment. Signals from epithelial progenitors instruct vasculogenic and angiogenic processes in endothelial progenitors in the splanchnic mesenchyme. Interactions among mesenchymal, vascular, and smooth muscle cells with the epithelial cells produce the basic branched structure of the embryonic lung during the process of branching morphogenesis. Paracrine and autocrine cell interactions are regulated by numerous signaling and transcriptional pathways that instruct cell proliferation, migration, and differentiation. Extensive progress has been made in recent years in understanding the signaling pathways, transcription factors, and molecular and cellular processes by which the trachea, bronchi, and peripheral airways are formed, and are reviewed elsewhere [5–10]. Knowledge of these signaling pathways and transcription factor networks will prove to be a fundamental tool in advancing our ability to repair and regenerate the injured lung [1,11–14].

During early embryonic development of the respiratory epithelium, pluripotent cells are initially programmed to produce endoderm and are subsequently restricted to anterior foregut endoderm. Next, cells within the anterior foregut endoderm are specified to produce lung epithelial progenitor cells that will in turn generate a diversity of respiratory epithelial cells that line the conducting airways and alveoli of the mature lung (Fig. 67.2). Wnt signaling from the splanchnic mesenchyme induces foregut endodermal cells to produce lung rather than esophageal cell progenitors. Suppression of BMP (bone morphogenic peptide) signaling, retinoic acid signaling, receipt of high

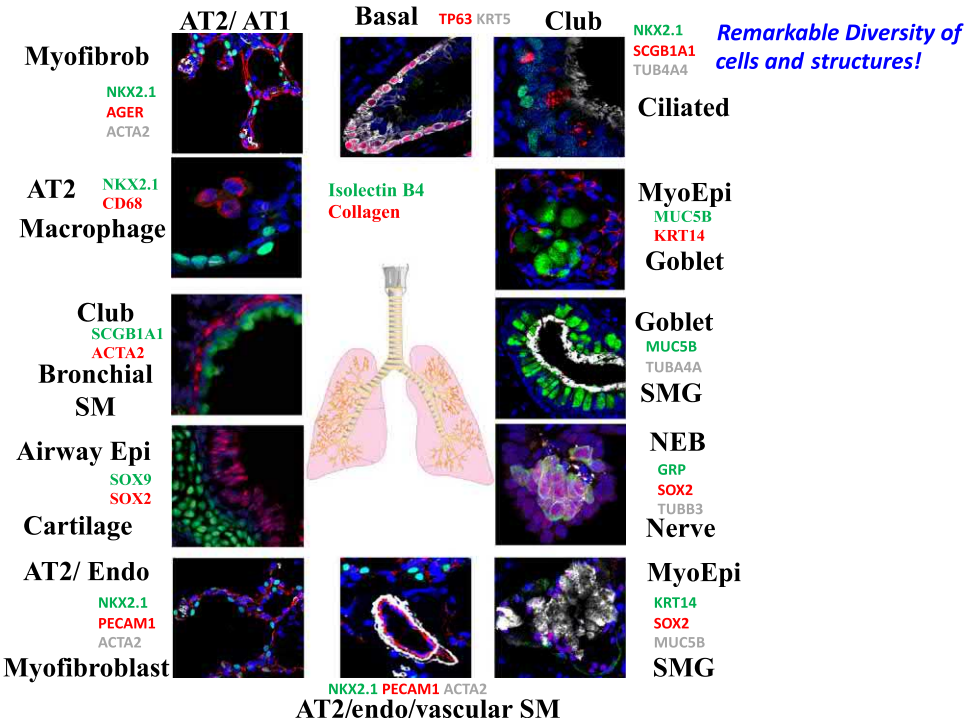

FIGURE 67.2 The complexity of the human lung: a challenge for cell and tissue-based therapy. The respiratory tract from trachea to alveoli is a remarkably complex organ whose structure is critical for respiration. The lung is composed of a diversity of cell types, located in precise anatomical niches that together provide ventilation for the alveolar gas exchange region and the lung periphery. Mucociliary clearance, innate and acquired immunity protect the lung from infection and injury. A diversity of progenitor cells responds to repair the lung after injury and to maintain homeostasis throughout life. Cell and regenerative therapies for lung disorders depend on knowledge of the formation and repair of lung structures, seeking to protect, repair, or replace lung structures critical for ventilation. *Adapted from Whitsett JA, Kalin TV, Xu Y, Kalinichenko VV. Building and regenerating the lung cell by cell. Physiol Rev 2019;99:513–54.*

levels of Fibroblast Growth Factor (FGF), and expression of specific Wnt ligands (Wnt2A/B) serve to specify lung epithelial cell progenitors from those destined to form other organs along the gut tube (e.g., esophagus, thymus, thyroid, the gastrointestinal tract, liver, and pancreas) and initiate branching morphogenesis, [15–24] knowledge useful in directing production of lung cells from embryonic stem (ES) and iPS cells. The commitment, restriction, and differentiation of endodermal cells to form the lung buds are first marked by the expression of NKX2-1 (previously known as thyroid transcription factor-1, TTF-1) [25]. While the trachea and main bronchi are found in NKX2-1 gene deleted mice, branching morphogenesis and differentiation of pulmonary epithelial cell types fail to occur. Complete separation of the trachea and esophagus requires NKX2-1 (thyroid transcription factor 1), SHH (sonic hedgehog), BMP, WNT, and SOX2 signaling, to name a few. In the mouse, lung tubules, stromal, and vascular components typical of the normal lung are lacking in the absence of NKX2-1 [26]. The activity of NKX2-1 is influenced by its interactions with other transcription factors and cofactors that regulate gene expression and differentiation in the various cell types that line the respiratory tract. NKX2-1 is coexpressed with a number of transcription factors, including FOXA2, FOXA1, GATA-6, NF-1, ETV5, SOX2, SOX9, and ETS family members (to name a few), to regulate gene expression and cell differentiation during the formation of the respiratory epithelium [27,28]. Early lung branching morphogenesis in mouse is a highly stereotyped process, and by this point in development, the basic proximal–distal patterning of the lung is established [29,30]. The distal tips of the branching lung contain progenitor cells marked by the expression of SOX9. Early in development, SOX9 + progenitor cells make both airway and alveolar epithelial cells but later during mouse lung morphogenesis, serve as progenitors for the alveolar epithelium [31–33]. In contrast, SOX2 is required for proper differentiation of the conducting airway epithelial cells [34,35]. The precise roles of SOX2 and SOX9, and the mechanisms delineating proximal and distal cell types in the human lung epithelium remain incompletely understood. A recent study identified airway cells coexpressing both of these critical transcription factors, a co-occurrence not observed in mouse [36]. Signaling between the lung mesenchyme and respiratory epithelial cells and between the subsets of cells establishes the number and sites of distinct cell types that line conducting and alveolar regions along the cephalocaudal and ventral–dorsal axes of the lung.

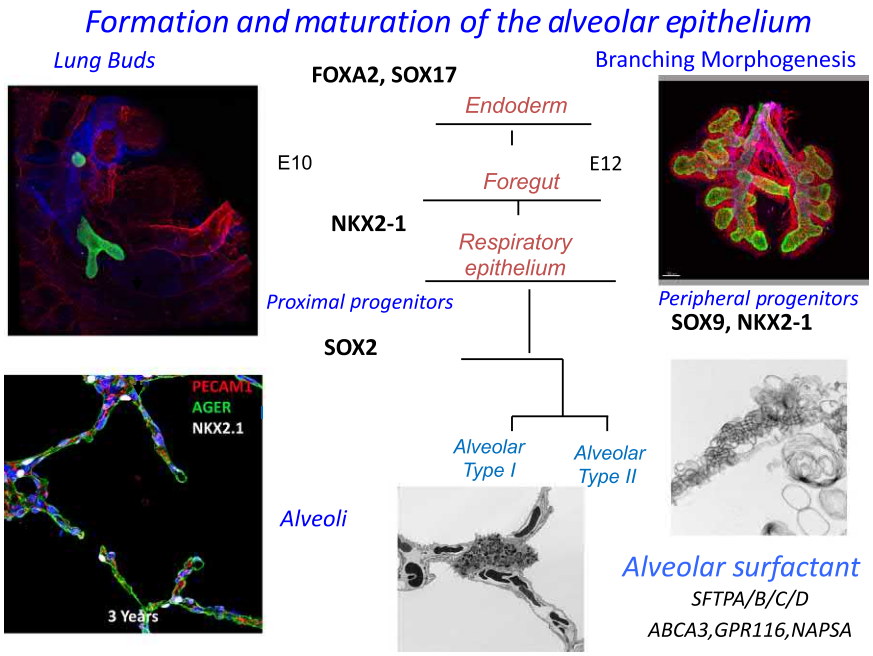

FIGURE 67.3 **From lung bud to alveolar epithelium.** Formation of the embryonic trachea and peripheral lung buds are identified in the fetal mouse embryo on embryonic day 9–9.5 by the expression of NKX2-1 (green) a homeobox gene critical for the formation of the respiratory tract and thyroid (upper left). The lung buds undergo growth and branching morphogenesis and the pulmonary vasculature (red) forms in increasingly close apposition to the epithelial tubules (green) (upper right). Before and after birth the lung undergoes sacculation and alveolarization to create the air spaces and an extensive gas exchange region wherein alveolar epithelial cells (AT1 and AT2 cells) are in close contact with the microvasculature (lower left). AT2 cells synthesize and secrete pulmonary surfactant needed to reduce surface tension and to maintain lung volumes during respiration (shown in the electron micrographs). Sox2, a transcription factor, is critical for the formation and differentiation of the conducting airway epithelium; Sox9 and NKX2-1 program the peripheral lung saccules from which the alveoli are formed during development. *Adapted from Whitsett JA, Kalin TV, Xu Y, Kalinichenko VV. Building and regenerating the lung cell by cell. Physiol Rev 2019;99:513–54.*

Integration and refinement of signaling and transcriptional pathways during lung formation

A number of signaling molecules mediate the autocrine and paracrine signals that are precisely regulated during lung formation. Wnt-β-catenin [15–19], FGF [20,21,37], SHH [38,39], BMP4 [17,22,40], Notch [41–44], retinoic acid [23,45], and Hippo-Yap [46–49] pathways play critical roles during the formation of the lung. Knowledge of the role that these signaling pathways play in the formation of the lung has been a key aspect of recent successes in differentiating human ES cells and iPS cells (iPSCs) into specific lung epithelial subtypes. Moreover, the role that these same signaling pathways play in regulating adult lung progenitor cell populations is an active area of investigation [50,51].

Although many of the core signaling pathways and transcription factors that direct lung development have been defined over the past several decades, mechanisms by which these signals are integrated and retained at the cellular level remain incompletely understood. For example, recent work highlights the role that noncoding RNAs, including microRNAs and long noncoding RNAs, play in providing additional layers of control over gene expression [52–56]. Establishment of proper patterns of chromatin "state," including DNA methylation, chromatin accessibility, histone post-translational modifications, chromatin conformation, and even the large-scale topographical configuration of the genome, are essential for normal development and cellular identity [57,58]. The role that epigenetic modifications play during the course of normal lung development and regeneration of the injured lung is just beginning to be explored.

The mature lung consists of diverse epithelial and mesenchymal cell types

Recent single-cell RNA sequencing identified the remarkable diversity of distinct cell types comprising the lung. For example, the normal mouse lung contains more than 25 major cell types including diverse epithelial, endothelial, mesenchymal, fibroblasts, smooth muscle, and bone marrow–derived cells that comprise the peripheral lung parenchyma [59–64]. The lung epithelium lines the entire airway tree and covers the massive surface area of the alveoli needed to facilitate gas exchange. The cell types present at each point along this proximal–distal

(cephalocaudal) axes of the lung are precisely patterned but vary greatly both in their location and relative distribution between species. Moreover, the number of airway branches, number of submucosal glands, and the extent to which the supporting cartilaginous rings and airway smooth muscle extend down the airway tree vary among species. However, the basic cell types making up the lung epithelium appear to be well-conserved in vertebrates.

The largest and most proximal airways are supported by a thick layer of surrounding mesenchyme, smooth muscle, and cartilaginous rings. The airway epithelium itself is lined primarily by ciliated, secretory, and basal cells but includes relatively rare, but highly specialized epithelial, cell types, including ionocytes, neuroendocrine cells, and brush cells. Neuroendocrine cells can be found as either isolated cells or as organized clusters called neuroepithelial bodies (NEBs), which are primarily located at branch points along conducting airways. NEBs are well innervated and likely serve an important sensory and immune role in the lung and may also provide a niche with unique repair capacity [65,66]. Single-cell RNA sequencing from large numbers of cells have identified brush type cells and ionocytes, which likely play important roles in chemo-sensing fluid and electrolyte homeostasis [67]. Large cartilaginous airways are rich in submucosal glands consisting of multiple epithelial cell types, including myoepithelial cells, goblet, club, and ciliated cells. Submucosal glands secrete fluids, electrolytes, mucins, and host defense proteins critical for mucociliary clearance. Basal cells lining the conducting airway and the submucosal glands are an important progenitor cell population, capable of generating the other airway epithelial cell types in response to injury [68–70]. Smaller, noncartilaginous airways are lined primarily by a more distinct, columnar epithelium consisting of ciliated and secretory cells.

The distal airspaces of the lung are lined by squamous AT1 and cuboidal AT2 epithelial cells. AT2 cells synthesize and secrete pulmonary surfactant required for lung inflation during the respiratory cycle. Lack of pulmonary surfactant in preterm infants causes neonatal respiratory distress syndrome (RDS), a potentially lethal condition. Ongoing dysfunction of AT2 cells after birth can cause diffuse, life-threatening lung disease [71,72]. Alveolar surfaces are lined primarily by AT1 cells, which provide a critical interface between the incoming air and the closely apposed underlying capillary network. Many of the key transcription factor networks coordinating gene expression within these two cell types have been defined with recent new insights gleaned from single-cell RNA-sequencing studies [1].

While cellular diversity within the lung mesenchymal cell populations is less well defined, recent studies have distinguished molecular features of this complex group of cells. Proximal regions of the lung are supported by cartilage, nerves, larger pulmonary arteries, veins, and lymphatics, as well as tracheal–bronchial glands. Pulmonary vessels (arteries, veins, capillaries, and lymphatics) are precisely aligned with the airway lobes and acinar segments and are supported by smooth muscle and a diversity of lung pericytes, fibroblasts, or "stromal" cells. In alveolar regions, mesenchymal cells are less abundant, and endothelial cells within the microvascular network come in close contact with AT1 epithelial cells. The alveoli are also supported by an elastic network consisting primarily of elastin and collagen.

The importance of mesenchymal cells, long thought to be a fairly homogenous population of "supporting" cells, is starting to become better appreciated. Single-cell RNA sequencing and lineage tracing identified Wnt responsive, Pdgfra + mesenchymal cells in alveolar regions, termed mesenchymal alveolar niche cells. These cells are critical for alveolar epithelial cell growth and renewal. In contrast an Axin2 + myofibrogenic progenitor cell forms myofibroblasts and airway smooth muscle cells and contributes to fibrotic responses after injury [73]. LGR5 and LGR6 demarcate distinct populations of mesenchymal cells, with LGR6 marking airway smooth muscle cells supporting bronchiolar epithelial differentiation. LGR5 marks mesenchymal cells supporting alveolar epithelial growth and differentiation [74]. These studies highlight the importance of autocrine–paracrine and direct cell–cell interactions among the various epithelial and mesenchymal cell populations to control proliferation and differentiation during both lung morphogenesis and repair of the adult lung after injury. Mitotic activity of the lung parenchyma is generally high during embryonic and early postnatal development of the lung. In contrast, proliferative rates in the mature lung are remarkably low, cell turnover of lung parenchymal cells occurs over many months in the absence of lung injury.

After birth the diversity of cells with the lungs are strongly influenced by acute and chronic injury. For example, goblet cell and squamous metaplasia are associated with asthma, COPD and other pulmonary disorders. A number of chronic lung diseases are associated with an abnormal expansion of mesenchymal cell populations, for example, in pulmonary fibrosis. Many of pulmonary disorders are also accompanied by inflammation. Dynamic changes in inflammatory cells and their activated following acute and chronic injury play important roles in repair processes.

Structure and function of pulmonary vasculature

Lung is one of the most vascularized organs in the body containing elaborate networks of blood and lymphatic vessels that support respiratory function, Fig. 67.4. Successful

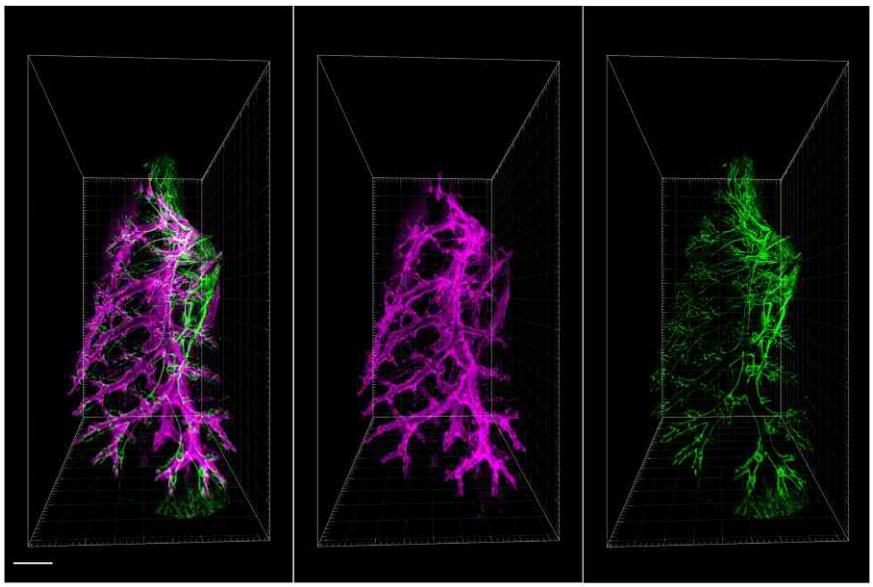

FIGURE 67.4 Complexity of lung architecture shown by confocal microscopy. Secondary harmonic image (purple) identifies collagen in vascular structures of a "cleared" normal mouse lung of 28 days of age (middle panel). Epifluorescence was used to image the airways from trachea to peripheral bronchiolar structure (green, right panel). The overlay of the two images is shown in the left panel demonstrating the bronchial structures and vasculature.

transplantation, cell and tissue-based therapies for the lung, requires the integrity of the pulmonary circulation. The human lung is perfused by both pulmonary arterial vessels, and a distinct bronchial circulation is a part of systemic blood circulation, which is supplied by circulation from the aorta. The bronchial circulation plays a major role in providing oxygen and nutrients to conducting airways. The pulmonary circulation is distinct from the systemic circulation, consisting of pulmonary arteries, veins, and the capillary microvascular networks that create the complex vascular bed within alveolar regions to facilitate gas exchange, Fig. 67.4. Pulmonary arteries deliver deoxygenated blood from the right ventricle of the heart, whereas oxygenated blood from alveoli returns to the left atrium via the pulmonary veins. The lymphatic circulation consists of the networks of lymphatic vessels and blunt-ended lymphatic capillaries that regulate pulmonary homeostasis by draining the interstitial fluid and immune cells into the thoracic duct, which drains into the systemic circulation.

Endothelial cells share the expression of cell surface adhesion molecules CD31 (*Pecam-1*) and VE-cadherin (*Cdh5*), produce PDGFb ligand, and form monolayers covering luminal surface of blood and lymphatic vessels. Arterial endothelial cells express Ephrin B2 (*Efnb2*) and Neuropilin 1 (*Nrp1*) as well as NOTCH 1 and 4, Fig. 67.5 and [75–77]. Venous endothelial cells selectively express Ephrin receptor B4 (Ephb4) and Neuropilin 2 (*Nrp2*), whereas lymphatic endothelial cells express Podoplanin (*Pdpn*), *Lyve1*, and the transcription factor *Prox1*, Fig. 67.5. Pulmonary capillaries consist of a single layer of microvascular endothelial cells that express CD34, FOXF1 transcription factor, and common endothelial markers and form an efficient gas-exchange unit with alveolar type I (AT1) epithelial cells.

Embryonic development of alveolar capillaries

Pulmonary vasculature is formed within mesenchyme located in close opposition to developing respiratory epithelial tubules. Development of vascular networks is dependent on vasculogenesis (de novo formation of blood vessels from endothelial progenitor cells) and angiogenesis (branching of preexisting blood vessels) [78–80], Fig. 67.5.

Large pulmonary blood vessels are generally considered to be formed by angiogenesis. However, recent studies demonstrated that vasculogenesis also contributes to the formation of the main pulmonary arteries and veins during early stages of lung and heart morphogenesis [81]. A common population of cardiopulmonary progenitor cells was shown to give a rise to mesodermal cell lineages that form endothelium, smooth muscle, and pericyte-like cells located in the cardiac inflow tract and large pulmonary vessels [82]. Formation of the microvascular network occurs through the differentiation of endothelial progenitors that initially migrate from splanchnic mesoderm into the lung and later expand within distal lung mesenchyme. Anastomoses between pulmonary blood vessels and the microvasculature occur between E11.5 and E13.5 of lung morphogenesis in the mouse [78–80,83,84]. This process is mainly dependent on leakage-proof remodeling of vessel walls since blood flow without vascular leak was detected as early as E11.5 [83,84]. Circulating endothelial progenitor cells also contribute to the formation of pulmonary blood vessels [85,86].

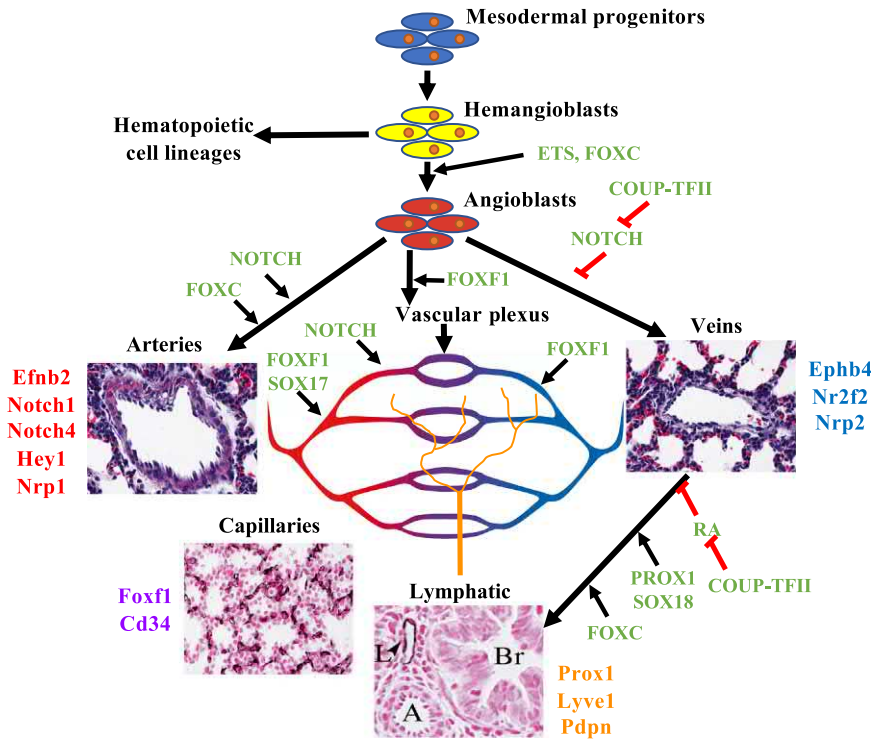

FIGURE 67.5 Embryonic development of arterial, venous, lymphatic, and capillary cell lineages. Schematic diagram shows the diversity of pulmonary endothelial cells. Mesoderm-derived bipotential hemangioblasts give a rise to hematopoietic progenitors and angioblasts (endothelial progenitors). Angioblasts differentiate into arterial, venal, lymphatic, and capillary cells. Differentiation toward arterial endothelial cell fate is dependent on NOTCH signaling. COUP-TFII stimulates venous endothelial differentiation by inhibiting NOTCH. Lymphatic endothelial differentiation is dependent upon PROX1, COUP-TFII, FOXC1/2, and SOX18. Development of pulmonary capillary endothelial cells is induced by FOXF1, SOX17, and NOTCH. Markers of each endothelial cell lineage are indicated next to microscope images. *Adapted from Whitsett JA, Kalin TV, Xu Y, Kalinichenko VV. Building and regenerating the lung cell by cell. Physiol Rev 2019;99:513–54.*

During transition between the saccular and alveolar stages of lung development, the capillary endothelium expands in close apposition to alveolar epithelial cells as AT1 and AT2 cells differentiate. The gas exchange interface is formed between capillary endothelial and AT1 epithelial cells, whereas AT2 secrete surfactant to decrease alveolar surface tension during respiratory cycles. Subsets of AT2 cells serve as progenitor cells during alveolar repair. Lung epithelium produces various growth factors and signaling molecules that regulate growth and expansion of embryonic lung microvasculature. These include VEGF, FGFs, TGF-β, SHH, WNTs. and NOTCH that act through transcription factors, including FOX, SOX, HOX, GATA, KLF, ETS, bHLH, TBX, MEF2, Nuclear receptor, and Zinc finger family members to regulate endothelial proliferation, migration, and survival (reviewed in Refs. [1,81,87–89]). Forkhead Box F1 (FOXF1) is a key transcriptional regulator of alveolar microvasculature [1,81,90]. Loss-of-function mutations in the *FOXF1* gene cause alveolar capillary dysplasia with misalignment of pulmonary veins [91,92], a severe congenital disorder associated with primary loss of alveolar capillaries, malposition of pulmonary veins, and respiratory insufficiency in the first month of life [93]. FOXF1 stimulates endothelial proliferation during embryogenesis through downstream target genes many of which are critical for VEGF, PDGF, NOTCH, and Angiopoietin/TIE2 signaling pathways [81,94,95].

Paracrine signaling between endothelial cells and pericytes is required for the formation of the pulmonary microvascular network. Endothelial cells produce PDGFb and ephrinB2 which signal through PDGF receptor β (PDGFRβ) and Eph receptor B3 (EphB3) that are expressed in pericytes [96]. Loss of either PDGFb or its receptor causes hemorrhaging due to diminished coverage of blood vessels by pericytes [97–99]. Inhibition of ephrinB2 or its receptor EphB3 decreases the number of pulmonary blood vessels and impaired alveologenesis [96,100], whereas intranasal administration of exogenous ephrinB2 prevents the loss of pulmonary capillaries and improved alveolar septation after neonatal hyperoxic injury. PDGFb provides chemoattractant stimulus to PDGFRβ-expressing pericytes as they migrate along newly formed endothelial sprouts to stabilize blood vessels [101,102]. Knowledge regarding the precise temporal and spatial coordination between signaling and transcriptional networks, which facilitate the interactions among pulmonary cell types to form and regulate pulmonary vasculogenesis and homeostasis, will be critical in developing regenerative therapies for pulmonary diseases, including idiopathic pulmonary hypertension.

Evidence supporting lung regeneration

Since the respiratory tract is continuously exposed to pathogens, including viruses, bacteria, fungus, toxic particles, and

toxicants, a remarkable system of innate defense has evolved to maintain pulmonary homeostasis throughout life. This is accomplished by the maintenance of the intrinsic integrity of the epithelial lining, functional mucociliary clearance, production of innate host defense molecules, and the instruction of acquired immune defenses that serve to maintain lung sterility after birth. Since many viruses and pathogens have developed strategies for targeting specific cells, vertebrates have also developed strategies to maintain cells capable of regeneration.

In general, the mature lung is remarkably quiescent. Proliferative rates of all types of pulmonary cells are remarkably slow in contrast to the rapid and ongoing turnover of cells lining the gastrointestinal tract or skin, wherein stem cells proliferate, differentiate, migrate, and senesce within days. Mouse lineage tracing studies suggest that approximately 1% of lung epithelial cells turn over every month of life, suggesting that some pulmonary cells may last the entire life of the animal.

After injury or resection, however, the lung is capable of remarkable proliferative responses, and repair of the respiratory epithelium occurs rapidly to maintain alveolar-capillary permeability and pulmonary homeostasis. Failure to repair is associated with the loss of alveolar epithelial integrity and capillary leak syndromes that can cause acute respiratory failure, as seen in Acute Respiratory Distress Syndrome (ARDS). Repair of the respiratory epithelium is dependent upon endogenous cells that line distinct regions of conducting and peripheral airways rather than bone marrow or progenitor cells produced by epithelial-mesenchymal transition. Epithelial cells that survive injury rapidly spread, migrate, and proliferate to restore the epithelium surfaces. One example is the postpneumonectomy response in rodents after ipsilateral lung resection that is followed by rapid proliferation of many cell types in the remaining lung tissue, serving to regenerate lung volume and function within several weeks after resection [103]. Lung regeneration depends on available space (chest volume), likely indicating that tissue stretch is an important component of the growth response as has recently been clearly demonstrated during development [104]. Although evidence of lung regeneration following pneumonectomy in human is less well documented, there is some evidence that the mature human lung is capable of regeneration, with younger patients demonstrating more robust regenerative capacity than older individuals. Regeneration after other injuries, including both viral and chemical, are reviewed later.

A diversity of lung epithelial progenitor/stem cells is active during regeneration

Immunohistochemistry, lineage-tracing analysis, cell sorting, in situ hybridization, and single-cell RNA profiling are being utilized to identify specific lung epithelial cell types and to identify progenitor cells (see Fig. 67.6). Cell survival, proliferation, and capacity for self-renewal and

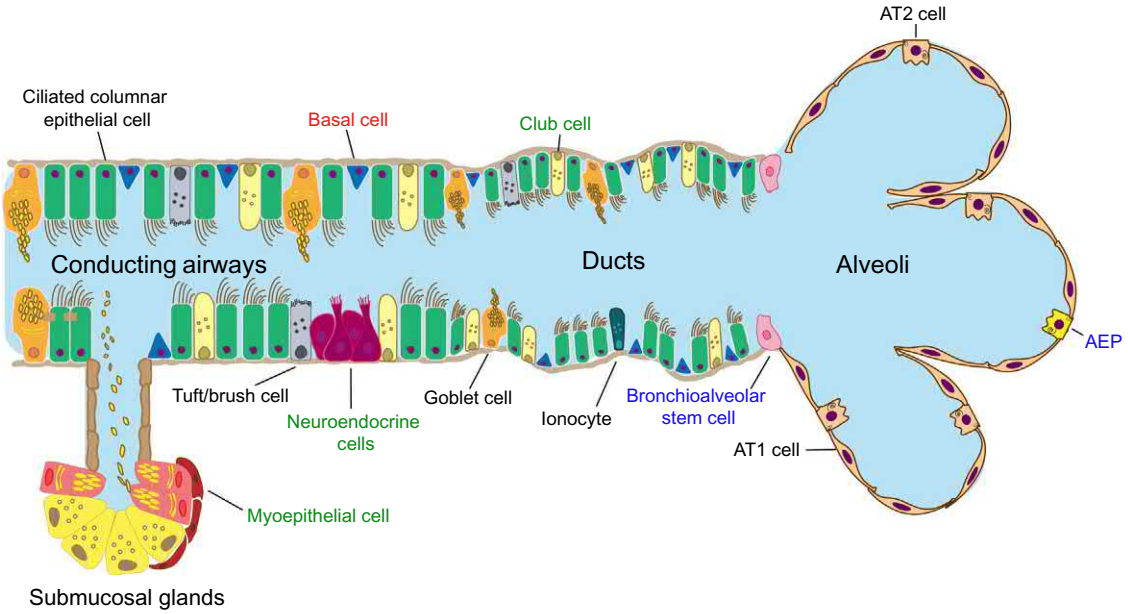

FIGURE 67.6 Progenitor relationships during lung regeneration. A diversity of lung epithelial progenitor cells maintains each area of the lung. The basal cell (*red text*) is a professional progenitor cell for the airway. Club, myoepithelial, and neuroendocrine cells (green) have plasticity and can participate in airway regeneration after certain injuries. The AEP (blue) cell subset of AT2 cells functions as an alveolar progenitor in both homeostasis and after injury, and BASC (blue) are rare cells capable of repairing both airway and alveolus depending on injury location. Cells which are predominantly without repair capacity are noted in black. *AEP*, Alveolar epithelial progenitor; *BASC*, bronchioalveolar stem cells.

differentiation differ amongst various cell types and regions within the lung [105–107]. In conducting airways the epithelium is repaired primarily by proliferation of basal cells and other nonciliated epithelial cells. Basal cells express p63 (Trp63) and variable patterns of cytokeratins (e.g., CK5 and CK14). Basal cells are capable of self-renewal and differentiate into ciliated, goblet, and other secretory cells in the airways in vivo and in vitro [105,108,109]. After severe lung injury, basal cells lining the airways and within the ducts of tracheal–bronchial glands migrate along the airway surfaces, proliferate and differentiate to contribute to repair the respiratory epithelium [105,110,111]. Lineage tracing studies demonstrate significant plasticity between basal cells and various subsets of nonciliated epithelial cells in the airway, with multiple cells capable of rapid migration, proliferation, and differentiation during repair of the conducting airways in animal models exposed to toxicants such as naphthalene or sulfur dioxide (SO_2) [70,105,109,112–120]. In addition, purified basal and secretory cells can reestablish a complex respiratory epithelium consisting of numerous airway cell types including ciliated cells, secretory, and goblet cells in vitro [121]. In contrast, lineage tracing experiment indicate that ciliated cells are not proliferative and do not serve a role as progenitor cells after injury to airway epithelium [122]. Together these data suggest a hierarchy of airway cells with varying stem/progenitor cell capabilities, with basal cells acting as the primary professional progenitor population and substantial facultative capacity within neuroepithelial and secretory cells. Regional differences in proliferation and progenitor cell behavior occur in NEBs near bifurcations of airways, in bronchoalveolar ducts, and along vessels and stroma. Mitotic activity is induced throughout the airways following injury, although selective anatomic regions of cytoprotection or enhanced proliferative capacity may serve unique functions during lung repair. Many of these responses, including which types of cells predominate in the regenerative response, depend upon the nature, chronicity, and severity of injury [123].

In smaller airways, much recent data has focused on a progenitor population within terminal bronchioles adjacent to the bronchoalveolar duct junction, termed bronchoalveolar stem cells (BASCs) [115,124]. BASCs were originally defined as CCSP- and pro-SPC-coexpressing cells that resist naphthalene injury and repopulate terminal bronchioles. Two independent lineage tracing experiments support the ability of the BASCs to renew and differentiate into various cell populations after injury, with alveolar injury biasing BASCs primarily to distal lineage differentiation and airway injury leading to primarily regeneration of the small airways [125,126]. BASCs are not abundant, and at present the relationship between BASCs and the more abundant cells progenitor cells of the airway (e.g., secretory and basal cells) or the alveolus (AT2 cells) is not clear. BASCs have to date not been identified in human lung, and while mice have a clear bronchoalveolar duct, human lung contains more extensive small airways and alveoli branch from respiratory bronchioles which are not present in mouse lung.

In the alveolar region of the lung, AT2 cell types contain substantial progenitor capacity and act to regenerate both ATI and AT2 cells after injury [127]. Proliferation of alveolar type 2 cells begins within days of alveolar injury, and it has been known for over 40 years that a subset of AT2 cells preferentially generates AT1 cells after injury [128,129]. Recent lineage tracing studies have demonstrated that Wnt signaling, a well-known factor in lung epithelial development, activates a subset of Wnt-responsive AT2 cells that functions as a facultative alveolar progenitor lineage. These Wnt-responsive AT2 cells, called alveolar epithelial progenitor (AEP) cells, function to maintain alveolar homeostasis and drive regeneration after influenza virus infection [50,51]. After injury, Alveolar Epithelial Progenitor (AEP) cells are preferentially recruited into the cell cycle and regenerate functional AT1 and AT2 cells. More limited evidence suggests that a separate population of distal $\alpha6\beta4$ integrin-expressing epithelial cells can also enter the cell cycle and participate in alveolar regeneration [130]. Type I cells are generally sensitive to injury and seldom proliferate though under specific circumstances can participate in limited alveolar repair [131]. After very severe alveolar injury that depletes these distal progenitors, a subset of basal cells migrate into the lung parenchyma and form a Krt5-positive epithelium [51,132–135]. These cells are driven to migrate by hypoxemia and fail to differentiate into normal alveolar cells, likely representing rapid but abnormal epithelial reconstitution rather than high fidelity alveolar regeneration. Self-renewal and differentiation of airway basal cells is influenced by Notch signaling [105,136], and aberrant Notch activity is present in reconstituted epithelium still present in distal lung scar months after injury [132–134].

Thus under physiologic conditions, repair is accomplished primarily by the proliferation of endogenous progenitor cells present in each of the compartments of the respiratory epithelium. As shown in Fig. 67.6, there is increasing evidence that these cells exist in a defined hierarchy of lung epithelial progenitors with substantial plasticity at least within each compartment. Understanding these normal repair processes will serve to inform the scarring and hyperproliferative responses seen following catastrophic or chronic injury that lead to airway epithelial metaplasia, dysplasia, and hyperplasia that are associated with lung fibrosis, remodeling, and cancer. In addition, recent single-cell RNA sequencing of tissue from idiopathic pulmonary fibrosis patients suggests abnormal differentiation of respiratory epithelial cells with expression

of both proximal and distal markers, suggesting pathological pathways may be distinct from physiological repair. Major challenges faced by the field today are to understand the relationship between these various cells and identify the conditions under which each progenitor population is activated for the most effective regenerative response. Whether distinct activities of subsets of respiratory epithelial cells contribute uniquely to normal or pathological repair processes and chronic lung diseases also remains to be clarified. True understanding of these relationships will be critical to define populations for engraftment and activation that could enable regenerative therapies for pulmonary diseases.

Role of lung microvasculature in lung repair

The alveolar microvasculature actively participates in regeneration of alveoli after acute and chronic lung injuries caused by chemicals, viral, and bacterial pathogens and various environmental irritants [95,137]. Alveolar repair and regeneration require coordinated signaling events between all cells comprising the alveolar wall, including endothelial cells, pericytes, type I and type II pneumocytes, fibroblasts, and alveolar macrophages. Circulating immune cells are also involved in alveolar repair by secreting various cytokines and chemokines that stimulate proliferation and migration of endothelial, epithelial, and stromal cells to restore the alveolar architecture after injury. Epithelial and immune cells in the site of injury produce VEGF, which has a dual role in the repair process. VEGF increases survival of endothelial cells and decreases alveolar damage after hyperoxia-induced neonatal lung injury in rodents [138]. VEGF increases neonatal lung angiogenesis by stimulating endothelial proliferation, migration, and survival via VEGF Receptor 2 (*Flk1*)-mediated activation of RAS/ERK and PI3K/AKT signaling pathways. Side effects of systemic VEGF administration have been also reported and attributed to acute increase in endothelial permeability and disruption of endothelial junctions, causing lung edema and inflammation [139,140]. Stem cell factor (SCF), which is produced by multiple cell types in the site of injury, signals through c-KIT receptor tyrosine kinase present in endothelial progenitor cells to increase cell proliferation and survival [141,142]. Systemic administration of SCF stimulates neonatal lung angiogenesis and accelerates alveolar repair after hyperoxic injury in newborn rats [143].

Vascular repair is directly coupled to alveolar morphogenesis after lung injury and during compensatory lung regrowth following partial pneumonectomy [144,145]. In response to VEGF and FGF, endothelial cells produce matrix metalloproteinase 14, which cleaves heparin-binding EGF-like growth factor and release the active EGF-like fragments. The active EGF-like fragments stimulate the proliferation of alveolar epithelial cells and BASCs during lung regeneration [144]. Microvascular endothelial cells stimulate differentiation of BASCs into Types I and epithelial cells in vitro and after subcutaneous injection [146]. This process is dependent on the production of thrombospondin-1 (TSP1) by pulmonary endothelial cells because $Tsp1^{-/-}$ endothelial cells are unable to support the differentiation of BASCs [146]. Increased expression of TSP1 at the sites on lung injury was linked to BMP4 and the calcineurin/NFATc1 signaling pathway [146].

Endothelial barrier function is critical for microvascular repair after lung injury [147]. Thrombin, bradykinin, histamine, reactive oxygen species, VEGF, TNF-α, and endotoxin increase endothelial permeability in vitro and in experimental animals (reviewed in Ref. [147]). In contrast, sphingosine-1-phosphate (S1P) and Angiopoetin-1 (Ang-1) have been shown to stabilize the endothelial barrier and decrease endothelial permeability [95,147]. Maintenance of endothelial barrier is critical to decrease lung edema and inflammation after lung injury. Endothelial proliferation in vivo requires tight endothelial barrier, which is needed to ensure vascular repair in the absence of vascular leak. Multiple transcription factors are implicated in the regulation of endothelial proliferation after lung injury, including STAT3, cMYC, E2F, and the Forkhead transcription factors FOXO1, FOXM1, and FOXF1 [1]. FOXF1 increases the expression of VE-cadherin and S1PR1, a receptor of S1P, maintaining endothelial barrier function after the injury [95], and stimulates endothelial proliferation by repressing cell cycle inhibitors *Cdkn1a* and *Cdkn2b* [145]. FOXM1, a downstream target of RAS/ERK pathway [148,149], induces endothelial proliferation by increasing the expression of cell cycle regulatory genes *Cyclin B1*, *Plk1*, and *Aurora B* [150,151]. In contrast, FOXO1 inhibits cell cycle progression by repressing cell cycle regulatory genes [152]. Altogether, these studies demonstrate that vascular repair after lung injury requires multiple signaling pathways and transcription factors to activate and execute the regeneration program.

Endothelial progenitor cells in lung repair

Endothelial progenitor cells (EPCs) consist of various cell populations capable of differentiating into mature cell types, including arterial, venal, lymphatic, and microvascular endothelial cells [81]. Among well-described EPCs are bipotential hemangioblasts and hemogenic endothelium, both of which are active in the yolk sac and dorsal aorta at early stages of embryogenesis [87,153]. During lung development, endothelial cell lineages mainly derive from lung resident EPCs, pericyte-like mesenchymal progenitors, and circulating endothelial cells, reviewed in [81]. c-KIT^{+}/$PECAM\text{-}1^{+}$/$CD45^{-}$ cells are abundant in parenchyma of embryonic and neonatal lungs [154] and

may represent the lung-resident EPCs since they are capable of self-renewal and differentiation to mature endothelial cell types [141,142]. In the adult lung, c-KIT-positive EPCs are rare and endothelial lining of blood vessels is mainly repaired by proliferation of resident endothelial cells that undergo dedifferentiation to enter the cell cycle [155]. Recent studies demonstrated that endothelial regeneration in large blood vessels requires the activation of stress response gene *Atf3* in differentiated endothelial cells adjacent to the site of injury, leading to appearance of a highly proliferative endothelial subpopulation expressing FOXM1 [156]. While endothelial repair in the adult lung is mostly driven by resident endothelial cells, bone marrow−derived circulating EPCs have only minor contribution to the repair process [155]. Bone marrow−derived EPCs have a low capacity to engraft into blood vessels, but these cells are capable of regulating vascular repair via paracrine mechanisms.

EPC-like cells were originally isolated from mononuclear cell fraction of peripheral blood [157]. These cells maintained their growth in vitro, expressed CD34, FLK1, and PECAM-1, formed endothelial-like sprouts on Matrigel, and supported angiogenesis in various ischemia models; however, these EPC-like cells were unable to maintain endothelial gene expression and were minimally proliferative [158]. Myeloid-derived EPC-like cells did not promote vascular repair through direct engraftment and replacement of injured endothelial cells but rather activated resident endothelial cells by releasing VEGF and HGF [158]. Myeloid-derived EPC-like cells did not maintain the endothelial phenotype a key cellular property used to define a progenitor cell [155]. In contrast to the myeloid-derived EPC-like cells the endothelial colony-forming cells (ECFCs), a rare cell subset isolated from peripheral blood [85], exhibited properties of endothelial progenitor cells, such as the ability to form clonal colonies in vitro, expression of endothelial cell-specific surface markers, the ability to form endothelial-like sprouts in Matrigel, and contribute to de novo vessel formation in mouse hypoxia models [85,86,159]. ECFCs were propagated in vitro without losing the progenitor properties [159].

Adult vascular endothelial cells (VESCs) have been recently identified and isolated from blood vessel endothelium using cell surface markers $CD31^+$ $CD105^+$ $SCA1^+$ $c\text{-}KIT^+$ [142]. VESCs self-renew, undergo clonal expansion in vitro and generate functional blood vessels connected to the host circulation [142]. While multiple types of endothelial progenitor cells, including VESCs, ECFCs, and lung resident EPCs, can contribute to vascular repair after injury, heterogeneity and hierarchy of lung EPCs remain unclear. Recent advances in single-cell sequencing may lead to the identification of additional populations of lung EPCs. Additional studies are needed to characterize functional properties of these cells and determine whether EPCs can be used for therapeutic purposes to stimulate lung repair after injury.

Pulmonary cell-replacement strategies for lung regeneration

Identification and expansion of progenitor cells capable of engrafting, proliferating, differentiating, and functioning after introduction into the injured lung represent an active area of research. While initial studies regarding multilineage replacement of lung and other tissues by c-Kit + positive progenitor cells was invalidated [160], cKit + progenitor cells do contribute to formation of the pulmonary vasculature, but not to the respiratory epithelium or other tissue compartments of the lung [141,161,162]. Nevertheless, a number of experiments support the ability of endogenous lung progenitors to engraft into the lung parenchyma after intratracheal instillation. For example, tracheal administration of fetal lung progenitors engrafted into the adult mouse lung but only after irradiation or chemical injury [163]. Human iPSC−derived lung cells differentiated into diverse lung epithelial cell types after transplantation into the kidney capsule of immunocompromised mice [36]. Advances in ex vivo lung perfusion and ventilation, may serve to enhance viability of lung explants, via cell-based therapy, thus increasing the availability of transplantable tissue. Ex vivo perfusion and ventilation provide a model useful in testing methods for conditioning explanted lungs and for the introduction of epithelial cells into the airways or endothelial cells in the pulmonary vasculature [164]. For example, isolated perfused lung is being used to test whether iPSCs, pulmonary progenitor cells, MSCs or MSC products enhance lung repair or regeneration during ex vivo perfusion [165]. Cells or cellular products are delivered via the trachea or via vascular perfusion to test engraftment, deliver potentially therapeutic cells, or products to condition lung explants for clinical use.

Induced pluripotent stem cells for study of treatment of pulmonary disease

Advances in reprogramming of somatic cells into iPS cells are transforming biology and medicine, enabling production of patient-specific iPS cells useful for study of the pathogenesis of disease and for cell-based therapies (Fig. 67.7) (for review Refs. [166−168]). The success of exogenous stem cell−based therapies for the lung and other organs will depend on the ability to isolate, culture, or genetically modify stem cells to correct gene mutations or to contribute to organ function. Because of their capacity for self-renewal and pluripotency, it may be possible

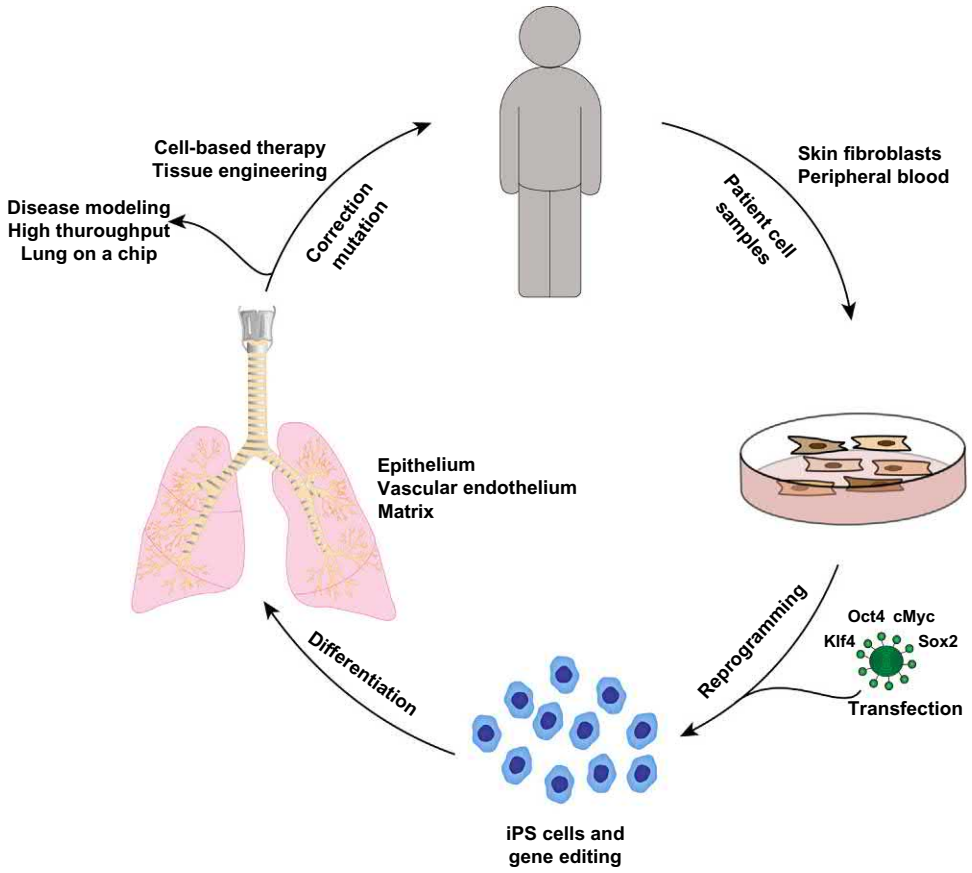

FIGURE 67.7 Induced pluripotent stem cells for study of lung regeneration. Patient fibroblasts or skin cells are grown in culture and reprogrammed by expression of transcription factors to form pluripotent stem cells. The iPSCs are cultured under conditions to induce differentiation into pulmonary endothelial and epithelial cell types. Effects of disease causing mutations on cellular functions are modeled in vitro. Mutations can be created or corrected by genetic engineering for the study of disease pathogenesis. Cells can be seeded onto biomatrices, decellularized lung scaffolds, grown in organoid cultures, and used for high throughput screening for gene and drug discovery. *iPSCs*, Induced pluripotent stem cells.

to generate large numbers of iPS cells for cell-based therapy. Reprogramming somatic cells into pluripotent stem cells overcomes social and religious barriers to the use of human ES cells. Patient-specific stem cells can be genetically modified for cell-based therapy that will substantially bypass the immunologic barriers intrinsic allograft transplantation. iPS cells are readily generated from patients' skin, blood, or other cells, and differentiated into multiple cell types in vitro, including respiratory epithelial cells. Gene transfer or genomic modification, for example, utilizing nonviral and viral vectors, TALENS, Zn-finger nucleases, and CRISPR-Cas provide the technologies enabling disease modeling and correction of genetic disorders in the future. iPS/ES cells are cultured under conditions to enhance respiratory epithelial cell differentiation. iPS/ES cells grown in defined media, at air/liquid interfaces, in organoids, or after engraftment are being used to produce a complex, highly differentiated epithelium with properties of conducting and peripheral airways. While ES/iPS cells expressing markers specific for respiratory cell types have been produced, it is unclear whether these cells fully recapitulate gene expression or other biological functions comparable to endogenous lung epithelial cells. Engineering ES/iPS cells capable of engrafting, proliferating, differentiating, and repopulating the respiratory epithelium continues to represent a considerable technical challenge.

Differentiation of induced pluripotent stem and embryonic stem cells to pulmonary epithelial cell lineages

Successful cell-based therapy for many genetic diseases affecting epithelial cell function (e.g., cystic fibrosis and mutations in genes controlling surfactant homeostasis) may require the permanent introduction of cells capable of maintaining stem cell activity as well as the ability to contribute to highly differentiate lung cell function. Differentiated respiratory epithelial cells have been produced from iPS, ES, and endogenous lung cells and expanded into organoid culture grown on various biomatrices, decellularized lung, and tracheal–bronchial grafts, in air–liquid interface cultures after instillation into the lung [163,169,170]. Cell sorting or selectable markers may be used to enrich differentiating iPS cells with lung epithelial cell characteristics during preparation. Use of cell-selection strategies and the expression of genes known to regulate differentiation of stem/progenitor cells into specific lung epithelial cell types may be used to

engineer specific cell types needed for treatment of pulmonary disorders [171]. Thus the elucidation of the signaling and transcriptional networks controlling lung cell differentiation during normal morphogenesis will be useful in guiding the production of stem cells for therapy of pulmonary diseases in the future.

Bioengineering of lung tissues

Advances in the identification and culture of endogenous lung progenitor cells and the ability to reprogram iPS or ES cells into respiratory epithelial-like progenitors enable experiments designed to seed cells into organ-like scaffolds prepared from decellularized lung tissue or on 3D-engineered scaffolds. Decellularized lung scaffolds are recellularized, reperfused, and ventilated in bioreactors for continued cell growth and differentiation [164,171]. Likewise, endothelial cells are perfused into the vascular compartment to repopulate the pulmonary microvasculature. Short-term physiological function was demonstrated after orthotopic transplantation of a recellularized lung, providing a model system with which to study lung cell biology and to test the feasibility of using various lung cell progenitor ES/iPS cells [172]. Completely synthetic scaffolds and microfluidic chambers, termed "lung on a chip," in which pulmonary cells are subjected to shear forces during ventilation and perfusion hold promise for study of lung regeneration and repair [173], Fig. 67.1.

Mesenchymal stromal cells and mesenchymal stromal cell products for the treatment of lung disease

A number of preclinical studies, primarily in rodents with infectious, chemical or ventilator induced injury, support the use of mesenchymal stem−stromal cells or their products for the treatment of acute lung injury (for review Refs. [174−176]). At present, there are approximately 80 MSC registered clinical studies designed to test their safety or efficacy for treatment of lung disease (clinicaltrials.gov). The safety of a single dose of MSCs to adult patients with ARDS was recently demonstrated [177]. MSCs are most frequently obtained from bone marrow, adipocytes, or umbilical cord blood and are being studied for treatment of various pulmonary disorders, for example, ARDS, bronchopulmonary dysplasia, lung transplant rejection, COPD, ILD, pulmonary hypertension, pulmonary cancer, and radiation pneumonitis. While early studies suggested the bone marrow cells could engraft and repopulate lung parenchyma, subsequent experiments support the concept that the cells produce paracrine factors that support tissues [178]. Conditioned media from MSCs enhanced pulmonary epithelial cell organoid proliferation and differentiation [174,179,180]. Efficacy, standardization of dose, methods of cell preparation and storage, administration, and mechanisms of action remain important issues to resolve regarding the MSC therapy for pulmonary diseases. There is increasing evidence that protective/therapeutic effects of MSCs can be conferred by exosomes, vesicles, or other products secreted by the cells. MSCs and MSC exosomes were effective in mitigating lung injury from experimental models of oxygen toxicity, ventilator, and radiation-induced lung injury in postnatal mice and are being studied for therapy of acute and chronic lung injury; for review [175,176,181−183].

Important role of the extracellular matrix in lung structure and repair

The architecture and function of the lung are dependent on the glycoprotein, collagen elastin rich extracellular matrix (ECM) that provides the scaffold upon which pulmonary cells reside and interact. Extracellular matrix supports the dynamic biomechanical forces inherent in lung ventilation and perfusion. Regenerative therapies, whether by cell or tissue replacement, will require knowledge of the multiple roles played by the ECM. Advances in imaging, proteomics, cell-matrix interactions and the use of bioreactors are providing insights into the structure and function of the pulmonary ECM or "matrisome." Pulmonary ECM is rich in elastin, collagens, glycosaminoglycans, as well as multiple signaling molecules that interact with pulmonary cells [184]. Detailed knowledge regarding composition, structure, synthesis, and remodeling of pulmonary ECM in health and disease will be needed to inform strategies to enhance lung regeneration, (for review, see Refs. [184,185]). While pulmonary scaffolds are often maintained after acute lung injury, pathological remodeling, for example, in COPD, emphysema, and pulmonary fibrosis, can be extensive; thus regenerative therapies will have to consider the abnormal tissue environments and abnormal structure of the ECM in pulmonary diseases. Successful therapies will need to repair both the abnormal cellularity, as well as the pathological scaffolds present in the diseased or injured lung. Advances in tissue engineering, for example, the use of organoids, "lung on a chip," and decellularized matrices, all represent important, recent experimental advances in the field [164,184−187]. Lung explants can be decellularized and, to remove cells of potential antigens, recellularized, with lung progenitor cells or iPSCs that are seeded onto the retained lung ECM. Procedures are being developed to reseed epithelial, endothelial, and stromal cells in ventilator-perfused explant models for study of lung regeneration. Microfluidic chambers enable coculture of

multiple cell types, recreating cell, and tissue interfaces to which biomechanical forces can be applied, for example, stretch, ventilation, and perfusion that will be useful for the study of normal and pathological pulmonary cells and tissues [188,189]. While present decellularized lung models are far from consideration for clinical application, the knowledge gained from experiments incorporating normal and pathological ECM and its recellularization will provide insights into how complex cells interact with pulmonary scaffolds to form, maintain, and repair lung structure.

Tissue engineering for conducting airways

The trachea and conducting airways are critical components of the respiratory tract whose patency and stability are required for ventilation. Airway collapse or obstruction caused by congenital malformations, tumors, or injury often requires resection and reanastomosis, surgeries that are complicated by stricture, scarring, and infection. A number of strategies have been developed, including decellularization and recellularization of bioengineered scaffolds, for tracheal repair [190]. The airways are highly complex structures whose repair is complicated by their separate bronchial circulation, abundant submucosal glands, and the complexity of the cell types and niches that comprise the trachea and bronchi. Cough and mucocilliary clearance require both stability of cartilage rings on the ventral aspect of the large airways and the flexibility of smooth muscle on the dorsal side. Stricture and scarring are common after surgical repair of the trachea or main bronchi. As such, tracheal allotransplantation has been largely unsuccessful for long segment repair of the airways. Initial encouraging reports using recellularized tracheal grafts or bioengineered tracheal grafts treated with MSCs for airway repair were not supported by subsequent clinical evaluations and were retracted from the literature [191]. Nevertheless, a variety of approaches are being studied to develop tissue and cell-based therapies for repair of tracheal–bronchial lesions, including 3D printed scaffolds which are populated with a variety of cell types [192,193].

Pulmonary macrophage transplantation for the treatment of interstitial lung disease

The pathogenesis of a number of chronic pulmonary diseases is related to defects in clearance of metabolic products from cells and tissues; for example, in hereditary storage diseases and pulmonary alveolar proteinosis (PAP). While bone marrow transplantation has been utilized to treat some of these disorders, recent experimental strategies include the correction of genetic disorders caused by defects in pulmonary macrophage function by intratracheal administration of alveolar macrophages. Hereditary PAP, a rare autosomal recessive disorder in which the lung fills with surfactant lipids and proteins, is caused by mutations in CSF2Ra and CSF2Rb (granulocyte-macrophage colony stimulating factor receptors) that impair GM-CSF signaling that controls alveolar macrophage differentiation and surfactant catabolism [194]. Mutations in the GM-CSF receptors cause pathological accumulation of surfactant proteins and lipids resulting in respiratory compromise. A single administration of normal alveolar macrophages or genetically corrected alveolar macrophage progenitors into the lungs of CSFR deficient mice, resulted in durable correction of GM-CSF signaling, restored surfactant homeostasis, and pulmonary function without the need for bone marrow transplantation [195–197]. Patient-derived bone marrow stem cells or iPSCs, which are differentiated into alveolar macrophage progenitors in vitro, are being studied for orthotopic pulmonary macrophage transplantation for the correction of hereditary PAP and other disorders of alveolar macrophage function.

Conclusion

Knowledge regarding the physiology, genetics, and cell biology of life-threatening pulmonary diseases is expanding rapidly. Likewise, progress in understanding lung morphogenesis and stem cell biology has accelerated. Together, technical and scientific advances raise hopes that novel cell and tissue-related therapies may be developed for life-threatening disorders in many organs including the lung. Major barriers to successful application of cell-based therapies for the lung remain and the ability to engineer lung tissue capable of enhancing respiratory function is presently conceptual rather than actual, Fig. 67.1. Nevertheless, rapid advances in stem cell biology, tissue engineering, and disease modeling are providing the tools that will enable discovery of the cellular and molecular processes mediating normal tissue regeneration and those needed to develop cell and tissue-based therapies for disorders affecting the respiratory tract.

Introduction

The ex vivo regeneration of lung requires the simultaneous resolution of a number of complex and interlocking engineering challenges. Functional lung tissue places blood and air in close proximity to each other while allowing nearly negligible quantities of trans-vascular leak. The alveolus, the functional unit of the lung, is a delicate tissue unit made up of precise mixture of cells, extracellular matrix, and secreted proteins that allow proper ventilation and subsequent gas exchange. The air surfaces of these alveoli are coated in surfactant, a mixture of lipid and protein that gives lung tissue a tightly regulated, and unusual, response to applied mechanical stress. The epithelium of the lung is nonhomogenous, containing specialized cell classes allowing the lung to regenerate epithelial layers during normal homeostasis and to recover following grievous injury. The endothelium in the lung lines a dense microvascular network, which, together with the alveolar epithelium, maintains robust cellular junctions integral to the blood−gas barrier. Mesenchymal cells are increasingly being found to be crucial for both endothelial and epithelial support. Immune cells, meanwhile, make up nearly 60% of the cells found in lung tissue and perform important roles in both innate immunity and in the maintenance of tissue homeostasis.

Functional tissue-engineered lungs must maintain homeostatic levels of blood−gas barrier integrity, permit easy gas ventilation when transplanted into the chest (the organ must have proper compliance/elasticity properties), produce and regulate sufficient surfactant to prevent tissue damage, and contain the proper cell populations to permit appropriate postimplantation tissue homeostasis. The net result of these design criteria is that whole-lung engineering is a challenge that has, as of this writing, not been comprehensively solved. The field of pulmonary regeneration, however, is rapidly advancing. This chapter provides a broad overview of work in pulmonary regeneration to date and postulates potential advances that might be achieved in the near future as this work comes closer to clinical translation.

Design criteria for pulmonary engineering

The most basic function of the lung is to bring air and blood in close proximity to allow gas exchange. To do this, the airway tree develops adjacent to the arterial vasculature and branches into tightly packed alveoli 100−200 μm in diameter [1] which collectively resemble a closed-cell foam [2]. The walls of this foam contain a dense capillary meshwork allowing deoxygenated blood to travel from the arterioles to the venules. The tissue layer separating air from these capillaries has a mean thickness of less than half a micron [2,3], which greatly facilitates gas diffusion and allows the perfused blood to gather oxygen and to release carbon dioxide. Although this blood−gas barrier is astonishingly thin, it is nonetheless quite strong compared to the mechanics forces acting on it, with a breaking stress exceeding that of most soft tissues per unit cross-sectional area [4], and it allows nearly negligible quantities of transcapillary leak into the alveolar compartment [5]. To be translatable, any engineered lung needs to maintain near-native levels of barrier integrity and gas diffusion rates. This barrier function is the result of combined effects from endothelial and epithelial tight junctions [6−8] and from solute transport pumps actively produced and regulated by alveolar cells [9,10]. The gas diffusion rate is proportional to both the air−blood boundary surface area and barrier thickness and associated diffusion coefficient [11].

Although much pulmonary engineering has focused on regeneration of an intact blood−gas barrier, it is also

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00070-8

important that the engineered construct contains well-epithelialized large airways. The large airways of the lung contain a variety of specialized mucociliary cells that are crucial in keeping the lung clear of debris and provide essential immune functions [12–14]. Most evidence suggests that tracheal and bronchial epithelial cells derive from underlying basal cells, a key homeostatic stem cell population in the pulmonary trachea and bronchi [15]. It is further important that an engineered lung have well-developed and fully endothelialized arteries and veins to allow patent blood flow to and from the capillary bed. Although the large vessels of the native organ contain mesenchymal cells key to regulating regional blood flow and pulmonary blood pressures, it is not clear if such cells are intrinsically essential for translatable pulmonary constructs. There is increasing evidence, however, that mesenchymal support of pulmonary microvessels is essential for barrier formation and regulation [16].

For transplantable constructs, it is crucial as well that the fabricated organs have the proper mechanical characteristics. A transplanted lung must be strong enough to withstand the negative pressure inflation found in the chest cavity, and compliant enough to respond to oscillatory ventilation. Further, the airway tree must be properly developed to allow ready gas flow from the oropharynx to the distal lung with very low resistance [17]. The mechanical characteristics of lung extracellular matrix are largely regulated by interstitial and mesenchymal cell populations in the lung, including fibroblasts, smooth muscle cells, and macrophages [18,19]. Perturbations to the regulation of these cell types are thought to underlie pathologies such as idiopathic pulmonary fibrosis and chronic obstructive pulmonary disease, in which the structural mechanics of the lung are severely compromised resulting in grave tissue malfunction (reviewed in Ref. [20]).

Finally, it is likely that a truly functional engineered lung will have to generate self-sustaining levels of pulmonary surfactant. Pulmonary surfactant is an amphiphilic lipoprotein complex that greatly reduces the surface tension in the alveoli of the lung and is a major cause of the physiologic hysteresis and governing mechanical forces present in normal lung tissue [21,22]. As any implanted lung will need to be ventilated with air, the construct needs to contain and longitudinally regulates the proper surfactants to modulate the nontrivial air–fluid surface-forces present in the alveoli [23]. A summary of these most essential design criteria is schematized in Fig. 68.1.

Decellularized scaffolds and biofabrication approaches

The first studies to demonstrate the concept of whole-lung regeneration relied on decellularized cadaveric scaffolds (see Fig. 68.2). These scaffolds retain nearly all of the key histologic features of lung tissues, including complete airway morphology, fully formed vascular trees, and a patent and perfusable alveolar microvascular bed [24–26]. As these constructs are made only from extracellular matrix components and are entirely acellular, the capillary walls are highly permeable to fluid flow. This means that without cells, the constructs themselves display very low levels of barrier function, allowing the majority of arterially perfused fluid to exit the vascular compartment and enter the alveolar space [27]. Further, the blood vessel walls display bare matrix, and therefore

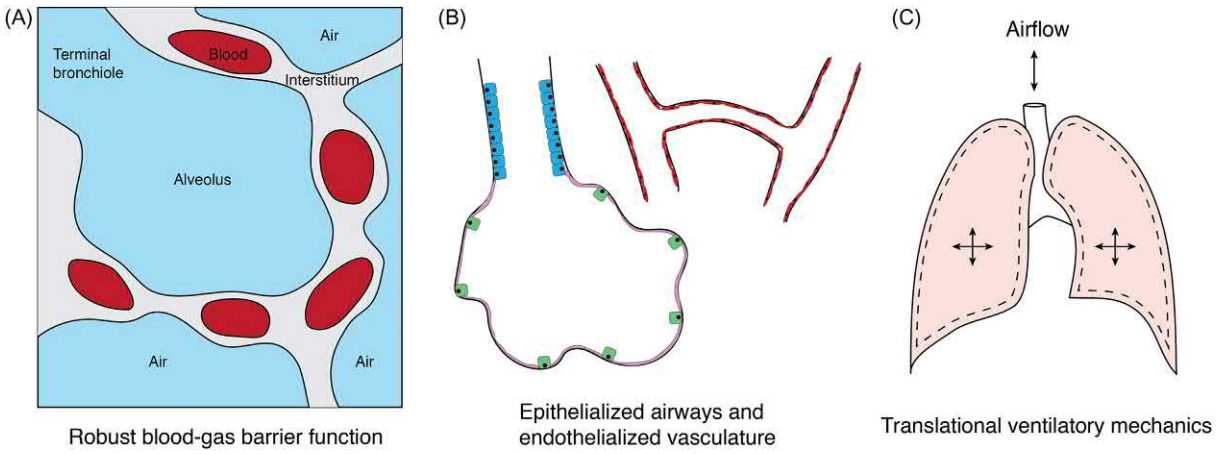

FIGURE 68.1 Essential design criteria for functional whole-organ pulmonary engineering. The primary function of the lung is to bring air and blood in close proximity to allow gas exchange. This requires a well-organized capillary–alveolar structure with robust blood–air barrier, preventing fluid leakage into the air-filled alveolus during capillary perfusion (A). Airways must be well epithelialized, and vessels must be patent and well lined with endothelium (B). Translational pulmonary constructs should have native-like mechanical characteristics to allow successful transplantation and ventilation in the chest (C).

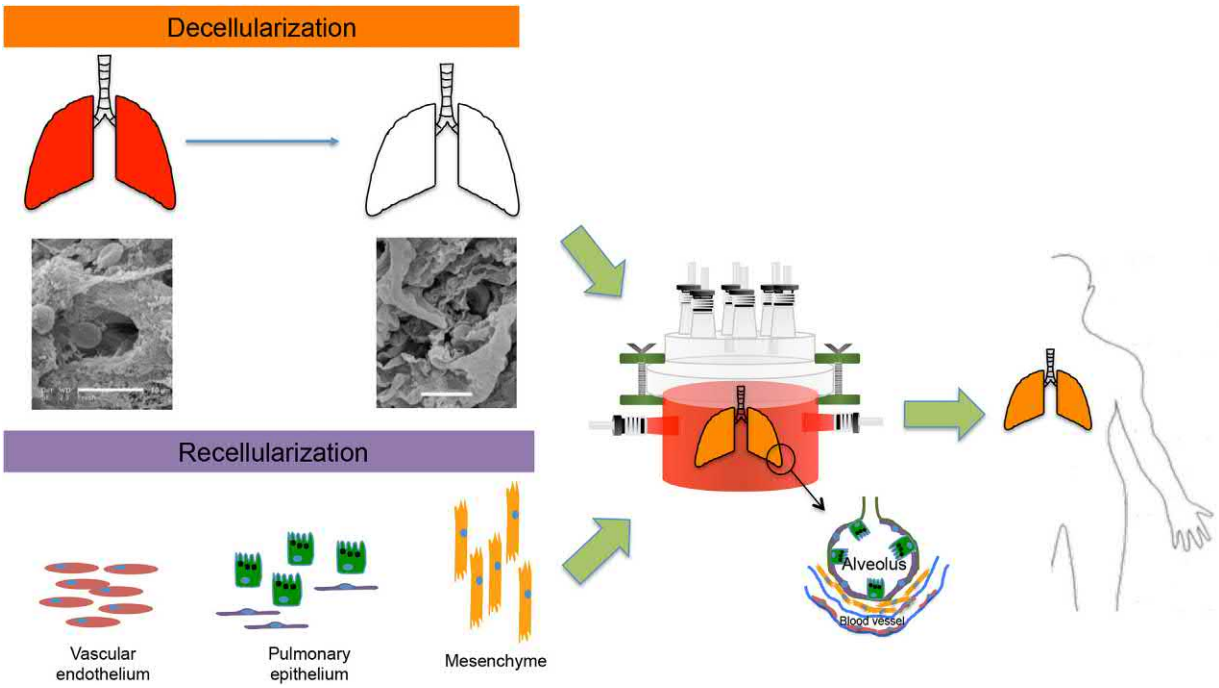

FIGURE 68.2 Schematic of whole-lung tissue engineering. The current paradigm of whole-lung tissue engineering has two separate parts: (1) Removal of cellular components from native lung tissues while preserving the intact 3D architecture and ECM components. (2) Repopulation of the decellularized scaffolds with patient-compatible cells, including vascular endothelium, pulmonary epithelium, and supporting cells such as mesenchyme to generate a bioartificial organ that provides physiological functions aiming to be an alternative source for lung transplantation.

decellularized lung is thrombogenic when implanted in vivo without sufficient endothelialization [28,29]. As there is no surfactant present, decellularized lungs are also much less compliant than native lungs when inflated with air. Decellularized scaffolds do, however, display near native levels of bulk mechanical moduli [24,30,31].

The first studies to yield decellularized lungs used a gentle perfusion of either sodium dodecyl sulfate (SDS) or 3-[(3-cholamidopropyl) dimethylammonio]-1-propanesulfonate (CHAPS) detergents to dissolve cellular components while retaining extracellular matrix [24,25]. Later studies found techniques based on Triton-X/SDS to be superior to CHAPS, allowing greater retention of native matrix characteristics based on quantitative proteomics [32]. In addition, it was found that decellularization at near-native pH improved the retention of matrix proteins and subsequent mechanical characteristics [33]. Although the vast majority of whole-lung studies use vascular perfusion to decellularize starting constructs, there have been some investigations into decellularization via tracheal instillation and ventilation [34,35]. In all cases, decellularized lungs present an attractive option for a starting pulmonary scaffold, as the vascular structure is preserved within the matrix and adequate mass transfer for regeneration is allowed [36]. Further, the decellularized matrix itself contains soluble and insoluble cues that drive pulmonary cell regeneration and provide spatially localized cues relevant to tissue organization and cell differentiation [37–40].

Thus far, all attempts to regenerate surgically transplantable lungs have employed decellularized whole-organ matrices. There are, however, next generation approaches on the horizon based on free-form fabrication techniques that may provide the requisite foundation to mass-produce scaffolds without the need for cadaveric donors. These scaffolds are unlikely to be fully vascularized in the near future, given the voxel resolution limits of current technologies, but can be made from biologic components retaining many desirable matrix properties and be crafted en-mass for clinically translational applications. Free-form reversible embedding of suspended hydrogels uses a gelatin support slurry to create complex three-dimensional hydrogel scaffolds [41]. This approach allows the fabrication of high-resolution complex structures from computed tomography data and is able to replicate some components of the complex branching vascular architecture necessary for whole-organ engineering with materials that promote microvascular angiogenesis [42]. Projection stereolithography is a promising ultrahigh-resolution technique capable of rapidly manufacturing complex three-dimensional structures mimicking those found in tissue extracellular architecture [43–46]. One recent and impressive topological example shows the ability to manufacture closely intertwined vascular and airway compartments [47].

Such studies clearly demonstrate that it is possible to fabricate macroscopic, perfusable constructs capable of supporting mixed cell types and performing translationally relevant gas exchange. While no study to date has shown the ability to directly manufacture constructs with the feature fineness or topological complexity of alveolar tissue, it is reasonable to predict that free-form fabrication technologies may advance sufficiently in the coming years to act as important tools in scaffold−craft for pulmonary regenerative medicine.

Pulmonary epithelial engineering

The airways and airway epithelium in the lung fulfill four major functional roles. First, the trachea, bronchi, bronchioles, and alveoli collectively form a contiguous pathway for air inhalation and exhalation, thereby enabling gas exchange with minimal applied mechanical work; second, the epithelium in the distal alveolar parenchyma is intimately involved in blood−gas barrier regulation and maintenance; without properly functioning epithelium, barrier function can be severely compromised, and fluid tends to leak into the air-filled alveolar compartment; third, pulmonary epithelium plays a crucial role in innate immunity, providing the first line of defense against inhaled pathogens; and fourth, like all epithelium in contact with the outside world, pulmonary epithelium is in a constant state of renewal, turning over in response to both grievous injury and to normal wear-and-tear. This places the epithelium in a key role in pulmonary tissue homeostasis in both the conducting and terminal airways. As epithelium in both the proximal and distal lung is nonhomogenous, there is currently significant drive to identify common progenitor cells capable of differentiating into the full variety of epithelial cells found within the native airway tree.

Proximal airway engineering

Recent single-cell studies have demonstrated that the conducting airways contain a variety of distinct, specialized epithelial cells cooperating to maintain a functional tissue layer. These cell populations include basal cells, secretory and ciliated respiratory epithelial cells, pulmonary neuroendocrine cells, and the recently profiled cystic fibrosis transmembrane conductance regulator (CFTR)-rich pulmonary ionocytes thought to be involved in the regulation of interairway ion gradients [12,13]. These cell types work together to create a robust immune barrier, secrete airway mucous, and clear inhaled particulates from the airway. There is significant evidence that basal cells act as a resident stem cell population for the proximal respiratory epithelium [48−50], with the ability to differentiate into both ciliated cells and SCGB1A1 + and MUC5AC + secretory cells [51]. This makes basal cells an attractive endogenous candidate for proximal airway regenerative engineering. Basal cells can be expanded in vitro with conditional reprogramming [52] and are thereafter capable of recapitulating tracheal epithelial morphology and phenotype when cultured on denuded or decellularized tracheas [53,54]. In studies of whole-lung recellularization, seeded basal cells successfully attach in the large airways but do not consistently recapitulate native conducting airway epithelial morphology [55], possibly due to suboptimal culture chemical and mechanical conditions during whole-organ perfusion culture.

There is some evidence that induced pluripotent stem cells (iPSCs) might be able to be used to generate translationally viable proximal airway progenitor cells. Protocols exist for generating epithelial populations expressing key proximal and distal markers, including those for basal cells; these protocols are limited, however, by their tendency to also produce contaminating mesodermal populations [56]. It should be noted, in addition, that the phenotypic regulation of regenerating epithelial populations is heavily guided by spatiotemporal cues present in both developing and native tissue, and that effective and safe protocols for generation of translational airway epithelium from iPSCs may require protocols more complex than those currently used [57].

Distal airway engineering

The alveolus of the lung has two primary cell types: alveolar type I (ATI) and alveolar type II (ATII) cells. ATII cells are large cuboidal epithelial cells that secrete pulmonary surfactant and are crucial for alveolar homeostasis [58]. ATI cells are flat, convoluted cells that make up only 7%−9% of lung cells by number but coat greater than 90% of the alveolar surface area and seal the outside of septal capillaries [59]. A single ATI cell can cover surface area in multiple alveoli, providing epithelial barrier over noncontiguous portions of the alveolar capillary network [60]. The blood−gas barrier is so thin in alveolar tissue that ATI cells and capillary endothelia generally share a common basement membrane [61]; gas exchange occurs across this very fine sandwich of ATI cell cytoplasm, matrix/interstitium, and endothelial cell cytoplasm [3]. ATII and ATI cells together are majorly responsible for the regulation of fluid balance in the alveolus and subsequently the efficacy of gas exchange [62].

ATII and ATI cells together form tight-junction networks that are integral to pulmonary blood−air barrier function [63]. The topological complexity of the pulmonary blood−gas barrier presents special challenges for reseeding and engineering efforts, considering that any seeded cells need to not only attach and be viable, but to organize their morphology and intra- and intercellular

machinery properly to recapitulate native levels of barrier hydraulic conductivity without compromising capillary flow. This is a nontrivial engineering requirement. To date, no whole-organ pulmonary engineering study has been published, which demonstrates native levels of capillary hydraulic conductivity and associated negligible trans-vascular leak.

Two primary approaches have been taken for the recapitulation of alveolar epithelium, namely, isolated or expanded primary cell seeding and the delivery of iPSC-derived populations. ATII cells have long been known to be the progenitor stem cell population for ATI cells, maintaining an injury-privileged population that sustains itself over time while reconstituting the ATI population when necessary [64,65]. Recent work has further identified a narrowly defined subpopulation of ATII cells dubbed alveolar epithelial progenitors with a distinct transcriptomic profile capable of regenerating the alveolar epithelium following injury [66]. ATII cells are therefore a promising candidate for the reconstitution of the alveolar epithelium. Early studies in lung distal airway recellularization used a mixed epithelial-enriched population isolated from fetal lungs that included both ATI and ATII cells and generally showed evidence of ATII cell engraftment and surfactant protein production [24,25,67]. A select few studies have investigated the option of engineering distal pulmonary epithelium from iPSC lineages. Ghaedi et al. showed in 2013 [68,69] that ATII- and ATI-like cells could be generated from human iPSC lineages and could successfully engraft in acellular matrices and retain key alveolar epithelial characteristics. Full characterization of and control over iPSC-derived alveolar progenitors will likely require sophisticated understanding and manipulation of genetic control modules governing the behavior of these inherently plastic cells [70–72].

Interestingly, conducting airway cells may also provide an avenue to alveolar epithelial regeneration. Studies of postinjury alveolar regeneration show that SFTPC + / SCGB1A1 + cells, labeled bronchioalveolar stem cells, are capable of regenerating epithelial layers in both the proximal and distal airways following injury [73,74]. Very recent work has suggested that proximal airway cells may even be capable of differentiating directly into ATI cells without traversing an ATII-phenotype intermediate [75]. Collectively, these studies do imply that a proximal progenitor stem cell, when coaxed appropriately, may be able to repopulate the full alveolar epithelium. Gilpin et al. showed evidence suggesting that an isolated primary basal cell population was able to colonize the distal region of decellularized lung tissue and expand to create flattened epithelial layers resembling those found in the native alveolus [55]. Such evidence supports the possibility that a common lung epithelial progenitor may either exist, or be engineered, to allow full pulmonary epithelial regeneration covering both proximal and distal populations.

Mesenchymal support of pulmonary epithelium

There is significant evidence that mesenchymal–epithelial cross talk influences epithelial phenotype. Although the first studies in whole-lung regeneration used a mixed cell type population isolated from fetal tissue, in general the focus was on epithelial and endothelial reseeding, and there is now a substantial body of literature showing that close consideration of mesenchyme and mesenchymal subtypes may be necessary to appropriately guide and regulate pulmonary epithelial regeneration in decellularized scaffolds. Both WNT and fibroblast growth factor (FGF) signaling are known to be important for lung epithelial morphogenesis during development [76]. Single-cell sequencing of the alveolus has revealed IL-6, BMP, and FGF signaling modalities to be key regulators of the ATII cell niche [77], and there is evidence that FGF10 is a key component of the basal cell niche [78]. Although these and other epithelial niche molecules can be dosed systemically to ex vivo engineered lungs, such an approach uniformly delivers soluble factors to the entire construct, which is unlikely to promote native-like histologic complexity. It is therefore preferable, and very possibly necessary, to provide appropriate cell populations to allow in-organ self-organization of the stem-cell niches necessary for normal organ homeostasis. The accurate mapping of cell niches is still in its infancy, but the advent of single-cell technologies is rapidly transforming this field and is likely to yield great insight applicable to pulmonary regeneration in the coming years.

Pulmonary endothelial engineering

Although pulmonary capillaries occupy only ~2% of lung anatomic volume, the microcirculation contributes to over 70% of gas exchange and nutrient transport to the whole parenchyma (reviewed in Ref. [79]). Endothelial cells, lining the inner surface of blood vessels, synthesize many factors, including nitric oxide, thrombomodulin, and prostacyclin, thereby regulating vascular homeostasis ([80–88] and reviewed in Ref. [89]). Dysfunction of pulmonary microvascular endothelial cells increases vascular permeability, leading to extravascular leak of protein-rich edema, polymorphonuclear leukocyte influx, microvascular thrombosis, and further lung dysfunction (e.g., acute lung injury and sepsis) [90]. In addition, microvascular endothelium plays an important role in the regulation of ATI and ATII epithelial cells, affecting both ion channel and barrier formation [91,92]. One of the key failure modes in engineered lung implantation is impaired endothelial coverage and insufficient microvascular barrier, which leads to thrombosis and

pulmonary edema, respectively [24,25]. Thus reconstruction of the pulmonary vasculature, especially the microvasculature, in decellularized lung scaffolds is of pivotal importance for maintaining pulmonary vascular homeostasis, alveolar function, and allowing complete lung regeneration.

Endothelial cell sources for lung tissue engineering

Pulmonary endothelial cells

Endothelium in lungs displays a distinct phenotype from endothelium in other organs. Lung microvascular endothelial cells (ECs) secrete markedly more urokinase-type plasminogen activator antigen than ECs from umbilical veins, angioma, or liver [93]. Nolan et al. established organ-specific molecular libraries of microvascular ECs and revealed that microvascular endothelium in lungs uniquely expresses many markers such as kit (CD117), CD36, and TBX3 as compared to ECs in brain, kidney, liver, and heart [94]. Endothelial cells are a heterogeneous population of cells not only with respect to different organs, but also among microvasculature, arterial, venous, and lymphatic systems. Pulmonary microvascular endothelium tends to uniformly bind *Griffonia simplicifolia* lectin, whereas endothelium from large vessels preferably binds to *Helix pomatia* lectin. These cells possess no Weibel–Palade bodies, less von Willebrand factor as compared to their counterparts in medium and large vessels ([95–97] and reviewed in Ref. [98]). In addition, under in vitro culture, microvascular ECs form significantly tighter barrier and proliferate faster than do ECs from large vessels [99,100]. This is supported by the fact that there is higher proportion of endothelial colony forming cells in microvasculature than in the large vessels [99]. Given the phenotypic discrepancy of endothelium in lung tissues, the ideal cell candidate for lung microvasculature engineering should be from the pulmonary microvasculature itself. We have previously repopulated decellularized lung scaffolds with pulmonary microvascular endothelium. The cells not only maintained their molecular phenotype but also displayed tight junctions after 8-day culture [24]. However, engineered lung explants in this study still showed impaired vascular barrier formation. Coculture of microvascular ECs with arterial and venous ECs in decellularized lung scaffolds increased their VE-Cadherin-based barrier function, suggesting a necessity of cell–cell cross talk for barrier function [101]. Although the field's current success is promising, it is well documented that lung allograft endothelium can initiate immune rejection through presentation of alloantigens to circulating T cells, natural killer cells, and macrophages (reviewed in Ref. [102]), which limits the use of primary pulmonary ECs for translational applications.

Induced pluripotent stem cell derived endothelial cells

iPSCs, derived from differentiated adult cells through genetic reprogramming, are not only theoretically able to generate unlimited numbers of cells but also to potentially bypass the issues of allogeneic immune rejection [103–105]. Differentiation toward endothelial cells from iPSCs usually applies growth factors, coculture with parenchymal cells, or two-dimensional culture on ECM proteins (reviewed in Refs. [106,107]). Ren et al. incorporated Wnt activation with CHIR99021, transforming growth factor (TGF)-β inhibition with SB431542 and hypoxic conditions in an 8 day differentiation protocol and achieved a homogenous population of endothelium [108]. After coculture with iPSC-perivascular cells in rat decellularized scaffolds, cell coverage reached ~75% of native counterparts, demonstrating the feasibility of using such cells for lung tissue engineering. Recent work by Prasain et al. identified a Neuropilin 1 (NRP-1) + / CD31 + /CD144 + subpopulation from iPSC-differentiated endothelial cells that maintained stable endothelial phenotype and function and did not undergo replicative senescence for 18 passages in vitro. These iPSC-NRP-1^{+}CD31^{+}ECFC showed capacity to form human vessels in mice and to repair the ischemic mouse retina and limb for >6 months with lack of teratoma formation [106,109]. Our lab went on to culture these cells in rat decellularized lung scaffolds [110]. After 5 days, H&E staining indicated native-appearing endothelial cell coverage in both large and small vessels throughout the organ, while the matrix remained intact. Interestingly, both protein and gene expression levels of PECAM1, CDH5, TEK, and ANGPT1 were higher in cells cultured in lung scaffolds as compared to cells on tissue culture plastic, indicating improved endothelial phenotype, which may be due to the influences from microenvironmental cues still present in decellularized tissues. Thus iPS-differentiated endothelium may be a viable cell source for the vascularization of engineered lung tissues. However, many hurdles remain to be overcome; first, iPSC-derived ECs are generally heterogeneous and may possess different phenotypes and functions as compared to native microvascular pulmonary ECs; second, the intrinsic qualities of self-renewal and pluripotency of iPSCs are responsible for tumorigenic potential, which is a huge safety issue for clinical applications [111]; finally, the immunogenicity from iPSCs remains controversial and requires more extensive investigations [112]. Thus iPSC-based therapies are still in their infancy, and key challenges must be overcome before their clinical application becomes a reality.

Endothelial seeding into lung scaffolds

Early studies demonstrated that endothelial cell seeding into the vasculature of decellularized lungs was possible.

However, vascular function was impaired, in terms of both barrier formation and thromboresistance, possibly due to insufficient cell seeding and improper culture conditions [24,25]. The seminal work by Ren et al. has moved the field forward by significantly improving the EC coverage in lung scaffolds [108]. They have used gravity-driven perfusion to sequentially inject cells into pulmonary artery (PA) and pulmonary vein (PV), respectively, to minimize the loss of hydrostatic pressure as the aqueous phase diffuses through the permeable basement membrane (Fig. 68.3). After coseeding with human umbilical vein endothelial cell (HUVECs) and human mesenchymal stem cells using this method, they achieved markedly higher EC coverage as compared to previous seeding strategies [108]. When seeded in a similar fashion with rat lung microvascular ECs, lungs reach ~80% cell coverage compared to native controls after 4 days of culture and are perfusable in an implantation model. However, following implantation the airspaces also contain blood, indicating the existence of significant vascular barrier leakage [29]. Although recent literature has reached a consensus that dual-side seeding from both PA and PV increases seeding efficiency [29,101,108], many other confounding factors such as the cell size, cell density, pump- versus gravity-driven perfusions, and careful monitoring of delivery pressures are crucial in the optimization of endothelial seeding techniques.

Organomimetic endothelial culture

Chemical and physical stimuli such as shear stress, substrate stiffness, oxygen tension, and growth factors in the microenvironment of pulmonary microvasculature are of vital importance for maintaining vascular homeostasis in vivo. Shear stress is the force per unit area created when a tangential force (blood flow) acts on a surface (endothelium). Endothelium lining the blood vessels is highly sensitive to hemodynamic shear stress that acts at the vessel luminal surface in the direction of blood flow (reviewed in Refs. [113,114]). Compared to cells under pathological disturbed flow, there was a downregulation of several proinflammatory cytokines, proangiogeneic factors, and proatherogenic factors in ECs under undisturbed physiological laminar flow [115]. Most recent studies, including ours, have used low arterial perfusion rates, which is markedly lower than physiological levels [116] to culture various endothelial cells in decellularized lung scaffolds [29,108,117]. Interestingly, these studies have all achieved relatively high cell coverage, suggesting high cell viability and proliferation, which may be due to sufficient nutrient transport across the entire organ. However, the wall shear stress in vasculature, especially microvasculature, is difficult to accurately model in decellularized organs due to the leaky nature of the constructs, which makes it hard to understand mechanical influence over cellular behaviors in this context.

Engineering pulmonary vasculature in decellularized rat and human lungs. Nat Biotechnol 2015;33(10):1097–102.*

Angiogenesis describes the formation of new vessels from existing blood vessels. This process usually involves proliferation, migration, and differentiation of endothelial cells. Many growth factors can regulate pulmonary angiogenesis, including vascular endothelial growth factor (VEGF), eNOS, FGF, TGF-β, and substance P (reviewed in Refs. [118−122]). Ren et al. have cultured HUVECs-seeded lung scaffolds in "Angiogenic medium" that had high levels of serum and angiogenic growth factors such as VEGF and FGF for 14 days. However, they have not obtained increased endothelial coverage nor barrier formation compared to 1 day after seeding, which may be due to matrix degradation during angiogenesis and impaired cell stability in the scaffold [108].

During EC angiogenesis, cells are activated upon exposure to pro-angiogenic factors. These cells are prone to matrix degradation, secrete pro-inflammatory molecules, show increased intercellular permeability, and participate in vascular remodeling. Thus maintenance of EC maturation and quiescence after proliferation is critical for the stabilization of new blood vessels. Chemical factors, including protease inhibitors, sphingosine 1-phosphate, and cyclic AMP, have been discussed to induce the quiescent state of endothelial cells and can be used for vascularization in lung scaffolds reviewed in Refs. [123−130]. Our recent study investigated whether various molecules could favorably impact endothelial functionality after seeding into decellularized lung scaffolds. We compared the effect of 11 different molecules that were previously reported to improve endothelial barrier function under various platforms, and we demonstrated that Epac-selective cAMP analog 8CPT-2Me-cAMP not only improved endothelial barrier but also sustainably maintained improved barrier function for at least 3 days. After culturing in decellularized lung scaffolds, treatment with the Epac agonist significantly improved the barrier function of iPSC-ECFC-repopulated lungs for at least 6 hours [110]. This study not only demonstrates that Epac agonists may be useful to improve endothelial functionality but paves the way for applying small molecules in whole-organ tissue engineering.

Mesenchymal support of pulmonary microvasculature

Pericytes are multifunctional mural cells that wrap around capillary endothelial cells. These cells can secrete many factors, including platelet-derived growth factor B receptor-β; S1P1-endothelial differentiation sphingolipid G-protein-coupled receptor-1 (EDG1); and angiopoietin 1-tie 2 to regulate vascular maturation (reviewed in Ref. [131]). Ren et al. cocultured iPSC-differentiated ECs with perivascular cells in decellularized lung scaffolds for 6 days and obtained better endothelial integrity and stability compared to ECs alone [108]. Consistently, Doi et al. found that preseeded ASCs differentiated pericytes stabilized the endothelial cell monolayer in nascent pulmonary vessels, thereby contributing to EC survival in the regenerated lungs. The ASC-mediated stabilization of the ECs clearly reduced vascular permeability and suppressed alveolar hemorrhage in an orthotopic transplant model for up to 3 hours after extubation [132]. Thus pericytes may represent a proper cell population to promote vascular maturation for long-term culture in a decellularized lung scaffold. However, the plastic nature of pericytes and their transition to myofibroblast phenotypes may damage vascular function and induce lung fibrosis [133,134]. In addition, current coculture studies used similar seeding techniques for both pericytes and ECs. In native lungs, pericytes are located on the basolateral side of endothelium. Further research on pericyte phenotype in decellularized lung scaffolds will help one to optimize culture protocols for maintaining their function.

Bioreactor technologies for pulmonary engineering

The ex vivo culture systems required to perform whole-lung engineering are complex bioreactors designed to replicate, as closely as possible, the conditions found in the chest cavity (Fig. 68.4). The majority of whole-lung reactors strive to provide pulsatile arterial perfusion, passive venous drainage, some degree of dynamic ventilatory control, and collection and recirculation of the transpleural effluent intrinsic to decellularized lung scaffolds [24,25,135−137]. In all cases these systems have to be engineered to maintain sterility through the entirely of setup and culture and should be built to allow necessary experimental interventions. Monitoring and regulation of nutrient, waste, pH, and gas levels is tantamount for success. Levels of dissolved gases have nonnegligible effects on cell development and phenotype [138]. Mechanical ventilatory strain affects barrier integrity in a nonlinear fashion [63,139,140], while pulsatile perfusion has been shown in multiple settings to have beneficial effects on both microvascular recruitment and endothelial function in the lung [141−143]. As this is still an evolving field, lessons are continually being learned from the closely related surgical discipline of ex vivo lung perfusion, in which intact native lungs are perfused in an operating room prior to transplant (reviewed in Refs. [144,145]). One recent advance from our laboratory now allows the real-time noninvasive calculation of capillary−alveolar barrier resistance [146], and we consider the adoption of such tools to be essential for accurate estimation of whole-organ barrier function. Although few studies have

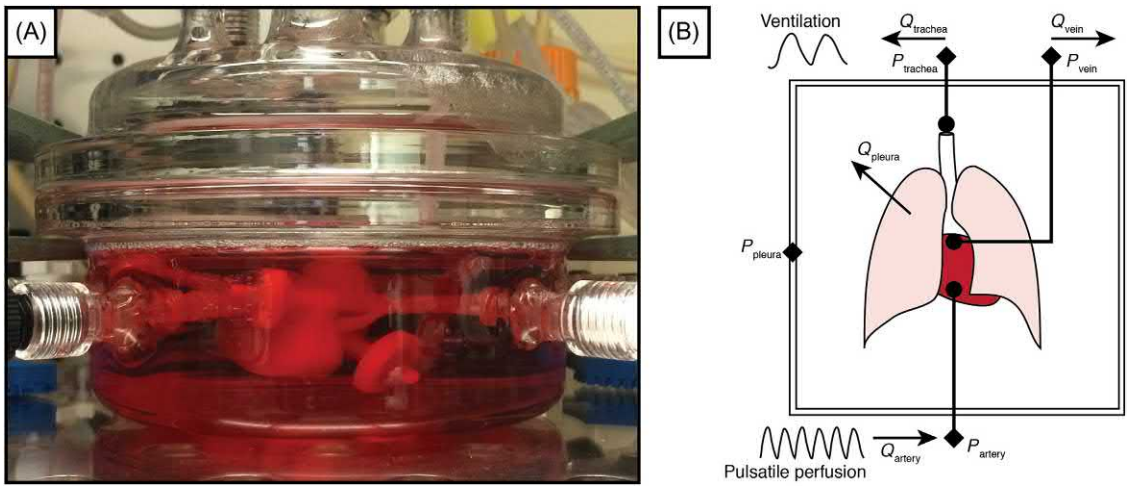

FIGURE 68.4 Cell-seeded lung scaffold cannulated and positioned within a biomimetic whole-organ lung bioreactor during organomimetic culture (A). Schematic of pulmonary bioreactor system and key culture parameters (B). Pulsatile perfusion and some degree of ventilatory stretch is generally applied. Accurate assessment of capillary–alveolar barrier function is greatly assisted by careful measurement of pressures and flows at the pulmonary artery, vein, trachea, and pleura. *(B) After Engler AJ, Raredon MSB, Le AV, Yuan Y, Oczkowicz YA, Kan EL, et al. Non-invasive and real-time measurement of microvascular barrier in intact lungs. Biomaterials 2019;217:119313.*

consistently applied negative-pressure ventilation to regenerating decellularized lungs, there is evidence suggesting that negative pleural pressure is beneficial to both vascular and airway mechanics in native whole lungs [147,148]. Due to a current dearth of data, further studies need to be performed to optimize ventilatory dynamics for engineered lung culture.

Conclusion

Whole-organ pulmonary regeneration is a nascent field barely 10 years old, which has the potential to transform the treatment of end-stage lung disease. The clinical application of this technology will require the solution of many fascinating challenges. At least four key cell types must be identified: translationally viable pulmonary epithelial progenitor populations, endothelial cells capable of recapitulating the pulmonary vasculature, mesenchymal subtypes necessary for lung stem-cell niche regulation, and immune populations integral to pulmonary tissue homeostasis. Further, any translational initiative will need to solve the problem of cell source, choosing to either isolate and propagate necessary cells from primary patient-unique tissues or derive the appropriate phenotypes from patient-specific iPSCs. Finally, although elaborate protocols exist for biomimetic ex vivo organ culture, the appropriate culture conditions for the regeneration of viable organs using decellularized scaffolds are by no means clear. Extensive work remains to be done to identify appropriate chemical milieus, mechanical conditioning, and experimental dynamics for the formation of an intact and well-organized parenchymal barrier in bioartificial lungs. This work, by its very nature, will likely require the collaboration of basic scientists, physiologists, medical practitioners, and engineers from both within and without the pulmonary disciplines.

Introduction

The epidermis consists of multiple cell types and layers. The outermost layer, called the stratum corneum, is composed of dead "corneocytes" that tightly adhere to each other to form a hydrophobic barrier that protects us against environmental insults, such as water loss and infection. The innermost layer at the base of the epidermis generates new cells that migrate to the surface while terminally differentiating, eventually forming the stratum corneum. Keratinocytes comprise the majority of epidermal cells; their main job is to produce intermediate filament proteins called keratins. The epidermis also houses melanocytes, fabricators of pigment; and Langerhans cells (LCs), sentinels against invaders that present foreign antigens to roaming T cells.

The epidermal surface is interrupted by orifices arising from skin appendages, such as the hair follicles (HFs) and sweat glands—these serve important functions in skin thermoregulation, sensation, lubrication, and protection. The epidermal basal layer is continuous with the adnexal epithelium, and basal cells from HFs and sweat ducts can move out and repopulate the epidermis in response to injury. The adnexal structures possess a greater degree of tissue complexity compared to the epidermis. For example, in contrast to the stratified squamous epithelium of the epidermis, the HF consists of at least eight different concentric layers of epithelia, which undergo degeneration and regeneration with each HF cycle.

The epidermis and HFs continuously generate new cells as old corneocytes and old hairs are sloughed off into the environment; thus their homeostasis and repair have been thought to depend on epithelial stem cells. Seminal work from many investigators has proven the existence of epithelial stem cells in the interfollicular epidermis (IFE) and the HF. Adult stem cells are quiescent in nature and are uniquely capable of both self-renewal and giving rise to differentiated progeny. In recent years, new evidence suggests that epidermal stem cells may not reside in the classic "epidermal proliferative unit" (EPU). In addition, the HF appears to contain additional stem and progenitor populations outside of the bulge. In this chapter, we will review old and new evidence to integrate historical dogma with newly emerging concepts in the evolving tale of skin regeneration.

Interfollicular epidermal stem cells

Physiological maintenance and renewal of the epidermis depends on proliferation of cells in the basal layer. Since epidermal renewal continues throughout ones' lifetime, it has been postulated that at least a portion of epidermal basal cells behave like stem cells (Fig. 69.1A for location of putative stem cells in interfollicular and follicular epidermis).

Bickenbach and Mackenzie, in pioneering work, devised "label-retaining cell" (LRC) methods for detecting quiescent cells in the epidermis [3]. Further, Morris showed that these cells retained carcinogen and possessed the quiescent characteristic of stem cells (reviewed in Ref. [4]). To test the concept that these cells give rise to all skin layers, a replication-deficient retroviral vector carrying the beta galactosidase gene was transduced with low frequency into the skin basal layer in vivo in mice [5]. Over a period of a month, discrete blue columns of cells could be visualized arising from the basal layer and progressing to the skin surface, thus supporting the existence of clonal EPUs—at least in the mouse epidermis. To further support this hypothesis, bromodeoxyuridine (BrDU) pulse-labeling of the basal layer revealed the presence of a small number of quiescent LRCs. Taken together, these data suggested that quiescent stem cells in

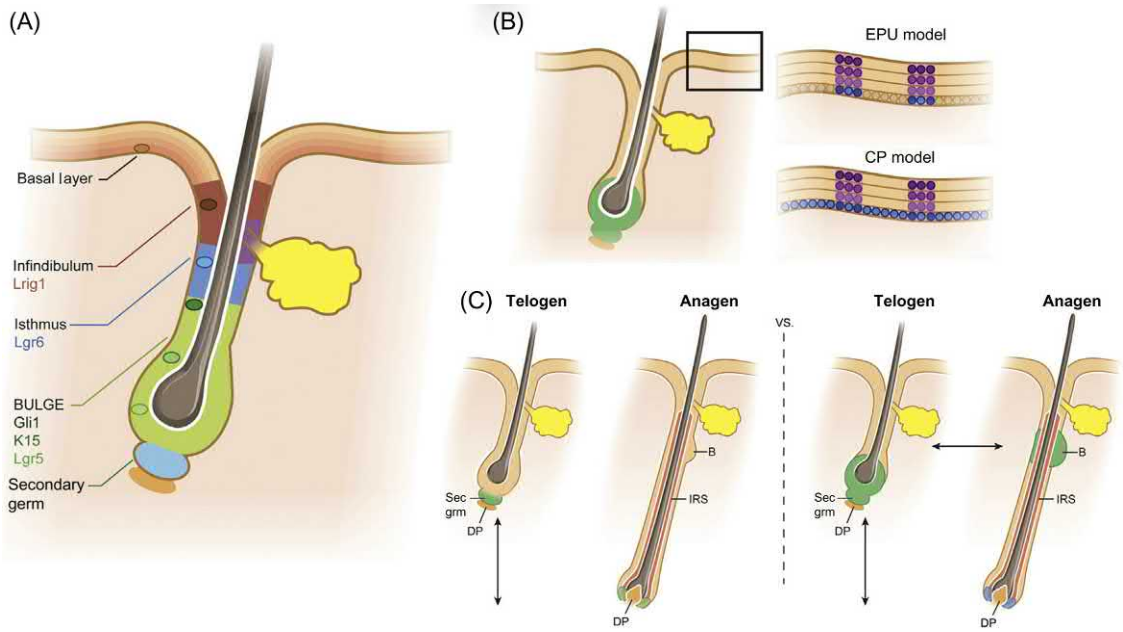

FIGURE 69.1 (A) Location of putative epidermal stem cells in the hair follicle and interfollicular epidermis. (B) Two models for interfollicular epidermal homeostasis. EPU model: in this model, rare stem cells (light blue) in the basal layer of the skin give rise to new progeny identical to itself (adjacent *dark blue cells*) or more differentiated progeny (*pink and purple cells* in upper layers). Each unit with a single central stem cell is termed an EPU. CP model: in this model, all cells in the basal layer have the same potential to make new identical progeny or more differentiated progeny. Therefore all cells in the basal layer are of the same color. (C) Two models for hair follicle regeneration during cycling. Historic model (left panel): "secondary germ cells" (named for their similarity to primary germ cells present during development) were thought to contain the stem cells for the follicle. It was thought that these cells migrate from the base of the telogen follicle to the bulb during anagen onset and then migrate back up during catagen. Current model (right panel): the secondary germ cells found at the base of the telogen follicle arise from the lowermost portion of the bulge at the end of catagen [1]. These cells migrate down into the secondary germ from their niche region where they alter their gene expression profile, proliferate, and ultimately provide all the cells for the new lower half of the anagen follicle [2]. *CP*, Committed progenitor; *EPU*, epithelial proliferative unit.

the basal layer serve to replenish the upper layers during homeostasis and following wounding. Ghazizadeh and Taichman [6] extended similar findings to human skin by using lentivirus-mediated genetic labeling of human epidermis, which showed that epidermal stem cells along the basal layer undergo an upward migration perpendicular to the epidermal surface, resembling the spatial organization of EPU.

Models for skin renewal: epidermal proliferative unit versus committed progenitor

Historically, the favored model has been that the basal layer stem cells provide "transit-amplifying" progeny that undergoes a limited number of divisions to generate the upper strata of the epidermis [7,8]. According to this model, two distinct cell populations—a slower cycling central cell and more rapidly proliferating surrounding cells—are roughly organized into a column of hexagonal unit of 10 basal cells, which lies beneath a single corneocyte (reviewed in Ref. [9], Fig. 69.1B). Based on these proliferative and morphological characteristics, the term "EPU" was coined to describe this architecture [4,8,9]. A study by Mascre et al. [10] confirmed the existence of these two described cell populations within the mouse tail IFE: a slow-cycling "stem cell" pool and a rapid cycling "progenitor" pool. Capitalizing upon the knowledge that heterogeneity in marker expression defines multiple populations within the epidermis, they followed the fate of two distinct basal populations, as defined by expression of involucrin. Their work demonstrates that involucrin-expressing basal cells divide rapidly (once per week) and quickly contribute to all layers of the epidermis, while some cells within the involucrin-negative population divide infrequently (4−6 times/year), have a distinct gene expression profile, and act as a primary contributor to reepithelization following wound repair. Work by Sada et al. [11] further supports the idea of these discrete interfollicular stem cell populations proposed by the EPU model. Utilizing GFP-tagged H2B histone (H2B-GFP) pulse-chase system in adult mouse skin, they put forward that epidermal LRCs and non-LRCs are molecularly distinct and can be differentiated by distinct genetic markings: *Dlx1-CreER* for LRCs and *Slc1a3-CreER* for non-LRCs. Long-term lineage tracing and mathematical modeling of H2B-GFP dilution data further showed that LRCs and

non-LRCs indeed constitute two distinct stem cell populations with different patterns of proliferation, differentiation, and upward cellular transport.

However, long-term lineage tracing studies have challenged the EPU-based model of epidermal regeneration. Using a low-frequency *Cre*-inducible genetic model, individual proliferating basal cells were marked and followed for 1 year in a long-term fate mapping study [12,13]. In contrast to the canonical EPU model, which predicts the size of each EPU to be finite, some epidermal clones were shown to continuously expand in size over a period of 1 year; other clones shrank and disappeared; and yet others behaved like typically expected EPUs. Mathematical modeling of these clone patterns suggested a stochastic model for epidermal renewal, in which each proliferating basal cell can give rise to two new proliferating basal cells, two differentiated progeny, or both [12]. According to this committed progenitor (CP) model, the epidermis is maintained by a uniform, equipotent population of epidermal progenitors via stochastically distributed symmetric divisions to maintain the basal layer and asymmetric divisions to generate more differentiated progeny [14]. In support of this model, data showed that a single basal epidermal cell could divide both symmetrically, producing two new basal cells, and asymmetrically, leading to more differentiated progeny [15]. Additional support for the stochastic CP model of epidermal progenitors comes from recent work by Rompolas et al., where they acquired series of temporal optical sections of the ear and paw epidermis from live H2B-GFP pulse-chased mice to track stem cell fate by position and cellular morphology [16]. From tracking cells for up to 2 weeks in the ear epidermis, they found global dilution of the H2B-GFP signal by 1 week. Furthermore, no detectable cells retained their GFP label over time, suggesting that the basal layer of the epidermis is composed of a single equipotent stem cell population that cycles at similar rates. Following the trajectory of individual cells from basal to the cornified layers above, they also found that the majority of committed cells organize into vertical columns, giving rise to the structures that encouraged the EPU hypothesis [8]. However, according to Rompolas et al., these columnar architectures would be better described as epidermal differentiation units rather than EPUs.

In reconciling the EPU and CP models, it appears that progenitor microenvironment may be the most critical regulator of stem cell fate, dynamics, and organization. Roy et al. [17] used multicolor lineage tracing with the so-called Rainbow reporter system to track individual keratinocytes in the dorsal skin epidermis of mice. Interestingly, they discovered that while IFE progenitors follow a nonhierarchical mode of development, the clones nearest to actively cycling HFs were considerably more proliferative and fast-growing than the ones more distant from the cycling HFs. This study raises a question as to whether the notion of cycling rates (slow cycling vs rapid cycling) is truly a reliable measure of evaluating "stemness" within the epidermis and suggests that spatiotemporal control of the stem cells by the microenvironment may be what is more important in regulating the potentialities of stem cells. Recent work by Liu et al. [18] suggests the differential expression of the hemidesmosome component collagen XVII (COL17A1) in individual cells guides whether a cell undergoes a symmetrical (high levels of COL17A1) or asymmetrical (low levels of COL17A1) division. Taken together, these findings suggest that the true clonal dynamics are simply too complex and condition-dependent to be reliably explained by one model, whether that is EPU or CP, and that many external factors such as the stem cell niche microenvironment may act as key regulators of stem cell potentialities.

Hair follicle stem cells

Similar to the epidermis, the HF generates a terminally differentiated keratinized end product, the hair shaft, which is eventually shed. However, in stark contrast to epidermis, the follicle undergoes a unique cyclical regenerative process known as the HF cycle [19]. As a result, the HF has a more complicated proliferative profile and architecture, with at least eight distinct epithelial lineages (Fig. 69.2). Hair is formed by rapidly proliferating matrix keratinocytes in the bulb located at the base of the growing (anagen) follicle. Interestingly, the duration of anagen varies drastically between hairs of differing lengths. For example, HFs of mouse and human eyebrow stay in anagen for only 2–4 weeks, while human scalp follicles can remain in anagen for many years. Nevertheless, matrix cells eventually stop proliferating, and hair growth ceases at catagen when the lower follicle regresses to reach a stage of rest (telogen). After telogen the lower hair-producing portion of the follicle regenerates, marking the new anagen phase (Fig. 69.2).

The bulge as stem cell source

Because the lower portion of the follicle undergoes natural cyclic bouts of rest (telogen) and growth (anagen), it was assumed that the HF stem cells (HFSCs) underlie this process. Historically, HFSCs were thought to reside exclusively in the "secondary germ," which is located at the base of the telogen HF (Fig. 69.1C). It was believed that the secondary germ moved downward to the hair bulb during anagen and provided new cells for the production of the hair. At the end of anagen the secondary germ was thought to move upward with the dermal papilla (DP) during catagen to come to rest at the base of the telogen follicle.

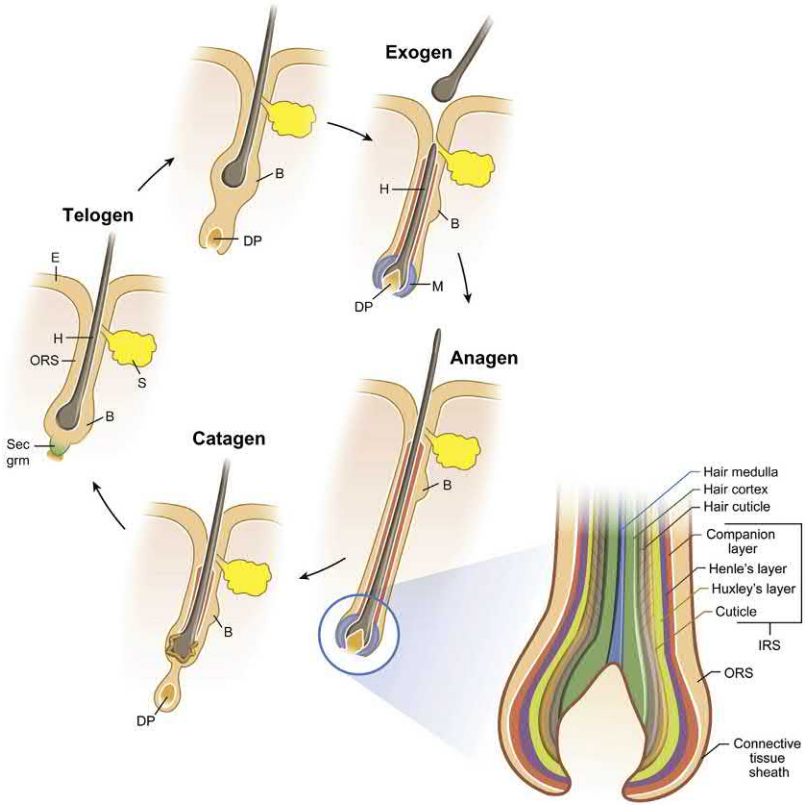

FIGURE 69.2 Hair cycle and anatomy. The hair follicle cycle consists of stages of rest (telogen), hair growth (anagen), follicle regression (catagen), and hair shedding (exogen). The entire lower epithelial structure is formed during anagen and regresses during catagen. The transient portion of the follicle consists of matrix cells in the bulb, which generate seven different cell lineages, three in the hair shaft and four in the IRS. *IRS*, Inner root sheath.

This scenario of stem cell movement during follicle cycling was brought into question when a population of long-lived cells, presumptive stem cells, was identified using LRC methods in the bulge and not the bulb [20]. Subsequent lineage studies and characterization of the bulge cells in both human and mouse follicles confirmed the bulge as the site of HFSC [20–22] (Fig. 69.3).

Defining characteristics of the bulge as a stem cell source

Multiple criteria define the bulge as the true stem cell source for HF regrowth. These include quiescence, gene expression signature, and multipotency—the ability of single cells to regenerate the entire HF in a skin reconstitution assay.

Quiescence

A salient feature of bulge cells in general is their quiescence. In both adult mouse and human skin grafted on an immunodeficient mouse, the administration of nucleoside analogs such as tritiated thymidine or BrDU, which are taken up by cells in S-phase, does not result in labeling of the bulge cells except at anagen onset [1,23]. Once labeled, bulge cells can remain labeled for 14 months in the mouse and at least 4 months (the longest period examined) in the human [21]. This prolonged quiescence is remarkable given that the surrounding cells proliferate at

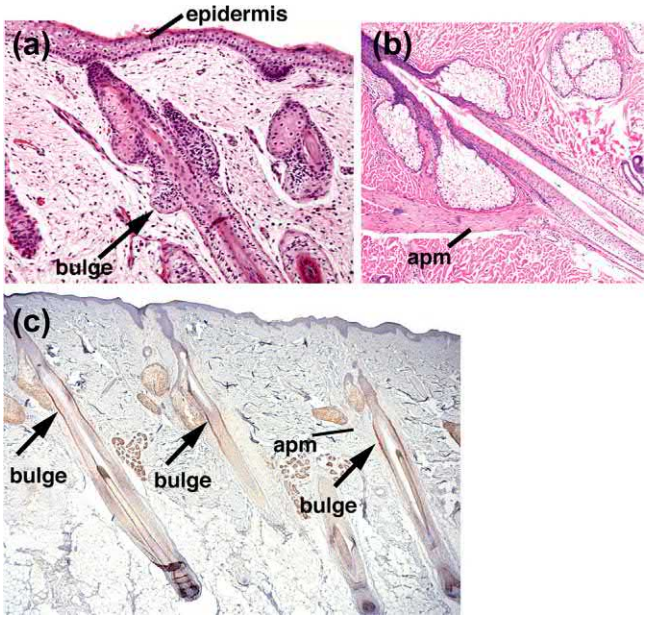

FIGURE 69.3 The bulge is a prominent structure in fetal skin (A), but generally is not morphologically distinct in the adult (B). Immunostaining for keratin 15 in scalp preferentially detects bulge cells (C). *apm*, Arrector pili muscle.

a much higher rate and further serves to suggest that bulge cells persist for the lifetime of the organism.

Several transcriptional regulators that govern bulge stem cell quiescence have been identified. Transcription factor such as nuclear factor of activated T cells c1 (NFATc1) is preferentially expressed by HFSCs and has been put forth as a key regulator involved in maintenance of bulge stem cell quiescence in all stages of the hair cycle [24]. Using immunofluorescence microscopy, the authors showed that NFATc1 exhibits a substantial overlap with CD34 and LHX2 protein expression, which are highly upregulated in quiescent bulge cells and are required for HFSC maintenance in the mouse. Another important regulator of bulge stem cell quiescence includes Forkhead box C1 (FOXC1) [25,26]. RNA sequencing (RNA-Seq) on wild-type and *Foxc1* knockout (KO) mice by Wang et al. showed that KO mice exhibited downregulation of genes associated with HFSC quiescence, including *Bmp6* and *Fgf18*. This suggests that FOXC1 is responsible for activating and maintaining quiescence gene networks in the HFSCs [25]. Lay et al. further corroborated the regulatory role of FOXC1 in HFSCs and suggested that loss of *Foxc1* lowers the threshold of HFSC activation and shortens the period in which bulge stem cells remain quiescent thereby also shortening periods between hair cycles [26].

One unique characteristic of the HFSCs is that they are able to quickly switch between quiescence and proliferation. While the precise mechanism for this is not wholly understood, recent evidence from Flores et al. [27] suggests that HFSCs maintain a metabolic state that allows them to remain dormant while still being able to quickly respond to appropriate proliferative stimuli. A transgenic mouse model with conditional alleles of lactate dehydrogenase A (*Ldha*) stopped the enzyme's production specifically in HFSCs, causing the cells to remain dormant. The LDHA enzyme is responsible for the conversion of lactate to pyruvate for energy production, thus lactate conversion seems critical for activation of HFSCs. Conversely, enhancing lactate production in HFSCs through KO of mitochondrial pyruvate carrier (*Mpc1*) resulted in accelerated activation of the hair cycle. This interesting result highlights the potential use of pharmacological disruption of lactate production to regulate the quiescence of HFSCs.

Molecular signature

Understanding the genes that distinguish bulge cells from progenitor cells in the HF and epidermis provides insights into the precisely orchestrated events of HF formation at anagen onset. Using gene expression arrays, large-scale comparisons of gene expression in bulge cells versus non-bulge basal keratinocytes [2,22] showed that genes involved in activation of the WNT pathway were generally decreased in the bulge, in line with evidence that WNT activation induces proliferation and cell differentiation and is a hallmark of anagen onset [28]. Global gene expression analyses of the human HF bulge showed many similarities to the mouse profiles, including expression of Keratin15 (KRT15), but also some important differences (Table 69.1) [31].

With the advent of single-cell RNA-Seq (sc-RNA-Seq), it has become possible to analyze the molecular signature of the bulge cells at a single-cell level. Single-cell

TABLE 69.1 Markers of stem cell subpopulations in murine and human hair follicle (HF) [bulge and hair germ (HG)].

	Murine HF stem cells (bulge)	Human HF stem cells (bulge)	Murine progenitors (HG)	Human progenitors (HG)	References

transcriptomics on murine telogen epidermis revealed that the bulge stem cell population segregates by distinct spatial signatures from the remainder of the epidermal cells but still shares a common basal-epidermal identity [45]. sc-RNA-Seq not only provides an unbiased, systematic way to reconstruct the transcriptional organization of the epidermis, but also it could allow for identification of previously unidentified molecular signatures that were not detectable with traditional methods such as microarrays.

Multipotency

If HFSCs are located in the bulge, then these cells should give rise to all of the epithelial cells in the lower HF. Early evidence supporting the concept that bulge cells generate the lower follicle includes proliferation studies showing that bulge cells preferentially proliferate at anagen onset [1,46]. More convincing evidence suggesting that the lower follicle originates from bulge cells came from in vivo labeling studies and transplantation studies. Taylor used a double-labeling technique to trace bulge stem cells in intact pelage follicles [47]. Faint labeling in a speckled pattern was detected in some cells of the lower follicle, suggesting that these cells had indeed originated from the bulge. Similarly, Tumbar et al. used persistence of GFP label as an indication that lower epithelial cells were progeny of the bulge cells [2]. However, neither study provided convincing evidence that all hair matrix keratinocytes in the bulb originated from bulge cells, and both suffered from inability to permanently mark bulge cells and their progeny.

Oshima et al. took a different approach and transplanted bulge regions from vibrissa follicles isolated by dissection from ROSA26 mice into non-ROSA follicles that were then grafted under the kidney capsule of an immunocompromised mouse. ROSA 26 mice express *lacZ* under the control of the ubiquitous ROSA promoter, thus the fate of the transplanted cells could be followed. After several weeks, they found labeled cells in the lower follicle, indicating that bulge cells or their progeny had migrated down the vibrissa follicle. At later time points, some follicles expressed *lacZ* in all epithelial cell layers of the lower follicle suggesting that bulge cells do generate all of the cells of the lower follicle. These elegant studies were limited by several caveats, including unclear origin of the marked cell population, the manipulation required for grafting, and the use of vibrissa follicles, which are markedly different from other mouse and human follicles.

Additional evidence for bulge cell multipotency in vivo was reported using the *Krt15* promoter to target these cells with an inducible Cre (CrePR1) construct [22]. In *Krt15-CrePR1* transgenic mice, CrePR1 remains inactive in the cytoplasm of the Krt15-positive cells except during RU486 treatment, which permits CrePR1 to enter the nucleus and catalyze recombination. Treatment of adult *Krt15-CrePR1;R26R* mice with RU486 results in permanent expression of *LacZ* in the bulge cells and their progeny. These studies showed that all epithelial cell types in the lower HF originated in the bulge.

Rompolas et al. used intravital microscopy with genetic lineage tracing at single-cell resolution to study the movement of cells throughout the follicle in live mice during HF cycling [48]. They demonstrated that the upper half of the bulge remained quiescent, whereas the lower bulge formed the new secondary hair germ (HG), which forms the new lower HF during anagen. Furthermore, they showed that when bulge HFSCs are ablated, progenitor populations above and below the bulge can directly restock the lost stem cell compartment and become bulge residents. Taken together, these results demonstrate the power of the surrounding niche for determining stem cell fate.

While the physiological roles of the observed heterogeneity and compartmentalization of HFSCs in the bulge still require further exploration, one function has been identified in the formation of tactile sensory units, which allows for relay of touch in HFs [49]. A recent report by Cheng et al. [49] showed that the epidermal stem cells in the upper bulge express a set of neurogenesis-related genes and deposit the unique protein EGF-like domain multiple 6 into the collar matrix. Meanwhile, proteins in the lower bulge remain quiescent and provide anatomically stable follicle−lanceolate complex interfaces for maintenance of robust relay of touch sensation. This unique work provides a new perspective on how sensory organs might take advantage of compartmentalized epidermal stem cell niche in order to coordinate distinct lineage tasks, all while maintaining sensory function within a structurally dynamic tissue environment.

Multiple hair follicle stem cell subpopulations by marker expression

Work from numerous labs over the last years has shown the existence of stem cell (SC) and progenitor cell populations with distinguishing marker expression:

Bulge

1. *Keratin 15 (KRT15):* KRT15 is one of the most widely used markers of bulge stem cells [21]. KRT15 mRNA and protein are reliably expressed at high levels in the bulge, but lower levels of expression can be present in the basal layers of the lower follicle outer root sheath (ORS) and IFE. Lineage tracing with a Krt15 promoter preferentially targeting the bulge stem cells showed that KRT15-targeted cells contribute to all HF

epithelial lineages [22], demonstrating its ability to serve as a powerful tool for studying bulge stem cells.

2. *Clusters of differentiation 34 (CD34)*: CD34 is a well-known marker of murine, but not human, bulge stem cells [30]. In human HFs, CD34 stains the basal cells immediately below the bulge and appear to be immediate descendants of the bulge cells. These cells are larger and more proliferative than bulge cells, thus they have characteristics of progenitor cells [33].
3. *SRY (Sex-determining region Y)-box 9 (Sox-9)*: Sox-9 is also a marker of the bulge stem cell population that is known to be one of the first genes to be expressed during HF induction in the mouse [50]. Its expression is first detected in the epithelial placode but becomes restricted to the ORS and the bulge over time. Deletion of *Sox-9* in mouse led to the development of small, atrophic hair and alopecia, illustrating the importance of Sox-9 as a functional stem cell marker that is crucial for HF homeostasis.
4. *Glioma-associated oncogene 1 (Gli1):* Zing finger protein gli1 expression defines a distinct population of stem cells in the upper bulge adjacent to perifollicular sensory nerve endings [43]. Remarkably, these nerve endings provide a niche environment by secreting sonic hedgehog protein (Shh), an essential component for the maintenance of the gli1$^+$ stem cell fate. Gli1$^+$ cells can reestablish the anagen follicle and they appear to contribute to long-term epidermal wound repair, which does not appear to be dependent upon Shh signaling (see later).
5. *Leucine-rich repeat-containing G-protein-coupled receptor 5 (Lgr5):* Lgr5, an R-spondin receptor implicated in canonical WNT signaling [51], marks a population of HF progenitors in the lower bulge and secondary HG during telogen, and in the lower ORS during anagen [38]. While Lgr5 expression is strongest in the secondary germ, it overlaps with the expression of KRT15. Lgr5$^+$ cells actively proliferate and contribute to all HG lineages during HF cycling [38,52]. Lgr5$^+$ cells can also reconstitute entirely new follicles when injected with dermal cells under the skin of nude mice [38]. The majority of evidence indicates that Lgr5$^+$ cells represent progenitors rather than true stem cells (see later).

Upper hair follicle

1. *Leucine-rich repeats and immunoglobulin-like domain protein 1 (Lrig1):* Lrig1$^+$ cells are actively cycling stem cells found in the junctional zone, just above the bulge and next to the sebaceous gland (SG) [53]. Lineage tracing experiments have shown that Lrig1$^+$ stem cells tend to be bipotent, physiologically contributing predominantly to infundibulum and SG lineages and only occasionally to the IFE. However, on wounding, progeny of Lrig1$^+$ stem cells have shown to be rapidly recruited to the site of injury to contribute to tissue regeneration [54]. Interestingly, mice lacking Lrig1 develop spontaneous epidermal hyperplasia and exhibit elevated levels of proproliferative cMyc protein. Further analyses indicate that Lrig1 is a downstream target of cMyc and may act to regulate cMyc expression in epidermis in a feedback loop [53].
2. *Leucine-rich repeat-containing G-protein-coupled receptor 6 (Lgr6):* Lgr6$^+$ stem cells have been reported to localize to the isthmus, immediately below the Lrig1$^+$ compartment [55]. While multipotent during embryonic development, Lgr6$^+$ stem cells undergo progressive developmental fate restriction, and in adults they participate mainly in epidermal and SG maintenance and homeostasis [55]. Interestingly, despite very close physical proximity, Gli1$^+$ stem cells in the upper bulge only marginally overlap with Lgr6$^+$ cells. In the face of trauma, Lgr6$^+$ stem cells actively contribute to closure of wounds as well as to hair neogenesis [55]. While it is a long-held belief that the Lgr6 is a marker of isthmus, a recent study has suggested that Lgr6 expression is scattered throughout the entire epithelium and may not be restricted to this particular area, warranting further research [54].

Stem cells of other ectodermal appendages

Sebaceous glands

Each HF is closely associated with the SG and, together, they constitute what is known as the pilosebaceous unit. The predominant cells in the SG, sebocytes, secrete lipid-rich products into the infundibular opening of the adjoining HF. Page et al. showed the presence of Lrig1-expressing population of stem cells within the pilosebaceous unit that are distinct from cells expressing Blimp1 [54]. By monitoring tdTomato-labeled Lrig1 progeny over time, they showed that Lrig1-expressing stem cells in the SG, initially negative for the marker Blimp1, eventually become Blimp1 positive and will renew Blimp1 + sebocytes. This result demonstrates that the Lrig1 marks a population within the SG stem cell compartment that is responsible for independent maintenance and replenishment of the SG. However, recent finding suggests that BLIMP1$^+$ cells might not be sebocyte progenitors [56]. By performing genetic lineage tracing experiments in mice, Kretzschmar et al. showed that BLIMP1-expressing cells are postmitotic and do not divide under homeostatic conditions and thus represent terminally differentiated epidermal cells within the SGs rather than a population of sebocyte progenitors.

Interestingly, cells within the SG also have been shown to be capable of dedifferentiating into stem cells in response to wounding, exhibiting a remarkable plasticity that has not yet been demonstrated in the epidermis or in other skin appendages. Using a reporter mouse model, Donati et al. demonstrated that upon IFE puncture, differentiated Gata6$^+$ sebaceous duct lineage cells in the HF duct migrate to the wound site, dedifferentiate, and start proliferating to regenerate the IFE in the wound bed as stem cells [57]. The authors also reported similar dedifferentiation of Blimp1$^+$ progenitors, hinting at the possibility that dedifferentiation may be a common attribute of terminally differentiated epidermal cells following injury.

Sweat glands

Acral skin (palms and soles in human and ventral paw in mouse) is hairless but contains eccrine sweat glands, a secretory type of ectodermal appendage that is essential for optimal thermoregulation. Eccrine glands have a relatively simple organization, consisting of a secretory glandular portion and ducts leading to the skin surface. Basal myoepithelial cells and suprabasal luminal cells comprise the glandular portion of the eccrine gland. Unlike HFs, eccrine glands are relatively quiescent. Lu et al. [58] showed that despite homeostatic quiescence, eccrine glands feature several distinct progenitor types and they exhibit regenerative potential stimulated by injury. Interestingly, sweat-producing luminal cells are maintained by suprabasal unipotent progenitors, largely independent of the basal myoepithelial cells. Neither myoepithelial nor luminal glandular cells contribute progeny toward the duct which, in turn, is maintained by its own basal unipotent progenitors. Unlike glandular cells, ductal progenitor cells become activated upon wounding and help to restore ductal openings onto the skin surface. While ductal progenitors preferentially regenerate the duct itself, they can also regenerate IFE immediately surrounding the sweat gland opening [58]. In this respect, ductal progenitors of the sweat gland share characteristics with the HF isthmus stem cells, which can also generate permanent epidermal progeny following injury [43,53,55]. Rittie showed that eccrine ductal cells also contribute to wound healing in human skin [59].

While identification of specific molecular mechanisms that underlie epithelial fate specification into different epithelial appendages is still in the works, a study by Plikus et al. [60] have highlighted the importance of bone morphogenic protein (BMP) pathway in specification of sweat gland fate decision. The study showed that overexpression of *Noggin*, a direct antagonist of BMP, in *K14-Noggin* transgenic mice results in increased HF density in body skin and transformation of sweat glands in footpads into HFs, disrupting the normal mesenchymal−epithelial BMP signaling that would have resulted in sweat gland fate specification. Similarly, a study by Lu et al. [61] identified the potential role of BMP and SHH antagonism within the epithelial bud in specifying sweat gland fate over HF fate [61]. In a genome-wide study where the back skin mesenchyme of the mouse, which is only capable of specifying to HFs, was compared to the foot skin mesenchyme, which can only make sweat glands, it was shown that the regional skin appendage specification results from differential mesenchymal expression of BMP. A strong BMP signal from the underlying mesenchyme resulted in sweat gland fate specification, whereas decreased BMP signal via SHH antagonism of BMP led to HF-specific gene expression. In fact, the authors showed that eccrine glands were converted to HF-like structures in KO mice of *Bmpr1a*, a key component of the BMP receptor kinase, demonstrating the positive role of the BMP pathway in determining glandular fate. The understanding of the role of BMP:SHH antagonism in sweat gland versus HF fate specification may help pave the path for future therapeutic advances in skin regeneration with both HFs and sweat glands.

A recent study by Yao et al. [62] has identified the transcription factor interferon regulatory factor 6 (IRF6) as another potential mediator of eccrine gland fate specification in epidermal progenitors. Using immunofluorescence, they showed that IRF6 is expressed in suprabasal epidermis in the developmental point at which eccrine gland placodes emerge, illustrating the inductive potential of IRF6 in directing sweat gland specification of epidermal progenitors [62]. Furthermore, they were able to show preferential glandular lineage differentiation in epidermal progenitor cells transfected with IRF6, demonstrating that IRF6 expression is sufficient to trigger sweat gland fate of epidermal progenitors.

Nails

The nail is a highly keratinized skin appendage covering the dorsal tip of digits, acting as an important protective covering for finger tips and toes. Just like other ectodermally derived follicular structures, the nail relies on tissue-specific stem cells to maintain homeostasis and to regenerate; however, unlike the HF bulge, the nail stem cell (NSC) niche has not yet been well-defined and its precise location still remains controversial.

The slow-cycling, label-retaining characteristics of stem cells have been used to identify quiescent reservoirs of stem cell niches in various organs, including the HF. Labeling techniques to identify in vivo LRCs have proven useful in detecting a population of nonproliferative, KRT15-positive cells organized in a ring-like cluster within the basal layer of the proximal nail fold [63]. KRT15-driven lineage tracing revealed that these cells

exhibit bipotent characteristics during normal homeostasis, in that they can contribute to both the nail structure and peri-nail epidermis, depending on the activating signals.

In contrast to the previous finding, a study by Takeo et al. [64] identified a different putative NSC niche in the proximal nail matrix using a tamoxifen-inducible lineage tracing of K14 + nail basal epidermal cells in a transgenic mouse. The lineage tracing experiment was further supported by histological analyses, which demonstrated that proximal matrix cells containing NSCs possess fewer interdigitations, a characteristic of undifferentiated epidermal cells. The Wnt pathway has important roles in hair bulge activation and HF cycling [65]. To ask if this signaling pathway was important for nail homeostasis, Takeo et al. [64] conditionally knocked out Wnt mediator ß-catenin in the epidermis of mice, and showed impaired nail growth. To ask about importance of this pathway to digit tip regeneration, they knocked out ß-catenin after tip amputation and showed that in addition to nail, bone and nerve regeneration were also impaired. The recent study by Lehoczky and Tabin [66] further confirmed the presence of this presumptive set of NSCs within the proximal nail matrix and showed that these NSCs collectively express Lgr6, an important agonist of the Wnt pathway. The dual function of Wnt signaling to induce multiple aspects of digit tip regeneration highlights the importance of this pathway that may be harnessed for new therapeutic strategies to treat amputees.

Hair follicle stem cells in skin homeostasis, wound healing, and hair regeneration

Homeostasis

In addition to the role of bulge cells in HF cycling, their contribution to the maintenance of HF homeostasis, including the IFE and SGs, has also been considered. Historically, one view was that bulge cells continuously provide progeny for repopulation of these skin regions [47,67]. However, fate mapping of bulge cells labeled in 3-week-old mice and followed for 6 months showed that the label was never observed within the IFE [22]. This indicates that $K15^+$ cells do not contribute to homeostatic maintenance of the epidermis. Furthermore, genetic ablation of $K15^+$ bulge cells does not result in IFE deficiency. Therefore these data collectively suggest that while $K15^+$ bulge stem cells can shift their fate toward the epidermal lineage, it is only in response to wound-induced signaling (see below, Ref. [68]). The other bulge populations, $Gli1^+$ and $Lgr5^+$, also appear to have no role in skin homeostasis [38,43].

Identifying the underlying mechanisms responsible for maintenance of HFs has fundamental importance in better understanding the complex process of homeostasis as well as in predicting how they will respond in face of physiological stress and injury. Choi et al. [65] proposed a key role for the Wnt/ß-catenin signaling pathway in maintenance of HF homeostasis, particularly the IFE. They showed that while short-term deletion of ß-catenin had no observable immediate effect on the $K15^+$ bulge stem cell compartment, there was a significant reduction in IFE proliferation, suggesting that IFE homeostasis and maintenance is closely regulated by Wnt/ß-catenin pathway. Another signaling pathway implicated in homeostasis, particularly in hair bulge stem cells, is the BMP/Wnt pathway [69]. By perturbing molecular signaling in the $K15^+$ stem cells, they showed that the balance between BMP and Wnt activity within each bulge stem cell is the determining factor as to whether the stem cell is activated toward HG fate (low BMP or high Wnt) or maintained in a quiescent state (high BMP, low Wnt). This suggests that the antagonistic competition between BMP and Wnt is important in balancing the stem cell activity for robust homeostasis.

Wound healing

In contrast to homeostasis, HFSCs display a remarkable degree of plasticity in response to injury. In fact, many recent studies have put forward that cellular malleability of these stem cells is what drives the repair of skin after injury [68,70,71]. Hoeck et al. [71] demonstrated that impaired hair regeneration from ablation of $Lgr5^+$ stem cells in the lower bulge is reversible, as they can be readily replaced by $CD34^+$ upper bulge cells during recovery. They showed that neighboring $CD34^+$ bulge stem cells are capable of direct conversion into $Lgr5^+$ HG stem cells, uncovering the compensatory relationship between neighboring stem cell populations that underlie regeneration from injury. Similar observation of cellular malleability has also been made outside of the bulge as well. Utilizing the *Krt15-CrePR;R26R* transgenic mouse, Ito et al. genetically marked $K15^+$ bulge cells in adult mice and showed that, in response to excisional wounding with a 4 mm (punch) trephine, the HFSCs rapidly exit the bulge and migrate upward into the neo-epidermis to participate in the reepithelization process [68]. At least 25% of the newly formed epidermis originated from these $K15^+$ bulge cells. While this transient lineage infidelity of stem cells that allows for redirection of fates is essential in wound repair and may open up new therapeutic avenues for wound treatments, a recent study suggested that a similar breakdown of stem cell lineage confinement may have an implication in cancer development [70]. This finding is in line with observations that genetically

enhanced skin stem cell activity not only closes wounds faster but also increases susceptibility to squamous cell carcinomas [72], demonstrating an intricate link between mechanisms of wound repair and the pathogenesis of cancer that still has yet to be fully explored.

Given the complexity of the wound healing process, details regarding coordination and kinetics of cellular repair as well as the effects on homeostatic functions remain largely unknown. Quantitative clonal analysis and lineage tracing of stem cells during the wound healing process revealed that the repair process does not induce a change in the balance between renewal and differentiation: the hierarchy of stem cells is maintained [73]. While the population of stem cells studied increased proliferation rates during the wound healing process, the homeostatic mode of division was conserved, leading to a linear increase in the individual clone size over time. Adding to the knowledge regarding the coordination of cellular behavior in wound repair, Park et al. [74] recently mapped the spatiotemporal dynamics of individual epithelial cells in real time following a wound. By combining intravital imaging with lineage tracing tools, they showed that the cells move out of highly proliferative zones and migrate toward the wound site, and the migration rates of these cells change depending on the distance from the wound; the migration rates are greatest closer to the wound. This coexistence of proliferation and migration in wounds impacts the stratification as well as local expansion and elongation of the repairing epithelium, contributing to its morphogenesis. Collectively, these findings all demonstrate how cellular behaviors are coordinated and orchestrated to support wound reepithelization and provide insight into how the epidermis may balance both cellular homeostasis as well as tissue regeneration in the setting of injury.

Wound-induced hair follicle neogenesis and regeneration

Harnessing the ability to grow new hair on a damaged or wounded skin is an unmet clinical need in dermatology. Pioneering work by Ito et al. demonstrated that completely new HFs can form in the center of large, full-thickness wounds via a Wnt signaling–dependent process resembling embryonic development [75]. This HF neogenesis is a relatively late event, contingent upon completion of wound reepithelialization. Neogenic HFs start as bud-like invaginations of the basal layer (*aka* HGs or placodes) and soon develop into elongated hair pegs that mature into hair shaft-producing anagen HFs within just a few days. Importantly, like normal HFs at the wound edge, these regenerated neogenic HFs have a prominent $K15^+$ bulge stem cell compartment, are able to undergo multiple HF cycles, and produce a functional hair shaft.

While wound-induced hair neogenesis serves as an illustration of adult organogenesis that is rarely observed among mammals, the molecular mechanisms and mediators that are responsible for reactivation of the observed embryonic morphogenetic programs remain poorly understood. In recent years, double-stranded DNA released from damaged skin has been identified to trigger initial skin regeneration via activation of Toll-like receptor 3, as evidenced by subsequent increases in markers of HF progenitors such as keratin 15 [76]. Epithelial expression of Msh homeobox 1 (Msx), a gene known for the induction of skin and its appendages in embryogenesis, is another potential positive mediator of wound-induced HF neogenesis (WIHN) [77]. Msx2-null mice fail to activate WIHN and successful neofolliculogenesis in wound require expression of epidermal Msx2 in two distinct temporal phases: early in the wound margin and late in the wound center [78]. Lim et al. [79] identified Shh signaling as another essential mediator for WIHN. New activation of otherwise stalled Shh signaling pathways in the wound dermis acts as a regenerative cue that overturns fibrotic Wnt-active dermal fibroblasts into a regenerative DP niche, promoting proper HF neogenesis without scarring. By demonstrating for the first time that de novo DP can be induced via modulation of Shh signaling in the dermis, the work hints at the potential of activating the Shh pathway as a therapeutic means to restore hair growth, particularly in wounded skin.

Epithelial stem cells in aging

With aging, human skin undergoes progressive architectural and physiological decline from a lifetime of different environmental insults causing damage. Age-associated degeneration of skin is usually marked by increased levels of proinflammatory mediators, decreased cell turnover, delayed wound healing, and a delayed immune response—all of which makes the skin more susceptible to breakdown and trauma [80]. However, exact mechanisms for both functional and structural decline of the skin over time are underexplored.

Recent studies suggest that some of these age-related changes are associated with loss of a hemidesmosomal transmembrane protein called type XVII collagen (COL17A1/BP180), a protein highly expressed by HFSCs for self-renewal and maintenance of their quiescence [81]. In vivo fate tracing of HFSCs revealed that HFSC aging can be triggered by neutrophil-mediated proteolysis of type XVII collagen in response to DNA damage, which eventually results in loss of stemness signatures and loss of epidermal commitment [82]. Follicle atrophy, hair loss and graying, and dysregulated hair

cycling (shortened telogen phase and prolonged anagen phase) were all observed in COL17A1 KO mice, suggesting that the type XVII collagen serves as a niche for HFSCs and plays a critical role in age-related changes to HFs.

In addition to the age-associated changes in stem cells themselves, impaired cross talk between resident immune cells and aging stem cells has been implicated in the functional decline of aging tissues, particularly with regards to delayed wound repair. Healthy murine epidermis harbors a unique population of dendritic epithelial T cells (DETCs), which promptly induce reepithelization following injury by producing keratinocyte growth factors to promote proliferation of basal progenitor keratinocytes [83]. Keyes et al. recently showed that wound edge keratinocytes in aged mice are incapable of upregulating Skints and STAT3, proteins required to activate DETCs to promote the reepithelization process following injury [84]. Notably, wound-induced reepithelization was significantly impaired in Skints KO mice, suggesting that epidermal progenitors are unable to effectively close the wound bed without the help of DETCs. While these findings do not have direct implications in humans as DETCs do not reside in the human epidermis, similar mechanisms of interaction between skin stem cells and skin-resident T cells could possibly regulate chronic wounds in aged individual.

Not all age-related skin changes are negative. In fact, dermatologists and plastic surgeons have observed that older people heal skin wounds with thinner scars. Nishiguchi et al. found that aged mice repaired back wounds with less scarring while younger mice produced more fibrotic scars, as observed from increased levels of myofibroblast marker α-smooth muscle actin [85]. In order to elucidate the mechanism mediating differential tissue repair in aged and young animals, they surgically connected the circulatory system of young and aged mice and observed that, as a result of the shared blood supply, the aged mice adopted the young mice's fibrotic wound phenotype. This intriguing work suggested that a circulating factor in the blood of young mice promotes scar formation and prevents tissue regeneration in aged mice. By comparing gene activity between injured young and aged human skin, they determined the culprit circulating factor to be stromal-derived factor 1 (SDF1), which is secreted by injured young keratinocytes to promote scar formation but is suppressed with increased activity of age-dependent EZH2. Young SDF1 KO mice indeed regenerated skin with no scarring, demonstrating that SDF1 promotes scar formation in young mice. Interestingly, SDF1 has previously been implicated in regulation of tissue regeneration not only in the skin [86] but also the liver [87]. From these findings, antagonists of SDF1 or increased expression of EZH2 may offer promising therapeutic strategies for skin scarring conditions such as keloids and hypertrophic scars.

Role of stem cells in alopecia

Compromised integrity of the stem cells in the HF bulge has been implicated in the development of alopecia. Ito et al. [68] used a transgenic mouse model to induce bulge cell destruction and demonstrated rapid and permanent loss of HFs. This work highlights the key role of the bulge cells in survival of HFs [68].

Alopecias can be classified into scarring and nonscarring types [88]; more importantly, dermatologists often further classify alopecias into temporary (reversible) or permanent (irreversible) hair loss. Recent studies suggest that the location of the perifollicular inflammatory infiltrate within the HF may explain why some types of inflammatory alopecias cause permanent follicle loss (such as lichen planopilaris and discoid lupus erythematosus), while others (such as alopecia areata) are reversible [89]. In cicatricial (scarring) alopecias, inflammation involves the superficial portion of the follicle, including the bulge area, leading to destruction of the epithelial HFSCs that are necessary for follicle regeneration. This results in permanent and irreversible loss of scalp hair. In contrast, the inflammatory injury of a nonscarring alopecia such as alopecia areata instead involves the bulbar region of the HF that is composed of bulge cell progeny. Because this area is immediately responsible for hair shaft production, its destruction leads to hair loss; however, since the bulge area is spared and remains intact, a new lower anagen follicle and subsequent hair shaft can be produced. It has been reported that patients with alopecia areata can regrow their hair, either spontaneously or in response to immunomodulation, even after having suffered from inflammation for many years.

Androgenetic alopecia (AGA, common baldness) is a genetically determined disorder that is considered to be a noninflammatory condition; however, the bulge may still be targeted for inflammation in AGA. Jaworsky et al. [90] showed that inflammatory cells localize to the bulge in patients with early AGA and postulated that this damage could contribute to the irreversible nature of AGA over time. To examine whether stem or progenitor cells are affected in AGA, Garza et al. [33] analyzed balding and nonbalding scalps from AGA patients for the presence of these cells. Fluorescence-activated cell sorting analyses showed that true noncycling $K15^+$ stem cells were retained in balding scalp, while more proliferative $Cd200^+$ progenitors residing in the lower bulge and secondary germ were markedly depleted. This result hints at insufficient stem cell activation and blunted replenishment of progenitors from bulge cells in the balding scalp of AGA, which contributes to the impaired hair

regeneration [33]. With respect to the mechanism of pathogenesis, prostaglandin D_2 (PGD_2) acts as a key inhibitor of HFSCs in AGA, and a key inhibitor of hair growth [91]. Further studies have supported this finding and showed that PGD_2 inhibits hair lengthening and HF regeneration through the G-protein-coupled receptor 44 (GPR44), highlighting the PGD_2-GPRR44 pathway as a target for treatment of AGA [91] as well as for induction of follicle neogenesis in wound healing [92].

Skin as an active immune organ

As the body's first line of defense against various toxins, pathogens, and physical stresses, the human skin is home to many immune cells. These include T cells, macrophages, and LCs; in fact, the skin harbors roughly 20 billion T cells, making the skin the largest reservoir of T cells in the body [93]. As an active immune "organ," the skin continually interacts with the circulating immune system, with resulting implications to many normal skin processes such as hair regeneration and to the pathogenesis of numerous skin diseases.

Cross talk between hair follicles and the immune system

Mammalian HFs are essential to homeostasis, regulation of body temperature, and the generation of hair shafts for protection against pathogens and physical stimuli. Apart from a protective role, mammalian HFs are a reservoir for various immune cells. Both the HF bulb and bulge are considered to be immune-privileged sites, and collapse of these areas have been associated with inflammatory disorders resulting in hair loss [94, 95], how and why the HF interacts with immune cells is still largely uncharted territory.

Ali et al. [96] found a functional link between skin-resident regulatory T cells (Tregs) and HF physiology. They showed that ablation of Tregs in mice significantly reduced anagen induction as well as successive hair regrowth, suggesting the role of Tregs in promoting the telogen-to-anagen transition. Furthermore, using immunofluorescence microscopy, they demonstrated that these skin-specific Tregs predominantly reside within 0−5 μm of the bulge region, a well-established niche for HFSCs and stimulate the proliferation and differentiation of bulge HFSCs through heightened expression of Notch ligand Jag1. Their work raises the novel possibility that immunomodulation of Tregs may be useful in devising new therapeutics for immune-mediated skin disorders such as alopecia areata.

Besides Tregs, HFs are also densely populated by unique epidermal myeloid cells known as LCs. LCs are known to provide defenses against skin pathogens such as *Candida albicans* [97] and also to help remove melanin from healthy scalp follicles during catagen [98]. But the origin of LCs in HFs is still incompletely understood. To better understand trafficking of these dendritic cells into the skin, Nagao et al. depleted LCs in Langerin-DTR (diphtheria toxin receptor) mice by injection of diphtheria and then undertook bone marrow reconstitution with CAG-eGFP bone marrow to follow eGFP-labeled LC differentiation and skin reconstitution in vivo. With induced mechanical stress, they observed infiltration and accumulation of $eGFP^+$ LCs near follicular structures, suggesting that HFs are important portals for the entry of LCs [99]. They also found that the production of CCL2 and CCL20 chemokines by HF keratinocytes is responsible for the recruitment of LCs and pre-LCs to the epidermis, further illustrating HF keratinocytes as a potent source of proteins regulating immune cell trafficking into the skin. Interestingly, they found that LCs were almost completely absent from the epidermis of scalps from subjects with lichen planopilaris, a condition characterized by inflammation and destruction of the HF bulge, corroborating the portal role of follicles and also hinting at the potential of immunomodulation as a treatment of lichen planopilaris.

Another important cutaneous immune cell population are macrophages. While the unquestionable importance of macrophages in wound healing has been known for many years, we are only beginning to elucidate their roles in HF and HFSC regeneration. Recently, Wang et al. [100] depleted $Ly6C^+$ monocytes and macrophages in mouse skin and noted delayed anagen in the wound-induced hair anagen reentry/growth (WIH-A) model, as well as in WIHN. When Ly6C + macrophages were depleted in the wound region, both WIH-A and WIHN were attenuated. This suggests that macrophages play critical roles in injury response via activation of HFSCs during anagen onset as well as HF regeneration following wounding. Subsequent microarray analysis of macrophages isolated from wound tissue also revealed tumor necrosis factor as a crucial mediator of macrophage-induced HF cycling and neogenesis in wounds.

But the role of macrophages goes beyond wound clearance and healing. In fact, macrophages have been implicated to be essential in homeostatic hair growth. Intracutaneous transplantation of bone marrow−derived macrophages into the dorsal skin of mice has been shown to strongly induce proliferation of epidermal basal cells and HF cells, including bulge stem cells, suggesting that macrophages can promote anagen [101]. Furthermore, Castellana et al. observed an apoptosis-induced decrease in the number of $F4/80^+$ $CD11b^+$ $Gr1^+$ skin-resident macrophages before the onset of anagen and showed that pathways regulating HFSC activation, such as β-catenin/Wnt signaling, are upregulated at this stage [102]. Further studies showed that

macrophage apoptosis in skin promotes premature anagen entry, possibly through release of Wnt ligands.

The inflammatory memory of skin cells

For a long time the paradigm of inflammatory memory was thought to be unique and solely restricted to innate immune cells. But recent studies have shed light on the capacity of epithelial stem cells to also document inflammatory encounters, which is notable as they frequently bear the brunt of inflammation and tissue damage. Using an in vivo mouse model of skin inflammation, Naik et al. showed that mice previously exposed to imiquimod, a Toll-like receptor-7 ligand that induces inflammation, healed the wound 2.5 times faster than controls [103]. Depletion of skin-resident B cells, T cells, and macrophages before wounding showed no effect on the healing rate postinflammation, suggesting that the epithelial stem cells are the primary cell type responsible for the observed hastened barrier restoration to the secondary challenge. The authors speculate that epithelial stem cells reprogram their chromatin and alter their accessibility in response to acute inflammatory assault. Thus upon a secondary inflammatory challenge (e.g., injury, physical stimuli), these "remodeled" stem cells rapidly upregulate transcripts governed by newly accessible chromatin domains associated with the previous stress response. A key mediator of this memory has been suggested to be inflammasome activator AIM2, which augments IL-1B to fuel the regenerative process following injury. While "inflammatory memory" by epithelial stem cells can help to quickly restore the skin barrier in response to a second breach, this heightened sensitivity to tissue damage is also likely to have many implications for skin homeostasis, cancer, and autoimmune disorders [104] such as psoriasis. Ongoing research on the inflammation-induced rewiring of epithelial stem cells is likely to provide future insights into the mechanisms of various skin diseases and bolster the development of potential therapeutic agents.

Tissue engineering with epidermal stem cells

Recent innovations in tissue engineering and biomaterials have propelled our understanding of the complex relationship between cells and their environment, allowing researchers to develop better models to study biological processes. With skin, tissue engineering with HFSCs has been implicated in the potential treatment of alopecia [105]. As a proof of concept, at least two groups have shown that freshly isolated bulge cells from adult mice, when combined with neonatal dermal cells, form HFs after injection into immunodeficient mice [22,106].

Many studies in the field looked into the self-assembling property of skin progenitor cells as a means to produce HFs from dissociated, individual cells. In fact, one of the major breakthroughs in tissue-engineered skin constructs include three-dimensional (3D) skin organoid cultures that resulted from the self-assembly of cells. By performing global gene expression analysis of human DP cells in both 2D and 3D cultures, Higgins et al. [107] discovered that there are molecular signature differences between the two environments that account for the loss of hair-inducing capacity in 2D. While assembled cells demonstrated an ability to successfully guide hair growth, this inductive property was absent from classic monolayer culture environment due to the loss of contextual and spatial signals from the neighboring epithelial cells. This demonstrates that the dermal spheroid culture better recapitulates and resembles the native, physiological tissue organization than the traditional 2D culture models, making it a potential model for applications in drug screening.

Considering the potential uses in drug screening and disease modeling, there have been a number of studies dedicated to building in vitro 3D culture systems that better capture the complex and delicate cellular cross talks of living tissue. These systems were built from mouse pluripotent stem cells [108] and even from dissociated neonatal human keratinocytes and dermal cells [109]. Weber et al. produced human hair peg−like structures in vitro from a 3D coculture of dissociated neonatal human keratinocytes and dermal cells. These cells self-organized through discrete stages, akin to early follicle development, to reach cellular configurations similar to hair pegs in situ, suggesting that these 3D culture systems can potentially provide a platform to study the spatiotemporal patterning and self-assembling behavior of skin progenitor cells. Time-lapse imaging from 3D cultures of dissociated mouse epidermal and dermal cells showed a progression through a series of morphological phase transitions, ultimately achieving a planar layer of hair primordia-bearing organoids, which resembled functional follicles: dissociated cells, cell aggregates, polarized cysts, cyst coalescence, planar skin, and hair-bearing skin [110]. Transcriptome profiling of the developing organoids revealed successive expression of distinct molecules, including growth factors and matrix metalloproteinases throughout the morphogenesis, suggesting not only that the self-assembly processes can be reinstated via environmental rewiring, but also that opportune supply of these critical regulatory molecules may be the key to successful hair formation in adult skin cells. This hints at the potential of in vitro culture systems to elucidate ways to restore and optimize HF regeneration as well as to support the production of complete HFs for possible transplantation.

Besides relying on the self-organizing ability of skin progenitor cells, there has been tremendous interest in

using bio-printed scaffolds to direct formation of HFs. For example, Abaci et al. recently demonstrated the use of 3D printing technology to incorporate HFs into human skin constructs (HSCs) [111]. By using a 3D-printed mold, they generated HF-like microwells on collagen gel in which they seeded distinct dermal cell types (fibroblasts, DP cells) in a way that recapitulated the 3D physiological conformation of cells in the native HF microenvironment. By employing this biomimetic approach, they were able to demonstrate, for the first time, the generation of human HFs in HSCs in an entirely ex vivo context. This 3D printing approach has several advantages over previously described methods that rely on spontaneous formation of HFs via self-assembly. 3D printing technology allows for tight control of spatial pattern and arrangement of cells, including HSCs, which is now known to be important for proper morphogenesis of progenitor cells into a functional follicle. Furthermore, printing density can be fully controlled, which may be advantageous in recreating the variations in hair density at the site of transplantation—something which can be personalized in transplants depending on the patient's need.

Epidermal stem cells as a therapy: the future

In recent years, combinatorial therapeutics using cultured epidermal autografts with gene therapy have emerged as a promising new concept for treating skin defects. Seminal work by Hirsch et al. [112] demonstrated that keratinocyte stem cells could be used to treat junctional epidermolysis bullosa (JEB), a severe, life-threatening congenital skin disease that is currently considered incurable. They performed an autologous skin biopsy of the patient from a nonblistering area and transduced the obtained primary keratinocytes with a retroviral vector expressing LAMB3, which is one of the mutations responsible for causing JEB. Using the cultured transgenic epidermal sheets, they were able to perform a whole-body epidermal replacement for the patient. A series of biopsies taken after grafting demonstrated successful regeneration of the entire epidermis by autologous transgenic epidermal culture and, most importantly, the epidermis had normal morphology with no sign of blisters or epidermal detachments that are hallmarks of JEB. Interestingly, clonal tracing by PCR showed that the regenerated epidermis postgraft is sustained and replenished not by equipotent progenitors but by a limited number of long-lived, self-renewing stem cells, detected as holoclones. This finding of holoclone niche supports the canonical EPU model of skin renewal [10] and suggests important implications in wound healing regarding the importance of having an adequate number of graft holoclones. While this was a single-case clinical intervention and warrants further study, these findings collectively underscore the clinical potential of genetically engineered and corrected cultured epidermal stem cells to treat wide variety of skin diseases.

Conclusion

Epithelial stem cells make essential contributions to maintenance and repair in both skin and hair. Balanced contributions by both interfollicular stem cells and more differentiated progenitors provide a constant supply of new cells during normal skin turnover and homeostasis. Interfollicular stem cells are also the primary source for new epidermis in wound healing. The HF cycles throughout the life of the individual. New work suggests that HF bulges are the likely source of true stem cells, giving rise to numerous progenitors throughout the follicle, each with distinct roles. As a mini-organ of the skin, HF macroenvironments have shown to harbor many types of immune cells, all of which are important and essential for homeostatic maintenance and regeneration after an injury. With the advent of tissue engineering, stem cells have been demonstrated as having therapeutic potential: we have seen uses in chronic wound repair, transplantation of engineered human hair, or in genetically corrected autologous epidermal sheets. Skin conditions that are considered incurable as of now may see new treatment innovations in the not-so-distant future.

Introduction

The skin is the largest organ in the body whose primary function is to serve as a protective barrier against the environment. Other important functions of the skin include fluid homeostasis, thermoregulation, immune surveillance, sensory detection, and self-healing. Loss of the integrity the skin due to injury or illness compromises its protective function and when the loss is extensive may result in significant disability or even death. It is estimated that in 1996, there were 35.2 million cases of significant skin loss (US figures) that required major therapeutic intervention [1]. Of these, approximately 5 million wounds become chronic.

The most common single cause of significant skin loss is thermal injury, which accounts for an estimated 1 million emergency department visits per year [2]. Other causes of skin loss include trauma and chronic ulcerations secondary to diabetes mellitus, pressure and venous stasis. Every year in the United States there are approximately 2 million cases of chronic diabetic ulcers, many of which eventually necessitate amputation. Pressure and leg ulcers, including venous ulcers, affect another 3 million people in the United States with treatment costs as high as $8 billion annually [3]. In 2011 a survey estimated the US market for advanced wound care products, including biological and synthetic dressings, approximately $3 billion and expected to increase significantly as the population ages, becoming more susceptible to underlying causes of chronic wounds [4]. The quality of life tolls of chronic wounds are extremely high.

Over the past two decades, extraordinary advances in cellular and molecular biology have greatly expanded our comprehension of the basic biological processes involved in acute wound healing and the pathobiology of chronic wounds [5,6]. One recombinant growth factor, platelet-derived growth factor (PDGF)-BB (Regranex, Ortho-McNeil), and several skin substitutes (e.g., *dermal substitutes*: Integra Matrix Wound Dressings, Integra Life Sciences; AlloDerm, LifeCell; OASIS Wound Matrix, Healthpoint; Dermagraft and TransCyte, Advanced BioHealing; and *Epidermal/dermal substitutes*: Apligraf, Organogenesis; Orcel, Forticell Bioscience; TissueTech, Fidia Advanced Biopolymers) have reached the market place for second-line therapy of recalcitrant ulcers [7]. These therapeutic interventions have added to the clinician ability to induce skin healing, but they have not had the impact that was predicted. Regardless of the advanced wound care product, the ideal goal would be to regenerate tissues where both the structural and functional properties of the wounded tissue are restored to the levels prior to injury.

In contrast to adult wounds, embryonic wounds undergo complete regeneration, terminating in a scarless repair [8,9]. Thus investigators are now using morphogenetic cues including hair development to develop engineered constructs capable of tissue regeneration [10,11]. Cellular response to biological stimuli depends on the mechanical strength of the extracellular matrix (ECM) [12]. Therefore the therapeutic successes of tissue-engineered constructs will depend not only on their molecular and cellular activity but also on their optimal mechanical properties [13]. This chapter will begin with an overview of the basic biology of wound repair, followed by a discussion of established practices and novel approaches to engineer tissue constructs for effective wound repair. A more extensive review of wound healing at a cellular level has been published recently [14].

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00072-1

Basic biology of wound repair

Wound repair is not a simple linear process in which growth factors released by phylogistic events activate parenchymal cell proliferation and migration but is rather an integration of dynamic interactive processes involving soluble mediators, formed blood elements, ECM, and parenchymal cells. Unencumbered, these wound repair processes follow a specific-time sequence and can be temporally categorized into three major groups: inflammation, tissue formation, and tissue remodeling. The three phases of wound repair, however, are not mutually exclusive but rather overlapping in time.

Inflammation

Severe tissue injury causes blood vessel disruption with concomitant extravasation of blood constituents. Blood coagulation and platelet aggregation generate a fibrin-rich clot that plugs severed vessels and fills any discontinuity in the wounded tissue. While the blood clot within vessel lumen reestablishes homeostasis, the clot within wound space acts as a growth factor reservoir and provides a provisional matrix for cell migration.

The primary cell types involved in the overall process of inflammation are platelets, neutrophils, and monocytes. Upon injury, successful reestablishment of homeostasis depends on platelet adhesion to interstitial connective tissue, which leads to their aggregation, coagulation and activation. Activated platelets release several adhesive proteins to facilitate their aggregation, chemotactic factors for blood leukocytes, and multiple growth factors [5,6], to promote new tissue formation.

Of the two primary phagocytic leukocytes, namely, neutrophils and monocytes, neutrophils arrive first in large numbers due to their abundance in circulation. Infiltrating neutrophils cleanse the wounded area of foreign particles, including bacteria. If excessive microorganisms or indigestible particles have lodged in the wound site, neutrophils will probably cause further tissue damage as they attempt to clear these contaminants through the release of enzymes and toxic oxygen products. When particle clearance has been completed, generation of granulocyte chemoattractants ceases and the remaining neutrophils become effete.

Transition from inflammation to repair

Macrophages are responsible for many of the tissue-level changes that occur as the wound progresses from inflammation to repair, as they serve important functions in both stages. It was previously held that blood monocytes would infiltrate the wound 24–48 hours after injury, during which time neutrophils accumulate in the wound. However, recent evidence suggests that monocytes can enter the wound through microhemorrhages in the wound bed within a few hours [15]. Once there, monocyte undergo phenotypic differentiation into macrophages. Macrophages exhibit a spectrum of functional phenotypes, but they are generally categorized into one of three groups: M1 or classical macrophages, M2 or nonclassical macrophages, and intermediate macrophages [16].

The current understanding of how macrophages regulate wound repair revolves around their M1 and M2 phenotypes. M1 macrophages phagocytose microbial invaders, cellular debris, and neutrophils. They aid in preventing infection and keeping the neutrophil population from overrunning the wound and causing more damage. M1 macrophages also release proinflammatory cytokines, fueling the inflammatory stage of wound repair. In contrast, M2 macrophages release growth factors to stimulate proliferation and antiinflammatory mediators to control the inflammatory response. Yet M2 macrophages still partake in the phagocytosis of neutrophils [17].

The current model of dermal wound healing identifies an "M1–M2 switch," in which the most abundant macrophage phenotype in the wound changes from M1 to M2, in accordance with the change from inflammation to repair. Evidence suggests that the microenvironment plays an important role in determining the phenotype of a macrophage. Danger-associated molecular patterns such as adenosine triphosphate (ATP) and pathogen-associated molecular patterns such as bacterial-essential polynucleotides cause monocytes to follow classical activation and become proinflammatory [15,17]. M2 activation is triggered by interleukin (IL) 3 and IL-13 instead [17]. It is not yet clear if these M2 macrophages differentiate from nonactivated monocytes or previously activated M1 macrophages [16].

Reepithelialization

Reepithelialization of a wound begins within hours after injury by the movement of epithelial cells from the surrounding epidermis over the denuded surface. Rapid reestablishment of the epidermal surface and its permeability barrier prevents excessive water loss and time of exposure to bacterial infections, which decreases the morbidity and mortality of patients who have lost a substantial amount of skin surface. If a wide expanse of the epidermis is lost, epidermal cells regenerate initially from stem cells in pilosebaceous follicles [18] but ultimately require interfollicular stem cells for completely competent regeneration of the epidermis [19]. Migrating epithelial cells markedly alter their phenotype by retracting their intracellular filaments, dissolving most of their desmosomes and forming peripheral actin filaments, which facilitate cell movement [20]. These migrating cells also undergo the dissolution

of their hemidesmosomal links between the epidermis and the dermis. All these phenotypic alterations provide epithelial cells with the needed lateral mobility for migration over the wound site. Migrating epidermal cells possess a unique phenotype that is distinct from both the terminally differentiated keratinocytes of normal (stratified) epidermis and the basal cells of stratified epidermis. It is now appreciated that the signals that control wound healing in the adult animal are similar to those that control epithelial fusion during embryogenesis [21]. A more comprehensive review of stem cells in reepithelialization has been recently published [22].

If the basement membrane is destroyed by injury, epidermal cells migrate over a provisional matrix of fibronectin, tenascin, and vitronectin, as well as stromal type I collagen and laminin [23,24]. Wound keratinocytes express cell surface receptors for fibronectin, tenascin, vitronectin, and laminin, which belong to the integrin superfamily. Integrins are distinguished by the α and β subunits (Table 70.1) [25]. In addition, α2β1 collagen receptors, which are normally disposed along the lateral sides of basal keratinocytes, redistribute to the basal membrane of wound keratinocytes as they come in contact with type I collagen fibers of the dermis. Although β1 integrins are clearly essential for normal reepithelialization [26], it is not clear which subtype is essential. It is most likely that there is a redundancy in the requirement for α5β1 and α2β1 in reepithelialization.

The migrating wound epidermis does not simply transit over a wound eschar but rather dissects through the wound, separating the fibrin/fibronectin-rich clot and desiccated dermis containing denatured collagen (together termed eschar) from underlying viable tissue [27]. The path of dissection appears to be determined by the array of integrins expressed on the migrating epidermal cells. Keratinocytes do not express αvβ3, the integrin receptor for fibrinogen/fibrin and denatured collagen [27]. Thus keratinocytes do not have the capacity to interact with fibrinogen/fibrin or denatured collagen. Furthermore, either fibrinogen or fibrin inhibits epidermal cell interactions with fibronectin, hence the migrating wound epidermis avoids the fibrin/fibronectin-rich clot but rather migrates along the type I collagen-rich wound edge via the α2β1 collagen receptor until it meets the fibronectin-rich granulation tissue and then proceeds to migrate over the newly forming tissue via fibronectin receptors α5β1 and αvβ5 (Fig. 70.1, from Ref. [27]).

ECM degradation is clearly required for the dissection of migrating wound epidermis between the collagenous dermis and the fibrin eschar and probably depends on epidermal cell production of collagenase, plasminogen activator, and stromelysin. Plasminogen activator activates

TABLE 70.1 Integrin superfamily.

Integrins	Ligand	Integrins	Ligand
β1 Integrins		αv Integrins	
α1β1	Fibrillar collagen, laminin-1	αvβ1	Fibronectin (RGD), vitronectin
α2β1	Fibrillar collagen, laminin-1	αvβ3	Vitronectin (RGD), fibronectin, fibrinogen, von
α3β1	Fibronectin (RGD), laminin-5, entactin, denatured collagens		Willebrand factor, thrombospondin, denatured collagen
α4β1	Fibronectin (LEDV), VCAM-1	αvβ5	Fibronectin (RGD), vitronectin
α5β1	Fibronectin (RGD + PHSRN, the synergy site)	αvβ6	Fibronectin, tenascin
α6β1	Laminin		
α7β1	Laminin	β2 Integrins	
α8β1	Fibronectin, vitronectin	αMβ2	ICAM-1, iC3b, fibrinogen, factor X
α9β1	Tenasin	αLβ2	ICAM-1, -2, and -3
		αXβ2	IC3b, fibrinogen
Other ECM integrins			
αIIbβ3	Same as αvβ3		
α6β4	Laminin		

ECM, extracellular matrix; *RGD*, arginine–glycine–asparatic acid.

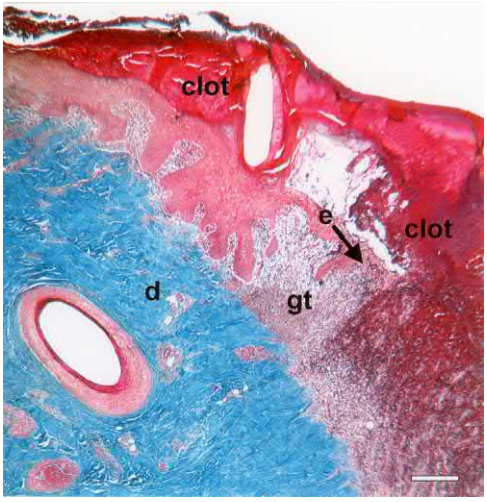

FIGURE 70.1 Histology of reepithelializing porcine wound. Full-thickness paravertebral skin wound was harvested on day 5, bisected, formalin fixed, and stained with Masson trichrome. The arrow resides on the tip of the migrating epidermis and points in the direction of migration. The eschar, which contains both clot and desiccated dermis, is denoted by "clot," normal dermis at the wound edge is indicated by the letter (d) and newly forming granulation tissue is noted by (gt). *From Kubo M, et al. Fibrinogen and fibrin are anti-adhesive for keratinocytes: a mechanism for fibrin eschar slough during wound repair. J Invest Dermatol 2001;117(6):1369–81, an Elsevier publication, with permission.*

collagenase matrix metalloproteinase 1 (MMP-1), as well as plasminogen and, therefore, facilitates the degradation of interstitial collagen as well as provisional matrix proteins. Interestingly, keratinocytes in direct contact with collagen greatly increase the amount of MMP-1 they produce compared to that produced when they reside on laminin-rich basement membrane or purified laminin [28]. The migrating epidermis of superficial skin ulcers and burn wounds, in fact, express high levels of MMP-1 mRNA in areas where it presumably comes in direct contact with dermal collagen [29]. A more comprehensive review of ECM attributes, as well as their deposition and degradation, during reepithelialization has been published recently [24].

One to two days after injury, epithelial cells at the wound margin begin to proliferate. Although the exact mechanism is still not clear, both proliferation and migration of epithelial cells may be triggered by the absence of neighboring cells at the wound margin (the "free-edge effect"). The "free-edge effect" in the wound epidermis may be secondary to the modulation of cadherins junctions as described for V-cadherins during angiogenesis [30]. In fact, studies indicate that epidermal desmosomes lose their hyperadhesiveness and cadherins switch from E-cadherins to P-cadherins at the wound edge [31]. Other possibilities, not exclusive of the former, are growth factors that induce epidermal migration and proliferation and/or increased expression of growth factor receptors. These growth factors find their way to epidermal cells by autocrine, juxtacrine, hormonal, or paracrine pathways. For example, transforming growth factor (TGF)-α and -β, which originate from keratinocytes themselves, can act either directly on the producer cell or on adjacent epidermal cells in an autocrine or juxtacrine manner, respectively. By contrast, insulin-like growth factor comes from the circulation and thereby act as a hormone, while other growth factors, such as heparin-binding epidermal growth factor (HB-EGF) and keratinocyte growth factor, are secreted from macrophages and dermal parenchymal cells, respectively, and act on epidermal cells through paracrine pathways of epidermal/dermal bidirectional networks [32]. As evidence of their importance, many of these growth factors have been shown to stimulate reepithelialization in animal models [5]. Furthermore, lack of some of these growth factors or their receptors in knockout mice support the hypothesis that their activation of keratinocytes is required for optimal epidermal migration and/or proliferation during normal wound healing [33]. It appears that growth factor stimulation of JNK signal transduction pathways may be the key for "resetting" the epidermal program from differentiation to proliferation, and possibly migration [34].

As reepithelialization progresses, basement membrane proteins reappear in an ordered sequence from the margin of the wound inward in a zipper-like fashion [5]. Epidermal cells revert to their normal phenotype once again firmly attaching to reestablished basement membrane through hemidesmosomal proteins, including $\alpha 6\beta 4$ integrin, laminin 332 (aka laminin 5), and 180 kDa bullous pemphigoid antigen [35]. At this stage, they reattach to the underlying neodermis through type VII collagen fibrils [36]. A more detailed review of cutaneous wound reepithelialization has been recently published [37].

Granulation tissue

New stroma, often called granulation tissue, begins to form approximately 4 days after injury. The name derives from the granular appearance of newly forming tissue when it is incised and visually examined. It is numerous new capillaries (neovasculature) that endow the neostroma with its granular appearance. Movement of macrophages, fibroblasts, and blood vessels into the wound space as a unit underscores the biologic interdependence of these cells during tissue repair. Macrophages provide a continuing source of cytokines necessary to stimulate fibroplasia and angiogenesis, fibroblasts construct new ECM necessary to support cell ingrowth, and blood vessels carry oxygen and nutrients necessary to sustain cell metabolism [38]. The quantity and quality of granulation tissue depends on biologic modifiers present, the activity

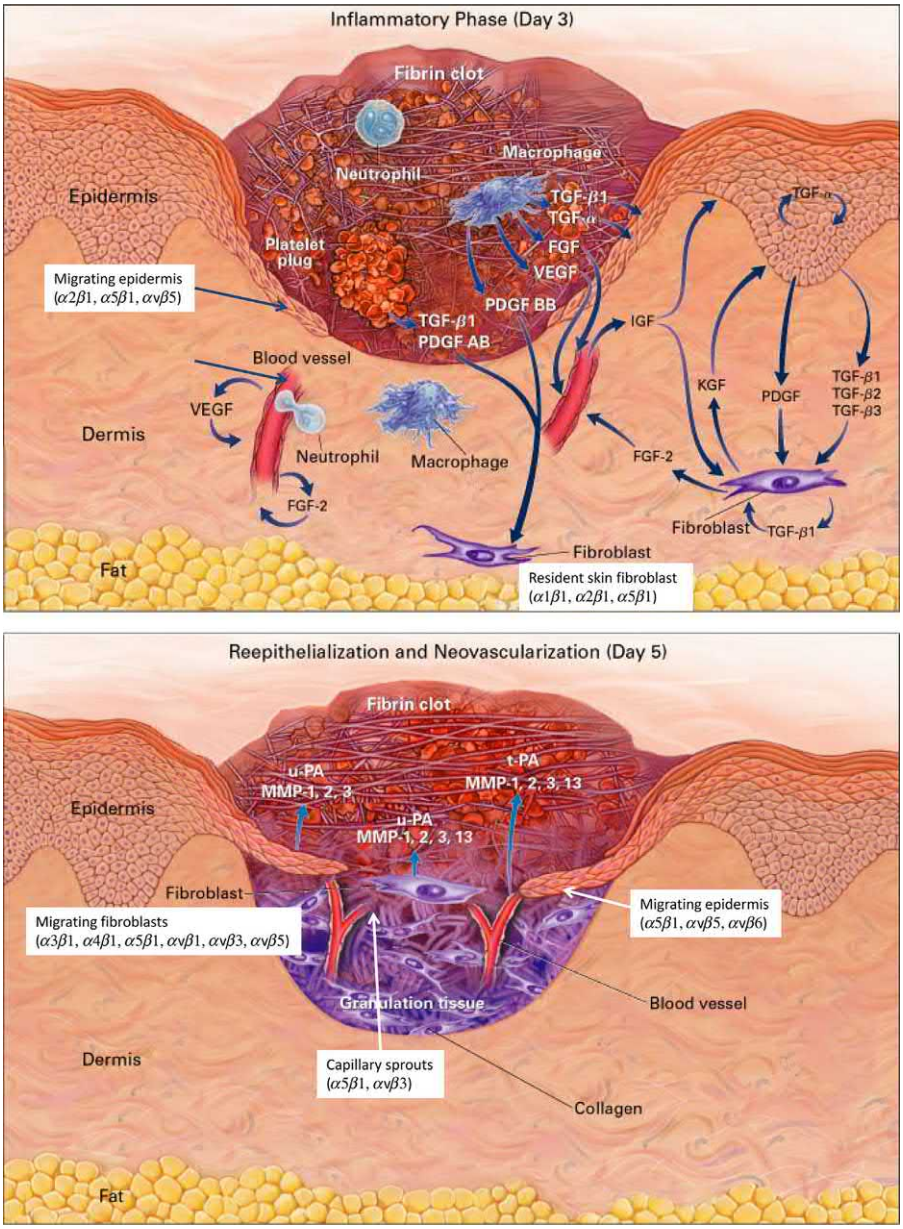

FIGURE 70.2 After injury the platelets, inflammatory cells, and the tissue cells (namely, fibroblasts, endothelial, and epidermal cells) secrete abundant quantities of multiple growth factors thought to be necessary for cell movement into the wound. However, it is the provisional matrix integrin expression that acts as the rate-limiting step in granulation tissue induction. Once the appropriate integrins are expressed on periwound endothelial cells and fibroblasts on day 3, the cells invade the wound space shortly thereafter (on days 4 and 5). Fibroblasts and endothelial cells express the fibrinogen/fibrin receptor avb3 and therefore are able to invade the fibrin clot; the epidermis, however, does not express avb3 and therefore dissects under the clot. Proteinases play an important role during granulation tissue formation by clearing the path for migrating tissue cells. Ultimately, the clot that has not been transformed into granulation tissue by invading fibroblasts and endothelial cells is dissected free of the wound and sloughed as eschar. *Modified from Singer AJ, Clark RA. Cutaneous wound healing. N Engl J Med 1999;341 (10):738–46 with permission.*

level of target cells, and the ECM environment. As mentioned in the "Inflammation" section, the arrival of peripheral blood monocytes and their activation into different subtypes of macrophages (see the "Transition from Inflammation to Repair" section) establish conditions for continual synthesis and release of growth factors. In addition, and perhaps more importantly, injured and activated parenchymal cells, for example, fibroblasts and epidermal cells, can synthesize and secrete growth factors. For example, migrating wound epidermal cells produce vascular endothelial cell growth factor (VEGF), TGF-β and PDGF-BB, to which endothelial cells and fibroblasts respond, respectively. The provisional ECM also promotes granulation tissue formation by positive feedback regulation of integrin ECM receptor expression [39]. Once fibroblasts and endothelial cells express the appropriate integrin receptors, they invade the fibrin/fibronectin-rich wound space (Fig. 70.2). Although it has been recognized for many years that ECM modulates cell differentiation by signal transduction from ligation of ECM receptors, more recently it has become evident that the force and geometry of the ECM influence cell behavior and differentiation [40–42].

Fibroplasia

Components of granulation tissue derived from fibroblasts including the cells themselves and the ECM are

collectively known as fibroplasia. Growth factors, especially PDGF and TGF-β, in concert with fibronectin as well as other provisional matrix molecules [43] presumably stimulate fibroblasts of the periwound tissue to proliferate, express appropriate integrin receptors, and migrate into the wound space. Many of these growth factors are released from macrophages or other tissue cells [5,6]; however, fibroblasts themselves can produce growth factors to which they respond in an autocrine fashion [44]. Multiple complex interactive biologic phenomena occur within fibroblasts as they respond to wound cytokines, including the induction of additional cytokines and modulation of cytokine receptor number or affinity. *In vivo* studies support the hypothesis that growth factors are active in wound repair fibroplasia. Several studies have demonstrated that PDGF, connective tissue factor, TGF-α, TGF-β, HB-EGF, and fibroblast growth factor (FGF) family members are present at sites of tissue repair [45–48]. Furthermore, purified and recombinant-derived growth factors have been shown to stimulate wound granulation tissue in normal and compromised animals [5], and a single growth factor may work both directly, and indirectly, by inducing the production of other growth factors *in situ* [49].

Structural molecules of the early ECM coined provisional matrix [50], contribute to tissue formation by providing a scaffold or conduit for cell migration (fibronectin) [51], low impedance for cell mobility (hyaluronan) [52], a reservoir for growth factors and cytokines [43,53], and direct signals to the cells through integrin receptors [25]. Fibronectin appearance in the periwound environment as well as the expression of fibronectin receptors appear to be critical rate limiting steps in granulation tissue formation [54]. In addition, a dynamic reciprocity between fibroblasts and their surrounding ECM creates further complexity [55]. That is, fibroblasts affect the ECM through new synthesis, deposition, and remodeling of the ECM while the ECM affects fibroblasts by regulating their function including their ability to synthesize, deposit, remodel, and generally interact with the ECM [39,56]. Thus the reciprocal interactions between ECM and fibroblasts dynamically evolve during granulation tissue development.

As fibroblasts migrate into the wound space, they initially penetrate the blood clot composed of fibrin and lesser amounts of fibronectin and vitronectin. Fibroblasts presumably require fibronectin in vivo for movement from the periwound collagenous matrix into the fibrin/fibronectin-laden wound space as they do in vitro for migration from a three-dimensional collagen gel into a fibrin gel [51]. Fibroblasts bind to fibronectin through receptors of the integrin superfamily (Table 70.1 *original*). The Arg–Gly–Asp–Ser (RGDS) tetrapeptide within the cell-binding domain of these proteins is critical for binding to the integrin receptors α3β1, α5β1, αvβ1, αvβ3, and αvβ5. In addition, the CSIII domain of fibronectin provides a second binding site for human dermal fibroblasts via the α4β1 integrin receptor [57]. In vivo studies have shown that arginine–glycine–asparatic acid (RGD)-dependent fibronectin receptors, α5β1 and αvβ3, are upregulated on periwound fibroblasts the day prior to granulation tissue formation and on early granulation tissue fibroblasts as they infiltrate the provisional matrix-laden wound [39]. In contrast the non-RGD-binding α1β1 and α2β1 collagen receptors on these fibroblasts were either suppressed or did not appear to change appreciably [39,58]. Furthermore, PDGF increases α5β1and α3β1 while decreasing α1β1 in cultured human dermal fibroblasts surrounded by fibronectin [58]. In addition, fibronectin or fibrin-rich environments promote the ability of PDGF to increase α5β1 and α3β1, but not α2β1 by increasing mRNA stability and steady-state levels [39]. These data strongly suggest that the type of integrin increased by PDGF stimulation appears to depend on the ECM context and suggests a positive feedback between ECM and ECM receptors.

Movement into a cross-linked fibrin blood clot or any tightly woven ECM may also necessitate active proteolysis to cleave a path for migration. A variety of fibroblast-derived enzymes in conjunction with serum-derived plasmin are potential candidates for this task, including plasminogen activator, interstitial collagenase-1 and -3 (MMP-1 and MMP-13, respectively), the 72 kDa gelatinase A (MMP-2), and stromelysin (MMP-3). In fact, high levels of immunoreactive MMP-1 has been localized to fibroblasts at the interface of granulation tissue with eschar in burn wounds [29] and many stromal cells stain for MMP-1 and MMP-13 in chronic ulcers [59]. TGF-β downregulates this proteinase activity, while PDGF stimulates the production and secretion of these proteinases [60]. From elegant knockout mouse studies, it is clear that the plasminogen activating system is critical for clearing the wound clot [61]. However, double knockout of MMP-13 (also called collagenase-3) and the plasminogen activating system in mice created more delay of healing compared to knockout of only the plasminogen activating system [62]. Furthermore, galardin, a broad-spectrum MMP inhibitor, slowed cutaneous healing, while MMP-9 deficient mice demonstrate altered fracture repair [63] and a knockout of MMP-8 (also called collagenase-2) adversely effected cutaneous wound repair [64]. Thus although there is great overlap in MMP function in tissue repair, their activity is clearly necessary for proper healing of cutaneous wounds.

When fibroblasts have completed their migration into the wound site, they switch their major function to protein synthesis [65]. Hence, the migratory phenotype is completely supplanted by a profibrotic phenotype characterized by

decreased α3β1 and α5β1 provisional matrix receptor expression, increased α2β1 collagen receptor expression, and abundant rough endoplasmic reticulum and Golgi apparatus filled with new collagen protein [39,65]. Accordingly, the fibronectin-rich provisional matrix is gradually supplanted with a collagenous matrix [56,65]. Under these conditions, PDGF, which is still abundant in these wounds [66], stimulates extremely high levels of α2β1 collagen receptor, but not α3β1 or α5β1 provisional matrix receptors, supporting the contention that the ECM provides a positive feedback for integrin expression [39]. TGF-β observed in wound fibroblasts at this time [56] can induce fibroblasts to produce great quantities of collagen [67]. IL-4 also can induce a modest increase in types I and III collagen production [68]. Since IL-4 producing mast cells are present in healing wounds, as well as fibrotic tissue, these cells may contribute to collagen matrix accumulation at these sites. Not surprisingly, the effect of IL-4 on healing tissue is strikingly dose and time dependent [69], as are the biological effects of most other cytokines and growth factors.

Mechanical stimuli have also been well-documented to induce fibroblast proliferation, migration, as well as production of growth factors, such as FGF, and TGF-β, and ECM proteins such as collagen [70,71]. These results have been shown both in vitro by subjecting fibroblasts to cyclical stretch and in vivo where negative pressure therapy stretches cells and can promote healing. Cells transduce these mechanical cues through integrins, ion channels, and growth factor receptors, which activate or modulate different signaling pathways. Integrins, in part, transduce their signals through focal adhesion kinase (FAK). Interestingly, knockout mice targeting fibroblast FAK experienced less inflammatory cell migration and fibrosis [70]. This evidence suggests mechanotransduction of cells, especially fibroblasts, during healing can modify fibroplasia to the benefit or detriment of healing, likely secondary to the degree and frequency of strain across the cells.

Once an abundant collagen matrix is deposited in the wound, fibroblasts cease collagen production despite the continuing presence of TGF-β [56]. The stimuli responsible for fibroblast proliferation and matrix synthesis during wound repair were originally extrapolated from many in vitro investigations and then confirmed by in vivo manipulation of wounds [20]. Both in vitro and *in vivo* studies suggest that gamma-interferon may be one such factor [72]. In addition, collagen matrix can suppress both fibroblast proliferation and fibroblast collagen synthesis [56,73]. In contrast a fibrin or fibronectin matrix has little or no suppressive effect on the mitogenic or synthetic potential of fibroblasts [56,74].

Although the attenuated fibroblast activity in collagen gels is not associated with cell death, many fibroblasts in day 10 healing wounds develop pyknotic nuclei [75], a cytological marker for programmed cell death (apoptosis). These results suggest that apoptosis is the mechanism responsible for the transition from a fibroblast-rich granulation tissue to a relatively acellular scar. Signal(s) causing apoptosis in wound fibroblasts have not been delineated, possibly attributable to the fact that in vitro experimental environments have not recapitulated the maturing wound environment, which may be required for priming wound fibroblasts for apoptosis [76]. Interestingly, fibroblasts in fibrotic diseases, such as keloid formation, morphea, and scleroderma, are also resistant to apoptotic signals and these signals may be disrupted either directly or indirectly [77].

Neovascularization

Fibroplasia would cease if neovascularization failed to accompany the newly forming complex of fibroblasts and ECM. The process of new blood vessel formation is called angiogenesis [78]. Many soluble factors that stimulate angiogenesis in wound repair have been elucidated [79]. Angiogenic activity can be recovered from activated macrophages as well as epidermal cells, fibroblast, endothelial cells, and numerous tumor cells [80]. Most biologically important angiogenic molecules have been identified and include vascular endothelial growth factor (VEGF), FGF-1 and FGF-2, TGF-α, TGF-β, TNF-α, platelet factor-4 (PF-4), angiogenin, angiotropin, angiopoietin, IL-8, PDGF, and low molecular weight substances including bioactive peptides, low oxygen tension, biogenic amines, lactic acid, and nitric oxide (NO) [5,6]. Some of these factors, however, are intermediaries in a single angiogenesis pathway, for example, TNF-α induces PF-4 that stimulated angiogenesis through NO [81]. Even more important, low oxygen tension stabilizes hypoxia inducible factor-1α (HIF-1α) that induces increased expression of VEGF [82]. To further complicate matters, not all growth factors within a family stimulate angiogenesis equally. For example, of four VEGF isoforms (VEGF-A, -B, -C, and -D) and 3 receptors (VEGFR1/Flt-1, VEGFR2/KDR/Flk-1, and VEGFR3), VEGF-A does not interact with VEGFR1 and VEGFR2 equally, and the signal transduction stimulated is not the same [83]. Furthermore, VEGF-C and -D stimulate lymphangiogenesis, rather than angiogenesis, through VEGFR3. Another complexity is that different growth factors effect blood vessel development at different stages. For example, VEGF-A stimulates nascent sprout angiogenesis, while angiopoietin induces blood vessel maturation [84].

Angiogenesis cannot be directly related to proliferation of cultured endothelial cells since endothelial cell migration is also required. In fact, Folkman and Shing [85] postulated that endothelial cell migration can induce proliferation. If true, endothelial cell chemotactic factors

may be critical for angiogenesis. Some factors, however, have both proliferative (mitogenic) and chemotactic (motogenic) activities, for example, PDGF [86] and EGF [87] are both motogenic and mitogenic for dermal fibroblasts, while VEGF is both motogenic and mitogenic for endothelial cells [88].

Besides growth factors and chemotactic factors an appropriate ECM is also necessary for angiogenesis. Three-dimensional ECM protein gels provide a more natural environment for cultured endothelial cells than monolayer protein coats [79] as is true for many other cultured cells [89]. Not surprisingly, different ECM proteins induce differential cell responses. For example, rat epididymal microvascular cells cultured in type I collagen gels with TGF-β produce capillary-like structures within 1 week [78]. Omission of TGF-β markedly reduces the effect. In contrast, laminin-containing gels in the absence of growth factors induce human umbilical vein and dermal microvascular cells to produce capillary-like structures within 24 hours of plating [90]. Matrix bound thrombospondin also promotes angiogenesis [91] possibly through its ability to activate TGF-β [92]. Although type I collagen does not induce angiogenesis without other contributing factors, it can protect newly formed blood vessels from apoptotic effects of angiostatic agents [93]. Together, these studies support the hypothesis that the ECM plays an important role in angiogenesis. Consonant with this hypothesis, angiogenesis in the chick chorioallantoic membrane is dependent on the expression of αvβ3, an integrin that recognizes fibrin and fibronectin, as well as vitronectin [94]. Furthermore, in porcine cutaneous wounds, αvβ3 is only expressed on capillary sprouts as they invade the fibrin clot [95]. In vitro studies demonstrate that αvβ3 can promote endothelial cell migration on provisional matrix proteins [96] and that human dermal microvascular endothelial cells can generate capillary sprouts in fibrin gels (αvβ3-dependent adhesion and migration) but not in collagen gels (α1β1- and α2β1-dependent adhesion and migration) [97].

Given the information outlined above, a series of events leading to angiogenesis can be hypothesized. Substantial injury causes tissue-cell destruction and hypoxia. Potent angiogenesis factors such as FGF-1 and FGF-2 are released secondary to cell disruption [98] while VEGF is induced by hypoxia. Proteolytic enzymes released into the connective tissue degrade ECM proteins. Specific fragments from collagen, fibronectin, and elastin, as well as many phylogistic agents, recruit peripheral blood monocytes to the injured site where these cells become activated macrophages that release more angiogenesis factors. Certain angiogenic factors, such as FGF-2, stimulate endothelial cells to release plasminogen activator and procollagenase. Plasminogen activator converts plasminogen to plasmin and procollagenase actives collagenase. These two proteases in concert digest basement membrane constituents.

The fragmentation of the basement membrane allows endothelial cells to migrate into the injured site in response to FGF, fibronectin fragments, heparin released from disrupted mast cells and other endothelial cell chemoattractants. To migrate into the fibrin/fibronectin-rich wound, endothelial cells express αvβ3 [94] and αvβ5 integrin [99]. Newly forming blood vessels first deposit a provisional matrix containing fibronectin and proteoglycans but ultimately form basement membrane. TGF-β may induce endothelial cells to produce the fibronectin and proteoglycan provisional matrix as well as assume the correct phenotype for capillary tube formation. FGF, and other mitogens such as VEGF, stimulate endothelial cell proliferation, resulting in a continual supply of endothelial cells for capillary extension. Capillary sprouts eventually branch at their tips and join to form capillary loops through which blood flow begins. New sprouts then extend from these loops to form a capillary plexus. Angiopoietin [100] and its recruitment of pericytes [101] are together important for the maturation and stabilization of newly formed capillaries. Furthermore, pericytes provide an important stem cell niche or act as stem cells themselves [102].

Within a day or two after the removal of angiogenic stimuli, capillaries undergo regression as characterized by mitochondria swelling in the endothelial cells at the distal tips of the capillaries, platelet adherence to degenerating endothelial cells, vascular stasis, endothelial cell necrosis, and ingestion of the effete capillaries by macrophages. Although αvβ3 can regulate apoptosis of endothelial cells in culture and in tumors [94], αvβ3 is not present on wound endothelial cells as they undergo programmed cell death indicating that their absence may be critical or that other integrins are involved. It is fairly clear that thrombospondin [103] or other ECM molecules are good candidate ligands for controlling endothelial cell apoptosis [104].

Wound contraction and extracellular matrix organization

During the second and third week of healing, fibroblasts begin to assume a myofibroblast phenotype characterized by large bundles of actin-containing microfilaments along the cytoplasmic face of the plasma membrane and the establishment of cell−cell and cell−matrix linkages [65,105]. In some [75], but not all [65], wound situations myofibroblasts express smooth muscle actin. Importantly, TGF-β can induce cultured human fibroblasts to express smooth muscle actin and may also be responsible for its expression in vivo [106].

The appearance of the myofibroblasts corresponds to the commencement of connective tissue compaction and the contraction of the wound. Fibroblasts link to the extracellular fibronectin matrix through α5β1 [65]; to collagen matrix through α1β1 and α2β1 collagen receptors [107]; and to each other through direct adherens junctions [65]. Fibroblast α2β1 receptors are markedly upregulated in 7-day wounds [39], a time when new collagenous matrix is accumulating and fibroblasts are beginning to align with collagenous fibrils through cell−matrix connections [65]. New collagen bundles in turn have the capacity to join end-to-end with collagen bundles at the wound edge and to ultimately form covalent cross-links among themselves and with the collagen bundles of the adjacent dermis [108]. These cell−cell, cell−matrix, and matrix−matrix links provide a network across the wound whereby the traction of myofibroblasts on their pericellular matrix can be transmitted across the wound [109].

Cultured fibroblasts dispersed within a hydrated collagen gel provide a reasonable functional in vitro model of wound contraction [110]. When serum is added to the admixture, contraction of the collagen matrix occurs over the course of a few days. When observed with time-lapse microphotography, collagen condensation appears to result from a "collection of collagen bundles" executed by fibroblasts as they extend and retract pseudopodia attached to collagen fibers [111]. More recent elegant studies have further defined fibroblast−collagen interactions [112]. The transmission of these traction forces across the in vitro collagen matrix depends on two linkage events: fibroblast attachment to the collagen matrix through the α2β1 integrin receptors [113] and cross-links between the individual collagen bundles [114]. This linkage system probably plays a significant role in the in vivo situation of wound contraction as well. In addition, cell−cell adhesions appear to provide an additional means by which the traction forces of the myofibroblast may be transmitted across the wound matrix [105]. Furthermore, gap junctions between wound fibroblasts probably provide the mechanism for contraction control across the cell population [115].

F-actin bundle arrays, cell−cell and cell−matrix linkages, and collagen cross-links are all facets of the biomechanics of ECM contraction. The contraction process, however, needs a cytokine signal. For example, cultured fibroblasts mixed in a collagen gel contract the collagen matrix in the presence of serum, PDGF, or TGF-β. Since TGF-β factor, but not PDGF, persists in dermal wounds during the time of tissue contraction, it is the most likely candidate for the stimulus of contraction [5]. Nevertheless, it is possible that both PDGF and TGF-β signal wound contraction: one more example of the many redundancies observed in the critical processes of wound healing. In summary, wound contraction represents a complex and masterfully orchestrated interaction of cells, ECM, and cytokines.

Collagen remodeling during the transition from granulation tissue to scar is dependent on continued collagen synthesis and collagen catabolism. The degradation of wound collagen is controlled by a variety of collagenase enzymes from macrophages, epidermal cells, and fibroblasts. These collagenases are specific for particular types of collagens, but most cells probably contain two or more different types of these enzymes [116]. Three MMPs have been described that have the ability to cleave native collagen: MMP-1 or classic interstitial collagenase that cleaves types I, II, III, X, and XIII collagens; neutrophil collagenase (MMP-8); and a novel collagenase produced by breast carcinomas that is prominent in chronic wounds (MMP-13) [59]. Currently it is not clear which *interstitial* collagenases are critical in the remodeling stage of human wound repair. For example, no wound-healing defect was observed in mice deficient of MMP-13 [117]; however, a double knockout of MMP-13 and the plasminogen activating system created an additional delay of healing compared to knockout of only the plasminogen activating system [62]. These findings are likely attributable to the redundancy of nature.

Cytokines such as TGF-β, PDGF, and IL-1, and the ECM itself clearly play an important role in the modulation of collagenase and tissue inhibitor of metalloproteinase (TIMP) expression in vivo. Interestingly, type 1 collagen induces MMP-1 expression through the α2β1 collagen receptor while suppressing collagen synthesis through the α1β1 collagen receptor [118]. Type I collagen also induces expression of α2β1 receptors [39], thus collagen can induce the receptor that signals a collagen degradation−remodeling phenotype. Such dynamic, reciprocal cell−matrix interactions appears to occur generally during tissue formation and remodeling processes such as morphogenesis, tumor growth, and wound healing to name a few [89].

Wounds gain only about 20% of their final strength by the third week, during which time fibrillar collagen has accumulated relatively rapidly and has been remodeled by myofibroblast contraction of the wound. Thereafter, the rate at which wounds gain tensile strength is slow, reflecting a much slower rate of collagen accumulation. In fact, the gradual gain in tensile strength has less to do with new collagen deposition than further collagen remodeling with the formation of larger collagen bundles and an accumulation of intermolecular cross-links. Nevertheless, wounds fail to attain the same breaking strength as uninjured skin. At maximum strength a scar is only 70% as strong as intact skin.

Chronic wounds

Acute wounds are those that heal through the routine processes of inflammation, tissue formation and remodeling,

which occur in a timely fashion. As discussed earlier, these processes may overlap temporally. However, prolonged continuance of any of these reparative processes may result in the formation of a chronic wound. Chronic wounds are often associated with underlying pathological conditions that contribute to an impaired healing. Venous leg ulcers and diabetic foot ulcers are common examples of chronic wounds caused or accentuated by an underlying disorder. While the former is being induced by insufficient venous flow that results in increased blood pressure in the lower limb microvascular bed and, therefore, increased vascular permeability, the latter is caused by peripheral neuropathy that leads to abnormal load distribution on the foot surface and decreased sensation [119]. Subsequently, these abnormalities cause a loss of tissue viability, suboptimal local tissue permeability, and an elevated and sustained inflammatory response.

Scarring

Injuries that require more time to healing, that is, an extensive or a chronic wound secondary to infection or other underlying adverse tissue condition, will create greater scarring. Furthermore, the injury must be deep enough for scarring to occur. For example, human dermal injuries must reach at least 0.51 mm from the epidermis for a noticeable scar to be observed 28 weeks later [120]. Scars can become problematic cosmetic or functional impediments depending on the location. For instance, a facial scar can cause psychological distress due to its appearance and functional impediment restricting facial muscle activity [17].

Scars are visibly distinct compared to normal skin due to their difference in architecture. Healthy skin is composed of chiefly type I collagen arranged in a "basketweave" pattern, whereas scar tissue is composed of type I collagen disposed in densely packed, parallel bundles secondary to wound contraction [14]. The compacted, parallel array of collagen bundles in scars compared to the "basketweave" architecture of collagen fibers in normal dermis, in part, explains why scars have about 20%−70% tensile strength compared to healthy tissue at 3 weeks and 6 weeks postinjury, respectively [70]. The difference in collagen bundle architecture also partly explains the difference in elasticity between normal skin and scar, as the basketweave pattern in healthy tissue allows for moderate stretch [121]. In addition, the lack of elasticity in scar is also secondary to the almost total lack of elastin in scars compared to normal skin.

Scars are also visibly different than normal skin due to the loss of both epidermal and dermal structures after injury. Severe skin injury, especially full-thickness damage as often occurs in burns, results in loss of melanocytes, absent or abnormal rete ridges in the epidermis, and destruction of dermal structures such as hair follicles, sebaceous glands, eccrine glands, nerves, and normal blood vessel plexi. These dermal structures are not restored without specialized cells so instead collagen and other ECM proteins fills this space.

Pathological scars

Pathological scars have unusual characteristics and compositions compared to normal scars. The most common pathological scars are hypertrophic scars and keloids. Hypertrophic scars are clinically defined as scars that are raised but remain within the wound bed, while keloids are clinically defined as scars that are raised and grow outside the wound bed. These are not tumors but primarily inflammatory disorders of the wound repair process. Hypertrophic scars appear within 4 weeks, while keloids appear after 3 months after injury. Also, after surgical intervention, hypertrophic scars tend not to recur, whereas keloids are known to recur [122]. These types of scars have become more common as more patients survive massive injury that in the past would be fatal [122]. A field that has seen a decrease in patient mortality but is accompanied with a rise in pathological scarring is in burn patients. Patients who have sustained high total body surface area burns are much more likely to survive but 70% of survivors develop severe pathological scars [123]. Beyond burn, patients can develop pathological scars after surgical procedures, but this is uncommon relative to postoperative normal scars [17].

It has been suggested that pathological scars develop due to chronic inflammation in the reticular dermis, mainly due to the observation that wounds that do not reach the reticular dermis do not form hypertrophic scars or keloids [124]. Local and genetic factors that augment inflammation are thought to influence hypertrophic scar and keloid development. Local factors such as rewounding and infection can result in a prolonged inflammation period, but the most significant local factors for pathological scar development are mechanical forces. Keloids are known to develop into predictable shapes depending on scar location and only develop on certain parts of the body. Modeling studies provide evidence that keloids adopt these shapes parallel to the direction of tension in the skin and only on skin that is frequently mechanically loaded [124]. Cells sense mechanical cues in the ECM such as tension, compression, or shear forces. Mechanotransduction of these cues signal the cell to respond in a variety of ways, such as proliferation, migration, and elongation, contributing to excessive fibrosis [71]. These mechanical signals also may contribute to a sustained myofibroblast phenotype that results in excessive contracture as observed in hypertrophic scars [70].

TABLE 70.2 Cellular and extracellular matrix (ECM) characteristics of normal scars, pathological scars, and scarless regeneration.

		Normal scarring	Hypertrophic scars	Keloids	Scarless regeneration
Cells	Myofibroblasts	Apoptose	Abundant and prolonged presence	Persistent	Absent
	Inflammatory cells and cytokines	↑	↑↑	↑↑	↓
ECM	TGF-β	TGF-β1	TGF-β1, TGF-β2	TGF-β1, TGF-β2	TGF-β3
	Collagen type	Type I > type III	↑ Type III and type V	↑ Type I	Type III > type I
	Collagen orientation	Parallel to epidermis	Parallel to epidermis	Disorganized	Basketweave
	Collagen bundle thickness	Small, parallel bundles	Thin nodules	Thick nodules	Small, thin bundles
	Collagen cross-linking	↓	↑	↑↑	↓
	Elastin	↓	↓	↑↑	↑
	Mechanical strain	↑	↑↑	↑	↓

TGF, Transforming growth factor.

Pathological scarring has thought to be determined by genetics as well. For example, many patients with pathological scars have a family history of pathological scarring, and scars are much more likely to develop in darker skinned and Asian individuals [70]. Notably, pathological scars never develop in albinos [124]. Unfortunately, not much research has been conducted to illuminate the genes that impact pathological scarring. However, the current prevailing theory is that single nucleotide polymorphisms are the cause for the differences in predisposition for pathological scarring [124]. In a recent study a specific variant of the CSMD1 gene that was predominately found in white males was linked to a lower likelihood of hypertrophic scarring [123].

An imbalance of MMPs may lead to an imbalanced remodeling process where too much collagen is deposited that cannot be properly remodeled. This results in a disproportionate ratio of collagen, contributing to pathological scars. Hypertrophic scars are reported to express less MMP-1, MMP-2, MMP-9, and MMP-13 than normal scars [121]. Similarly, keloids express low levels of these MMPs, save for MMP-9 which is found at comparable concentrations as normal scar [125]. In both hypertrophic scars and keloids, tissue inhibitor of matrix metalloproteases 1 and 2 (TIMP-1 and TIMP-2) are increased compared to normal scar. This leads to hypertrophic scars having 33% type III and 10% type V collagen organized parallel to the epidermis in thin nodules and keloids to have much more type I and little type III collagen disorganized in thicker nodules. In both cases, collagen synthesis is much higher than in normal scars. Fibroblasts in hypertrophic scars and keloids deposit collagen seven times and twenty times faster than those in normal scars, respectively [125]. Both hypertrophic scars and keloids have higher concentrations of TGF-β receptor, TGF-β1, and TGF-β2 compared to normal scar. Hypertrophic scars also have more fibronectin and hyaluronan in the ECM, assisting cell migration [123]. The reddened appearance characteristic of pathological scars is due to dysfunctional angiogenesis and microvessel invasion. Microvessels infiltrate normal scar but eventually recede at the remodeling stage, but in pathological scars, they persist and become hypervascular [17]. Major differences in pathological scars compared to normal scars are summarized and can be found in Table 70.2.

Scarless healing

Scarring is an expected consequence of the need for wound healing in humans to be rapid and efficient to stave off infection. The only exception of scar formation postinjury in humans is the fetus and the oral mucosa, both of which can regenerate tissue damage without scar formation [70,121,126]. In these rare cases of scarless healing, also known as regeneration, the healed tissue is virtually identical to uninjured tissue, possessing the dermal structures, proper collagen type ratios, and collagen organization seen in healthy skin [70]. For fetal healing

the transition from regenerative healing to normal healing is around 24 weeks of gestation. Before this time point the fetus can regenerate the damage sustained with no scar formation. After this point, scar is formed such as normal adult wound healing. Scarless healing in the fetus follows the typical wound healing steps but begins with a much less effective and shorter inflammatory stage. During this stage, less neutrophils and macrophages migrate to the wound, and cytokines are released in different concentrations. For example, IL-6 and IL-8 concentrations are lower, whereas IL-10 concentration is significantly increased compared to concentrations found in adult wound healing [70]. Not only are cytokine concentrations different but growth factors are as well. Important growth factors in adult normal wound healing such as PDGF, TGF-β1, and TGF-β2 are significantly reduced and instead TGF-β3 is much higher [70,121]. In addition, all MMPs synthesized in the wound are upregulated, and TIMPs are downregulated, promoting collagen degradation and remodeling earlier on than normal healing. Interestingly, fetal fibroblasts can simultaneously deposit collagen and proliferate, whereas adult fibroblasts can only efficiently perform one task at a time [126]. The collagen deposited in fetal healing is organized as thin bundles of primarily type III collagen along with some type I collagen, of which has a low resting mechanical stress [126].

In adult humans the oral mucosa can heal with insignificant scar as well. This tissue has some similarities to fetal tissue in which the environment is consistently hydrated, experiences little mechanical stress, and has a stunted inflammatory response. Studies have been conducted transplanting dermal fibroblasts and oral mucosa fibroblasts to damaged tissue of the others' origin [70]. The oral mucosa fibroblasts transplanted into a skin wound healed with less scar than dermal fibroblasts that were transplanted into an oral mucosa wound. This suggests that intrinsic factors of cells also play a role in scarless healing.

Tissue engineered therapy with skin cells

Initial attempts to speed up wound repair and improve the quality of healing in chronic or burn wounds involved the use of synthetic, composite synthetic, or biological dressings [127]. Although temporarily effective, these dressings did not offer any permanent treatment since eventually, an autograft had to be implanted to achieve complete healing. The advent of tissue-engineered constructs has, however, benefited the wound healing care [128]. These constructs could be classified into two main categories: cellular and acellular. In both cases the basic building blocks are a biomimetic and a scaffolding material. While the biomimetic functions to stimulate cell recruitment and the desired cellular functions, the scaffold typically provides a mechanical support for the cells. Scaffolds prepared from naturally occurring biopolymers tend to provide the correct biological stimuli to support cell function and tissue formation [129]. Nevertheless, whether the scaffold is natural or synthetic, the goal is to promote faster healing that results in the development of a new tissue that bears structural and functional resemblance to the uninjured, host tissue. A comprehensive list of current cell therapeutics, biologic dressings, and skin substitutes for acute and chronic skin wounds has been recently published [7].

Engineered epidermal constructs

Immediate wound coverage, whether permanent or temporary, is one of the cornerstones of wound management. Doing so reduces the chances of infection, promotes wound closure, reduces chance of hypertrophic scarring, and reduces scar depth. Engineered epidermal constructs with attributes similar to those of autologous epidermis have been used to facilitate repair of partial-thickness wounds where the major damage is to the epidermis.

Cultured autologous keratinocyte grafts were first used in humans by O'Conner et al. [130]. Subsequently, there has been extensive experience with cultured epidermal grafts for the treatment of burns as well as other acute and chronic wounds [131,132]. Epicel (Genzyme Tissue Repair) is an example of an engineered epidermal autograft. The potential advantage of this technique is the ability to provide autologous grafts capable of covering large areas with reasonable cosmetic results. Another significant advantage of autologous grafts is their ability to serve as permanent wound coverage, since the host does not reject them. However, a major disadvantage is the several week lag between host skin harvest and the availability of sufficient quantities of keratinocytes, the need for an invasive procedure to obtain autologous donor cells, and the large costs incurred. Furthermore, graft take is widely variable based on wound status, patient age, general host status, and operator experience.

Cultured keratinocyte allografts were developed to help overcome the need for biopsy and separate cultivation for each patient to produce autologous grafts and the long lag period between epidermal harvest and graft product. Cultured epidermal cells from both cadavers and unrelated adult donors have been used for the treatment of burns [133] and chronic leg ulcers [134]. Although allografts made from neonatal foreskin keratinocytes were more responsive to mitogens than adult (cadaver) cells and, therefore, initially preferred for cultured allografts, a later investigation revealed that such allografts were more immunogenic than the regular culture skin substitutes and thus potentially problematic [135].

To facilitate mass allograft production and wide availability, cryopreserved allografts have been developed and were fairly comparable to fresh allografts [136]. Despite these advances, the culture epidermal grafts have failed to produce satisfactory response. The primary reasons include the lack of mechanical strength and graft site susceptibility to wound contractures. As an alternative, keratinocyte delivery systems were developed where the cells were delivered to the injury site via a biodegradable scaffold. For example, laser skin, produced by Fidia Advanced Biopolymer, Italy, is used to deliver keratinocytes via a chemically modified hyaluronan membrane, which is perforated with micron-sized holes that allow cells to grow to confluence.

Another approach has been to isolate fresh keratinocytes from the patients and then spray them onto the wound site [137,138]. For example, RECELL is a system developed by AVITA Medical that harvests autologous cells from a patients' donor site to create an autologous cell suspension that can be sprayed onto a wound bed with no cell culture involved [139]. RECELL treated wounds at 4 weeks showed comparable wound closure and scarring to control split-thickness autografts but also claim to reduce scar pain and pruritus at 16 weeks [139]. This system is advantageous over the current gold standard because it significantly reduces the amount of donor tissue to be harvested for an autograft. RECELL is reported to treat 80 cm^2 of area per 1 cm^2 of collected tissue [139,140]. One study saw a donor tissue reduction of 97.5% [139] and 32% in another [140], both with comparable outcomes to split-thickness grafts. In addition, the suspension consists of autologous tissue that provides the necessary cells such as fibroblasts, keratinocytes, and melanocytes in physiological concentrations to support regeneration and reepithelialization of the wound. Nevertheless, The National Institute for Health and Care Excellence found that healing and scar appearance were not significantly improved compared to split-thickness grafts, but RECELL did reduce the need of subsequent grafts, indicating that this system has potential to reduce autograft cost [141].

Engineered dermal constructs

While the use of cultured keratinocytes to enhance wound healing has met with modest success, it lacks a dermal component that, if present, would provide greater mechanical stability and possibly prevent wound contraction. Allografts containing dermis, for example, pig skin or cadaver skin, have been used for many years as temporary coverage, but they tend to induce an inflammatory response [142]. However, such skin can be chemically treated to remove the antigenic cellular elements (AlloDerm, LifeCell Corporation, Woodlands, TX) and used alone or in combination with cultured autologous keratinocytes for closure of various chronic wounds and burns [143]. In spite of these modifications, allogenic grafts, when compared with autologous grafts, have been shown to promote lower percent reepithelialization and excessive wound contraction [144]. Furthermore, the overall therapeutic outcome of a skin graft depends also on the site from which the cells were isolated (during biopsy) [145].

Burke et al. [146] developed an acellular composite skin graft made of a collagen-based dermal lattice (containing bovine collagen and chondroitin-6-sulfate) with an outer silicone covering. After placement on the wound the acellular dermal component recruits the host dermal fibroblasts while simultaneously undergoing degradation. About 2–3 weeks later the silicone sheet is removed and covered with an autograft. This composite graft has been used successfully to treat burns [147] and has received FDA approval for this indication as well as for reconstructive surgery (Integra, Integra Life Sciences Corporation, Plainsboro, NJ) [148]. However, these constructs cannot be used in patients who are allergic to bovine products.

Another rendition of a dermal substitute is TransCyte (Dermagraft-TC) (Advanced BioHealing, La Jolla, CA). This product consists of an inner nylon mesh in which human fibroblasts are embedded together with an outer silicone layer to limit evaporation. The fibroblasts are lysed in the final product by freeze–thawing. Prior to that time, the fibroblasts had manufactured collagen, matrix proteins, and cytokines all of which promote wound healing by the host. TransCyte has been used successfully as a temporary wound coverage after excision of burn wounds [149] and has been approved by the FDA for this indication. Dermagraft is a modification of this product in which a biodegradable polyglactin mesh is used instead of a silicone layer and the fibroblast remain viable [150].

Engineered skin substitutes

Full thickness wounds involve the loss of both the epidermal and dermal layers of the skin. To treat such extensive wounds, Bell et al. first described a bilayered skin composite consisting of a collagen lattice with dermal fibroblasts that was covered with epidermal cells [151]. Modification of this composite consisting of type I bovine collagen and live allogeneic human skin fibroblasts and keratinocytes has been developed (Apligraf, Organogenesis, Canton, MA). It has been used successfully in surgical wounds, venous leg ulcers, and diabetic foot ulcers [152], despite the fact that it is not a permanent skin replacement [153]. In a large multicenter trial, this product resulted in accelerated healing of chronic

nonhealing venous stasis ulcers when compared to standard compressive therapy [154].

StrataGraft, a product developed by Mallinckrodt, is a biomimetic construct composed of human neonatal immortalized keratinocytes (NIKS), complete with dermis and stratified epidermis [155]. This product can be sutured, stapled, or otherwise secured in the wound bed and serves to reduce infection, promote early wound closure, and optimize healing properties. These purposes can be achieved without the risk associated with allografts, such as disease transmission, because the NIKS cell line has been well-characterized and proven safe, eliciting no immune response or adverse reaction [156]. Currently, the FDA designates StrataGraft as a Regenerative Medicine Advanced Therapy as it is a therapeutic tissue-engineering product that can be used to fulfill an unmet, life-threatening clinical need. This designation places StrataGraft on a priority pathway for approval, and the FDA is anticipated to conclude its review of StrataGraft in 2020 after phase III trials, which focus on efficacy and safety after 3 months post StrataGraft application. Phase I and II trials of StrataGraft analyzed immune response at 1 and 2 weeks, wound closure at 3 months, and adverse effects up to 12 months after StrataGraft application, but the longer term appearance and quality of healing as well as patient safety when using these spontaneously immortalized cells have not been as thoroughly investigated.

Skin autograft harvesting without scarring

Another strategy for skin replacement is to use microcolumns of autologous skin for autologous grafting [157]. These microcolumns are about 400−700 μm in diameter and contain all the elements that make up human skin. In addition, these elements are in their natural anatomical locations relative to one another. The microcolumns can restore many functional parts of the skin, such as neurons and sweat glands, when grafted into a wound in animal models. Such a wide range of regeneration has only been seen with full-thickness skin grafts; however, harvesting full thickness skin results in damage to the donor site. In contrast the donor site of skin microcolumns has been observed to undergo full regeneration without scarring. In its current iteration the microcolumns have been placed into the wound with random orientations rather than having the upper layers of skin on top. However, split-thickness skin grafts lead to wound reepithelialization even when placed onto the wound upside down, if the wound is kept hydrated. Therefore the authors suggest that while preserving the proper orientation of the microcolumns may improve their efficacy, it is not critical for wound healing. Nevertheless, their ongoing work is focused on solving this problem.

Tissue-engineered therapy with stem cells, bioactives, and biomaterials

Although the increased healing rates observed with the use of these engineered constructs show promise for the treatment of burn and/or chronic wounds, they have several intrinsic disadvantages that limit their use—(1) the epidermal grafts are very fragile and therefore difficult to handle, (2) it is difficult to quality control the large-scale production of any cell-populated matrix, and (3) while autografts require skin biopsy, allografts may experience early rejection. Moreover, these constructs in general are only about 25% efficient, implying that they must be applied on at least four patients before their effect can be seen. These limitations suggest that further improvements be made so that tissue-engineered constructs are not only more effective but also less complex.

Two approaches emerge from the foregoing discussions. The first tissue-engineering design utilizes cells that resist rejection and/or provide a more robust clinical outcome that makes their use cost-effective despite the absolute costs required to produce them. Alternatively, second-generation, acellular tissue-engineered products are being developed that more effectively recruit host tissue cells into the wound and then provide biological signals for the accumulated tissue cells to induce tissue regeneration rather than scar. To address the first approach, many groups are trying to isolate the "right" stem cells to stimulate wound repair or preferably tissue regeneration. For the skin, both epidermal stem cells [19,158] and bone marrow- or adipose-derived mesenchymal stem cells (MSCs) have been isolated by numerous methods and delivered by many different methods [159,160]. For example, adipose tissue removed via liposuction can be enzymatically digested to get a stromal vascular fraction. ASCs and primary adipocytes can then be separated from this solution via centrifugation. Although these cell populations tend to aggregate, ASCs can be isolated by tissue culture [161]. New and better methods for isolating and standardizing MSCs are greatly needed and several investigators are assiduously tackling this problem [162]. Better understanding of the niche where stem cells normally reside will help elucidate the microenvironment that the cells need to self-renew versus differentiate along the appropriate path [163,164].

For the acellular "smart" matrix tissue-engineering approach, clues learned from embryogenesis, morphogenesis, and wound repair should be implemented to engineer revolutionary constructs that facilitate and synchronize tissue repair. The transformative acellular product must be conductive to rapidly recruit the host tissue cells and inductive to stimulate the invading cells to proliferate, synthesize new ECM, and then differentiate appropriately to regenerate the lost tissue.

Various engineered skin constructs have used collagen as the preferred scaffolding material for cell seeding [165]. The huge popularity of collagen can be attributed to its abundance in skin, its interaction with cells, and its ability to markedly increase mechanical strength to the skin through forming cross-links with itself and other extracellular matrix molecules [166]. However, during wound repair, collagen appears only during the later stages after the invading and proliferating fibroblasts have filled the wound space. Therefore collagen may not be optimal for initial cell migration. Since fibronectin and hyaluronan are present during early stages of embryogenesis, morphogenesis, and wound healing [20], these biomaterials or their derivatives are favored to design "smart" matrix for cutaneous wound repair.

Hyaluronan is a nonsulfated glycosaminoglycan that is present in most human tissues. During wound repair, it serves multiple important functions, ranging from regulating inflammation to promoting fibroblast migration and proliferation [167]. Interestingly, hyaluronan has been implicated in the scarless or minimally scarred repair of fetal wounds, perhaps owing to its role in regulating the inflammatory response [168] and collagen deposition [169]. Furthermore, similar to synthetic polymers, hyaluronan can be chemically modified to obtain a variety of stable derivatives [170]. Therefore by offering the advantages of both natural and synthetic materials, hyaluronan promises to be a more suitable scaffolding material for acellular matrices as compared to collagen. Indeed, chemically modified hyaluronan scaffolds have been successfully used for various tissue-engineering applications, including wound repair [171].

Since fibroblast migration is the rate-limiting step in granulation tissue formation [54], a biomaterial ± biomimetic must support maximal fibroblast migration. Fibronectin is a favorable candidate since (1) it appears together with hyaluronan at times of cell migration during embryogenesis, morphogenesis, and wound repair [20,52]; (2) fibroblast migration on hyaluronan/fibronectin gels is far greater (approximately fourfold) when compared to that on fibrin/fibronectin gels (Greiling and Clark, unpublished observation), (3) fibronectin has been shown to be required for fibroblast transmigration from a collagen gel to a fibrin gel [51], and (4) fibronectin is absent in chronic wounds, where it is produced normally [172] but eliminated rapidly by the abundant proteases present in chronic wound fluid [173,174]. Although fibronectin appears to be an ideal biomimetic for use in hyaluronan scaffolds, its stability in the proteolytic environment of chronic wounds is a major concern.

Alternatively, the proteolytically stable RGD peptide sequence, the smallest cell recognition sequence in the 10th module of type III repeat of fibronectin, can be used to support key cell functions [175]. RGD has been widely used to promote cell attachment and spreading in various tissue-engineering applications in general [176] and wound-healing applications in particular [177]. This is perhaps because the RGD sequence is found in a variety of ECM molecules and, therefore, recognized by the transmembrane integrin receptors of multiple cell types, including dermal and epidermal tissue cells [178]. Our previous study has shown that hyaluronan hydrogels decorated with RGDS support NIH 3T3 fibroblast functions in vitro [179] and when seeded with 3T3 fibroblasts and implanted in nude mice, produce granulation-like tissue in 4 weeks. Therefore RGD-modified hyaluronan hydrogels appeared to possess great inductive properties. However, these hydrogels neither supported optimal human adult dermal fibroblast functions nor demonstrated conductive properties required of any acellular scaffold [179].

To impart our construct with both inductive and conductive properties, we selected, as the biomimetics, three FN functional domains, namely, $FNIII_{(8\text{-}11)}$, $FNIII_{(12\text{-}15)}$, and $FNIII_{(12\text{-}V\text{-}15)}$, that are necessary and sufficient for optimal dermal fibroblast migration in vitro [180]. Indeed, these hydrogels were successful in supporting dermal fibroblast functions in vitro and promoting wound repair in vivo [181]. Since these hydrogels can be formulated at room temperature and physiological pH, they are compatible with both cells and the incorporated biological molecules. In addition, their rapid gelation (<10 minutes) advocates their possible injectable use. However, manufacturing a tissue-engineered implant containing three recombinant proteins raises concerns related to cost, quality control, sterilization, and shelf-like of the product. To solve such issues, we are currently working to develop fibronectin-derived peptides that substitute for the three domains previously used [182].

With a similar objective, several other groups have also developed "intelligent" scaffolds for tissue repair [183]. These approaches commonly employ synthetic materials to build scaffolds since they allow great flexibility during formulation. To impart bioactivity, these scaffolds contain potent biomimetics that can be recognized by tissue cells. However, as discussed earlier, cell invasion during granulation tissue formation occurs concurrently with matrix degradation, which can be typically observed when using naturally derived materials. To elicit a similar response in synthetic materials, protease-sensitive sequences are incorporated within the scaffold that are cleaved upon contact with the cell-secreted proteolytic enzymes [184,185]. Therefore these scaffolds combine the advantages of both natural and synthetic biomaterials to facilitate wound repair.

Traditionally, the structural component of the tissue-engineered constructs has been viewed as providing only a passive mechanical structure. This design reflects our common understanding that cells primarily respond to biological signals. However, over the past decade it has

become increasing clear that mechanical forces alone can govern cell and tissue phenotype in ways similar to biological stimuli [186]. Further studies have revealed that cells use an active tactile sensing mechanism to feel and respond to substrate mechanics [40,41] and that stem cells use clues from this mechanical sensing to select pathways for differentiation [12]. The latter observation was not too surprising since it had already been demonstrated that dermal fibroblasts respond to substrate mechanics by regulating levels of gene transcription that eventually lead to differential ECM synthesis and their transformation into myofibroblasts [109]. Since these processes are critical during wound repair, effective tissue-engineering approaches for wound repair would require optimization of both biological and mechanical effectors.

The acellular tissue-engineered constructs discussed so far utilize scaffolding materials to provide mechanical support for tissue ingrowth and biomimetics to induce key cell functions. The primary goal of these novel approaches is to mimic the attributes of fibrin clot for parenchymal cell migration. However, a fibrin clot is not only composed of a fibrin/fibronectin scaffold and an array of clotting and fibrinolytic enzymes, but also a plethora of growth factors that had been released during platelet aggregation [187]. Growth factors play a crucial role in the overall healing response where they function to stimulate cell migration, proliferation, differentiation, and angiogenesis. Furthermore, growth factor deficiency often leads to impaired wound repair [188]. As a result, several groups have investigated the use of tissue-engineered constructs for local growth factor delivery, where the release of appropriate growth factors produced an increase in angiogenic activity [189,190].

It is interesting to note that despite the release of growth factors immediately after wounding, there remains a 3-day lag before granulation tissue is formed. This suggests that the growth factors may be retained and functional within the clot. This form of "solid-state" biochemistry may be unconventional but is backed by studies that demonstrate that numerous growth factors, which are bound to specific molecular domains of FN, retain or have accentuated bioactivity [191–194]. Interestingly, while some investigators have shown that increased angiogenesis driven by excess activity of VEGF or other angiogenic factors actually decrease the healing of skin wounds [195], we have found a peptide cP12 from fibronectin that enhances PDGF-BB activity in vitro and also promotes faster burn wound healing in vivo [182]. Therefore by incorporating the appropriate growth factor-binding sequences/domains, tissue-engineered construct can be used as a growth factor repository, causing an increase in local concentration that may, in some cases, accentuate cell functions.

In conclusion, wound healing is a dynamic and fine-tuned cellular response aimed at reinstating tissue homeostasis after an insult. Vigorous cellular activities observed during wound repair are similar to those occurring during embryogenesis and morphogenesis, which indicates the enormous complexity of this physiological reparative process. That may also explain why despite over two decades of intense research and development, we have still not identified an "ideal" therapy. However, novel tissue-engineering approaches are showing tremendous promise and aiming to push the limits of human expectations of wound therapy.

Chapter 71

Bioengineered skin constructs

Vincent Falanga[1,2,3]

[1]Department of Dermatology, Boston University School of Medicine, Boston, MA, United States, [2]Department of Biochemistry, Boston University School of Medicine, Boston, MA, United States, [3]Wound Biotechnology Foundation, Boston, MA, United States

Introduction

Cutaneous wounds normally heal by the formation of epithelialized scar tissue rather than regeneration of full-thickness skin. Consequently, strategies for the clinical management of wound healing have depended historically on providing a passive cover to the site of the wound while allowing the reparative mechanisms of wound healing, including reepithelialization, remodeling of granulation tissue, and formation of scar tissue, to occur, and therapy could do little more than facilitate these processes. However, advances in our understanding of wound healing, wound assessment, the concerted action of several growth factors, the role of the extracellular matrix (ECM) in regulating the healing process, and the demonstrated ability of bioengineered constructs to promote wound healing highlight the potential for intervening therapeutically in tissue repair by providing new epithelium, stimulating dermal repair, and reconstituting full-thickness skin.

Bioengineered skin substitutes can be classified as either cell-based constructs that actively stimulate wound healing or acellular constructs that provide a substrate or covering to facilitate wound healing. Cell-based constructs include, though not exclusively, autologous epidermal cell sheets (Epicel, Vericel Corp.), allogeneic dermal substrates (Dermagraft, Organogenesis, Canton, MA), and human skin equivalents (HSEs) composed of both dermal and epidermal components (Apligraf, Organogenesis Inc., Canton, MA; Orcel, Ortec International Inc.; StrataGraft, Stratatech, Madison, WI) and acellular products (Transcyte, Shire Regenerative Medicine, San Diego, CA; Integra Dermal Regeneration Template, Integra Life Sciences, Plainsboro, NJ; Biobrane, UDL, Rockford, IL). Another construct, comprising cultured keratinocytes and fibroblasts in bovine collagen, is the living cellular sheet, GINTUIT (Organogenesis Inc., Canton, MA), indicated for topical application to a surgically created vascular wound bed in the treatment of mucogingival conditions. A recent publication summarizes many of the worldwide products (Int J Mol Sci. 2017 Apr; 18(4): 789). A difficulty is that there is considerable change in the companies manufacturing these products. Therefore one must keep in mind this flexibility. Although not all of these products are still commercially available, they represented the first of their kind and are the result of basic research in the biology of skin and wound healing and in clinical experience with skin grafts, cultured keratinocyte grafts, acellular collagen matrices, cellular matrices, and cultured composite grafts [1–4].

Skin structure and function

Skin has several distinct functions. As the interface between the environment and the body, skin provides a protective barrier from microbes, toxins, ultraviolet radiation, and abrasion/ulceration, while also preventing water loss. In addition, skin enables the body's ability to sense heat and cold, pressure, vibration, and pain and regulates body temperature through perspiration and blood flow. The passive and active functions of skin are carried out by specialized cells and structures located in its two main layers: the epidermis and the dermis (Fig. 71.1). Complex functional relationships between these two anatomic structures of skin maintain skin's normal properties. Tissue engineering applications in skin depend upon an understanding of the structural components of skin, the spatial organization, and the functional relationships of skin's components.

The epidermis

As stated earlier, skin is a physical barrier between the body and the external environment. The outermost layer

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00073-3

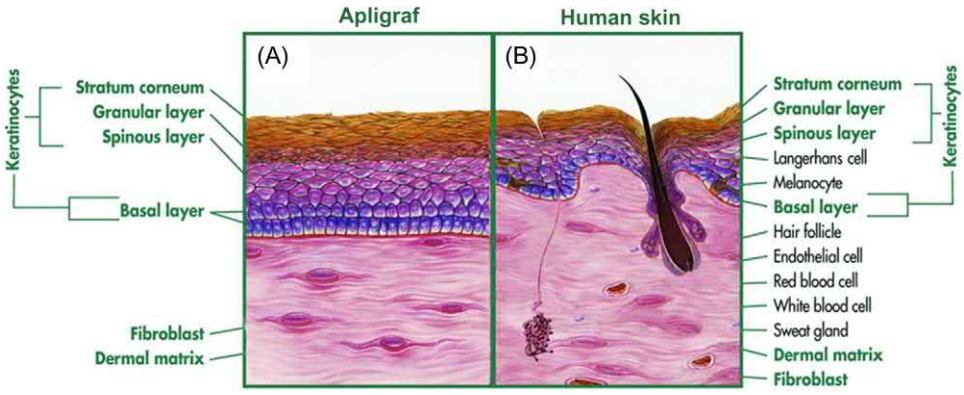

FIGURE 71.1 The basic components of skin and engineered skin equivalent.
(A) Diagram showing the major cell types of skin and their organization. Note that stratified keratinocytes make up the epidermis and display distinct morphological phenotypes. (B) A histological section of Apligraf HSE, (hematoxylin and eosin, 142×). Italics indicate cell types present in real skin but not in the engineered skin equivalent.

of skin, the epidermis, is the layer that is impermeable to toxic substances and harmful organisms. It is also the layer that controls the loss of water from the body to the relatively drier external environment.

The epidermis is composed primarily of keratinocytes, which form a stratified squamous epithelium (Fig. 71.1). Proliferating cells in the basal layer of the epidermis and structural components of the basements membrane anchor the epidermis to the dermis and replenish the terminally differentiated epithelial cells lost through normal sloughing from the surface of the skin. The basal cells stop proliferating and terminally differentiate into squamous keratinocytes as they move from the basal layer through the suprabasal layers to the surface of the epidermis. Keratin filaments and desmosomes contribute physical strength in the living layers and maintain the integrity of the epidermis. The cornified envelopes serve as the bricks and the lipids as mortar.

The most superficial keratinocytes in the epidermis form the stratum corneum, which represents the dead outermost structure that provides the physical barrier of the skin. In the last stages of differentiation, epithelial cells extrude lipids into the intercellular space to form the permeability barrier. The cells break down their nuclei and other organelles and form a highly cross-linked protein envelope immediately beneath their cell membranes. The physically and chemically resilient protein envelope connects to a dense network of intracellular keratin filaments to provide further physical strength to the epidermis.

Additional cells and structures in the epidermis perform specialized functions (Fig. 71.1). Skin plays a major role in alerting the immune system to potential environmental dangers. The interacting cells in skin comprise a dynamic network capable of sensing a variety of perturbations (trauma, ultraviolet radiation, toxic chemicals, and pathogenic organisms) in the cutaneous environment, and rapidly sending appropriate signals that alert and recruit other branches of the immune system [5,6]. To restore homeostasis in the skin immune system, the multiple proinflammatory signals generated by skin cells must eventually be counterbalanced by mechanisms capable of promoting resolution of a cutaneous inflammatory response. Dendritic cells of the immune system (Langerhans cells) reside in the epidermis and form a network of dendrites through which they interact with adjacent keratinocytes and nerves [7]. Melanocytes distribute melanin to keratinocytes in the form of melanosomes. Melanin protects the epidermis and underlying dermis from ultraviolet radiation. Sweat glands help to regulate body temperature through evaporation of sweat secreted onto the skin surface. Sebaceous glands associated with hair follicles secrete sebum, an oily substance that lubricates and moisturizes hair and epidermis. Hair keeps the body warm in many mammals, although maintaining body temperature is not an important role of hair in humans. Hair follicles, however, are an important source (a reservoir) of proliferating keratinocytes during reepithelialization after wounding.

The dermis

The dermis underlies the epidermis (Fig. 71.1). The dermis is divided into two regions: the papillary dermis, which lies immediately beneath the epidermis, and the deeper reticular dermis. The papillary dermis is composed of loose connective tissue and form papillae that intertwine with the rete ridges of the epidermis. The reticular dermis is more acellular and has a denser meshwork of thicker collagen and elastic fibers than the papillary dermis. The reticular dermis provides skin with most of its strength, flexibility, and elasticity. Loss of reticular dermis can often lead to excessive scarring and wound contraction.

The dermis provides physical strength and flexibility to skin as well as the connective tissue scaffolding that supports the extensive vasculature, lymphatic system, and nerve bundles. The dermis is relatively acellular, being composed predominantly of an ECM of interwoven collagen fibrils. Interspersed among the collagen fibrils are elastic fibers, proteoglycans, and glycoproteins.

Fibroblasts, the major cell type of the dermis, produce and maintain most of the ECM (Fig. 71.1). Fibroblasts in the papillary dermis and reticular dermis have greater proliferative and secretory activity, respectively. Endothelial cells line the blood vessels and play a critical role in the skin immune system by controlling the extravasation of leukocytes. Cells of hematopoietic origin in the dermis (e.g., macrophages and lymphocytes) contribute to a surveillance function. A network of nerve fibers extends throughout the dermis, which serves the sensory role in the skin (and, to a more limited extent, a motor function). These nerve fibers also secrete neuropeptides that influence immune and inflammatory responses in skin through their effects on endothelial cells, leukocytes, and keratinocytes [8].

The process of wound healing

Wound healing progresses through three distinct phases, inflammation, proliferation, and remodeling. These phases, which have considerable overlap, are somewhat theoretically artificial but provide a conceptual framework. It should also be emphasized that much of what we know about these overlapping healing phases come from experimental animal studies, and the findings are generally extrapolated to humans. The immediate tissue response to wounding is clot formation to stop bleeding. Simultaneously, there is a release of inflammatory cytokines that regulate blood flow to the area, and recruitment of lymphocytes and macrophages to fight infection. This initial inflammatory phase stimulates angiogenesis, fibroblast proliferation, and collagen deposition [8], which marks the proliferation phase. Fibroblasts rich in smooth muscle actin, called myofibroblasts [9], are recruited through the action of factors such as platelet-derived growth factor (PDGF) and transforming growth factor-β (TGF-β; generally the TGF-β1 isoform). These latter processes result in the formation of granulation tissue, a highly vascularized and cellular wound connective tissue. In the remodeling phase of healing, granulation tissue is gradually replaced by scar tissue through the action of the myofibroblasts and factors such as TGF-β. Keratinocytes are stimulated to proliferate and to migrate into the wound bed to restore epidermal coverage.

Impaired healing and its mechanisms

Although there have been many recent advances in our understanding of the scientific basis of tissue repair, the treatment of chronic wounds with impaired healing has been very challenging. The healing of chronic wounds is impaired for a number of reasons, and in general these types of wounds remain challenging because of our inability to completely correct their fundamental pathophysiological abnormalities [10]. Preparatory steps before the use of advanced treatments seem to be required; this preparatory phase may not have received proper attention in the past. This situation is slowly being corrected, but much more needs to be implemented in preparing the wound for the optimal success of advanced wound healing factors and bioengineered constructs. Several years ago, we proposed the notion of "wound bed preparation" (WBP) as a series of steps to improve the wound before advanced products are used [11]. This concept has gained acceptance (see later).

Acute versus chronic wound healing

One of the basic differences between acute and chronic wounds is that in the former the sequence of steps and phases involved (clot formation, inflammation, migration and proliferation, and remodeling) occurs in a very orderly and linear fashion. On must be fully aware of the fact that the often cited steps involved in wound healing come from observations in experimental animal wounds, generally in mice and rats. Therefore, at least theoretically, the steps may be significantly different in human wounds. Anyhow, the orderly steps involved in acute wounds are not the same as in chronic human wounds, where there is a fundamental asynchrony of the healing process. Within the chronic wound, the various phases of wound repair may be occurring at the same time, or not in the appropriate sequence. WBP is a way to get the chronic wound to behave more like an acute wound. Often, surgical debridement is all that is required. At other times, treatment of bacterial infection, removal of edema, etc., are essential additional steps [11].

Bacterial colonization

Bacterial and, in some cases, fungal colonization or infection is a fundamental problem with nonhealing wounds. Some of the causes that foster this colonization and the development of occult infection have already been addressed. These factors include absent epithelium and its barrier properties, the constant wound exudate resulting from bacterial products and inflammation, and poor blood flow and hypoxia [10]. It is well established that wounds have a "bacterial burden" that interferes with healing. Thus there is evidence that, regardless of the type of bacteria present, a level greater than or equal to 10^6 organisms per gram of tissue is associated with serious healing impairment [12]. The configuration of the bacterial sheets or colonies within wounds is also important. Therefore there is a great deal of interest at this time in the role played by biofilms, which represent bacterial colonies surrounded by a protective coat of

polysaccharides. Biofilms develop mechanisms for antibiotic resistance [13].

Growth factor imbalances

The poor healing response in chronic wounds has also been attributed to an imbalance of one or more growth factors [14]. Identification of putative wound healing factors has led to several attempts to speed wound healing by local application of one or more factors that promote cell attachment and migration. However, most if not all, growth factor–based approaches have had marginal success. TGF-β, epidermal growth factor, vascular endothelial growth factor (VEGF), and PDGF have been candidates for this purpose [15–19]. Of these, only PDGF has shown efficacy in clinical trials and has FDA approval for clinical use (Regranex, HealthPoint Biotherapeutics Ltd., Ft. Worth, TX).

The arginine–glycine–aspartic acid (RGD) matrix peptide sequence has been found to promote the migration of connective tissue cells and thus stimulate production of a dermal scaffold within the wound bed. This approach has been shown to accelerate healing of sickle-cell leg ulcers [20] and diabetic ulcers [21], compared with placebo, but not when compared with standard care.

Complex cell extracts have been used in hopes of providing the appropriate mixture of elements. These include the use of platelet extract to provide primarily PDGF [22] and other stimulatory factors, and the use of conditioned growth medium to provide a complex mixture of elements derived from rapidly growing keratinocytes [23]. Again, these approaches have met with marginal effects, in part due to the complex nature of the wound healing response [24]. In addition, the use of factors is not a sufficient approach, in and of itself, in situations where there is severe or massive loss of skin tissue.

Matrix metalloproteinase activity

The nonhealing wound microenvironment can best be described as hostile. Wound exudate, in general, the vast abnormalities in the release, activation, and persistence of matrix metalloproteinases (MMPs), lack of cell adhesion to substrates within the wound bed all may render the growth factors and cytokines unavailable to the healing process. A concept that takes into account these various components has been called the "trap hypothesis" [25]. It has been hypothesized that nonhealing wounds, particularly in response to bacterial antigens, are characterized by chronic leakage of macromolecules into the wound. These macromolecules may impair healing by "trapping" cytokines and growth factors. The trap hypothesis suggests that, in spite of achieving adequate levels and even the properly orchestrated release of these growth factors, the polypeptides are quickly bound and unavailable to the healing process. Common macromolecules that might be involved in trapping include albumin, fibrinogen, and α-2-macroglobulin. The latter is particularly important because it is an established scavenger for growth factors. Fibrinogen can bind to fibronectin, providing a mechanism for the trapping of TGF-β1 [26].

Moist wound healing in chronic wounds

Moist wound healing has been shown experimentally to accelerate reepithelialization of acute wounds [27], and these observations have led to a number of moisture retentive dressings [28]. For chronic wounds, moist wound healing has not been clearly shown to improve epidermal healing or resurfacing, but we do know that moist wound healing helps in the formation of granulation tissue and in relieving pain. Painless debridement, too, is another important property of moisture retentive dressings [28]. The properties of moist wound healing are important in the field of bioengineered skin constructs, because such constructs lead to increased moisture in the wound bed. Proposed advantages of moist wound healing include retention of cytokines within the wound, general prevention of wound crust and facilitation of keratinocyte migration, prevention of bacterial entry, and even poorly understood but favorable electrical gradients. For example, acute wound fluid stimulates the in vitro proliferation of fibroblasts, keratinocytes, and endothelial cells. However, fluid and exudate from chronic wounds appear to have a definite adverse effect on cellular proliferation and contain excessive amounts of MMPs, which can break down key matrix proteins critical to cell migration, such as fibronectin and vitronectin [10]. There is a great deal of information we still need about MMPs and their inappropriate activation in chronic wounds. Some of the information is often contradictory. For example, interstitial collagenase (MMP-1) is essential for keratinocyte migration. However, other enzymes (MMP-2 and MMP-9) may prevent or interfere with healing [10].

Ischemia

An ultimate goal for tissue engineering constructs would be to offset very fundamental abnormalities that lead to impaired or slow healing. We have been discussing components of impaired healing that in some way or another can be approached or at least partially corrected by already available means. However, one important component of impaired healing is ischemia, due to poor arterial supply because of narrowing of blood vessels (i.e., atherosclerosis) or, indirectly, because of pressure upon those blood vessels (i.e., pressure ulcers and diabetic

neuropathic ulcers). The ischemia, of course, has important consequences for the other components of impaired healing we have discussed, such as bacterial colonization and infection. A challenge is how to use available tissue engineering products or modify and develop new ones to correct the problem of ischemia. There are some interesting possibilities that one can use as proof of principle. An example is the role of oxygen tension. Thus there is no debate over the fact that long-term hypoxia is detrimental to the healing process. This has been readily shown with diabetic ulcers, where low levels of transcutaneous oxygen tension ($TcPO_2$) correlate with inability to heal [29]. However, as this makes sense even from a teleological point of view, short-term hypoxia actually stimulates healing. It has been shown that hypoxia can increase fibroblast proliferation, fibroblast clonal growth, and the synthesis of several growth factors, including PDGF, TGF-β, and VEGF [10]. Therefore modulation of the oxygen environment within the wound may offer the possibility of accelerating the healing process. Hypoxia-inducible transcription factors represent now well-established mechanisms for how cells sense hypoxia.

Abnormalities at the cellular level

A very important mechanism for impaired healing is the phenotypic makeup of wound cells. This has critical implications for the use of bioengineered skin constructs, in that these constructs may offset cellular phenotypic abnormalities. There is increasing evidence that the resident cells of chronic wounds have developed phenotypic changes that interfere with their response to growth factors and cytokines. Such abnormalities may affect cellular proliferation, locomotion, and the overall capacity to heal [10]. Also, the signaling mechanisms, which are so critical to the action of cytokines, may be impaired. For example, at least in venous ulcers, there is decreased phosphorylation of Smad2/3 and MAPK p44/42 [30], and a complete deregulation of keratinocyte differentiation and activation and therefore wound closure [31], a result of impaired TGF-β signaling [32].

Engineering skin tissue

Although the epidermis has an enormous capacity to heal, there are situations in which it is necessary to replace large areas of epidermis, or in which normal epidermal regeneration is deficient. The dermis has very little capacity to regenerate. The scar tissue that forms in the absence of dermis lacks the elasticity, flexibility, and strength of normal dermis. Consequently, scar tissue limits movement, causes pain, and is cosmetically undesirable. Engineered tissues that not only heal wounds but also stimulate the regeneration of dermis would provide a significant benefit in wound healing.

Bioengineered skin equivalents should incorporate as many of these factors as possible:

1. an ECM;
2. dermal fibroblasts;
3. an epidermis containing keratinocytes; and
4. a naturally occurring semipermeable membrane, the stratum corneum to provide barrier function (Fig. 71.2).

These components may act alone, but more importantly and likely, they act in concert as part of a fully integrated tissue to protect the underlying tissues of a wound bed and to direct healing of the wound [33]. Dermis containing fibroblasts may be necessary for the maintenance of the epidermal cell population [34]. In turn, the epidermis is necessary for the formation of the so-called neodermis, in the absence of a dermal layer [35], and can dramatically influence underlying connective tissue responses. The formation of the epidermal barrier also likely influences these processes through control of epidermal water loss and its influence on epidermal physiology [36].

Design considerations

Tissue engineering has not focused on regenerating certain skin structures, such as hair follicles or sebaceous glands, loss of which is clinically less significant than the loss of dermis and epidermis needed to cover and protect the

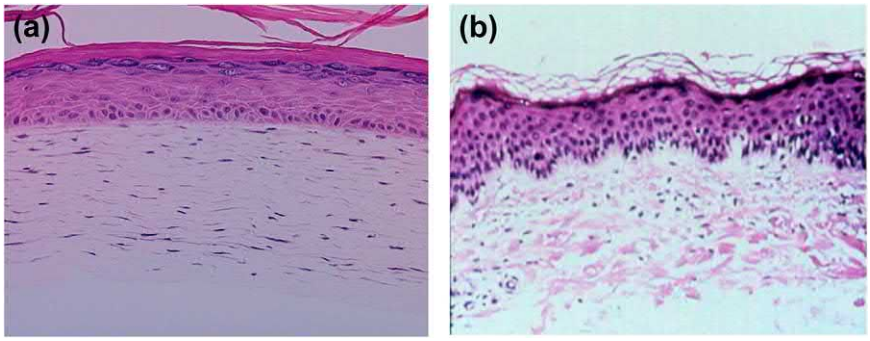

FIGURE 71.2 Histological appearance of Apligraf.

underlying tissues. Despite some early evidence for rudimentary eccrine tubules within the HSE [37], the full development of functioning adnexal structures is likely to be several years away, although progress is being made. There has also been little need to extraneously stimulate regeneration of other dermal components (e.g., blood vessels and cells of the immune system) through tissue engineering methods because these components have the ability to repopulate quickly and to normalize the area of a wound. Langerhans cells, for example, have been shown to migrate and repopulate effectively within months [9]. Control of vascularization is dependent on the makeup of the ECM and the degree of inflammation present in the wound. Whether modification of vascularization through the use of exogenous factors will be of additional benefit for certain wounds still remains to be determined. While pigmentation is not critical for wound healing, as far as we can determine at this time, clinical studies using Apligraf, which lacks melanocytes, have shown repigmentation of the grafted areas through repopulation of the area with host melanocytes, resulting in normal skin color for many patients. The constructs should have sufficient mechanical strength to allow for clinical manipulations (Fig. 71.3). The approach skin tissue engineering has taken has been to focus primarily on providing or imitating structural and biological characteristics of dermis, epidermis, or both.

Following are the key features to be replicated in an engineered skin construct:

- a dermal element capable of aiding appropriate dermal repair and epidermal support;
- an epidermis capable of easily achieving biologic wound closure;
- an epidermis capable of rapid reestablishment of barrier properties;
- a permissive milieu for the components of the immune system, nervous system, and vasculature;
- a tissue capable of achieving normalization of structure and additional functions such as reduction of long-term scarring and reestablishment of pigmentation;
- active cellular component(s) capable of responding to different wound types and conditions;
- sufficient mechanical strength to allow for clinical manipulation; and
- persistence of cells in the wound for multiple weeks to stimulate the healing process through delivery of cytokines and matrix proteins.

Commercial considerations

Engineered skin constructs, by virtue of being the first bioengineered products to be commercialized, have been at the forefront of science, industry, and regulation. In recent years, more attention has been given to the subject of their commercialization. Jaklenec et al. published a review of the tissue engineering and stem cell industry [38]. The authors reported that there was approximately a threefold increase in commercial sales, generating $3.5 billion from 2008 to 2011. During that time the number of tissue engineering companies increased from 171 in 2007 to 202

in 2011, with 62% of them based in the United States. These companies are spending $3.6 billion and employ 13,810 people. The findings indicate that the tissue engineering and stem cell industries are stabilizing.

Early industry leaders, Organogenesis, Advanced BioHealing (now Shire Regenerative Medicine) and Forticell Biosciences, initially struggled with the task of commercializing their technologies. The focus at Organogenesis, in the case of Apligraf, has been on understanding the cost of manufacturing and working to reduce those costs while increasing efficiency and maintaining high quality. Organogenesis has also built robust sales and marketing, customer service, reimbursement, and distribution functions to drive Apligraf sales. Having all of these functions within the same organization is proving to be of benefit by allowing for a more integrated, strategic company.

Process considerations

Consideration should be given to the design of the manufacturing process early in the product concept stage. Elements such as critical process parameters, quality control assays, production components and materials, process equipment, production facility requirements, product's shelf life, and distribution methods need to be developed in detail. From this design the cost of manufacturing and strategies for scale-up and automation can be developed. The requirements for the manufacturing facility are directly related to the design of the manufacturing process. For example, a manual process generally requires a large highly specialized staff and a relatively large manufacturing floor space, whereas an automated process requires less specialized staff and potentially less manufacturing floor space. An aseptic process where the culture vessels are periodically opened to facilitate feeding and other manipulations requires tighter environmental controls to mitigate risk from contaminants on work surfaces or in the air, whereas developing a closed process that eliminates aseptic manipulations reduces the need for tight environmental controls, thus reducing facility costs. All of these elements impact the cost of manufacturing and the potential for scale-up.

Process components that will pose significant barriers to scale-up or automation can be identified and addressed while the product is still in research and development. This is critical when you consider that the further you advance in the development process the more committed you become to the process design. The cost of making a significant process change increases the closer you get to manufacturing and becomes exponentially more expensive and time-consuming after product launch. Along these same lines, materials used in the process that are ill-defined, cell-based, single sources or of limited supply can contribute to a manufacturing process that is difficult to scale-up and control from a quality standpoint. These factors will influence the yield from the manufacturing process or, stated another way, the scrap rate for the product. High scrap rates increase manufacturing costs and create issues for inventory management. The pioneering lessons learned by early industry leaders in process scale-up apply to the broader field of tissue engineering. Ultimately, strategies for scale-up and automation can be evaluated and planned for.

Regulatory considerations

The Center for Devices and Radiological Health at FDA requires products to be developed following design control procedures (21 CFR 820.30). These design guidelines are in place to ensure that the products that are developed will be safe, effective and have a market research–based justification for the product design. Establishing a design control system early will help refine the business model throughout the development life cycle. Design control is not only a regulatory requirement, but also it makes good business sense. HSEs have historically been classified and regulated as medical devices, though the trend at FDA is to regulate products having a cellular component as biologics. A case in point is the recent approval of GINTUIT, a fibroblast- and keratinocyte-containing construct, as a combination product (containing biologic and devices components) by the Center for Biologics Evaluation and Research (CBER) [39]. Finally, agencies such as the US Center for Medicare and Medicaid Services and foreign government reimbursement agencies (e.g., UK National Institute for Health & Clinical Excellence) are increasingly requiring convincing data on the value and effectiveness of therapy as compared to standard of care or competing technologies [40].

It should be noted that, when it comes to academic investigators (typically in a University Medical Center) developing novel and experimental bioengineered skin constructs, a new reality has developed in the last several years with regard to regulatory requirements. It used to be that regulatory agencies, such as the FDA, may not have held the noncommercial product development with the same stringency and requirements. It is now well established the good manufacturing practice facilities are required. This degree of stringency now also extends to the evaluation of National Institutes of Health (NIH) awards for new and novel projects. Thus, within the NIH, committees have been established, which collaborate and communicate with federal regulatory agencies for absolute safety of the products being developed and tested.

Immunological considerations

The ability to utilize allogeneic cells rather than autologous cells facilitates the reproducible, large-scale commercial manufacture of an HSE [37], because large cell banks can be created, allowing manufacture of thousands of units of product from one or few comparable cell strains and enabling a more accurate forecast of manufacturing demands. However, the problem of rejection needs to be taken into consideration when using living allogeneic cells in wound healing applications.

The first stage in the induction of a primary immune response after skin allografting is the presentation of antigen by donor dendritic cells (Langerhans cells with dermal dendritic cells), the professional antigen-presenting cells (APCs) in skin. These cells migrate out of the skin to the draining lymph node, where they can activate T cells directly through the presentation of MHC-class II antigens and costimulatory molecules, thereby eliciting both cell-mediated and humoral (antibody-mediated) immune responses to the grafted skin. Although cell-mediated cytotoxicity is a component of rejection, the primary mode of skin rejection is likely mediated via an attack on the vasculature present in a normal skin graft by recipient antibodies [41,42].

For the most part, bioengineered skin constructs are fabricated from highly purified banks of fibroblasts, keratinocytes, or both, which are either poor or deficient in dendritic and other APCs found in skin. This has important implications for the use of allogeneic cells in the treatment of acute and chronic wounds. In the absence of APCs, fibroblasts and keratinocytes are the only cells capable of presenting donor antigen to the recipient. Under normal conditions, keratinocytes and fibroblasts do not express MHC-class II antigens. They can be induced by interferon-γ to express MHC-class II molecules and thereby acquire the ability to present antigen to T cells; however, keratinocytes and fibroblasts do not express costimulatory molecules [43,44], so antigen presentation by keratinocytes and fibroblasts does not result in T cell activation. Instead, this antigen presentation can result in T cell nonresponsiveness [45,46] or T cell anergy [47]. It should be noted that there are continued efforts to develop, test, and commercialize constructs comprising also endothelial cells and/or adnexal skin structures. Therefore the abovementioned immunological aspects will need to be considered when creating and testing even more complex constructs.

Autologous HSEs would avoid issues of immunogenicity, of course, but autologous grafts have significant limitations. The process of growing constructs' components from skin biopsies takes several weeks, the donor site creates another wound and, in some patients (e.g., severe burn victims), there may be no appropriate and safe donor site. Reproducibly making complex HSE constructs to order from autologous cells would be time-consuming, and very costly. Therefore the ability to effectively use allogeneic human cells is a key element in the commercial success of engineered skin therapies.

Summary: engineering skin tissue

In summary, good science alone is not enough to ensure success. There are critical considerations to commercialization along the entire continuum from product concept, development, clinical evaluation, FDA and other regulatory agency approval, product launch, reimbursement, and commercial-scale manufacturing. Developing a comprehensive business model that takes all of these factors into account will increase the likelihood for a profit-generating product. Understanding the challenges and working to incorporate process designs that are forward-looking, will be amenable to scale-up, address regulatory hurdles, and are supported by a viable business model are necessary for companies to be successful and the industry to grow.

Epidermal regeneration

Reepithelialization of the wound is a paramount concern. Without epithelial coverage, no defense exists against contamination of the exposed underlying tissue or loss of fluid. The approaches to reestablishing epidermis are numerous, ranging from the use of cell suspensions to full-thickness skin equivalents possessing a differentiated epidermis. Silicone membranes have been used as temporary coverings in conjunction with dermal templates [48], porcine skin and cadaver skin have been used in burn victims. Regardless of approach, living epidermal keratinocytes are necessary to achieve permanent, biologically based wound closure.

Green et al. [49,50] developed techniques for growing human epidermal keratinocytes from small patient biopsy samples using coculture methods [51]. The mouse 3T3 fibroblast feeder cell system allows substantial expansion of epidermal keratinocytes and can be used to generate enough thin, multilayered epidermal sheets to resurface the body of a severely burned patient [52]. Once transplanted, the epidermal sheets quickly form more differentiated epidermis and reestablish epidermal coverage [35]. With time, the cultured epithelial autograft (CEA) stimulates the formation of new connective tissue (neodermis) immediately beneath the epidermis [53], but scarring and wound contraction remain significant problems [54]. Studies have shown that grafting of a CEA onto pregrafted cadaver dermis greatly improves graft take [55]. CEAs (Epicel, Genzyme, Cambridge, MA) have been available since the late 1980s.

Dermal replacement

Dermal replacement is an essential first step in restoring normal skin structure following injury and leads to better cosmesis in full-thickness soft tissue defects. In one of the earliest tissue engineering approaches to improving dermal healing, Yannas et al. [56] designed a collagen-glycosaminoglycan sponge to serve as a scaffold or template for dermal ECM. The goal was to promote fibroblast repopulation in a controlled way that would decrease scarring and wound contraction. A commercial version of this material composed of bovine collagen and chondroitin sulfate, with a silicone membrane covering (Integra, Integra Life Sciences, Plainsboro, NJ) has received regulatory approval for use in burns [48,57]. The dermal layer is slowly resorbed, and the silicone membrane is eventually removed, to be replaced by a thin autograft [58].

Biobrane is a nonviable temporary covering for burns, in which a nylon mesh, coated with porcine collagen−derived peptides and layered with a nonpermeable silicone membrane serves as a platform for deposition of human matrix proteins and associated factors by host wound−derived dermal fibroblasts. After epidermalization the construct becomes nonadherent and is removed from the wound bed. A similar product, Transcyte (Advanced BioHealing, Westport, CT) [59], consists of a porcine collagen−coated nylon mesh that is incubated with human neonatal fibroblasts, which secrete ECM proteins and growth factors. The material is then frozen to preserve the matrix and factors produced by the fibroblasts, although the fibroblasts themselves are nonviable when the construct is applied to the wound. The temporary silicone covering is removed to allow epidermalization or prior to application of an autograft.

Although matrix scaffolds have shown some improvement in scar morphology, no acellular matrix has yet been shown to lead to true dermal regeneration. This may be due in part to limits in cell repopulation, the type of fibroblast repopulating the graft, and control of the inflammatory and remodeling processes (i.e., the ability of the cells to degrade old matrix while synthesizing new matrix).

The inflammatory response must be controlled in dermal repair in order to avoid the formation of scar tissue. Therefore dermal scaffolds must not be inflammatory and must not stimulate a foreign body reaction. This has been a problem in the past for some glutaraldehyde cross-linked collagen substrates [60]. The ability of the matrix to persist long enough to redirect tissue formation must be balanced with effects of the matrix on inflammatory processes. One way to achieve this is to form a biological tissue that is recognized as living tissue, not a foreign substance.

There have been advances in the design of in vitro grown dermal tissues using living human neonatal fibroblasts grown on rectangular sheets of biodegradable vicryl mesh (Dermagraft, Shire Regenerative Medicine, San Diego, CA). The fibroblasts propagate among the fibers of the mesh, producing ECM in its interstices [61]. Like Transcyte, the final Dermagraft construct is then frozen, but in a manner that preserves approximately 60% fibroblast viability upon thawing and placement on the wound [62].

Bioengineered living skin equivalents

HSEs have been generated by seeding cultured keratinocytes onto the surface of a variety of scaffolds, including artificial membranes, deepidermalized dermis, collagen gels, chitosan-GAG sponges, or fibroblast-populated nylon meshes [63]. One of the first attempts to replicate a full-thickness skin graft was by Bell et al. [64] who described a bilayered skin equivalent, which was the predecessor to Apligraf (Organogenesis, Canton, MA). The dermal component consisted of a lattice of type I collagen contracted by tractional forces of rat dermal fibroblasts trapped within the gelled collagen. This contracted lattice was then used alone or as a substrate for rat epidermal keratinocytes. These primitive skin equivalents were further demonstrated to take as skin grafts in rats. This technology has now advanced to enable the production of large amounts of the Apligraf construct from a single donor [37].

Boyce et al. modified the approach first proposed by Yannas et al. to form a bilayered composite skin by using a modified collagen-glycosaminoglycan substrate seeded with fibroblasts and overlaid with epidermal keratinocytes [65]. An autologous form of this composite skin construct was used to treat severe burns with some success [66]. An allogeneic form of the construct showed improved healing in a pilot study in chronic wounds [67]. A similar technology has been studied in the treatment of patients with genetic blistering diseases [68]. Using methods of organotypic culture that provides a three-dimensional culture environment that is permissive for proper tissue differentiation, the resulting HSE develops many of the structural, biochemical, and functional properties of human skin [65,69−71], apart from the aforementioned lack of adnexal structures.

The process for the formation of HSEs has been covered in detail many times [37,65,72] and will not be detailed here. However, there are points to be made about the approach to these procedures. The culture of an HSE proceeds best with minimal intervention. Normal keratinocyte populations seem to have an intrinsic ability to reexpress their differentiation program in vitro. A medium that supplies adequate amounts of nutrients, lipid precursors, vitamins, and minerals may be all that is required [37]. This has now been achieved with both normal human keratinocytes (Apligraf, Orcel) and with immortalized human keratinocytes (StrataGraft) [73]. Another

element is the environmental stimulus provided by culture at the air–liquid interface, which promotes differentiation and formation of the epidermal barrier [65,69]. In the case of StrataGraft the trisomy that caused immortalization of the cell line has apparently not affected the capacity of the cells to undergo differentiation in organotypic culture [73].

L'Heureux et al. were able to take advantage of the fact that mesenchymal cells secrete their own ECM when cultured in the presence of ascorbic acid, to generate sheets of ECM, in the absence of a bovine collagen scaffold, from cultured fibroblasts and smooth muscle cells. Initially, these ECM tissues were used to generate the first tissue-engineered blood vessels [74]. Subsequently, the same technology was used to generate a scaffold-free HSE [75], in which the dermal layer normally constructed with bovine collagen was replaced with a completely fibroblast-derived ECM. The epidermis of the HSE was generated by seeding keratinocytes onto the self-assembled ECM and incubating at the air–liquid interface to promote stratification and differentiation. After 4 weeks of culture a fully stratified and differentiated epithelium developed, which expressed the normal markers of differentiation. The tissue also included an organized basement membrane, including laminin and collagens IV and VII. Since this early work a few groups have investigated the physical and biochemical properties of self-assembled ECMs [75–77] and have used these self-assembled constructs as in vitro models of percutaneous absorption [75] and hypertrophic scarring [78,79]. However, self-assembled HSEs have yet to become a clinical and commercial reality.

Bioengineered skin: FDA-approved indications

Cutaneous indications

As discussed earlier, the rather formidable obstacles to healing chronic wounds have made it difficult for the simple topical application of growth factors and cytokines to have a successful outcome. It can be argued that tissue engineering, particularly with living cells, has an advantage in that cells may be capable of responding to the microenvironment and thus behave in a "smart" way from an engineering point of view. Because of these considerations, cell therapy with bioengineered skin has been tested in difficult to heal wounds. Figs. 71.2 and 71.3 show Apligraf before and after meshing and fenestration, as well as its histological appearance. Venous leg ulcers (VLUs) and neuropathic diabetic foot ulcers (DFUs) have received the greatest attention. Two main types of living bioengineered skin have been proven to be effective in diabetic neuropathic foot ulcers and have received regulatory approval from the FDA. In a randomized 12-week trial of 208 patients with neuropathic ulcers, Apligraf led to complete wound closure in 56% of patients, compared to 38% in the control group [80]. The Kaplan–Meier median time to complete wound closure was 65 days for Apligraf and 90 days for control. Fig. 71.4 shows a

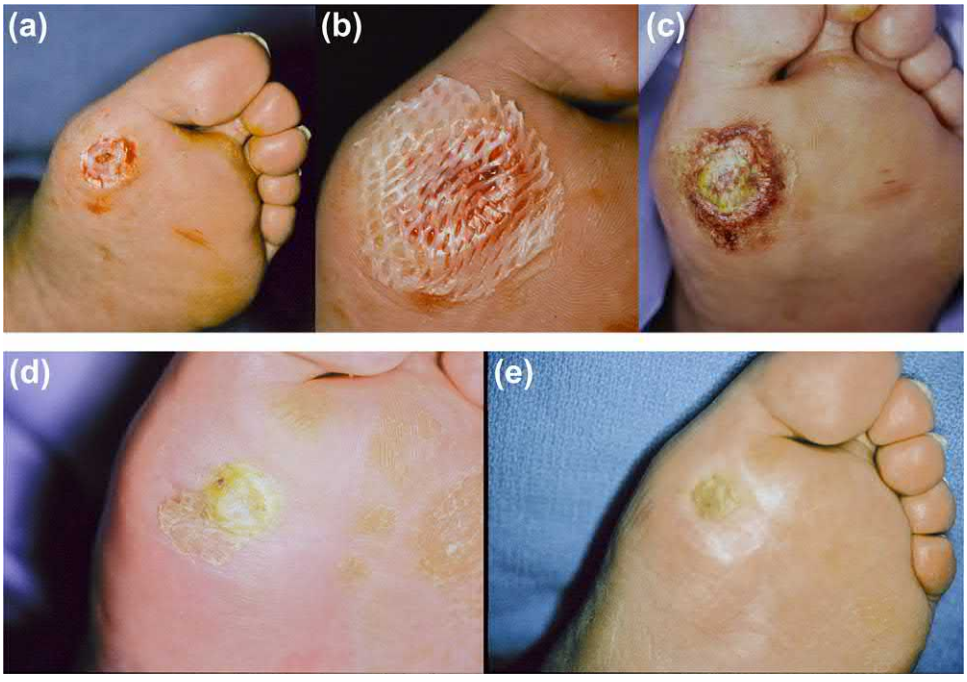

FIGURE 71.4 Diabetic neuropathic foot ulcer successfully treated with Apligraf.

diabetic neuropathic foot ulcer successfully treated with Apligraf. In an evaluation of the clinical trial adverse events, Apligraf treated patients had significantly fewer amputations/resections of the study limb and less incidence of osteomyelitis. These results on key complications of DFUs may have been due to faster healing. Another living cell product, Dermagraft, was shown in a 12-week randomized study to heal neuropathic foot ulcers, with an incidence of closure of 30% and 18% for the active and control arm, respectively [81]. It is perplexing that the rate of healing in the control was widely different between Apligraf (38%) and Dermagraft (18%), but no definite explanation has surfaced for that discrepancy.

In addition to its indication for diabetic ulcers, Apligraf also remains the only approved bioengineered product for venous ulcers. In a pivotal multicenter randomized study of 293 patients with VLUs, Apligraf was more effective than leg compression alone (control) in the percentage of patients who healed by 6 months (63% vs 49%) [82]. That study also showed that Apligraf healed ulcers, which were larger and deeper than those in the control group. No evidence of sensitization was observed with the bioengineered skin product. Interestingly, a subsequent reanalysis of the data from this pivotal trial, limited to 120 patients having venous ulcers for over 1 year, showed that Apligraf healed 47% of patients, compared to 19% in the control group [83]. This observation, taken together with the mechanisms underlying impaired healing, suggests that cell therapy might have a greater effect when there are more substantial abnormalities leading to a prolonged failure to heal.

Oral indications

Like skin, soft tissues in the oral cavity need to be replaced or repaired after physical/surgical trauma, disease processes, or congenital defects. Successful treatment of soft tissue defects in the oral cavity has been accomplished by either secondary intention healing (removing the diseased tissue and allowing it to heal on its own), by the use of flaps (a graft that is advanced over a defect and contains its own blood supply), or by the use of free grafts (tissue that lacks its own blood supply). Depending on the procedure, auto- or allografts may be used. Autografts are generally harvested from the palate and are associated with significant donor site morbidity. However, some groups have had success with autologous epithelial cells, and with injected autologous mucosal fibroblasts [84].

Two types of allogeneic, tissue-engineered constructs have been used in the oral cavity. Dermagraft has been used in the oral cavity to treat gingival recessions, in which the amount of attached gingiva was insufficient. As with its DFU indication, it is thought that the Dermagraft construct provides a scaffold for mucosal keratinocyte migration, and that it secretes growth factors and cytokines that promote secondary intention healing. Dermagraft has been the subject of a controlled within-patient clinical trial in the oral cavity, in which its efficacy was compared to that of a gingival autograft for the treatment of gingival recessions [85,86]. Treatment with Dermagraft resulted in an increase in the amount of attached gingiva, although the amount of keratinized tissue was inferior to that generated by the autograft, as expected from a construct that promotes secondary intention healing rather than immediate coverage.

GINTUIT, a product derived using a similar technology platform as Apligraf, has also been evaluated for its ability to replace a connective tissue autograft in the treatment of gingival recessions in a free gingival graft procedure [87]. Like Apligraf in the DFU and VLU indications, GINTUIT did not persist long-term in the oral cavity. Like Dermagraft, GINTUIT was found to be superior to a gingival autograft in terms of color and texture match to surrounding tissue. In the pilot and pivotal studies, treatment with GINTUIT resulted in regeneration of ≥ 2 mm of keratinized gingiva in 81.8% and 95.3% of patients, respectively, which is clinically accepted as a level important for periodontal health. GINTUIT was the first living cell–based therapy that has FDA approval for the treatment of oral soft tissue defects [39]. Although derived from the same technology platform as Apligraf, GINTUIT was approved as a combination product (containing biologic and devices components) by the CBER [39] and is therefore subjected to additional product release criteria compared to Apligraf. Interestingly, the platform that gives rise to Apligraf and GINTUIT is able to regenerate tissue in a site-appropriate manner, in that it promotes secondary intention healing of difficult to heal cutaneous soft tissue defects, and also promotes regeneration of keratinized gingiva site-appropriately in the oral cavity.

Apligraf and Dermagraft: off-label uses

Off-label use is the practice of using products for purposes not approved by the FDA. Physicians can prescribe and use products as they see fit because they are not regulated and are recognized as experts in their fields. Manufacturers of the products are not permitted to promote off-label use; however, data generated by off-label use can be very valuable and lead to new insights into product function and potentially to clinical trials for new indications, therefore the following discussion has been included in this chapter. It must be emphasized, however, that the determination of off-label use is not always clear-cut when it comes to chronic wound etiology. In some cases applicable to Apligraf, for example, a scalp or hand

wound, one is clearly using the product off-label because that construct is FDA approved for venous and diabetic neuropathic foot ulcers. However, for many lower extremity wounds, the situation is much more complex. Thus a patient may have a mixed etiology for the ulcer (e.g., lymphatic and venous insufficiency) and will therefore not heal until the venous component is properly addressed. In addition to the use of standard care for venous insufficiency, such as compression bandages and wound dressings, one could make the argument that Apligraf is indicated in that clinical setting because the construct has indeed been proven to improve venous ulcers. It would be difficult, perhaps impossible, to conduct clinical studies that address ulcers of mixed etiology in a scientifically sound way. An even more complex clinical setting is when one treats patients who appear to have inflammatory ulcers (i.e., pyoderma gangrenosum, ulcers due to or associated with vasculitis and cryoprotenemias) on a lower extremity that also exhibits definite signs and findings of venous insufficiency. The question then centers upon the predominant etiology of the ulceration. From a clinical standpoint, it can become very difficult to make that determination. Yet treatment of that ulcer with Apligraf to improve the venous component can lead to complete wound closure (V. Falanga, personal observation as of 2019). These are challenging situations, but, in our experience and exchanges with colleagues, these types of ulcers are probably not uncommon. Still, while being able to use certain constructs off-label, the clinician must keep in mind the appropriate approved indications for that product and not be swayed in his or her clinical judgment as to what is indeed the primary cause of the ulcer.

From both a therapeutic and purely scientific standpoint, of critical importance in the context of the clinical trials for venous leg and DFUs that have been detailed is that, for the very first time, one has been able to show a beneficial effect of bioengineered products in situations of impaired healing. Understandably, clinicians have also used Apligraf off-label to accelerate healing in wounds not due to venous disease or diabetes [88]. Wounds that have been treated off-label with Apligraf include acute wounds after extensive skin surgery, donor sites after split-thickness skin harvesting, traumatic wounds, burns, inflammatory ulcers such as pyoderma gangrenosum and vasculitis, scleroderma digital ulcers, wounds after keloid removal, genetic conditions such as epidermolysis bullosa (EB), and a variety of situations that defy proper diagnosis because of their complexity. In these cases, bioengineered skin treatment with Apligraf seems to offer a viable alternative to stimulate wound healing and relieve unacceptable pain and suffering. For example, pyoderma gangrenosum is an inflammatory ulcer often associated with rheumatoid arthritis, inflammatory bowel disease, IgA gammopathy, among other predisposing factors. A peculiar feature of pyoderma gangrenosum is that it worsens with extensive surgical manipulation and even develops at distant and normal looking skin that are traumatized; thus autologous grafting is a contraindication, and bioengineered skin is an attractive therapeutic modality [89]. In a patient with multiple myeloma undergoing conditioning for bone marrow transplantation, extravasation of the chemotherapeutic drug adriamycin occurred in his chest and created a very large, deep, and painful wound. Apligraf played a major role in healing the full-thickness wound (Fig. 71.5) and led to a dramatic relief in pain. Pressure ulcers, too, have been treated with Apligraf. This is of particular interest because, based on the engineering aspects of the construct, one would have expected that very deep wounds with loss of a great deal of tissue would not respond to Apligraf. Yet it appears that in such cases Apligraf is able to stimulate tissue regrowth in deep ulcers, and not just reepithelialization from the edges of the wound (Fig. 71.6). Scleroderma digital ulcers are ischemic in nature and have no known accepted treatment. Yet Apligraf appears promising in those wounds (Fig. 71.7). There is no evidence that Apligraf stimulates malignancy within the wound bed, possibly due to its stimulatory action. An interesting case in point is shown in Fig. 71.8, where multiple and ulcerated basal cell carcinomas in the foot of a patient with the hereditary form of basal cell nevus syndrome were treated with Apligraf.

EB is a genetic skin disorder characterized by blistering of the skin and mucosae following mild mechanical trauma [90,91]. Falabella et al. performed an open-label uncontrolled study of 15 patents with EB treated with Apligraf [91]. The conclusion was that Apligraf induced rapid healing; the wounds remained healed for some weeks and there was no acute rejection reaction or other adverse effects related to the treatment. Currently, there is no specific treatment for EB, and the nature of the condition is that these wounds tend to heal slowly and in some instances fail to heal, becoming chronic wounds. Fig. 71.9 shows an example of a pediatric EB patient who was treated with Apligraf.

These considerations are not applicable to only Apligraf, although there has been more experience with that construct. A case of vasculitis treated with Dermagraft is another good example of the use of a tissue-engineered construct to promote closure of a difficult to heal wound (Fig. 71.10). The patient (48 years old) had a severe course of cutaneous polyarteritis nodosa, which did not involve her kidneys. She was always in severe pain and could not be healed by conventional means. Dermagraft proved useful in terms of alleviating pain and promoting epidermalization. Stimulation of epidermal migration was observed by Day 14 after

The child had been treated with Apligraf. *V. Falanga, ©2006.*

application of the construct. After the wound healed the patient was placed on an anti-TNF-α biological agent to prevent recurrence and she remains healed.

The importance of wound bed preparation

Shortly after the FDA approval of two major products for the treatment of nonhealing chronic wounds (topical PDGF for diabetic neuropathic foot ulcers and Apligraf for venous ulcers), it became apparent that many clinicians were either not well versed in the treatment of chronic wounds or could not easily incorporate these novel and advanced therapeutic technologies into their management strategies. The initial clues to this problem came from obviously suboptimal results when compared to those obtained in the clinical trials, or the apparent use of these technologies at inappropriate times during the healing or nonhealing trajectory of the wounds. In an editorial we published at that time [11], we laid down what we thought to be the reasons for these observations and focused on a new term, WBP, which we described as a global approach to the wound to improve its wound bed at multiple levels (optimizing the granulation tissue, decreasing the bacterial burden, removing phenotypically abnormal cells, and enhancing epidermal migration) and

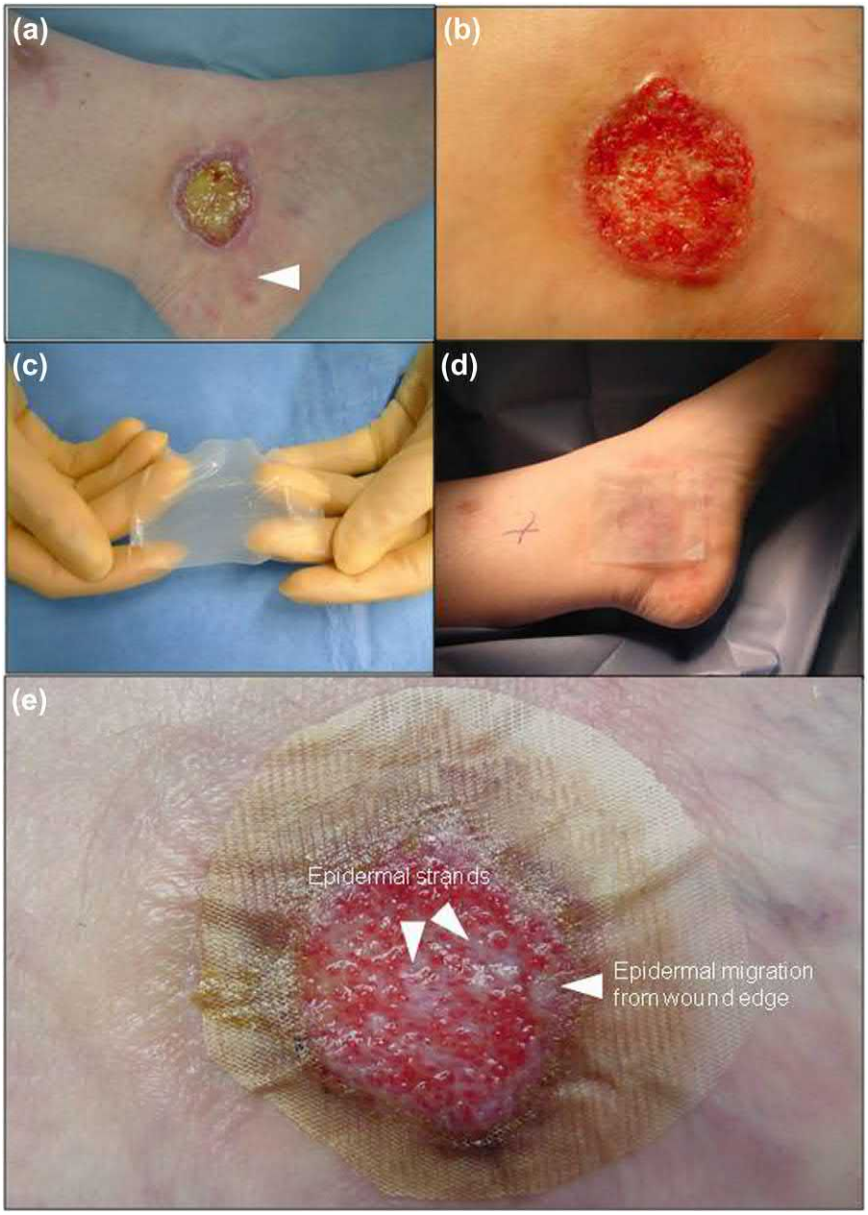

FIGURE 71.10 Treatment of vasculitis with Dermagraft.

(D) Dermagraft applied to wound. (E) Wound appearance 14 days after applying Dermagraft. Granulation tissue has developed and there is evidence of epidermal migration (*arrowheads*). *V. Falanga, ©2012.*

which would then lead to a better outcome upon treatment with growth factors, bioengineered skin constructs, and other advanced therapeutic agents. Since then, WBP has dominated the chronic wound field and has provided a more consistent way of approaching chronic wounds. Other publications on this subject have followed Refs [92,93].

There has been some struggle to define exactly what constitutes optimal WBP, but we have prepared a working scoring system to begin to investigate this issue [94]. Fig. 71.11, taken from that publication, summarizes the scoring system. The wound bed score (WBS) gives each of eight clinical parameters, assessable at the bedside a score of 0, or 1, or 2. The maximum and best score is 16. Our experience with the WBS indicates that it is a useful starting point for deciding when to use a complex and advanced biological therapy.

Proposed mechanisms of action of bioengineered skin

As stated in the previous section, there are a number of bioengineered skin products that have been designed. Still, in all cases, the exact or even main mechanisms of action (MOA) by which these bioengineered skin remain unknown. Despite this still poor understanding of mechanisms, there is some strong evidence that supports

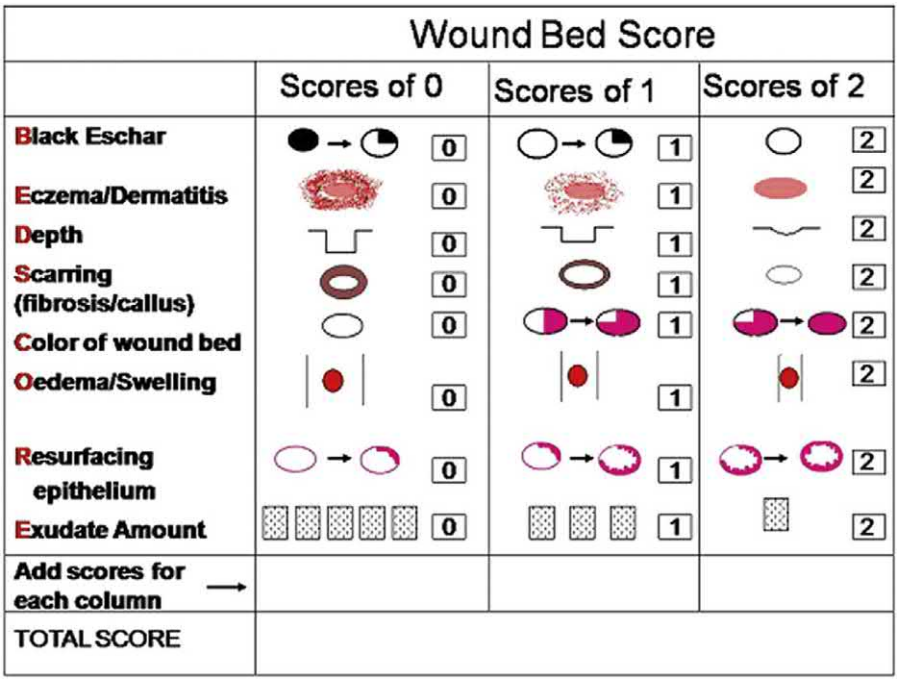

FIGURE 71.11 Wound bed scoring scheme. *V. Falanga, ©2007.*

plausible explanations of MOA. It has been stated that the delivery of living cells is associated with the release of growth factors and cytokines [62,95]. For example, it has previously been shown that, when wounded in vitro, Apligraf undergoes a staged expression of inflammatory cytokines and, later, growth factors, that is very much reminiscent of the normal process of wound healing [95]. Furthermore, a host of cytokines are produced by Apligraf, and there is evidence that its epidermal and dermal components work in concert to produce these mediators that would not normally be detected with the epidermal and dermal component alone [94].

Another interesting property of Apligraf, which is due to its unique bilayered configuration, is that it undergoes epiboly in vitro [96]. This ability to migrate over its own dermis suggests a very viable epidermal component, capable of allowing the construct to heal itself after injury [95].

The available evidence shows that the cells from several allogeneic constructs, including Apligraf, do not persist in wounds [97,98]. This has been shown in acute wounds as well as in venous ulcers, where the DNA from donor allogeneic cells is not detectable at 4–6 weeks, based on PCR-based detection of donor cells. Thus there is strong evidence that true engraftment or prolonged persistence of cells from these allogeneic constructs does not occur. Apligraf may possibly persist longer when applied to patients with certain genetic conditions, as suggested by reports that Apligraf specific DNA may be detectable many more weeks or even months when the construct is applied in the wounds of young patients with EB, a condition characterized by a variety of genetic defects in molecules responsible for anchoring the epidermis to the dermis (i.e., laminin 5 and type VII collagen) [99,100]. Still, in spite of lack of longevity of the construct, the clinical trial results indicate that even a few days or weeks of exposure of the wound to Apligraf have beneficial effects. Possible mechanisms include a more orderly and orchestrated release of cytokines, deposition of ECM material important for early migration of mesenchymal cells and keratinocytes, and even in the attraction of progenitor or stem cells from deep in the tissue or from the circulation [10].

Although it is tempting to think of Apligraf as a "graft," available evidence indicates that this construct promotes secondary intention healing in an otherwise stalled wound. We have already discussed the issue of allogeneic cell longevity, which in itself speaks against the idea of Apligraf being a graft. Moreover, there is no evidence that wound bed blood vessels grow into Apligraf, as is commonly observed with autologous grafts. Perhaps most telling is the fact that, uniformly, Apligraf seems to stimulate the edges of the wound to migrate toward the center. This "edge effect," which has also been reported with the application of living keratinocyte sheets, is the predominant observation with successful Apligraf treatment (Fig. 71.12). The edge effect strongly suggests that Apligraf does not act as a tissue replacement but, rather, stimulates secondary intention healing. Indeed, the rate at which the edges of a wound

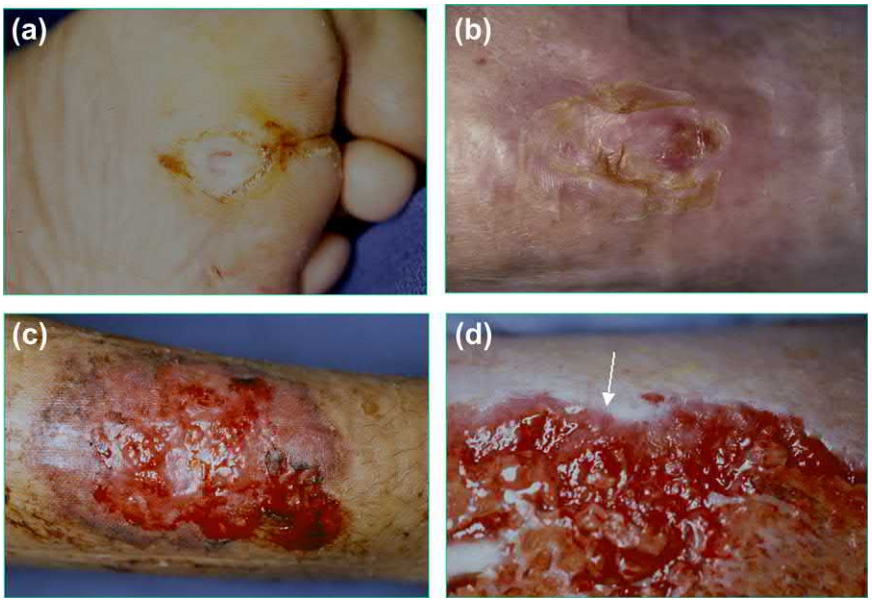

FIGURE 71.12 Different clinical appearances of wounds after Apligraf application. (A) Diabetic foot ulcer with white center representing degraded Apligraf remnants 3 week after application. (B) Venous ulcer 6 weeks after application. (C) Pyoderma gangrenosum only 2 weeks after Apligraf application and with thin layer of epidermis completely covering the wound bed. (D) Classical "edge effect" (*arrow*) at the margins of a venous ulcer treated with Apligraf. The yellow material at the bottom of the pictures represent what is left of meshed Apligraf applied 3 weeks earlier. *V. Falanga, ©2006.*

migrate toward the center has been used to determine whether eventual wound closure will occur, and Apligraf appears to accelerate wound edge migration [101]. The author has performed a clinical study, still unpublished, whereby the Apligraf is placed in chronic wounds and 1 cm away from all edges. The "edge effect" from the surrounding epidermis was still readily observed (V. Falanga, as of 2019).

Construct priming and a new didactic paradigm for constructs

Two new concepts, priming and use of the construct in conjunction with stem cells, have emerged in our understanding of how constructs could potentially be used in different ways, even without modifying the initial manufacturing process of the product. These concepts are also mentioned by one of the authors (V. Falanga) in one of his publications on bioengineered skin [101]. The priming of a bioengineered skin construct is particularly intriguing and promising, and a recent publication [102] by the laboratory team of the author shows evidence for this approach. If priming proves to be clinically feasible, it would lead to a construct containing a richer and augmented repertoire of activated genes and proteins before it is applied to the wound. It has been demonstrated that this is possible using Apligraf as proof of principle in vitro and in vivo [102]. Indeed simple incubation of the construct for 24 hours in Dulbecco's Modified Eagle Medium plus 10% FBS leads to increased transcription (up to 200-fold) of hundreds of genes related to cellular proliferation and migration [102]. The results obtained by microarray suggest that IL-6 is the most stimulated gene after using this priming step, and the results have been confirmed by western blot and by immunohistochemistry.

Another potentially useful concept, especially with the current interest in stem cells, is that bioengineered skin could be used in conjunction with stem cells to provide them with a didactic component and guidance for their differentiation. The wound bed can be treated with autologous bone marrow–derived cultured mesenchymal stem cells, and bioengineered skin can then be placed over the stem cells. We have successfully used this approach with scleroderma digital ulcers (V. Falanga, unpublished), and by delivering the stem cells with a modified fibrin spray. However, more work needs to be done to confirm these findings and to conduct appropriate clinical studies. Fig. 71.13 illustrates this type of approach [102]. The use of stem cells, including mesenchymal stem cells, can obviously considered a type of bioengineered skin. This is particularly appropriate when the stem cells are delivered topically. We showed this in a publication where autologous bone marrow–derived cultured mesenchymal stem cells were delivered in a fibrin spray to accelerate healing in murine and human wounds [103]. The polymerized fibrin in that study proved to be a rather ideal vehicle for the spraying of the stem cells onto the wound. The study made use of a double-barreled syringe, with fibrinogen in one side and thrombin in the other barrel; the stem cells were suspended in the fibrinogen solution. Upon pushing the plunger of the double-barreled syringe (connected to a CO_2 source), the cell-containing fibrinogen was mixed with thrombin, thus resulting in polymerization to a fibrin spray. The movie clip (approximately 10 seconds) shows how this approach works [104]. This initial publication has been followed by a double-blind, randomized, placebo-controlled trial in venous ulcers, which was also

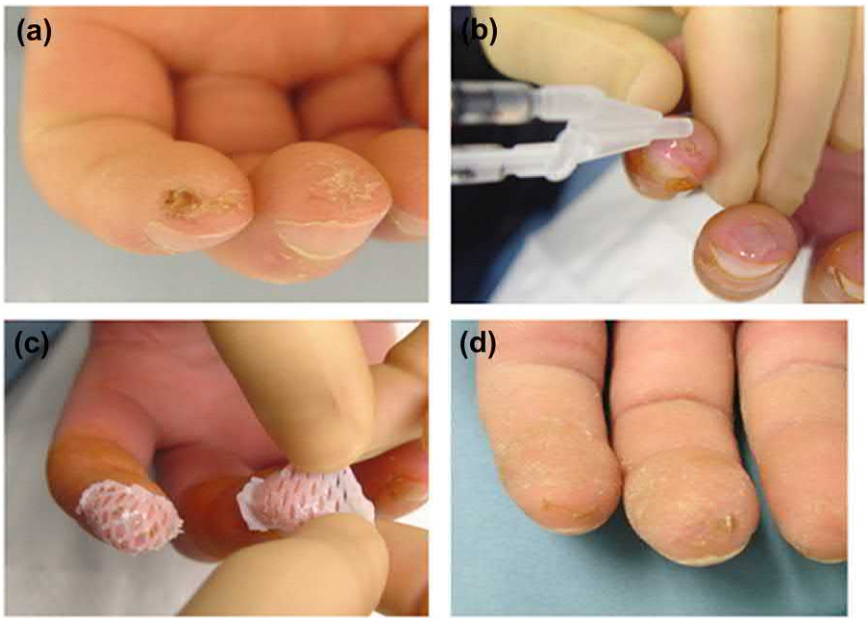

FIGURE 71.13 (A) Digital ulcers in a patient with systemic sclerosis (scleroderma). (B) autologous cultured bone marrow–derived mesenchymal stem cells being applied within a fibrin delivery system. (C) The digital ulcer was dressed with bioengineered skin (Apligraf). (D) Results observed 1 month later. *V. Falanga, ©2011.*

sponsored by the NIH. The results showed that the mesenchymal stem cells will accelerate venous ulcer healing (V. Falanga, 2019; unpublished at this time).

For every effort in bioengineered skin and its success in clinical trials of chronic wounds, there are multiple other efforts that are unsuccessful. In spite of recent regulatory guidelines that require investigators and companies to show the final results (even if not successful) there are surely situations whereby the final results are not reported in a timely fashion. One exception of the difficulties with clinical trials and bioengineered skin constructs was the study by Kirsner et al., where initially they published and reported success in venous ulcers with a staged spray of fibroblasts and keratinocytes [105]. However, this was a small study (phase 2) with a limited number of patients. Based on that initial study, a decision was made to proceed further with the smaller concentration of cells. However, when testing was expanded to a phase 3 trial, comprising a total of 673 patients with venous ulcers, no difference was found between the active group and placebo cohort [106]. The authors suggested that the negative results may have been due to differences over time in cell viability. However, it is quite possible that the phase 2 trial did not have the stringency to justify a very large and expensive phase 3 trial, at least without repeated, confirmatory testing of the cell concentration that was to be used.

Other considerations

It is very easy to be and remain excited about the prospects and the future of bioengineered skin. In the author's opinion, acute wounds and burns remain a prime target, likely leading to increasingly successful outcomes. The question is whether healing impaired wounds, where a definite healing defect plays a major role, may require a different or alternative approach. Here one needs to consider whether bioengineered skin, or similar approaches, may actually increase the energy requirement of the wound. Thus overstimulation of the wound may, possibly, not be necessarily ideal. Thus there may be an initial successful early outcome that is eventually not sustained. One possible solution is to combine the use of bioengineered skin with efforts to decrease those energy requirements of the chronic wound. This notion may require manipulation of cells, epigenetic approaches, and more creative construct materials to achieve and maintain wound coverage.

Conclusion

Bioengineered skin constructs have played a lead role in the tissue engineering field, particularly in terms of commercial successes. Like the natural tissue, these constructs are designed to mimic, the engineered tissues are proving to be dynamic in the way they respond to environmental stimuli. The understanding of how these products induce healing is evolving. Greater understanding of how engineered tissues promote wound healing is being achieved through the clinical research, presented earlier, being done with Apligraf in different wound types. Initially the action was believed to be similar to skin grafts where the patient's native tissue was replaced with the graft tissue. It is now believed that the mode of action is more complex. Stimulation of healing by secondary intention appears to be the primary mode of action; however,

there may be other mechanisms at work as well. The work being done in this area is very exciting, and researchers have only begun to scratch the surface in terms of understanding the mechanisms and environmental stimuli involved.

Chapter 72

Principles of tissue engineering for food

Mark Post[1] and Cor van der Weele[2]

[1]Department of Physiology, Maastricht University, Maastricht, The Netherlands, [2]Department of Social Sciences, Wageningen University, Wageningen, The Netherlands

Introduction

Most techniques in tissue engineering are being developed for medical applications. The potential benefits of tissue engineering and regenerative medicine for the repair of nonregenerative organs in the human body have not really been questioned. It is generally accepted that these technologies offer therapeutic opportunities where very limited alternatives are at hand to improve the quality of life. Therefore a tremendous amount of government-funded research and business R&D has been and continues to be devoted to tissue engineering. Still, 30 years after its introduction, regenerative medicine by tissue engineering is not part of mainstream medical therapy, and developments in regenerative medicine are moving into either cell-free biomaterials [1] or into cell therapy, cytokines, or small molecules [2]. This suggests that the technical challenges to generate tissues that are fully functional and vital upon implantation are substantial.

As a spin-off from this research activity, techniques in tissue engineering and regenerative medicine may be used to produce organ tissue as food. This idea is not new and has in fact been proposed by Winston Churchill in his 1932 book "Thoughts and adventures" [3] and by Alexis Carrel [4]. Although the biological principles of tissue engineering for food are very similar to the medical application, there are also differences in goals, scale of production, cost–benefit ratio, risk–benefit ratio, ethical–psychological considerations, and regulatory requirements.

To date, no products are yet on the market, but more than 20 startup companies worldwide and one medium-sized enterprise are working toward market introduction in the coming years. They are mostly funded by private capital including investments by large traditional animal protein suppliers.

In this chapter the specifics and the challenges of tissue engineering for food production are highlighted and discussed. The focus will be mainly on tissue engineering of meat as a particularly attractive and suitable example.

Why tissue engineering of food?

Growing food through domestication of grasses, followed by other crops and by animals, had a 13,000 years head start. The success of large-scale food production likely determined the growth and sophistication of our civilization [5]. Why would we try to replace the relatively low-tech, cheap, and easy natural production of food by a high-tech complicated engineering technology that is likely to be more expensive? There are two main reasons why current ways of food production need to be reconsidered.

First, with projected growth of the world population to 9.5 billion and an even faster growth of the global economy, traditional ways of producing food, and in particular meat, may no longer suffice to feed the world [6]. Meat production through livestock, for example, already seems maximized by the occupation of 70% of arable land surface, yet the demand for meat is projected to increase by 70% over the next four decades [7]. Without change, economic theory dictates that the resulting scarcity will lead to uneven distribution and high prices. This may lead to further intensification of meat production, which will increase the pressure on crops for feeding livestock rather than people. The arable land surface could be increased but this would occur at the expense of forests with, predictably, unfavorable climate consequences. A technological alternative such as tissue engineering of meat might offer a solution. In fact, the production of meat is a good target for tissue engineering and especially beef, as cows are very inefficient in transforming vegetable proteins into edible animal proteins, with an average bioconversion rate of 15% [8]. If this bioconversion efficiency can

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00074-5

be improved through tissue engineering, it will predictably lead to less land, water, and feedstock use, while the potential energy requirement is debated [9–11].

The second major reason for considering alternatives to livestock is greenhouse gas (GHG) emission. Livestock accounts for approximately 20% of the total greenhouse emission [12], partly due to fermentation of feed-in ruminants such as the cow. Fermentation produces methane that is a 20 times more powerful GHG as carbon dioxide, yet shorter lived. GHG also comes from crop growth and energy consumption across the entire chain from feed production to transport to the supermarket. Tissue engineering of meat also takes energy, but even if more energy is needed, this in the future does not necessarily equates with more GHG emission, when renewable energy will become mainstream.

In addition to these major issues with industrial dimensions of livestock breeding and feeding, there is an increasing public pressure to improve animal welfare and to reduce the risk of zoonoses.

Although there are other alternatives to avert an imminent meat and food scarcity, tissue engineering of skeletal muscle and fat to form meat is one that is being explored. It could be an excellent example of valorization of medical technologies that goes well beyond the traditional medical need and market.

Specifics of tissue engineering for medical application

The general outline of tissue engineering for food is exactly the same as for tissues constructed for medical purposes, although currently developed meat products are based on small organoids of skeletal muscle and adipose tissue or on cells only, sufficient to create minced meat variants. For larger full-thickness tissue, somatic cells are seeded onto or printed with a temporary scaffold made of biocompatible natural or synthetic polymer. Subsequently, the cell scaffold combination is cultured under tissue-specific biochemical and physical conditions to mature into the target tissue until it reaches maximum resemblance with the targeted tissue.

However, there are differences as well that could have major implications for the technologies that need to be developed and used.

Uniqueness

To avoid immunologic or physiologic host versus graft reactions, medical tissue engineering aims to create a tissue construct that is mostly personalized and produced as a unique sample or at best in limited numbers [13]. Its uniqueness is determined by its shape and form and by the cells. The shape and form is adapted to the particular environment in the recipient by, for instance, rapid prototyping, molding, or casting [14].

In many examples of medical tissue engineering, cells producing the construct are of homologous origin, thus patient derived [15]. The number of tissue-specific cells or even progenitor cells that you can harvest from patients is typically small and needs to be expanded before they can be used to populate a construct. The amount of cell culture that is required to reach sufficient cell numbers is a time- and labor-intensive process, especially when performed for a personalized, unique product. In many cases the tissue still needs to undergo some form of conditioning, which again is time and labor intensive.

Thus producing patient-specific products is labor and time intensive and therefore extremely costly. In medical applications the cost of production is weighed against the benefit for the patient, which is usually expressed in quality-adjusted life years (QALYs) that are gained through therapy. The value of a single QALY is set at approximately 40,000 USD [16], which sets the economic boundary condition of producing tissue-engineered constructs for medical application. The cost–benefit analysis is therefore very different for medical application or food production.

Function

Once implanted, the tissue-engineered products need to be functional and metabolically active, which means that they need to integrate with the circulation, the nervous system, and the endocrine regulation. The integration is not only important to sustain and coordinate function [15], but it is also crucial for homeostatic control by the recipient body. A good example is tissue-engineered myocardium to replace scar tissue in the heart that has developed after myocardial infarction. Myocardial tissue is continuously active in a highly coordinated manner and is internally as well as externally regulated. Implanted tissue-engineered constructs need to be fully integrated to maximize efficacy and minimize the risk of adverse effects (see box).

(Perhaps separate box, vignette) Myocardial tissue has an extremely high metabolism to support the arduous labor of continuously alternating contraction and relaxation. To supply the tissue with sufficient nutrients and oxygen and to remove waste, the heart is highly vascularized with a microvascular density of 1 capillary per cardiomyocyte [17]. Without sufficient blood supply, tissue-engineered myocardial constructs would die within 30 minutes. The newly implanted myocardium also needs to integrate electrically with its neighboring myocardial cells. The heart shows continuous and highly integrated electrical activity as illustrated by the typical monomorphic and regular ECG. Failure to integrate through

dyssynchronous electrical activation or through regional changes in conduction velocity can lead to lethal arrhythmias. Indeed in early trials using skeletal myoblasts to replace myocardial tissue, arrhythmias constituted the principle risk [18]. In addition to these already challenging forms of integration, the heart is a key effector in the homeostatic control of the body for instance during exercise, meals, or abrupt changes in temperature. The heart is therefore under tight control of the autonomic nervous system that regulates heart rate, contractility, and coronary flow according to requirements imposed by the body. The implanted tissue needs to respond to these stimuli in concert with the native tissue to avoid dyssynchrony in electrical and mechanical activity during exercise for instance. An even more sensitive homeostatic mechanism that is essential to coronary flow regulation is the autoregulatory control of blood vessel diameter through organ-specific myogenic responses of the vascular smooth muscle cells [19]. Organs such as the brain, heart, and kidney have an important autoregulatory blood flow control that is partly dependent on these myogenic responses. At present, it cannot be predicted how the lack of this response would affect the function of the implanted tissue-engineered myocardium, but it would be safe to optimize engineered tissues for anatomic, histologic, as well as physiologic characteristics.

The example of the heart illustrates the immense challenge for engineers and biologists to create a fully integrated tissue from cells of defined stages of differentiation and from biomaterials. Some of these challenges might be theoretical and will be resolved by remodeling of the construct after its implantation, but others might prove essential for safety and function.

Although function is a criterium in food as well, it typically refers to material (dough formation, water retention, and cooking behavior) and organoleptic functions, that is, sensory qualities during eating.

Skeletal muscle and fat tissue engineering

To understand the specific requirements of tissue engineering of consumption meat, a brief summary of the state-of-the-art techniques to tissue engineer skeletal muscle and fat is necessary. It is envisaged that the first tissue-engineered meat will be a form of processed meat such as in hamburgers or sausages, although a first proof of concept for a full-thickness meat product has been introduced recently [20]. Producing processed meat in a minced meat scenario is translated into tissue engineering of a large number of separate pieces of muscle and fat tissue that are later combined into a patty or a sausage (Fig. 72.1).

Tissue engineering of skeletal muscle

Cells

The satellite cell is considered to be the tissue-specific stem cell, responsible for in situ regeneration of damaged muscle, although more pluripotent skeletal muscle–derived stem cells have been described as well (Figs. 72.1 and 72.2) [21]. Culturing of skeletal muscle cells from satellite cells includes a proliferation phase of myoblast offspring followed by further differentiation into skeletal muscle.

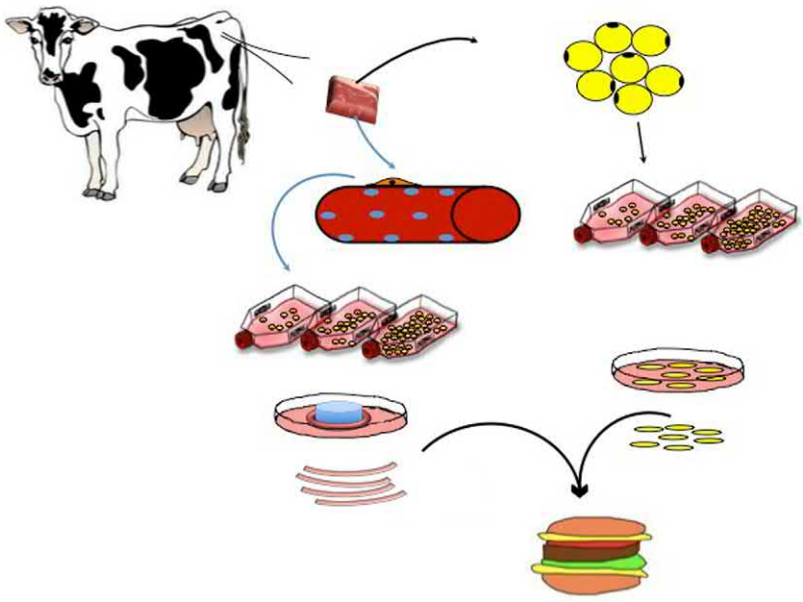

FIGURE 72.1 Tissue engineering of meat.
From a biopsy of a cow, ASCs and satellite cells are harvested and cultured separately. The satellite cells are seeded in a gel onto a culture plate in a ring around a central column. They self-organize into a bioartificial muscle. The ASCs are differentiated into adipocytes and cultured in a gel or scaffold, without the need for anchors. Minced meat, a hamburger, for example, will be constructed from a mixture of bioartificial muscles and fat tissue. *ASCs*, Adipose tissue–derived stem cells.

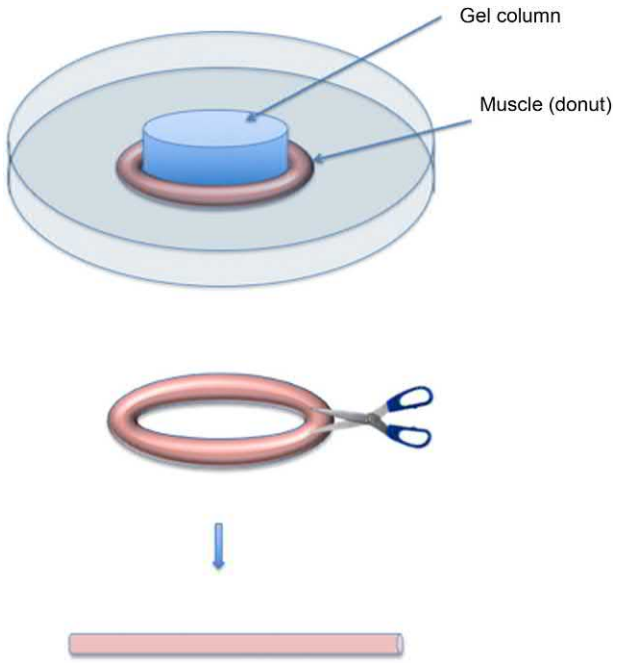

FIGURE 72.2 A bioartificial muscle from bovine satellite cells, 3 weeks after loading the gel onto the culture dish in ring structure around a central column. After 3 weeks the rings are harvested, cut open and as strands incorporated into meat product.

The goal of the proliferation phase is to maximize the number of doublings. With the current isolation and culturing methods for myoblasts, more than 30 doublings can be achieved. With proper conditions, this can probably be improved to 50–70 doublings [22], in accordance with the Hayflick limit. A major improvement to keep the myoblasts in the replication phase comes from harvesting them through a combination of mild enzymatic treatment and trituration of skeletal muscle fibrils according to Collins et al. [23], although the exact optimized method may be species specific. During harvest the stem cell behavior is maintained in a niche environment [24]. The elasticity of the substrate, for instance, is important to maintain the stemness of satellite cells that are cultured [25]. During the proliferation phase of myoblasts in our hands, the effect of physiologic substrate stiffness on proliferation was mild, higher than on very flaccid substrates (3 kPa range) but not significantly different from stiff, plastic, and surfaces [26]. Coating the culture surface with laminin and collagen IV, two major basal membrane proteins, has also some impact on the proliferation rate of myoblasts [27]. In addition, there are many biochemical stimuli reported to have an effect on stemness such as TGFβ1, Pax7, Notch, and Wnt [28], which should lead to higher doubling numbers. These mechanisms can be targeted with specifically designed agonists or with known biological modulators in order to delay differentiation. For instance, we recently established that inhibition of MAPK P38 prolongs stemness and increases the amount of doublings in bovine myoblasts without affecting their differentiation capacity [29]. Once sufficient numbers of cells have been generated, groups of cells can be stimulated to differentiate.

Gel and seeding

Differentiation is primarily initiated by reducing the serum concentration in the medium. Cells are typically cast in a collagen gel with or without Matrigel supplement or they are seeded into a biodegradable polymer structure. When taken up in the gel, it is important to provide anchor points in the culture dish. Alternatively, the cell–gel mixture can be deposited around a central column. Typical for mesenchymal cells, differentiating satellite cells will organize the gel to the smallest structure possible. For this the gel has to be functional so that cells can contract the gel.

In addition to the specific functionality of the gel, the conditions for the biomaterial component of muscle (and fat) tissue–engineered constructs for food purposes are as follows:

1. Nontoxicity of biomaterial or its degradation products upon digestion.
2. Nonallergenicity of biomaterial or its degradation products upon digestion.
3. Residual biomaterial should be digestible.
4. Supply of material in industrial quantities, not coming from livestock.
5. Material should be cheap.

Any of these characteristics is unchartered territory and the present information on biomaterial–cell combinations should be reevaluated in the light of these requirements.

It is likely that nontoxicity of ingested material correlates with biocompatibility in current cell-based assays. If a particular biomaterial is not cytotoxic in direct exposure to cells, it probably is not toxic after ingestion either. In fact, the absence of toxicity in cell-based assays might be too stringent a criterium as some materials will be digested before absorption or may not be digested or absorbed at all. These reasonable hypotheses, however, should all be formally tested for each biomaterial as it is equally conceivable that rapid mechanic and enzymatic degradation by the gastrointestinal system release other metabolites that are cytotoxic. The biomaterials that have been tested with muscle cells and adipocytes all comply with the requirement of being noncytotoxic, but none of them have been tested after oral intake.

Nonallergenicity is less obvious. Most ingested proteins or materials do not lead to an allergic reaction, but some foods, such as eggs, milk, shellfish, and peanuts,

are particularly allergenic [30]. Biomaterials used in tissue engineering for food therefore will have to be tested for allergenicity as well.

In a functionalized gel, satellite cells or myoblasts will gradually compact the gel in a process called gel contraction or collagen contraction if the gel is collagen based. With the anchors provided the smallest configuration upon compaction is a thin tissue strip in between the anchors. When the cell−gel combination is placed in a ring, it remains a ring structure, just more compacted. This will later form the myooid or bioartificial muscle (BAM) (Fig. 72.2) [31]. Differentiation leads to the merging of myoblasts into primitive skeletal muscle cells, called myotubes. At this time, the cells will start to express early stage skeletal muscle markers such as MyoD, myogenin, and embryonic isoforms of muscle myosin heavy chain [32]. This cues for subsequent hypertrophy: metabolic, biochemical, and mechanical. After organization into a BAM and with subsequent differentiation, the muscle will develop increasing tension in the ring structure as it compresses the noncompressible central column. The resulting tension is a major trigger for protein production [33], the optimization of which is the final goal of tissue engineering of food. Several other mechanical stimuli such as passive cyclic stretch and electrical stimulation have been investigated. Interestingly, cyclic stretch did not further improve protein synthesis but had in fact a slight negative effect [34,35]. This result is somewhat controversial as others have observed positive effects of cyclic stretch on muscle maturation [36]. In addition to passive stretch and tension, we and others have investigated the effect of electrical stimulation to further stimulate protein production and force generation [37]. In combination with specific coatings, electrical stimulation did lead to earlier maturation of the skeletal muscle fibers and more protein production. More extensive data on the modes and efficacy of mechanical stimulation for muscle differentiation can be found at Refs. [38−40].

With the above-described techniques, it is feasible to generate BAMs of small dimensions, with limited mass transfer of nutrient and oxygen through diffusion. No attempts have been made yet to create large BAMs with a built-in blood vessel or channel system conducting a continuous flow of oxygenized, nutrient-rich medium. However, printing and biomaterial technologies have been described, which would make this possible and certainly testable [41−43].

Although contractile proteins comprise the bulk of protein content and quality of muscle tissue, there are other proteins that are important for texture, color, and taste of the muscle tissue. One particularly important protein is myoglobin. As a heme-carrying protein it is responsible for the pink color of meat and a major carrier of iron. It contributes nutritional value and will likely determine taste as well. The transcriptional regulation of myoglobin is reasonably well understood and involves the transcriptional activators MEF2 and NFAT/calcineurin [44] and coactivator PGC-1α. It appears that contractile activation of muscle in the setting of hypoxia will stimulate myoglobin maximally. We have indeed observed that in differentiating bovine myoblasts the expression increases with decreasing oxygen concentration (unpublished data). It is therefore feasible to increase the myoglobin content using stimuli that are compatible with tissue engineering for food.

In summary the effective culture of skeletal muscle is possible with current technology. There are numerous options for refinement and extension suggesting that it will take time and effort to optimize the product. In 2013 we presented the first hamburger made from cultured bovine skeletal muscle that was cooked and eaten (Fig. 72.3). It was identified as meat by the tasters and was reported to have a meat-like texture. It was presented as a proof of principle and not as a real product yet as exemplified by the astronomical cost and the fact that a traditional, nonscalable, cell culture method was used for its production.

Tissue engineering of fat

Cells

Tissue engineering of fat tissue is less advanced than that of skeletal muscle because the medical need seems less pressing. Indeed, for the purpose of plastic surgery, tissue engineering of fat might be applicable in the clinic and scant efforts have therefore been made to create adipose tissue constructs [45]. However, differentiation of mesenchymal stem cells (MSCs) into adipocytes is one of the hallmarks of MSC phenotyping, and as a result the

FIGURE 72.3 The World's first hamburger cultured exclusively from bovine myoblasts. The hamburger was presented to the public in August 2013. The individual strands are clearly identified.

various steps toward differentiation into adipocytes have been described in great detail.

Preadipocytes are precursors of fat cells and characterized by the expression of PREF-1 (preadipocyte factor 1 aka Dlk-1 or delta-like 1 homolog), CD105 (endoglin), and the absence of CD45 and CD31. These cells are typically fat tissue derived and therefore often referred to as adipose tissue−derived stem cells (ASCs). ASCs are extracted using a combination of mechanical disruption and collagenase treatment. ASCs adhere to plastic and form initially a heterogeneous population [46] that can differentiate into adipocytes, chondrocytes, and osteocytes. Unfortunately, these cells undergo limited proliferation, and after a couple of passages, they lose their capacity to differentiate [47] and are therefore not suitable for tissue engineering for food. In contrast, human multipotent adipose-derived stem cells (MADS) that are derived from infants continue to proliferate and retain their differentiation capacity [47]. It remains to be shown whether this is a consistent finding across species. If so, MADS can be harvested from young animals, and these cells can then be used for tissue engineering of edible fat. An alternative cell source for the production of fat tissue has been obtained by so-called ceiling culture of digested human adipose tissue [48]. In this technique, two types of fibroblast-like cells can be distinguished, both of which have a strong capacity to proliferate while retaining their ability to differentiate into adipocytes. It is likely that these cells can be harvested from bovine adipose tissue, as it has already been successfully done in humans, rats, and sheep [48].

Finally, it is possible that satellites themselves may differentiate into adipocytes as shown by Asakura et al. in mouse satellite cell−derived primary myoblasts [49]. The species dependency of this phenomenon requires further study.

Biochemistry of adipocyte differentiation

Differentiation of preadipocytes is typically initiated by starvation, that is, reduction of fetal bovine serum (FBS) and a temporary cocktail of isobutylmethylxanthine (IBMX), dexamethasone, and insulin. In some protocols, triiodothyronine [50] and/or the PPAR-γ ligand rosiglitazone [51] are added to the differentiation stimulus. It remains to be shown how much and if any of these stimulators are still present upon harvesting of the tissue after 3−4 weeks of differentiation, but it is safe to assume that these agents should be replaced by approved food additives (see next). IBMX is a very potent methylxanthine and a nonselective phosphodiesterase inhibitor that is not approved as a drug. IBMX induces the activation of PPAR-γ, a critical transcription factor required for adipocyte differentiation [52]. It probably acts through induction of intracellular cAMP. If so, other agents that act through induction of cAMP and that are approved for drug or food purposes could replace IBMX. Dexamethasone is a glucocorticosteroid that acts through the intracellular glucocorticosteroid receptor (GR) with a number of intermediate products that eventually upregulate C/EBPα (CCAAT enhancer binding protein). Together with PPAR-γ, C/EBPα is a key transcription factor for adipogenesis. The steroid-stimulated GR requires interaction with promoter elements in the intermediate products; therefore it will be difficult to find a suitable substitute. The third component is insulin, which is typically short lived and natural, and is therefore less likely to be a regulatory issue.

Given that most free fatty acids (FFAs) are natural ligands for PPAR-γ, we and others set out to study a range of saturated, ω-5, ω-7, and ω-9; unsaturated; and branched FFAs for their ability to differentiate bovine preadipocytes and indeed found some FFAs that have the same performance as the dexamethasone/IBMX/insulin cocktail while being perfectly food compatible [53].

Scaffold and cell seeding

The fat cells can and should be captured in a scaffold to form fat tissue. The same considerations for the biomaterial apply that were presented for skeletal muscle tissue engineering, yet the specific biochemical and physical cues needed to mature and maintain fat cells are different from satellite cells. It is evident from the experience of many investigators that mature fat cells are fragile, prone to apoptosis, and are terminally differentiated. For that reason, most cell seeding on scaffolds is performed in the preadipocyte stage [54−57] or is even performed with cell lines such as the mouse 3T3L1. In the vast majority of studies, the constructs were implanted at an early stage, and in vivo adipogenesis was allowed to develop for a couple of weeks after which the state of differentiation was assessed. This suggests that it is difficult or time-consuming to reach full adipocyte differentiation and mature fat tissue by in vitro conditioning alone. A good summary of material and cell combinations that have been studied can be found at Refs. [58,59].

Bio-based materials that have been used for engineering adipose tissue include collagen [60], hyaluronic acid [61], fibrin [62], and chitosan [63], which are already present in our diet; so it is not to be expected that tissue-engineered food with these materials will augment the risk of toxicity or allergy.

Of the synthetic or semisynthetic biomaterials, polylactic-co-glycolic acid (PLGA) [64] and esterified hyaluronic acid [61,65] are the most promising in terms of in vivo differentiation of adipocytes. In some studies the addition of FGF-2 seemed to facilitate adipose

differentiation. Confirming the results of others, but using bovine ASCs, we observed little development of fat tissue in electrospun PLGA scaffolds and fibrin sheets, but acceptable adipogenesis in alginate and in RGD functionalized alginate (unpublished data). A recent study showed full-blown human adipocyte differentiation using a combination of alginate and collagen [66], strongly suggesting that the right choice of biomaterial can be crucial in driving adipogenesis.

Similar to skeletal muscle engineering and MSC differentiation, stiffness of the matrix may be an interesting parameter to affect specification and maturation of ASCs in vitro [67]. Human bone marrow–derived MSCs assume quiescence when placed on a 250 Pa surface, which represents the natural elasticity of fat tissue. In this quiescent state, they cease to proliferate, enter differentiation, and develop into adipocytes that form adipose tissue [68].

As of late, the use of decellularized extracellular matrix has been gaining attention in regenerative medicine [69]. It is obvious that this technology will not be applicable in tissue engineering of food since it requires harvesting massive amounts of original tissues, and the animals would still have to be bred as donors of these tissues.

In summary, growing edible pieces of fat through tissue engineering requires an optimal combination of biomaterial and chemical, biochemical, and physical conditioning. The goals are in part different from fat tissue engineering in, for instance, reconstructive surgery, and many variables have yet to be optimized.

Specifics of food tissue engineering

The two major advantages of tissue engineering for food are that the eventual product can be made in large series and that it requires no functional integration. Instead, food tissue engineering faces at least three new challenges.

The first is the need to generate sufficient tissue volume to feed large populations. The scale of cell and tissue culture will be several orders of magnitude higher than needed for medical applications: the hamburger presented in 2013 was made from 10^{10} bovine myoblasts. The focus of tissue engineering for food will therefore shift from creating individualized constructs to mass production. This shift has major implications for bioreactor design, biomaterial selection and production, culture medium optimization, optimization of tissue conditioning, and quality control of, for instance, the genetic stability of the cells.

Second, food production by tissue engineering can only be a viable alternative to conventional livestock meat production if the bioconversion of vegetable proteins to edible animal proteins is more efficient than in the common domestic animals such as cows and pigs. To attain this efficiency in cell culture, it is highly likely that medium has to be recycled after having been spent.

The third challenge is that tissue-engineered food needs to be very similar to, if not exactly the same as, the conventionally produced food it intends to replace. Meat, for example, has been replaced with very limited success by products made of vegetable proteins. The typical texture, color, and taste of meat are apparently still very difficult to mimic through current innovations in food technology, although the recent addition of leghemoglobin to plant-based substrates gives the appearance of "bleeding" and arguably the required taste. In some cases the science of these characteristics is not far enough advanced to design rational strategies for synthesis. For instance, the chemistry of the taste of meat is very complex and incompletely understood and therefore mainly relies on subjective analysis by taste panels [70]. The only rational strategy therefore is to strive for the best mimicking biochemical composition, that is, the one most closely resembling that of livestock meat.

Scale

The volume of global meat production is 330 million tons/year of which 79.8 million tons is beef [71]. Given that each gram of muscle tissue contains approximately 5×10^6 cells, this amounts to 1.5×10^{21} cells/year, provided that all muscle progenitor cells differentiate into mature skeletal muscle cells and get incorporated into skeletal muscle. This number may be an order of magnitude off, due to inaccuracies with respect to muscle type, fat content, etc., but it provides the rough scale to which cell production needs to be industrialized.

Currently, large bioreactors contain up to 25,000 L or more with a maximum cell load of 7×10^6 cells/mL so 35×10^9 cells/bioreactor [72,73], provided that the cells are cultured in suspension. Mesenchymal cells such as satellite cells or myoblasts need to adhere to surfaces to sustain proliferation and survival. Several microcarriers have been designed to grow large numbers of adherent cells in bioreactors [74]. This would require a stage in the process where cells are again detached from the carriers, which could be as simple as just changing temperature [75]. The limits on bioreactor size and number of cells per mL further depend on a number of factors such as oxygen transfer, nutrient delivery, and washout of waste. These factors are all related to unequal mixing of the fluid. Stirring or otherwise agitating the cell mixture might solve most of the problems, but there is a limitation to the agitation that mammalian cells can handle in the absence of a firm cell wall that withstands high shear stresses [76].

As a result, the cells may suffer from insufficient and inhomogeneous transfer of oxygen and nutrients [76].

Inadequate mixing of bulk fluids also becomes more difficult as the volume of the bioreactors increases. Simulations in smaller tanks show that gradients of pH and nutrients reduce cell growth and maturation [77]. Another important factor in scaling-up cell culture in large bioreactors is adequate removal of CO_2. Carbon dioxide is typically removed from the medium through a combination of agitation and sparging: controlled air bubble inlet to retrieve CO_2 from liquid and bring it into the gas phase. Accumulation of CO_2 presents an important limit to mammalian cell culture due to the relatively low agitation and air sparging rates that are utilized [78]. The optimal dissolved carbon dioxide (dCO_2) level at which cells thrive varies between cell types, but relatively high dCO_2 levels universally inhibit cell growth and protein production [79,80].

Even when the technical limitations of large-scale cell culture are overcome, the sheer number of cells needed to produce sufficient meat to feed the world population in 2050 would still require a mind-boggling amount of bioreactor space. Assuming that each bioreactor has a 4-week turnover of its cell content and would therefore have 13 operation cycles per year, one would still need 600 million bioreactors of 25,000 L, roughly 1 for every 10 humans, again the numbers can be an order of magnitude off. These already staggering figures do not even take into account that a seed train is needed to get sufficient cells for the initial start of a large volume bioreactor culture [73]. In addition, for skeletal muscle production to produce protein-rich and firm muscle tissue, the proliferation phase should be followed by differentiation and conditioning of the muscle progenitor cells, which also requires bioreactor space.

For this volume of bioreactor space, one needs equivalent volumes of culture medium. The production and storage of these amounts of medium will be a logistic challenge unless powder formulations are being developed that can be easily reconstituted within the same production line as the cell culture. In making powder formulations of medium, the addition sequence and the milling equipment are important parameters [73].

Directly related to the scale of cell culture is the quality control of the progenitor cells. Cells may undergo differentiation toward undesirable phenotypes, they may be epigenetically modified or they can accumulate karyotypic abnormalities over time. For safety and efficacy reasons, these undesirable outcomes should be detected and controlled [81,82]. Current technologies such as PCR and fluorescent in situ hybridization are not designed for large sample sizes or for in-line monitoring of quality. Several other techniques based on surrogate physical parameters such as electric conductivity or Raman spectra have been developed, which are capable of in-line monitoring of the cell culture process, which will hopefully be sufficiently robust to guarantee the quality of the cell culture [83]

From these considerations, it may be clear that scaling-up mammalian cell culture to the level that is needed for safe and high-quality production of one of our basic foods is a nontrivial enterprise and involves substantial innovation through chemical and mechanical engineering in close collaboration with cell biologists.

Efficiency

Although cell culture of mammalian cells has been evolving over the last five decades, relatively little attention has been paid to optimizing the culture process in terms of efficiency.

In such an optimization strategy, hundreds of variables can be—and have to be—controlled to make the process reliable and efficient. These variables include all individual components of medium and serum but also physical culture conditions. The vast number of variables that likely interact and therefore need to be approached in their contexts creates challenges as well as opportunities. The level of each variable (e.g., feed component, biochemical, and biophysical culture conditions) and the possible interactions with other variables need to be established. Current culture protocols have largely been developed through trial and error, leading to a gradual optimization, whereas it clearly requires a more systematic approach. For bacteria and simple eukaryotic organisms such as yeast, a systems biology approach is starting to be developed [84–86]. Ideally, a biological systems strategy should be established for more complex mammalian cells as well. Alternatively, a large-scale, high-throughput analysis is used to optimize culture media. This is true for the nutrient part of the culture medium as well as for the FBS, together, a formidable task. Cell culture media for tissue engineering of food and arguably for other applications as well should be completely synthetic and chemically defined. A limited number of such products have been developed for medical purposes, and it is to be expected that more of these will become available [87]. In our hands, a selection of xeno-free media supports bovine myoblast proliferation, although serum-based media is still superior (unpublished data).

Opportunities to increase the efficiency of skeletal muscle cell culture are also numerous. In the production phase, recycling mechanisms and combining culture with nutrient supplying systems through, for instance, photosynthesis would create substantial benefit and value [11,88]. Given the scale of cell culture, these recycling mechanisms need to be an integral part of the production chain.

Taste, texture, juiciness

A large number of small peptides and fat dissolved aromatic substances have been described that contribute to

the taste of meat [70,89–92]. However, the relative importance of each component is unknown. The reaction between certain sugars or glycosylated peptides and fatty acids probably interacts especially during cooking of the tissue to create the specific taste of meat in the so-called Maillard reaction [93,94]. Taste is a subjective sensation and blinded panels in fact still primarily judge the taste of meat. To add to the complexity, in addition to the chemistry of the meat, the cultural background of the panelists appears to weigh in on the evaluation of meat products [70]. It has become clear that the taste of meat can be affected by feed and not so much by the strain of cattle [91], suggesting that the feed conditions of the cultured skeletal muscle can also be important for taste development. Even postmortem conditions determine the taste of meat as a result of oxidation of proteins, sugars, and fatty acids during controlled decay of the muscle [90]. Thus in tissue engineering of meat, taste is an extremely important feature to be investigated and taken into account. On the other hand, it should be borne in mind that today most processed meats are artificially flavored. The flavor industry has reached a level of sophistication where numerous flavors can be added to food components with such subtlety that it stays unnoticed by the nonexpert consumer.

Texture of meat is mainly determined by the presence of intramuscular connective tissue and its perimysial distribution [95] and the amount and distribution of fat [96]. Fat is also the main determinant of juiciness, although the percentage of fat in various meats shows modest variability between 0.5% and 8.0% with a 3% average [97]. As intramuscular connective tissue and content can be affected by feed and cell mixture, these characteristics can likely also be optimized in cell/tissue culture and should be primary targets to produce high-quality meat.

It is not obvious that tissue engineering for food is a cheaper proposition than other alternatives such as vegetable protein meat replacers. Therefore the outcome should be indistinguishable from livestock grown meat in terms of taste, color, texture, and juiciness. The quality should also be constant and preferably more predictable than for the natural product.

Although primarily meant as a credible alternative for consumption meat, culturing of meat under precisely determined conditions will greatly contribute to meat science in general and in particular to the determinants of taste, texture, nutritional value.

Enhanced meat

Tissue engineering of meat enables the creation of novel products. All vertebrate animals have satellite cells in their muscles, and currently, there is reason to believe that skeletal muscle can be tissue engineered from these species. We have found that very little adjustments in protocols were needed to transfer satellite cells from mice, rats, pigs, or cows into mature skeletal muscle. Novel meats from hitherto unused species or from a combination of cell sources could be made. It is, however, more important to design and produce cultured meat that is healthier than the original product.

One particularly interesting example is to increase the content of conjugated linoleic acid (CLA) (octadecadienoic acid 18:2). CLA is naturally present in meat, and the main source of our dietary CLA is beef fat and bovine milk [98]. CLA is formed in the stomach by bacteria that conjugate linoleic acid, which is subsequently taken up by the fat cells. This mechanism can be used to load tissue-engineered fat with CLA to increase it to levels that are associated with anticarcinogenic, antidiabetic, and antiatherogenic effects, as well as a strengthening of the immune system, bone metabolism, and improvements in body composition [98].

Another health issue associated with the consumption of red meat is the increased risk of colorectal cancer [99]. It is not completely clear what the causal factor in meat drives the increased risk, but heme iron or its associated oxidative effect has been frequently incriminated. If this indeed turns out to be a causative factor, meats can be produced with less heme iron content, since this content is already lower than normal when culturing under ambient oxygen conditions.

Other foods

Although tissue engineering of meat is probably the first and best example of food production through this technology, there are other foods that could be tissue engineered. Currently, the pressing need to create an efficient and environmentally sound alternative to agricultural food production focuses our tissue engineering endeavors first and foremost on beef. Other staple meat products are being pursued for different reasons such as poultry to improve animal welfare, or fish, for maintenance of biodiversity. In fact, the first showcase of tissue-engineered food constituted goldfish meat to be used by astronauts on their space missions [100].

Milk production by tissue-engineered mammary glands might also be feasible in the future. If cows are no longer needed in large numbers for meat production, an alternative method to produce milk should also be found. Bovine mammary gland stem cells can be isolated with techniques described earlier for their human counterparts. The bovine stem cells recapitulated the organization of bovine mammary tissue, and they produced milk. The investigators conclude that there is a potential for novel engineering and transplant strategies and a variety of commercial applications, including the production of

modified milk components for human consumption [101]. Alternatively, an arguably easier, milk is reconstituted from, among many other components, proteins such as lactoglobulin, whey and casein that are made through recombinant technology [102].

Last, organ meats such as stomach, liver (foie gras), kidney, or sweet bread might be future target foods to be tissue engineered.

Consumer acceptance

Cultured meat cannot be bought yet; how to produce it is still the subject of increasingly intensive research and development. At the same time the last decade has seen many attempts to estimate as precisely as possible how promising it is as a potential solution for the problems of traditional meat. For example, the first—very tentative and very promising—life cycle analysis (LCA) dates from 2011 [11] and several more have followed [9,10]. More recent LCAs no longer see energy reduction as a very promising aspect of cultured meat, while other advantages, such as great reductions in land use, still hold. Such attempts are informative but also have inherent limitations, since companies are still working hard on production processes, including their efficiency and sustainability. Similar limitations apply to attempts to predict consumer acceptance. For many people, cultured meat is still an unexpected idea that they find very strange when they first hear of it. Just like the technological development of cultured meat, its societal development is a process that takes time. In the course of this process the idea slowly becomes more familiar, its meaning is being explored from various sides, and mixed feelings are sorted out. Measuring responses at any particular moment cannot do justice to such time aspects and, perhaps not surprisingly, results of consumer surveys differ greatly, depending, for example, on how questions are framed [103]. In order to understand changes in the run-up to the introduction of cultured meat, getting in touch with the relevant processes, complicated though that may be, is needed.

Meat is in motion. For decades now the problems of traditional meat have been increasing, and its moral reputation is in decline. Mixed feelings are all around: while most people find meat delicious and consider it a cherished part of their traditional diet, many also increasingly worry about animal suffering, the ecological footprint of meat eating, and the health aspects of eating too much of it. Announcements and expectations of cultured meat have become part of this moving field, together with other alternatives. We aimed to get in touch with this process of change through studying responses to cultured meat over the years, complemented with workshops and focus groups. Focus groups allow people at least a little time, following their first surprise, to consider and discuss the issue.

In focus groups the idea of cultured meat always quickly triggered mixed feelings about both cultured and traditional meat. For example, when someone commented on the unnaturalness of cultured meat, someone else was bound to wonder how natural our ordinary meat still is, and discussions then shifted to the many ambivalent feelings concerning meat. This led to changes in meaning and appreciation: after such discussions, normal meat had become somewhat less normal, cultured meat had become somewhat less strange. This shift was also illustrated in the *Times* the day after the proof-of-principle hamburger of 2013, when the commentator wondered "How absurd is it to imagine all our meat one day being produced by a similar [tissue culturing] process? Not much more absurd than it is to imagine all our meat continuing to be produced as it is now" [104].

Ambivalence is psychologically uncomfortable. One way to diminish such discomfort is to change behavior, but other forms of "coping behavior" are also available, such as "strategic ignorance": not wanting to know too much, in order to avoid the discomfort. In a study on food and information, we indeed found that many people avoid information about meat, not because they are indifferent but in order to cope with ambivalence [105].

Although many people may not be quick in changing their meat consumption, they do gradually become more open to change. In our focus groups, age was a factor here. While people of all ages after some discussion tended to sympathize with the idea of cultured meat to some extent, older people were more explicitly open to the prospect of changing diets, based on their more explicit mixed feelings toward traditional meat and also on their experiences of earlier diet changes. Margarine was also very strange at first, as the oldest among them remarked. They contemplated on how they were not immediately inclined to adapt individually ("I like meat far too much"), but instead hoped for change on other, more collective levels ("McDonalds should do this") [106].

Will big companies take over the role of farmers? Cultured meat will be disruptive for traditional livestock farming; it is clearly a threat for farmers. But it has also been proposed that cultured meat might perhaps be best produced on a small scale, even on farms, in reactors fed by cells from free-ranging animals—so that it might in fact become a new opportunity for farmers [107]. This is part of the search for how cultured meat might become a societally attractive option.

Societal indecisiveness and a lack of clear direction may be typical of (early) periods of big moral change: many people are not ready for individual action, but "under the surface" the status quo becomes instable.

For quite a while, individuals and groups remain busy sorting out the issues: finding their traditional distinctions and frameworks no longer quite adequate, making sense of new options, fitting in with technological and social environments in new ways. Understanding these processes requires us to pay attention to ambiguous meanings and ambivalent evaluations; they may look formless but they involve important moral work. The imminent appearance of cultured meat products on the market will no doubt lead to more concrete directions in this moving field.

Regulatory pathway

Because of the manufactured nature of cultured meat, it will likely have to undergo specific regulatory approval before it can enter the market, equivalent but not equal to new medical therapies or devices. In Europe, cultured meat has been designated a "Novel Food," which means that the European Food Safety Agency (EFSA) has to approve cultured meat as being safe under the just-revised Novel Food regulation [108]. Once EFSA has approved cultured meat, member states are likely to open their markets to cultured meat. Postmarket surveillance is then executed at a member state level. A similar process may be followed in the United States, where FDA and USDA have stated to jointly regulate cultured meat. This process will take time and effort, but when food safety considerations guide the choice of processes and materials during the production of cultured meat, there is no reason to assume that there will be safety issues.

Conclusion

Cultured meat is an interesting and potentially very useful application of tissue engineering. It shares technologies with medical applications, but in the implementation, there are major differences not only in scale, economy, social acceptance, and regulation but also in functional requirements. Taste, texture, and cooking behavior are important functions and are not easy to achieve. On the other hand, there is no need for structures that require functional integration of the tissue upon implant, thus reducing complexity. Overcoming the specific challenges of tissue engineering for food may have spillover effects to tissue engineering for medical therapy, for instance, on large-scale cell production.

Tissue engineering for food is still in its infancy as there are currently no products on the market yet. However, momentum is increasing as exemplified by the rapidly increasing business activity. At the same time, rigorous scientific work is needed in order to reach the full potential of cultured foods such as meat.

Introduction

Current meat production systems are a major source of pollution and a significant consumer of fossil fuels, land, and water resources. Nutrition-related diseases, foodborne illnesses, resource use and pollution, and use of farm animals are some of the serious consequences associated with them. Globally 30% of the land surface is used for livestock production with 33% of arable land being used for growing livestock feed crops and 26% being used for grazing [1]. The livestock sector contributes 18% of anthropogenic greenhouse gas (GHG) emissions to the atmosphere worldwide [1]. This contribution, as measured in carbon dioxide equivalents, is higher than the share of GHG emissions from transportation [2]. The livestock sector produces 37% of anthropogenic methane, which has 23 times more global warming potential than carbon dioxide, and 65% of human-related nitrous oxide, another powerful GHG that has 296 times more global warming potential than carbon dioxide, most of which comes from manure [2]. Livestock also contributes 68% to total ammonia emissions [2]. The animals themselves are mostly responsible for the emission of GHGs [3]. The demand for meat is expected to grow worldwide, and global meat production is anticipated to increase to 465 million tonnes by the year 2050, which is anticipated to be accompanied by a rise in annual GHG emissions to 19.7 Gt of carbon dioxide, carbon equivalent [1]. Meat production is also responsible for the emissions of nitrogen and phosphorus, pesticide contamination of water, heavy metal contamination of soil, and acid rain from ammonia emissions [4]. The water used for livestock and accompanying feed crop production has a dramatic effect on the environment such as reduction in fresh water supply, erosion, and subsequent habitat and biodiversity loss [5,6]. The irrigation of feed crops for cattle alone accounts for nearly 8% of global human water use [2].

Until 2020 meat demand is expected to increase highly in developing countries and slightly in developed countries [7,8]. To meet these increased meat demands of modern society, animals are kept intensively, and production is optimized disregarding the well-being of the animals. Much of the growing demand for animal products worldwide is being met by concentrated animal feeding operations, or factory farms [2,9]. Factory farms account for 67% of poultry meat production, 50% of egg production, and 42% of pork production [10]. Globally some 56 billion animals and birds are raised and slaughtered for food each year [11]. Herding of animals in confined spaces in unfavorable conditions is practiced. Many of world's 17 billion hens and meat chickens each live in an area that is less than the size of a sheet of paper [12]. Cattle in feedlots often stand knee-high in manure and arrive at slaughterhouses covered in feces [13]. The adaptability of animals is not high enough to cope with these unnatural conditions and high stress levels are observed, resulting in disease, abnormal behavior, and death [14]. Furthermore, such operations are increasingly located in or near cities in the developing world, making urban areas the center of industrial meat production in some countries. This extraordinary proximate concentration of people and livestock poses probably one of the most serious environmental and public health challenges for the coming decades [15]. The World Organization for Animal Health (OIE) estimates that not less than 60% of human pathogens and 75% of recent emerging diseases are zoonotic [2]. Another problem is that of animal

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00075-7

disease epidemics and more serious threat is posed by the chicken flu, as this can lead to possible new influenza epidemics or even pandemics, which can kill millions of people [16]. Foodborne illnesses have become increasingly problematic with a sixfold increase in gastroenteritis and food poisoning in industrialized countries in the last 20 years [17] and the most common causes of foodborne diseases in EU, the United States, and Canada are contaminated meats and animal products [18–21]. Nutrition-related diseases, such as cardiovascular disease and diabetes, associated with overconsumption of animal fats are now responsible for a third of global mortality [22]. In addition, there is a problem of antibiotics being used as growth promoters for animals kept in intensive farming. In the United States, livestock consumes 70% of all antimicrobial drugs [23]. This use probably contributes to the emergence of multidrug-resistant strains of pathogenic bacteria [24].

Furthermore, livestock competes with humans for crops and grains as they detract more from food supply than they provide. Livestock consume 77 million tons of protein contained in feedstuff that could potentially be used for human nutrition, whereas only 58 million tons of protein are contained in food stuffs that livestock produce and in terms of energy the relative loss is much higher [2]. Thus current meat production methods have several health, environmental, and ethical issues associated with them [5,6]. Continuation of meat production as usual will lead to further environmental degradation and destruction of habitats. However, solutions are within reach, many of which are from the scientific sector, and will need investment in form of time and money, and possibly changes in consumer's habits. Scientific innovations can and should come from all sectors involved, and a significant contribution can be made through generation of meat alternatives using improvements of already existing concepts and products. An example of such a concept is biofabrication, that is, production of complex living and nonliving biological products. A new approach to produce meat is probably feasible with existing tissue engineering techniques and has been proposed as a humane, safe, and environmentally beneficial alternative to slaughtered animal flesh. The industrial potential of biofabrication technology is far beyond the traditional medically oriented tissue engineering and organ printing, and, in the long term, it can contribute to the development of novel biotechnologies that can dramatically transform traditional animal-based agriculture by inventing "animal-free" food, leather, and fur products. The techniques required to produce cultured meat are not beyond imagination, and the basic methodology involves culturing muscle tissue in a liquid medium on a large scale; however, the production of highly structured unprocessed meat faces considerably greater technical challenges, and a great deal of research is still needed to establish a sustainable in vitro meat culturing system on an industrial scale. In the long term, cultured meat is an inescapable future of the humanity. In the short term, extremely high prohibitive cost of meat biofabrication is the main potential obstacle, although large-scale production and market penetration are usually associated with a dramatic price reduction. This chapter discusses various technological, regulatory, and ethical aspects associated with cultured meat production. A detailed attention has been paid to the challenges that need to be met for commercial feasibility and success of cultured meat production, which include finding an appropriate stem cell source, their growth in a three-dimensional environment inside a bioreactor, providing essential cues for proliferation and differentiation and evolving new processing technologies.

Need and advantages of cultured meat

1. This novel production system will significantly reduce the animal use as theoretically a single farm animal could be used to produce world's meat supply. Cultured meat has the potential to greatly reduce animal suffering and make eating animals unnecessary while satisfying all the nutritional and hedonic requirements of meat eaters [25]. In comparison with animals a product from a bioreactor could be attractive as it does not come with all the vicissitudes of animals. Cultured meat is potentially a much more reliable alternative and is not bound to soil or place, which opens possibilities for new places of production and for alternative land use. Considering cyanobacteria as a source of energy and nutrients, this production system has the potential to reduce 82%–96% of water usage, 78%–96% GHGs, and 99% land use associated with traditional meat production [26]. However, from a perspective of social acceptance, the technological character of cultured meat can have a negative value and associations with Frankenstein, cloning, transgenesis, and unknown risks are close at hand.
2. In theory, cells from captive rare or endangered animals (or even cells from samples of extinct animals) could be used to produce exotic meats in cultures as global trade of meats from rare and endangered animals has reduced wild populations of several species in many countries.
3. The chances of meat contamination and the incidence of foodborne diseases should be lower in an in vitro meat production system due to comprehensive monitoring systems and strict quality control rules, such as good manufacturing practice, that are impossible to introduce in modern animal farms, slaughterhouses, or meat packing plants. In addition, other risks such as exposure to pesticides,

arsenic, dioxins, and hormones associated with conventional meat should be significantly reduced.

4. With advent of functional and designer foods, consumers are more willing to try products that have been altered to have particular nutritional characteristics [27,28]. There are several possibilities to alter the functional value and nutritional profile of cultured meat to produce designer meat. The flavor and fatty acid composition of cultured meat could be influenced by manipulating the composition of the culture medium. Health aspects of the meat could be enhanced by adding factors such as certain types of vitamins to the culture medium, which might have an advantageous effect on health [29]. Coculturing with other cell types could enhance the meat quality. The ratio of saturated to polyunsaturated fatty acids could be better controlled, although the fat content could also be controlled by supplementation of fats after production.
5. Only muscle tissues will be developed in an in vitro meat production system and no other biological structures such as bones, respiratory system, digestive system, nervous system, and the skin will be involved, which should significantly reduce the amount of nutrients and energy needed for growth and maintenance of muscle tissue.
6. It takes several weeks (for chickens) or years (for pigs and cows) before the meat can be harvested in the current meat production systems. It will take significantly lower amount of time to grow the meat in vitro. Since the amount of the time needed to maintain the tissue is much lower in an in vitro meat production system, the amount of nutrients and labor required per kg of cultured meat should be much lower.
7. Since bioreactors for cultured meat production do not need extra space and could be stacked up in a fabric hall, the nutritional costs for cultured meat should be significantly lower than conventional meat. The financial advantages are not clear yet, and it might very well be that the decrease in costs of resources, labor, and land will be compensated by extra costs of a stricter hygiene regime, stricter control, computer management, etc.

   Although cultured meat is believed to significantly reduce the water and carbon foot print associated with meat production, the energy use associated with this novel production system is not clear yet and is expected to be more than poultry but lower than beef and possibly pork [26,30]. While comparing the environmental impact of different meat alternatives in a life cycle assessment, Smetana et al. [31] reported that cultured meat had higher impact on most categories when compared to other alternatives (plant-based, mycoprotein-based, and dairy-based) and chicken due to its higher level of energy requirements. However, the energy consumption associated with cultured meat production could be reduced by employing several innovative options in future.
8. There are several situations when it is costly to resupply people with food and it is more economical to produce food in situ. These include scientific stations in polar regions, troop encampments in isolated theaters of war and bunkers designed for long-term survival of personnel following a nuclear or biological attack. The long-term space missions such as a settlement on the Moon or a flight to Mars will likely involve some food production in situ within a settlement or spacecraft to reduce liftoff weight and its associated costs.
9. Need for other protein sources to meet the protein requirements of increasing population also demands the production of cultured meat. A definite market is available for meat substitutes, examples are legume-based and mycoprotein-based meat substitutes. Cultured meat may be a preferred alternative because it is, unlike other products, animal-derived and with respect to composition most like meat. A small market comprising the vegetarians that do not eat meat for ethical reasons may also be available.

   Demand for meat is increasing both in developing as well as developed countries, and it will not be possible to produce all the meat in an environmental- and animal-friendly way. Thus there is rather a conventional meat market for in vitro meat.
10. Cultured meat is expected to liberate itself of religious associations, such as *Kosher* and *Halal*, making it a universal product equally acceptable to whole spectrum of consumers. This could be an advantage for its marketing and should likely affect its consumer base. The concept of cultured meat has intrigued all religious bodies and institutions and several debates and discussion were held recently about the acceptability of this novel source of meat with favorable outcomes. Several Muslim scholars have suggested *Halal* nature of cultured meat provided the cells to begin with were harvested from *Halal* animals (permissible by the Islamic law) and all culture media components were *Halal* [32]. Although there is no consensus due to disparate nature of certifying bodies, most rabbis agree that cultured meat will be Kosher (permissible by Jewish laws) if cells were harvested from a kosher animal slaughtered according to Jewish law [33–35].
11. Other factors such as possible impact on reducing cardiovascular diseases and GHG emissions, liberation of land for nature (including wild animals), prevention of animal suffering, and prevention of food scarcity expected with an increasing world population will push the production of cultured meat in future.

Cultured meat

The idea of cultured meat for human consumption is not new but was predicted long back by Winston Churchill in the 1920s. In essay "Fifty Years Hence" later published in "Thoughts and adventures" in 1932, he declared, "Fifty years hence, we shall escape the absurdity of growing a whole chicken in order to eat the breast or wing by growing these parts separately under a suitable medium." In 1912 Alexis Carrel managed to keep a piece of chick heart muscle alive and beating in a Petri dish. This experiment demonstrated that it was possible to keep muscle tissue alive outside the body, provided it was nourished with suitable nutrients. It was much later in the early 1950s when Willem van Eelen of The Netherlands independently had the idea of using tissue culture for the generation of meat products. Since at that time the concept of stem cells and the in vitro culture of cells still had to emerge, it took until 1999 before van Eelen's theoretical idea was patented. Some efforts have already been put into culturing artificial meat. SymbioticA harvested muscle biopsies from frogs and kept the tissues alive and growing in culture dishes [36]. In 2002 a study involving the use of muscle tissue from common goldfish (*Carassius auratus*) cultured in Petri dishes was published in which the possibilities of culturing animal muscle protein for long-term space flights or habituation of space stations were explored. In this study, muscle tissue cultured with crude cell extracts showed a limited increase in cell mass and the cultured muscle explants so obtained were washed, dipped in olive oil with spices, covered in breadcrumbs, and fried. A test panel judged the processed explants and agreed that the product was acceptable as food [37]. Thus some efforts have already been put into culturing artificial meat; but obviously, small biopsies will not be practical for large-scale meat production. Therefore it was proposed to use tissue engineering to produce meat in vitro. Tissue engineering is a powerful technique used to mimic neo-organogenesis ex vivo and is mainly designated for regenerative medicine in a wide variety of tissues and organs for the treatment of various diseases and surgical reconstruction [38,39]. Tissue engineering of skeletal muscle has several applications, ranging from in vitro model systems for drug screening [40], pressure sores [41], and physiology to in vivo transplantation for the treatment of muscular dystrophy and muscular defects [42]. Obviously, tissue engineering could also be employed for in vitro production of skeletal muscle tissue from farm animals for consumption purposes [43].

Given the benefits of an in vitro meat production system, it is not surprising that several parties have proposed and patented the methodology for actualizing this idea [29,43,44]. However, none of these processes, though detailed, have been tested, this chapter introduces the techniques so far proposed. This is partially because farm-animal cell lines have not been well-established in vitro [45] and because growing muscle cells in vitro on a large scale is certainly a vast and unexplored undertaking. The technical demands of large-scale production are unseen in the world of medical research where most efforts in growing tissue ex vivo have been directed. The nutritional composition of ex vivo engineered muscle tissue has not yet been paid much attention. As a result, establishment of an in vitro meat production system is faced with many unique challenges so far unexplored in the field of tissue engineering.

The only aim to develop an in vitro meat production system is the proliferation of animal muscle tissue. Meat is already cultured on small and early scales using a variety of basic procedures, including techniques that use scaffolds and those that rely on self-organization [43]. There are different design approaches for an in vitro meat production system, all of which are designed to overcome the diffusion barrier, ranging from those currently in use to other speculative possibilities.

Scaffolding techniques

In scaffold-based techniques, embryonic myoblasts or adult skeletal muscle satellite cells are proliferated, attached to a scaffold or carrier such as a collagen meshwork or microcarrier beads, and then perfused with a culture medium in a stationary or rotating bioreactor. By introducing a variety of environmental cues, these cells fuse into myotubes, which can then differentiate into myofibers [46]. The resulting myofibers may then be harvested, cooked, and consumed as meat (Figs. 73.1 and 73.2).

Currently, there are two detailed proposals based on emerging field of tissue engineering [47,48] for using cell culture for producing in vitro meat. Both these proposals are similar in nature. One of the two proposals to create an in vitro meat production system has been written by Vladimir Mironov for the NASA [49] while the other proposal has been written by Willem van Eelen who also holds a worldwide patent for this system [29]. However, Catts and Zurr [36] appear to have been the first to have produced meat by this method. Both systems work by growing myoblasts in suspension in a culture medium. Mironov proposal uses a bioreactor in which cells are grown together with collagen spheres to provide a substrate onto which the myoblasts can attach and differentiate, whereas van Eelen's proposal uses a collagen meshwork and the culture medium is refreshed from time to time or percolated through the meshwork. Once differentiated into myofibers, the mixture of collagen and muscle cells can be harvested and used as meat. Other forms

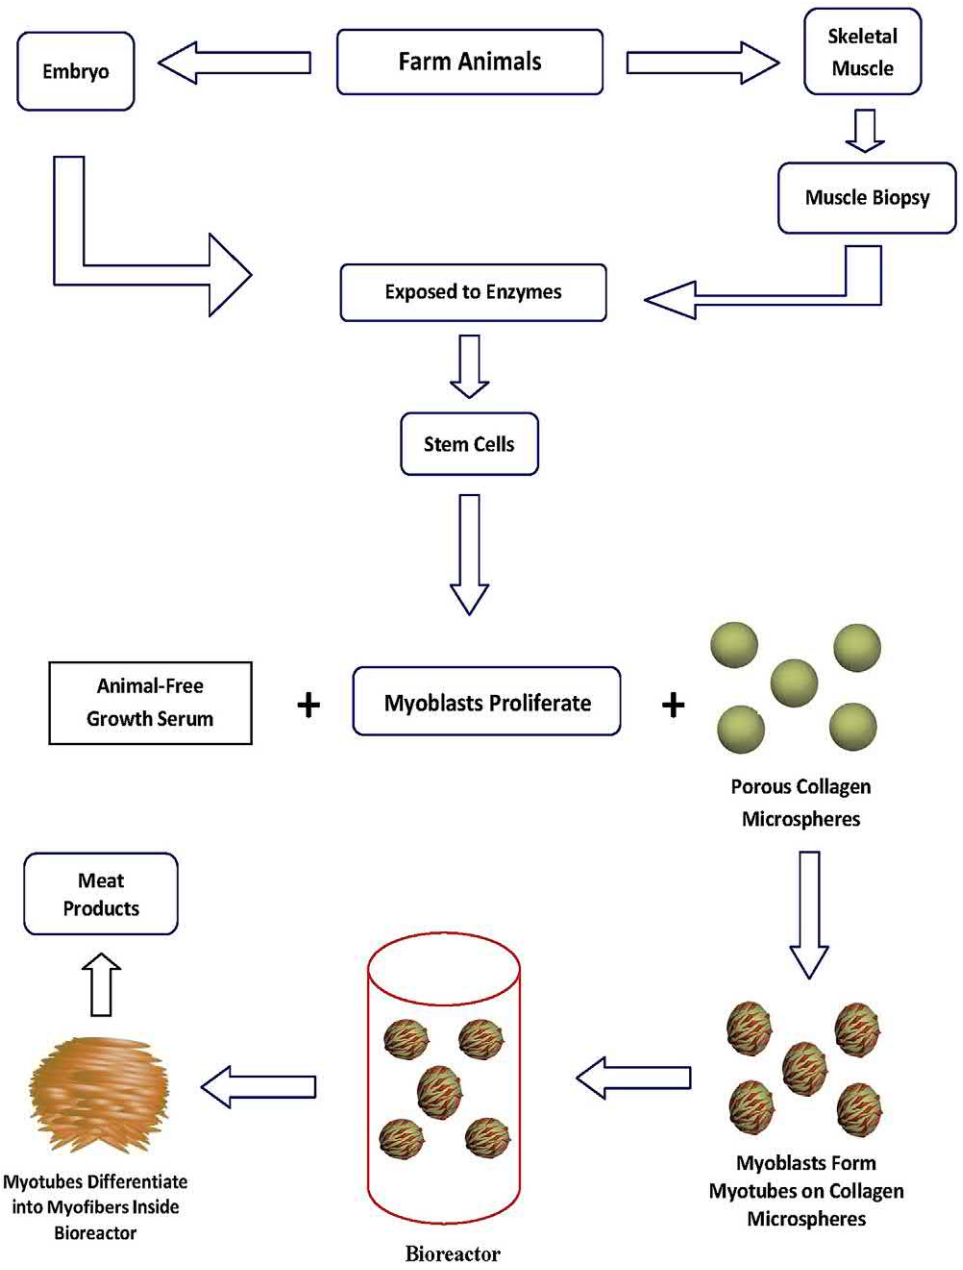

FIGURE 73.1 Scaffold-based cultured meat.

of scaffolding could also be used, for example, growing muscle tissue on large sheets of edible or easily separable material. The muscle tissue could be processed after being rolled up to suitable thicknesses [43]. While these kinds of techniques work for producing ground processed (boneless) meat with soft consistency, they do not lend themselves to highly structured meats such as steaks. However, cells can also be grown in substrates that allow for the development of "self-organizing constructs" that produce more rigid structures.

Self-organizing tissue culture

To produce highly structured meats, one would need a more ambitious approach, creating structured muscle tissue as self-organizing constructs [50] or proliferating existing muscle tissue in vitro, such as Benjaminson et al. [37] who cultured goldfish (*C. auratus*) muscle explants. They took slices of goldfish tissue, minced and centrifuged them to form pellets, placed them in Petri dishes in a nutrient medium and grew them for 7 days. The explanted tissue grew nearly 14% when using fetal bovine

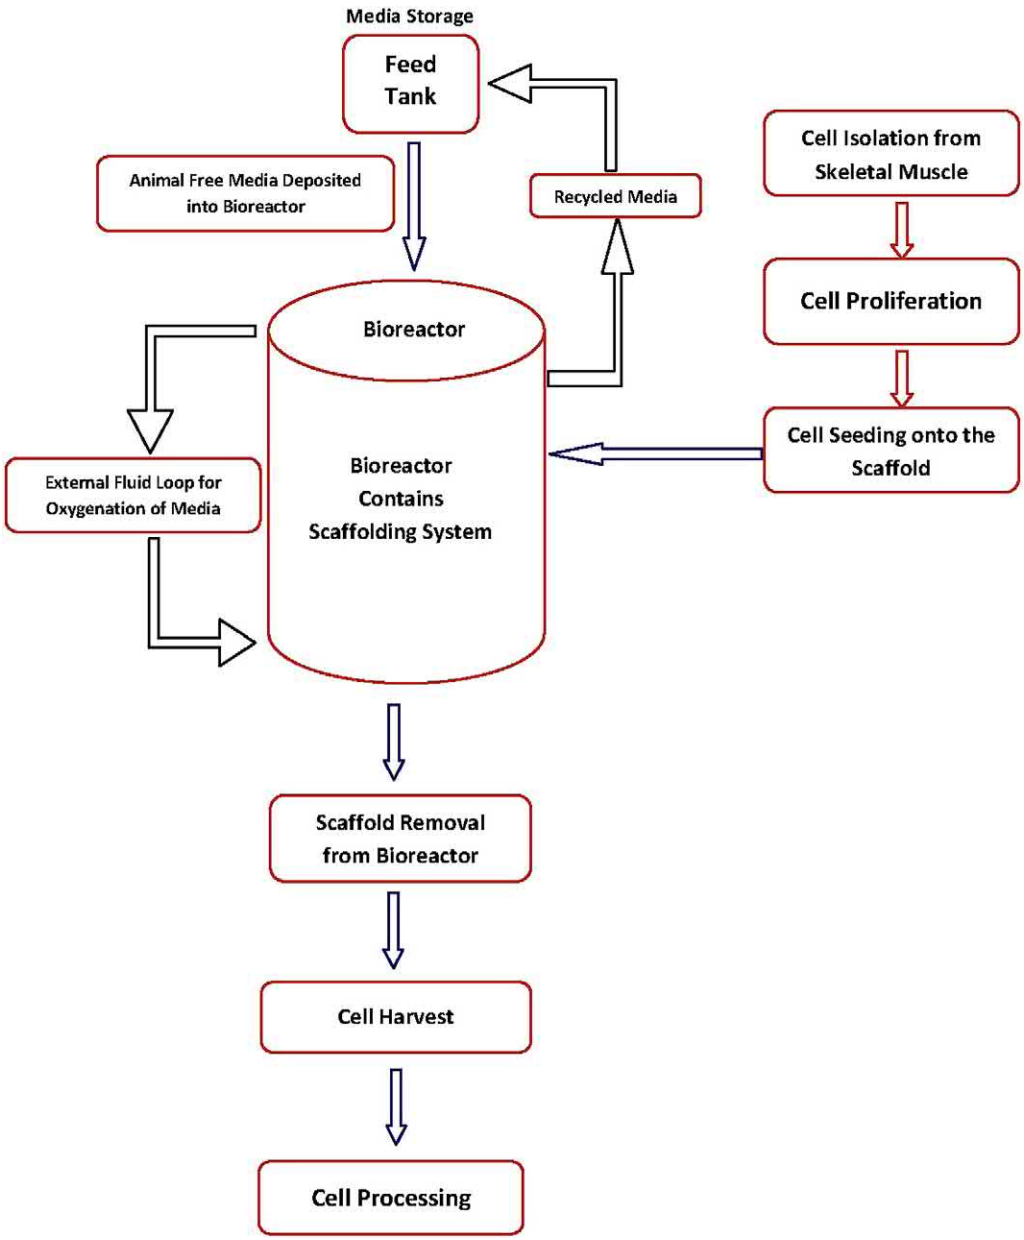

FIGURE 73.2 Possible in vitro meat production scheme.

serum as the nutrient medium and over 13% when using maitake mushroom extract. When the explants were placed in a culture containing dissociated *Carassius* skeletal muscle cells, explant surface area grew a surprising 79% in a week's time. After a week the explants and their newly grown tissue, which looked like fresh fish filets, were cooked (marinated in olive oil and garlic and deep-fried) and presented to a panel for observation. The panel reported that the fish looked and smelled good enough to eat [37,51–53]. Benjaminson et al. in another experiment kept chicken muscles alive in a Petri dish for at most 2 months before it got necrosed [49].

Tissue culture techniques have the advantages that explants contain all the tissues that make up meat in the right proportions and closely mimic in vivo situation. However, lack of blood circulation in these explants makes substantial growth impossible, as cells become necrotic if separated for long periods by more than 0.5 mm from a nutrient supply [50]. According to Vladimir Mironov, entirely artificial muscle can be created with tissue engineering techniques by a branching network of edible porous polymer through which nutrients can perfuse and myoblasts and other cell types can attach [49]. Such a design using the artificial capillaries for the

purpose of tissue engineering has been proposed [48]. Small muscle–like organs have been demonstrated to grow from cocultures of myoblasts and fibroblasts. These organs, termed myooids, can contract both spontaneously and by electrical stimulation, albeit with only a fraction of the force observed in control muscles probably because of lack of innervation [50,54,55]. The diameter of myooids is limited at most to 1 mm [55] due to the lack of perfusion, which is probably the biggest problem to overcome in designing an in vitro meat production system. Like the myooids, it is possible to coculture the myoblasts with other cell types to create a more realistic muscle structure that can be organized in much the same way as real muscles [50,54,55].

Organ printing

The problems associated with current tissue engineering techniques are that they cannot provide consistency, vascularization, fat marbling, or other elements of workable and suitably tasting meat that are not simply versions of ground soft meat. A potential solution to such problems comes from research on producing organs for transplantation procedures known as organ printing. Organ printing uses the principles of ordinary printing technology, the technology used by inkjet printers to produce documents. Researchers use solutions containing single cells or balls of cells and spray these cell mixtures onto gels that act as printing paper. The "paper" can be removed through a simple heating technique or could potentially be automatically degradable. What happens is essentially that live cells are sprayed in layers to create any shape or structure desired. After spraying these three-dimensional structures, the cells fuse into larger structures, such as rings, tubes, or sheets. The organs would not only have the basic cellular structure of the organ but also include appropriate vascularization providing a blood supply to the entire product. Essentially, sheets and tubes of appropriate cellular components could create any sort of organ or tissue for transplantation or for consumption [25,56,57]. For applications focused on producing meat, fat marbling could be added as well, providing taste and structure.

Biophotonics

Biophotonics is a new field that relies on the effects of lasers to move particles of matter into certain organizational structures, such as three-dimensional chessboard or hexagonal arrays. In general, biophotonics refers to the process of using light to bind together particles of matter, and the mechanisms of this field are still poorly understood. A surprising property of interacting light is that this phenomenon produces so-called optical matter in which the crystalline form of materials (such as polystyrene beads) can be held together by nets of infrared light that will fall apart when the light is removed. This is a phenomenon a step-up from "optical tweezers" that have been used for years to rotate or otherwise move tiny particles in laboratories. This has a binding effect among a group of particles that can lead them not only to be moved one by one to specific locations but also that can coax them to form structures. Although primarily there is sparking interest in medical technologies such as separating cells or delivering medicine or other microencapsulized substances to individual cells, there is an intriguing possibility that such a technology could be used to produce tissues, including meat [25]. Arrays of red blood cells and hamster ovaries have already been created using this technology [58]. Given the success of creating two-dimensional arrays, there is a possibility of producing tissue formations that use only light to hold the cells together, thus eliminating the need for scaffoldings [25].

Nanotechnology

The ability of optical tweezers to rotate or move tiny particles has intrigued nanotechnologists, who have inventive plans for what to do with the molecular scale–sized robots they would like to create (but so far, having few tools with which to make them). Nanotechnology (the production and alteration of materials at the level of the atom and molecule) holds out enormous possibilities and the holy grail of nanotechnology is some version of an "assembler," a robot the size of a molecule that would allow moving matter at the atomic and molecular level. The obvious power of such a technology, given that everything is made of the same basic atoms but simply arranged in different ways, is that we would be able to construct virtually any substance we wanted from scratch by putting together exactly the molecules we wanted. Interestingly, one of the first examples given of the speculative technology of nanotechnology was that of synthesized meat. Thus technologies ranging from the actual to the speculative promise a variety of ways to create real meat without killing animals. Though commercially not feasible now or in some cases technologically infeasible for several years to come, the point here is not to be distracted by the fact that we cannot yet make use of these technologies but rather to decide whether we should support the development of these technologies [25].

Challenges and requirements for industrial production

There are two different ideas regarding the concept of cultured meat. Because people like meat and cultured meat is explicitly introduced as an alternative to the problems of normal meat, it should be as meat-like as possible in

order to be a real alternative for "traditional" meat from animals. It is therefore important that an alternative should have a similar taste and nutritional value. On the other hand, a new product needs a profile of its own otherwise it will not be able to compete. From this perspective, it is not essential for the product to resemble and should in fact be clearly distinctive from traditional meat.

Cultured meat technology is still in its infancy, and the most important challenge is insufficient knowledge on the biology of the stem cells and its differentiation into muscle cells. Tissue engineering on a very large scale is the second requirement along with the maintenance of constant conditions around all individual cells in a large-scale reactor with sophisticated instrumentation for measuring and controlling conditions. Need of cell growth and differentiation and subsequent release from support without damage upon harvesting is third requirement along with the need for on-site cleaning and sterilization systems in the large-scale reactors. Studies are required to determine the consumer preferences and marketing strategies. When meat from animals is available why would a consumer prefer cultured meat and if it is all about sustainability or animal welfare issues, eating more plant proteins and less animal protein is a good alternative. The following challenges have to be met before cultured meat can be produced on a commercial scale.

Generation of suitable stem cell lines from farm-animal species

In vitro meat can be produced by culturing the cells from farm-animal species in large quantities starting from a relatively small number. Culturing embryonic stem (ES) cells would be ideal for this purpose since these cells have an almost infinite self-renewal capacity and theoretically it is being said that one such cell line would be sufficient to feed the world. In theory, after the ES cell line is established, its unlimited regenerative potential eliminates the need to harvest more cells from embryos; however, the slow accumulation of genetic mutations over time may determine a maximum proliferation period for a useful long-term ES culture [59]. While ES cells are an attractive option for their unlimited proliferative capacity, these cells must be specifically stimulated to differentiate into myoblasts and may inaccurately recapitulate myogenesis [39]. Although ES cells have been cultured for several generations, so far it has not been possible to culture cell lines with unlimited self-renewal potential from preimplantation embryos of farm-animal species. Until now, true ES cell lines have only been generated from mouse, rhesus monkey, human, and rat embryos, [45] but the social resistance to cultured meat obtained from mouse, rat, or rhesus monkey will be considerable and will not result in a marketable product. The culture conditions required to keep mouse and human embryonic cells undifferentiated are different from the conditions that will be required for embryonic cells of farm-animal species and fundamental research on early development of embryos of these species can provide clues.

Different efforts invested into establishing ungulate stem cell lines over the past two decades have been generally unsuccessful with difficulties arising in the recognition, isolation, and differentiation of these cells [60]. According to Bach et al. [39], myosatellite cells are the preferred source of primary myoblast; however, they have the disadvantage of being a rare muscle tissue cell type with limited regenerative potential because they recapitulate myogenesis more closely than immortal myogenic cell lines. Myosatellite cells isolated from different animal species have different benefits and limitations as a cell source and those isolated from different muscles have different capabilities to proliferate, differentiate or being regulated by growth modifiers [61]. Myosatellite cells have been isolated and characterized from the skeletal muscle tissue of cattle [62], chicken [63], fish [64], lambs [65], pigs [66], and turkeys [67]. Porcine muscle progenitor cells have the potential for multilineage differentiation into adipogenic, osteogenic, and chondrogenic lineages, which can play a role in the development of cocultures [66]. Advanced technology in tissue engineering and cell biology offers some alternate cell options having practical applications and multilineage potential allowing for coculture development with suitability for large-scale operations.

Alternatively, we can use adult stem cells from farm-animal species, and myosatellite cells are one example of an adult stem cell type with multilineage potential [68]. Adult stem cells have been isolated from different adult tissues [69]; however, their proliferation capacity is limited in vitro and could proliferate for several months at most. These cells have the capacity to differentiate into skeletal muscle cells although not very efficiently but for now these are the most promising cell type for use in the production of cultured meat. A rare population of multipotent cells found in adipose tissue known as adipose tissue−derived adult stem cells (ADSCs) is another relevant cell type for cultured meat production [70], which can be obtained from subcutaneous fat and subsequently transdifferentiated to myogenic, osteogenic, chondrogenic, or adipogenic cell lineages [71]. However, adult stem cells are prone to malignant transformation in long-term culture [72] that is the greatest matter of debate. It has been observed that ADSCs immortalize at high frequency and undergo spontaneous transformation in long-term (4−5 months) culturing [73], while evidence of adult stem cells remaining untransformed has also been reported [74]. To minimize the risk of spontaneous transformation,

reharvesting of adult stem cells may be necessary in an in vitro meat production system and as such obtaining ADSCs from subcutaneous fat is far less invasive than collection of myosatellite cells from muscle tissue.

Matsumoto et al. [75] reported that mature adipocytes can be dedifferentiated in vitro into a multipotent preadipocyte cell line known as dedifferentiated fat (DFAT) cells, reversion of a terminally differentiated cell into a multipotent cell type. These DFAT cells are capable of being transdifferentiated into skeletal myocytes [76] and appear to be an attractive alternative to the use of stem cells. This process known as "ceiling culture method" certainly seems achievable on an industrial scale but Rizzino [77] has put forth the argument that many of the claims of transdifferentiation, dedifferentiation, and multipotency of once terminally differentiated cells may be due to abnormal processes resulting in cellular look-alikes.

Safe media for culturing of stem cells

Cultured meat would need an affordable medium system to enjoy its potential advantages over conventional meat production and that medium must contain the necessary nutritional components available in free form to myoblasts and accompanying cells. Myoblast culturing usually takes place in animal serum, a costly medium that does not lend itself well to consumer acceptance or large-scale use. Animal sera are from adult, newborn or fetal source, with fetal bovine serum being the standard supplement for cell culture media [78]. Because of its in vivo source, it can potentially introduce pathogenic agents and have a large number of constituents in highly variable composition [79]. The harvest of fetal bovine serum also raises ethical concern; and for generation of an animal-free protein product, the addition of fetal calf serum to the cells would not be an option and it is therefore essential to develop a serum-free culture medium. Commercially available serum replacements and serum-free culture media offer some more realistic options for culturing mammalian cells in vitro. Serum-free media reduce operating costs and process variability while lessening the potential source of infectious agents [80]. Improvements in the composition of commercially available cell culture media have enhanced our ability to successfully culture many types of animal cells and serum-free media have been developed to support in vitro myosatellite cell cultures from the turkey [81], sheep [82], and pig [83]. Variations among different serum-free media outline the fact that satellite cells from different species have different requirements and respond differentially to certain additives [84]. Ultroser G is an example of a commercially available serum substitute containing growth factors, binding proteins, adhesin factors, vitamins, hormones, and mineral trace elements and has been designed specially to replace fetal bovine serum for growth of anchorage-dependent cells in vitro [85]. Benjaminson et al. [37] succeeded in using a serum-free medium made from maitake mushroom extract that achieved higher rates of growth than fetal bovine serum, and recently it has been shown that lipids such as sphingosine-1-phosphate can replace serum in supporting the growth and differentiation of embryonic tissue explants. In most cases, serum-free media are supplemented with purified proteins of animal origin [86].

Indeed, such media have already been generated and are available from various companies for biomedical purposes; however, their price is incompatible with the generation of an affordable edible product. Therefore a cell culture medium must be developed that does not contain products of animal origin and enables culturing of cells at an affordable price.

Safe differentiation media to produce muscle cells

For culturing stem cells, it is important that the cells remain undifferentiated and maintain their capacity to proliferate, whereas for production of cultured meat, a specific and efficient differentiation process initiated with specific growth factors is needed. These growth factors are synthesized and released by muscle cells themselves and are also provided by other cell types locally (paracrine effects) and nonlocally (endocrine effects) in vivo. An appropriate array of growth factors is required for growth of muscle cells in culture in addition to proper nutrition. The myosatellite cells of different species respond differentially to the same regulatory factors [61] and as such extrinsic regulatory factors must be specific to the chosen cell type and species. Furthermore, formulation may be required to change over the course of the culturing process from proliferation period to the differentiation and maturation period, requiring different set of factors. A multitude of regulatory factors have been identified as being capable of inducing myosatellite cell proliferation [87]. Regulation of meat animal−derived myosatellite cells by hormones, polypeptide growth factors, and extracellular matrix proteins has been investigated [83,84]. Purified growth factors or hormones may be supplemented into the media from an external source such as transgenic bacterial, plant, or animal species, which produce recombinant proteins [88]. Alternatively, a sort of synthetic paracrine signaling system can be arranged so that cocultured cell types can secrete growth factors that can promote proliferation and cell growth in neighboring cells. Appropriate coculture systems, such as hepatocytes, may be developed to provide necessary growth factors, such as insulin-like growth factors, which

will stimulate myoblast proliferation and differentiation [89] as well as myosatellite cell proliferation in several meat-animal species in vitro [84]. Typically, investigators initiate differentiation and fusion of myoblasts by lowering the levels of mitogenic growth factors, and the proliferating cells then commence synthesis of insulin-like growth factor-II, which leads to differentiation and formation of multinucleated myotubes [90] and stimulate myocyte maturation [91]. Thus a successful system must be capable of changing the growth factor composition of the media. Currently, the most efficient method to let stem cells (mouse) differentiate into skeletal muscle cells is to culture them in a medium that contains 2% horse serum instead of 10% or 20% fetal calf serum. However, for the generation of cultured meat, it is essential that the cells are cultured and differentiated without animal products, so a chemically defined culture medium must be developed that enables the differentiation of stem cells to skeletal muscle cells.

Tissue engineering of muscle fibers

The possibility to form a three-dimensional structure of cells is restricted in the absence of blood flow that provides oxygen and nutrients to the cells and removes metabolic end products. Because of the limitations in nutrient diffusion, in vitro culturing of cells is limited to only a few layers of cells. A solution to this problem may be provided by culture of cells on edible or biodegradable synthetic or biological scaffolds, which would provide shape and structure to the engineered tissue. Another solution could be the processing of these thin layers of cells into a meat-based product. Alternatively, deformable microcarrier beads of edible (nonanimal) material may be developed that would enable production of secondary myotubes in suspension, which may be used as an animal protein ingredient for a wide variety of products. Products with a meat-like appearance and texture could be developed by addition of fibroblasts (for firmness) and fat cells (for taste) to the myotubes.

Scaffolds

As myoblasts are anchorage-dependent cells, a substratum or scaffold must be provided for proliferation and differentiation to occur [92]. Scaffolding mechanisms differ in shape, composition, and characteristics to optimize muscle cell and tissue morphology. An ideal scaffold must have a large surface area for growth and attachment, be flexible to allow for contraction as myoblasts are capable of spontaneous contraction, maximize medium diffusion, and be easily dissociated from the meat culture. A best scaffold is one that mimics the in vivo situation as myotubes differentiate optimally on scaffold with a tissue-like stiffness [93] and its by-products must be edible and natural and may be derived from nonanimal sources, though inedible scaffold materials cannot be disregarded. New biomaterials may be developed that offer additional characteristics, such as fulfilling the requirement of contraction for proliferation and differentiation [94]. Thus challenge is to develop a scaffold that can mechanically stretch attached cells to stimulate differentiation and a flexible substratum to prevent detachment of developing myotubes that will normally undergo spontaneous contraction.

Edelman et al. [43] proposed porous beads made of edible collagen as a substrate while as van Eelen et al. [29] proposed a collagen meshwork described as a "collagen sponge" of bovine origin. The tribeculate structure of the sponge allows for increased surface area and diffusion but may impede harvesting of the tissue culture. Other possible scaffold forms include large elastic sheets or an array of long, thin filaments. Cytodex-3 microcarrier beads have been used as scaffolds in rotary bioreactors, but these beads have no stretching potential. One elegant approach to mechanically stretch myoblasts would be to use edible, stimuli-sensitive porous microspheres made from cellulose, alginate, chitosan, or collagen [43], which undergo, at least, a 10% change in surface area following small changes in temperature or pH. Once myoblasts attach to the spheres, they could be stretched periodically provided such variation in the pH or temperature would not negatively affect cell proliferation, adhesion, and growth. Jun et al. [95] observed that growing myoblasts on electrically conductive fibers induces their differentiation, forming more myotubes of greater length without the addition of electrical stimulation, but use of such inedible scaffolding systems necessitates simple and nondestructive techniques for removal of the culture from the scaffold.

Furthermore, there are greater technical challenges in developing a scaffold for large and highly structured meats due to the absence of vascular system. There is a need to build a branching network from an edible, elastic, and porous material, through which nutrients can be perfused and myoblasts and other cell types can then attach to this network. Edelman et al. [43] acknowledged that a cast of an existing vascularization network, such as that in native muscle tissue, can be used to create a collagen network mimicking native vessel architecture. Taking this a step further, Borenstein et al. [96] have proposed an approach to create such a network by creating a cast onto which a collagen solution or a biocompatible polymer is spread and after solidification seeding the network with endothelial cells. Following dissolution of the polymer mold, successful proliferation could theoretically leave behind a network of endothelial tissue, a branched network of micro-channels, which can be stacked onto each

other to form a three-dimensional network onto which one could grow myocytes. A synthetic vascular system would then require a circulation pumping system and a soluble oxygen carrier in the medium to be fully functional. However, currently creation of these artificial vascular networks does not translate well into mass production due to the requirement of microfabrication processes. Alternatively, Benjaminson et al. [37] proposed an attempt to create a highly structured meat without a scaffold by solving the vascularization problem through controlled angiogenesis of explants.

Another important factor is the texture and microstructure of scaffolds as texturized surfaces can attend to specific requirements of muscle cells, one of which is myofiber alignment. This myofiber organization is an important determinant for the functional characteristics of muscle and the textural characteristics of meat. Lam et al. [97] cultured myoblasts on a substrate with a wavy micropatterned surface to mimic native muscle architecture and found that the wave pattern aligned differentiated muscle cells while promoting myoblast fusion to produce aligned myotubes. While using scaffold-based techniques for meat culturing, micropatterned surfaces could allow muscle tissue to assume a two-dimensional structure more similar to that of conventional meat. Riboldi et al. [98] utilized electrospinning, a process that uses electrical charge to extract very fine fibers from liquids, by using electrospun microfibrous meshwork membranes as a scaffold for skeletal myocytes. These membranes offer high surface area−to-volume ratio in addition to some elastic properties. Electrospinning creates very smooth fibers, which may not translate well into a good adhesive surface; however, coating electrospun polymer fibers with extracellular matrix proteins, such as collagen or fibronectin, promotes attachment by ligand−receptor binding interactions [98]. Electrospinning shows promise for scaffold formation because the process is simple, controllable, reproducible, and capable of producing polymers with special properties by cospinning [98].

Production of meat by scaffold-based techniques also faces a technical challenge of removal of the scaffolding system. Confluent cultured cell sheets are conventionally removed enzymatically or mechanically, but these two methods damage the cells and the extracellular matrix they may be producing [99]. However, thermoresponsive coatings that change from hydrophobic to hydrophilic at lowered temperatures can release cultured cells and extracellular matrix as an intact sheet upon cooling [100]. This method known as “thermal liftoff” results in undamaged sheets that maintain the ability to adhere if transferred onto another substrate [100] and opens the possibility of stacking sheets to create a three-dimensional product. Lam et al. [101] have presented a method for detaching culture as a confluent sheet from a nonadhesive micropatterned surface using the biodegradation of selective attachment protein laminin. However, culturing on a scaffold may not result in a two-dimensional confluent “sheet” of culture. The contractile forces exerted after scaffold removal by the cytoskeleton of the myocyte are no longer balanced by adhesion to a surface that causes the cell lawn to contract and aggregate, forming a detached multicellular spheroid [100]. To remove the culture as a sheet, a hydrophilic membrane or gel placed on the apical surface of the culture before detachment can provide physical support and use of a fibrin hydrogel is ideal for skeletal muscle tissue because cells can migrate, proliferate, and produce their own extracellular matrix within it while degrading excess fibrin [101]. These two-dimensional sheets could be stacked to create a three-dimensional product as suggested by van Eelen et al. [29].

Industrial bioreactors

Production of cultured meat for commercial purposes will require large-scale culturing in large bioreactors for the generation of sufficient number of muscle cells. Cultured meat production is likely to require the development of new bioreactors, which would maintain low shear and uniform perfusion at large volumes. The bioreactor designing is intended to promote the growth of tissue cultures that accurately resemble native tissue architecture and provide an environment, which allows for increased culture volumes. A laminar flow of the medium is created in rotating wall vessel bioreactors by rotating the cylindrical wall at a speed that balances centrifugal force, drag force, and gravitational force, leaving the three-dimensional culture submerged in the medium in a perpetual free-fall state [102] that improves diffusion with high mass transfer rates at minimal levels of shear stress, producing three-dimensional tissues with structures very similar to those in vivo [103]. Direct perfusion bioreactors appear more appropriate for scaffold-based myocyte cultivation allowing flow of medium through a porous scaffold with gas exchange taking place in an external fluid loop [104]. Besides offering high mass transfer they also offer significant shear stress, so determining an appropriate flow rate is essential [103]. Direct perfusion bioreactors are also used for high-density, uniform myocyte cell seeding [105]. Another method of increasing medium perfusion is by vascularizing the tissue being grown. Levenberg et al. [106] induced endothelial vessel networks in skeletal muscle tissue constructs by using a coculture of myoblasts, embryonic fibroblasts, and endothelial cells coseeded onto a highly porous biodegradable scaffold. Research size bioreactors for mesenchymal stem cells have been scaled up to 5 L [107] and, theoretically,

scale-up to industrial sizes should not affect the physics of the system.

Adequate perfusion of the cultured tissue is required to produce large culture quantities, and it is necessary to have adequate oxygen perfusion during cell seeding and cultivation on the scaffold as cell viability and density positively correlate with the oxygen gradient in statically grown tissue cultures [105]. Adequate oxygen perfusion is mediated by bioreactors that increase mass transport between culture medium and cells and by the use of oxygen carriers to mimic hemoglobin provided oxygen supply to maintain high oxygen concentrations in solution similar to that of blood. Oxygen carriers are either modified versions of hemoglobin or artificially produced perfluorochemicals that are chemically inert [108]. Several chemically modified hemoglobins have been developed, but their bovine or human source makes them an unsuitable candidate for cultured meat production; however, hemoglobins have also been produced from genetically modified plants [109] and microorganisms [110].

Fields

Proliferation and differentiation of myoblasts have been found to be affected by the mechanical, electromagnetic, gravitational, and fluid flow fields [46,94]. Repetitive stretch and relaxation equal to 10% of length, six times per hour increase differentiation into myotubes [111]. Myoblasts seeded with magnetic microparticles induced differentiation by placing them in a magnetic field without adding special growth factors or any conditioned medium [112]. Electrical stimulation also contributes to differentiation, as well as sarcomere formation within established myotubes [46].

Atrophy and exercise

One of the potential problems associated with cultured meat is that of atrophy or muscle wasting due to the reduction of cell size [113] caused by lack of use, denervation, or one of a variety of diseases [114,115]. Regular contraction is a necessity for skeletal muscle and promotes differentiation and healthy myofiber morphology while preventing atrophy. Muscle in vivo is innervated, allowing for regular, controlled contraction, whereas in vitro system would necessarily culture denervated muscle tissue, so contraction must be stimulated by alternate means. It might be possible that mechanical or electrical stimulation can promote growth and structure of cultured meat as newly formed myotubes in culture start to contract spontaneously [116] or as a matter of fact, myooids also contract spontaneously at approximately 1 Hz once formed [50]. So, exercise by electrical stimulation might be a viable solution to overcome atrophy in an in vitro meat production system. Cha et al. [117] have found that administration of cyclic mechanical strain to a highly porous scaffold sheet promotes differentiation and alignment of smooth muscle cells. Edelman et al. [43] and van Eelen et al. [29] proposed mechanical stretching of scaffolds and expandable scaffold beads to fulfill the requirement of providing contraction. De Deyne [94] noted that external mechanical contraction is less effective than electrical stimulation in promoting muscle development. Electrical stimulation, feasible on a large scale, induces contraction internally as opposed to passively and aids in differentiation and sarcomere formation. Even growth on electrically conductive fibers without application of electrical stimulation sufficed in reaping the benefits of induced contraction [95].

Neuronal activity can be mimicked by applying appropriate electrical stimuli to in vitro cultures [118] and has proven to be pivotal in the development of mature muscle fibers [119]. It has been shown that induction of contractile activity promoted the differentiation of myotubes in culture by myosin heavy chain expression of different isoforms and sarcomere development [120,121]. Electrical stimulation can provide a noninvasive and accurate tool to assess the functionality of engineered muscle constructs [122]. Functional muscle constructs will exert a force due to active contractions of the muscle cells by generating a homogeneous electrical field inside the bioreactor; but so far, these forces generated by engineered muscle constructs only reach 2%−8% of those generated by skeletal muscles of adult rodents [54]. Thus functional properties of tissue-engineered muscle constructs are still unsatisfactory at this moment.

Mechanotransduction is the process through which cells react to mechanical stimuli and is a complex mechanism [123,124] that is another important biophysical stimulus in myogenesis [125]. It is mainly by means of the family of integrin receptors that cells attach to the insoluble meshwork of extracellular matrix proteins [126] transmitting the applied force to the cytoskeleton. The resulting series of events shows parallels to growth factor receptor signaling pathways, which ultimately lead to changes in cell behavior, such as proliferation and differentiation [123]. Muscle growth and maturation is affected by different mechanical stimulation regimes, and the application of static mechanical stretch to myoblasts in vitro results in a facilitated alignment and fusion of myotubes and also results in hypertrophy of the myotubes [125]. Furthermore, cyclic strain activates quiescent satellite cells [127] and increases proliferation of myoblasts [128]. Thus all these results indicate that mechanical stimulation protocols affect both proliferation and differentiation of muscle cells, and different parameters that presumably influence the outcome of the given stimulus are percentage of applied stretch, frequency of the stimulus, and timing in the differentiation process.

Senescence

Cultured meat production system based on satellite cells still imposes a challenge of senescence that can be tackled either by starting fresh cell culture whenever needed or by immortalizing cell culture or by using ES cell cultures. Fresh satellite cells can be extracted without harming the animal donors [29] from time to time to start new cell cultures, although animal slaughter is a more common practice [61]. Second approach involves modification of the cells in culture so that senescence can be overcome by involving the ectopic expression of the gene for the telomerase enzyme [129]. An additional expression of an oncogene may be required to overcome senescence [130–133], but this method falls within the domain of genetic modification, which might severely hinder consumer acceptance. Third approach involves ES cells that are pluripotent and apparently have an unlimited capability for division [134], and thus ES cell culture derived from a single donor can be theoretically propagated unlimited, but ES cells have to differentiate to muscle cells before they can be used.

Meat processing technology

Since three-dimensional fully structured meat is not possible with existing bioengineering technologies, the cultured meat is likely to be introduced in the form of comminuted meat products such as patties, nuggets, balls, and sausages. Cultured meat produced currently lacks in certain sensorial attributes, such as color, texture, and juiciness; and the processing phase will have to take care of these shortcomings and come up with nutritionally and sensorially acceptable meat products. New industrial-scale processing technologies are required to make cultured meat–based products more attractive and at least sensorially as acceptable as conventional meat products. Although an imaginary "The *in vitro* meat cookbook" was launched in 2014 that covered 45 different recipes [135], the research is totally lacking on product processing part and needs immediate scientific attention.

Associated dangers and risks

Since every new technology brings new risks and dangers with it, cultured meat may have a completely different risk profile than conventional meat. Much attention would require to be paid to the safety of added substrates and other compounds of the culture medium. Cultured meat may have some environmental advantages than conventional meat; however, production may be associated with some new risks of contamination. The meat will be cultured under sterile conditions within a closed bioreactor making sure that aseptic conditions are used during this phase of production. So, there are fewer risks with respect to microbial contamination but more risk of contamination of substrates. After the culturing phase of production, the cultured meat will be dealt with similar quality control and hygienic conditions as applicable to any regular standard meat settings. Thus during this phase, there will be similar risks and dangers as are expected in regular meat production and need to be dealt with accordingly.

Since more skilled personnel and perhaps robotics and automation would be required to manage this more sophisticated production system, it will certainly affect the job opportunities for less skilled persons associated with conventional meat industry. Although it is hard to evaluate the possible health hazards and risks associated with this production system beforehand, certain probable outcomes such as there will be lesser open lands in rural areas and more forests as fodder requirements will be significantly reduced. There will be for sure some favorable outcomes on animal welfare and environmental front. However, some of the areas such as genetic instability of multiple cell divisions [136] and the issues with media components [137] may require special attention. Future efforts in culturing meat will have to address the limitations of current techniques making cultured cells, scaffolds, culture media, and growth factors edible and affordable.

Regulatory issues

There are no regulatory guidelines issued for this new product because the production of cultured meat is currently limited to research level. Being essentially a consumable meat product, this new production system is likely to be overseen by the food safety authorities and is expected to vary from one country to the other and at least at par to regular standard meat production settings. Although there is also a possibility that the initial stages of the production involving the cell collection, maintaining the cell banks, and cell growth and differentiation, considered as a domain for medical expertise, could fall under the medical supervision. A comprehensive monitoring system needs to ensure that the process could be aborted in the case of deviations at the critical control points and start over the process a fresh. This production system may be more complicated than the conventional meat production; however, it inherits certain advantages in terms of meat safety for being grown under microbiologically and contamination-free environment.

Recently, a public meeting was held by the US Food and Drug Administration (FDA) and the US Department of Agriculture (USDA) to discuss the use of poultry and livestock cell lines to develop food products based on cell-cultured meat [138]. It was concluded and later announced that there will be a joint regulatory framework

and both the FDA and the USDA will jointly oversee the production of cell-cultured meat and meat products. The stages involved in the beginning of the production process such as cell collection, cell banks, and cell growth and differentiation will be monitored by the FDA, whereas the later stages involving the production and labeling of the cultured meat products will be overseen by the USDA, thus benefiting from the expertise of both the regulatory bodies, that is, the FDA's experience of handling living biosystems and cell-culture technology and the USDA's experience of regulating the meat production.

Consumer acceptance and perception

Several aspects of cultured meat have been studied by several researchers, including the acceptance and perception of consumers toward this novel product (Table 73.1). While Mattick and Allenby [139] analyzed the consequences of a potential shift from livestock agriculture to cultured meat, Hocquette et al. [140] studied the limitations associated with cultured meat such as economic, social, and technical constraints, also including the uncertain consumer acceptance. Post [141] identified public perception as the least studied aspect of cultured meat while highlighting the various technological challenges that lay ahead. While studying the consumers reaction and attitude formation to the cultured meat, Verbeke et al. [142] reported that the initial reactions of the consumers upon learning about in vitro meat were underpinned by feelings of disgust and considerations of unnaturalness. Siegrist et al. [143] reported a low level of acceptance for cultured meat due to perceived unnaturalness and disgust and pointed out that the perception of the participants was highly influenced by the description of the product. Rather than giving more importance to the production method, the product needs to be highlighted and labeled and introduced in a nontechnical way highlighting the similarities of cultured meat with conventional meat. Content-based information can play a significant role and influence the attitude of the people for the commercial success of cultured meat [144].

Although information about the sustainability and a positively perceived sustainable product could contribute to commercial success and to the acceptance of cultured meat [144], how customers see this new commodity in relation to conventional meat is mainly going to decide its commercial success [145]. Educated consumers (scientists and students) believe that cultured meat is not going to be accepted by the consumers and it is not a solution for the problems associated with the current meat production [146]. Given the conditions that prices were equal, and burgers tasted the same, only 11% of the participants opted to purchase the cultured meat–based burger in comparison to a conventional beef burger [147]. The demand for cultured meat was also reported to be price sensitive as 6% increase was seen in the share of regular beef with 1$ increase in the price of cultured meat–based burger (base price of 4$), emphasizing that the benefits of the production system might be insufficient for increasing acceptance of the consumers due to lack of naturalness associated with it [148]. This unnaturalness perceived by the consumers could be reduced by small-scale production methods that can help in reversing the feelings of alienation by allowing close contact with cell-donor animals [149]. Novel food technologies may face a lack of acceptance even if the risks are lower and benefits are higher [150,151].

Role of media in publicity of cultured meat

Media has played a great role in publicity of this new product and has been mostly projecting it as a potential solution to several problems associated with conventional meat production. While studying the media coverage of cultured meat, Goodwin and Shoulders [152] reported that several sources, mostly advocates of cultured meat, have covered many aspects of this new product such as benefits, history, process, and time and particularly highlight the problems associated with current livestock agriculture. While studying the media coverage of the tasting event of cultured meat burger in 2013, Hopkins [153] reported that there has been an over emphasis on the coverage and tenure of the coverage, particularly in Canada, the United States, and the United Kingdom. By over emphasizing the acceptance of cultured meat among vegetarians and highlighting its potential in mitigation of the environmental and animal welfare issues associated with conventional livestock agriculture, the Western media neglects the technological challenges and gaps in the knowledge that are in the way of commercial success and acceptance of this novel product [153].

Market for cultured meat

While media has given enough publicity and there has been an increased interest in cultured meat production, some of the recent studies have presented mixed results regarding the expected market size for cultured meat. Despite of the facts that an overall positive view of the consumers was reported about the cultured meat [145] and 91% of the participants agreed to the idea of giving a try to this new product in a study carried out by Verbeke et al. [154], there are some less favorable results reported by several studies such as Verbeke et al. [142], Siegrist and Sütterlin [148], Hocquette et al. [146], and Verbeke et al. [154] about the potential market for the cultured meat. However, new information through marketing campaigns or social norms have an influence and could

TABLE 73.1 Acceptance and perception of consumers toward cultured meat.

Authors	Aspect studied	Findings
Slade [147]	A hypothetical choice experiment was performed to study the consumer preference for burgers based on cultured meat	Given the conditions that prices were equal and burgers tasted the same, 65% of the consumers opted to purchase the regular beef burger and only 11% consumers chose to purchase the cultured meat burger
Siegrist et al. [143]	How does the perceived naturalness and evoked disgust affect the acceptance of cultured meat	A product-oriented approach focused on the merits of the product and explained in a nontechnical way will be more effective for the acceptance of cultured meat
Bryant and Barnett [155]	A systematic review of the available literature was done to elucidate the acceptance of consumers toward cultured meat	The authors studied various factors that affect the acceptance of cultured meat and its demographic variations, consumer objections, perceived benefits and areas of uncertainty. The study concluded that consumers perceive the environmental benefits and animal welfare advantages; however, these are only going to have minor influence on their buying decisions
Bekker et al. [144]	How does the information provision on implicit and the explicit attitude influence consumer acceptance toward cultured meat	The explicit attitude toward cultured meat can be influenced by the information about the sustainability of this production system and a positively perceived sustainable product
Siegrist and Sütterlin [148]	How does the perceived naturalness affect the acceptance of cultured meat	Despite the fact that this novel production system seems more environmental-friendly and humane, lack of naturalness perceived by consumers might reduce the acceptability of cultured meat
Verbeke et al. [142]	Reactions toward cultured meat and attitude formation of the consumers from Portugal, the United Kingdom, and Belgium was studied	Initial reactions of the consumers toward cultured meat were underpinned by the feelings of disgust and considerations of unnaturalness leading to some kind of fear of the unknown. The consumers acknowledged the global and personal merits of this production system
Verbeke et al. [154]	The authors studied the prospects and challenges of cultured meat in terms of consumer acceptance	Sensory characteristics and price of the product were identified as the major factors to influence the acceptance of cultured meat
Hocquette et al. [146]	The study mainly involved students and scientists and evaluated what educated consumers think about cultured meat	While only a minority (5%–11%) of consumers accepted to eat or recommend cultured meat, majority of consumers believed that cultured meat would not be tasty and healthy and will not solve the problems associated with current production systems
Welin [156]	The authors studied the prospects and problems associated with cultured meat	The perceived "unnaturalness" was identified as the biggest barrier for acceptance of consumers toward cultured meat

change the consumer preferences and affect the market size [144].

Conclusion

Cultured meat is promoted as a humane and clean production system offering several advantages, including animal welfare, environmental considerations, process monitoring, efficiency of food production, and reduced resource use. The composition, nutritional value, and functional role of cultured meat seem to be more manipulatable. This system holds great promises as an alternative to conventionally produced meat provided consumer resistance can be overcome. There are several technological

challenges in the path of success of cultured meat and a great deal of research is still required to fill the gaps in our knowledge. Production on an industrial scale would be feasible only when a cost-effective process creating a product qualitatively competitive with existing meat products is established. Government subsidization like that provided to other agribusinesses can play a role during initial establishment of this industry.

Chapter 74

Three-dimensional bioprinting for tissue engineering

Jun Tae Huh, James J. Yoo, Anthony Atala and Sang Jin Lee

Introduction

Tissue engineering strategy aims to develop biological substitutes to overcome the high shortage of autologous tissues and organs for transplantation. Although tissue engineering applications have progressed rapidly over the past two decades, the conventional fabrication methods are limited in their abilities to create clinically applicable tissue constructs with well-interconnected pores, complex architectures, patient-specific geometries, and heterogeneous material distributions. Over the past few years, three-dimensional (3D) bioprinting strategy has been applied to address these limitations [1–4]. It allows for the fabrication of tissue constructs with unique spatial control over the deposition of cells, biomaterials, and bioactive molecules, resulting in higher regenerative capability after implantation [5,6]. 3D printing or additive manufacturing was developed in the 1980s, and it included various approaches to create objects from a computer-generated file [7]. This technology quickly became a powerful tool in tissue engineering and biomedical research [8]. In the structure-based bioprinting, bioinert or bioactive materials such as metals, ceramics, and polymers are used to develop a tissue structure followed by precisely depositing cells and bioactive molecules to it [9,10]. In the cell-based bioprinting, high density of cells is patterned spatially with a prescribed organization in a layer-by-layer fashion forming tissue-like constructs [3,9].

Thus 3D bioprinting allows the creation of tissue-specific architectures with precise geometries that have been limited to conventional fabrication methods. Landers et al. first introduced 3D bioprinting as an extrusion-based method to continuously dispense cells within a hydrogel material (the bioink) from a dispensing head to a stage based on patterns predesigned through computer-aided design/manufacturing (CAD/CAM) tools [11,12]. Various types of 3D bioprinting methodologies are now available to meet the specific requirement in tissue engineering applications.

3D Bioprinting strategy: from medical image to printed bioengineered tissue

3D bioprinting strategy aims to achieve reproducible, complex tissue structures that are well vascularized and suitable for future clinical use. Since human tissues and organs have arbitrary 3D shapes composed of multiple cell types and extracellular matrix (ECM) with the functional organization, this strategy can be the most effective way to achieve this goal [1]. The CAD/CAM processes are important technologies needed for the future clinical applications of 3D bioprinting because these processes provide an automated way to replicate a 3D shape of a targeted tissue structure [13]. In general, the process starts by scanning the patient to produce 3D volumetric information of a target object using medical imaging modalities such as computed tomography (CT) and magnetic resonance imaging. These imaging tools acquire information from cross-sectional slices of the body, and the data is stored in the Digital Imaging and Communications in Medicine (DICOM) format that is a standard format for digital imaging in medicine. This information is transformed into a 3D CAD model by the reverse engineering process. This process starts with interpolation of points within and between image slices to improve resolution and generate voxels from the measured data. This CAD model is created by the extraction of localized volumetric data from a targeted tissue structure to generate a surface model. In this step the sophisticated reconstruction of the CAD model is required for bioprinting process due to a complexity of tissue or organ. A motion program, which

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00076-9

is instructional computer codes for the printer to follow designed paths, is generated with a CAM system. This CAM process is divided into three steps: slicing, tool path, and motion program generation. Slicing is to obtain information of sliced two-dimensional (2D) shapes of an object for the layer-by-layer process. Then tool path generation is for creating a path for the tool to follow to fill the cross-sectional space of each layer. The printed tissue-specific architecture has the proper inner functional structure constructed with multiple cellular components for efficient tissue regeneration. Therefore a well-organized strategy for tool path generation is required. Fig. 74.1 shows 3D bioprinting strategy from the medical image to the printed tissue constructs developed by CAD/CAM process and automated printing of 3D shape imitating target tissue or organ [1,13].

Three-dimensional bioprinting techniques

A variety of 3D printing techniques has been developed to bioengineer 3D human tissue/organ constructs for tissue engineering applications. The effectiveness of each printing technique relies heavily on biomaterials choice and targeted applications. In general, bioprinters consist of three main components: three-axis stage, printing cartridges, and the dispenser. Stage controllers move the printer head in the *X*, *Y*, and *Z* directions. Printing cartridges, usually in the form of a syringe, store either the polymeric components of the scaffold or the cell-laden hydrogel components, and they include a nozzle that determines the amount of material dispensed at set printing parameters. The dispenser system is the final component, which causes the deposition of materials, and it varies between the printing techniques (Fig. 74.2).

Jetting-based bioprinting

Boland et al. demonstrated the deposition of living cells using modified commercial thermal inkjet printer [20]. Similar to the inkjet printer used to apply ink onto a paper, the jetting-based bioprinters dispense a controlled volume of liquid to a predefined location through non-contact deposition (Fig. 74.2A). Selected hydrogel acts as an "ink" in this case where it can be dispensed in volumes between 10 and 150 pL depending on the dispensing modules used [21]. The two common dispensing methods to generate droplets in inkjet printers are thermal and piezoelectric actuators. Thermal inkjet bioprinters use a thermal actuator that locally heats up the bioink to generate small bubbles in the printhead. These bubbles collapse to create pressure pulses that force droplets of liquid out of the nozzle. Although thermal inkjets use heat around 200°C−300°C, the duration of heating is typically around 2 μs which studies have found to result in only a 4°C−10°C rise in hydrogel temperature [4]. Piezoelectric inkjet bioprinters use a polycrystalline piezoelectric actuator that changes its shape when a voltage is applied. The change in the volume of the printhead induces a pressure pulse that ejects the droplet of bioink [21]. The volume of the dispensed bioink is dependent on various factors such as the temperature gradient of the printhead, the frequency of the pressure pulse, and the viscosity of the ink itself. Finally, *X* and *Y* position of

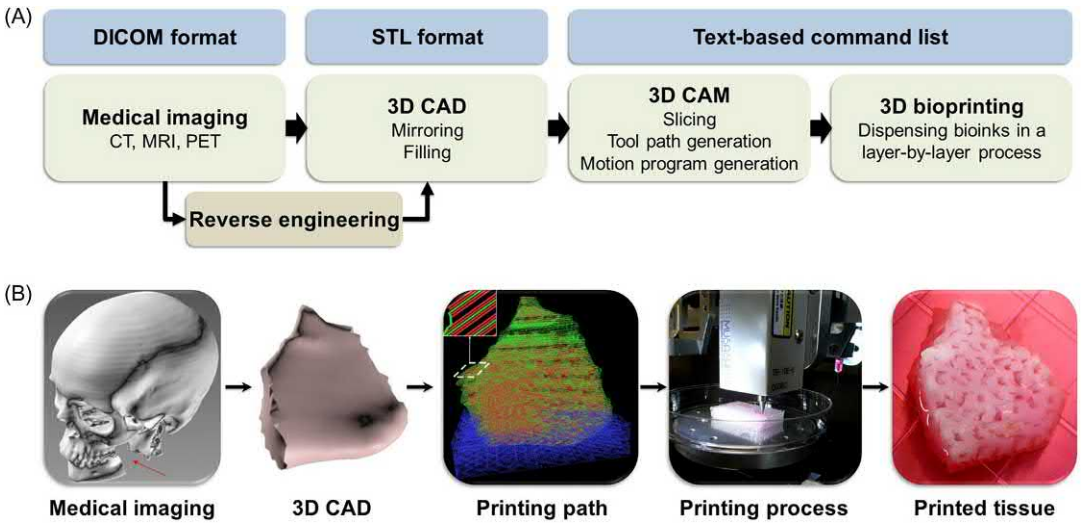

FIGURE 74.1 3D bioprinting strategy from medical imaging to printed tissue construct: (A) schematic diagram and (B) example of a CAD/CAM process for automated printing of 3D shape imitating target tissue or organ. A 3D CAD model developed from medical image data generates a visualized motion program, which includes instructions for *XYZ* stage movements and actuating pneumatic pressure to achieve 3D bioprinting. *3D*, Three-dimensional; *CAD/CAM*, computer-aided design/manufacturing.

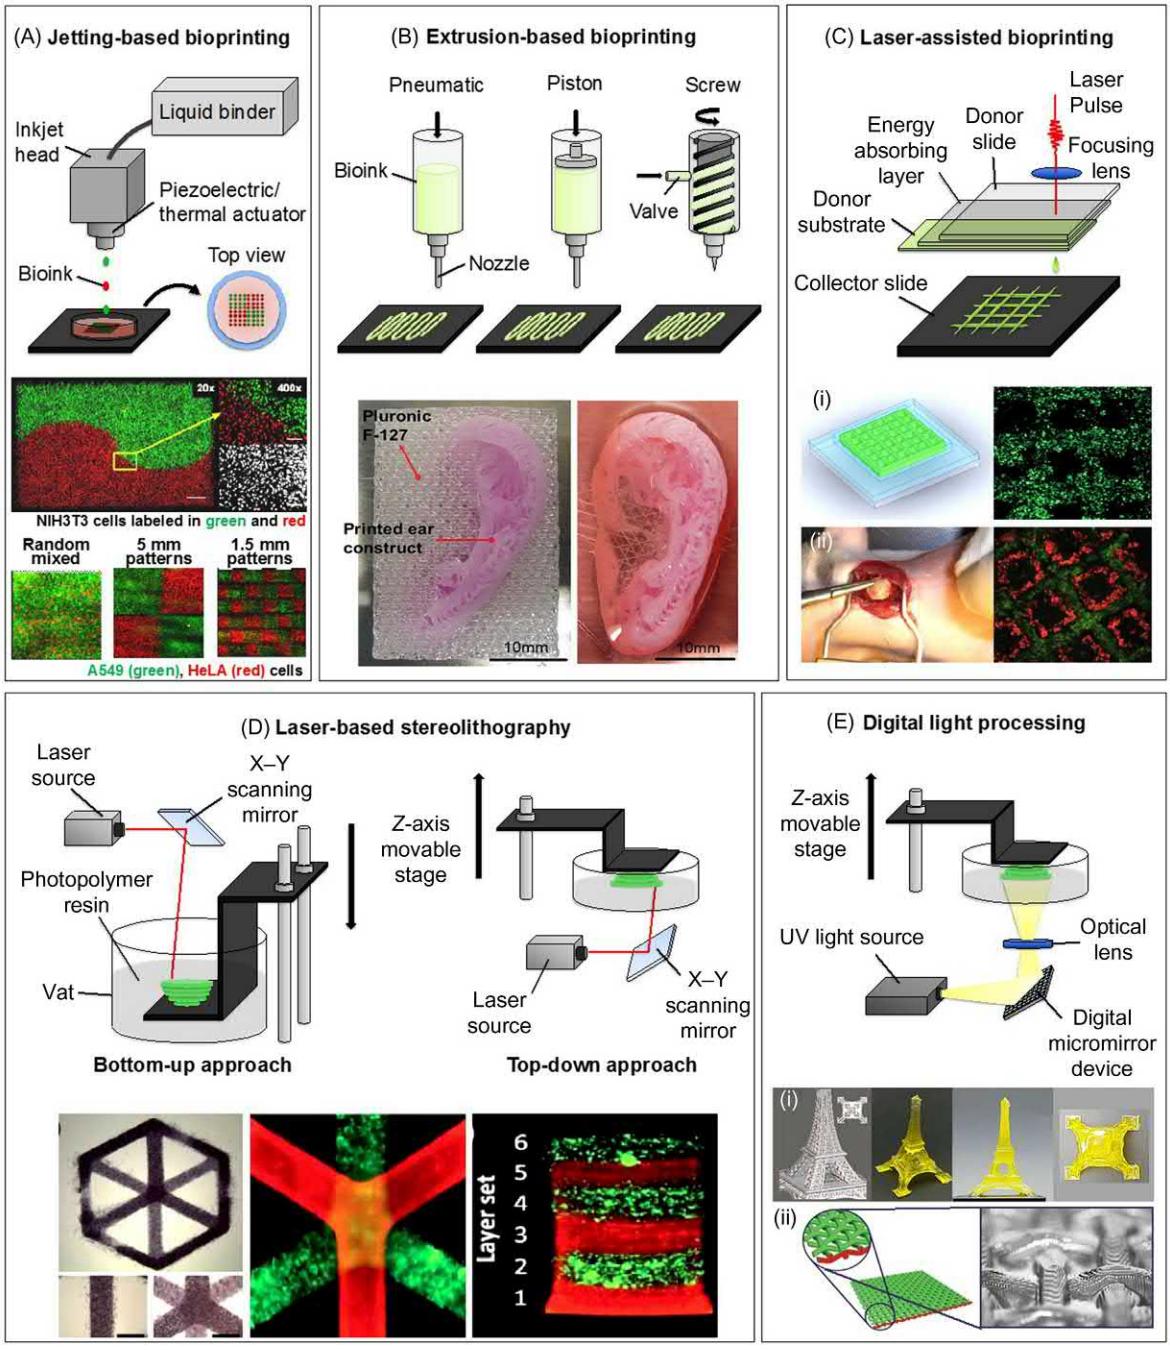

FIGURE 74.2 Schematic diagrams and examples of 3D bioprinting technologies. (A) Inkjet-based bioprinting: NIH/3T3 cells were labeled with green and red fluorescent dyes and patterned (above) [14]. A549 (green) and HeLa (red) cells were patterned in checkerboard designs with different sizes of inner squares using direct inkjet printing (bottom). (B) Extrusion-based bioprinting: auricular implant was printed with cell-laden hydrogel, PCL, and Pluronic F-127 through an extrusion-based method using pneumatic dispenser [1]. (C) Laser-assisted bioprinting: human adipose-derived stem cells-laden 3D graft (C-i) [15] and cardiac patch with HUVECs and hMSCs (C-ii) [16] were printed with laser-assisted techniques. (D) SLA: spatial 3D multilayer cell patterning of fibroblasts in PEGDA hydrogels were printed using laser-based SLA [17]. (E) DLP: a miniature of Eifel tower printed with methacrylated silk fibroin hydrogel (E-i) [18] and woven chain mail structure printed with PVAMA/GelMA bioink (E-ii) [19] using DLP bioprinter. *3D*, Three-dimensional; *DLP*, digital light processing; *GelMA*, gelatin methacrylate; *HUVECs*, human umbilical vein ECs; *EC*, endothelial cells; *PVAMA*, poly(vinyl alcohol) methacrylate; *PEGDA*, poly(ethylene glycol) diacrylate; *SLA*, stereolithography.

the nozzle head can be precisely controlled in a scale of micrometers to allow high-resolution bioprinting.

Jetting-based bioprinting offers many advantages. First, the patterning of various designs with different cell types is possible. For instance, Park et al. used a direct inkjet printing technique to directly pattern living cells (Fig. 74.2A) [14]. Initially, they printed the NIH/3T3 cells labeled with green and red fluorescent dyes to show the feasibility of heterotypic cell patterning. Then they labeled the A549 and HeLa cells with green and red fluorescent dyes, respectively, and patterned checkerboard shape with different sizes of inner squares. Inkjet printers also offer a high printing resolution where concentration gradients of cells, biomaterials, or bioactive molecules throughout the structure can be controlled by altering drop sizes and densities [4]. For instance, droplets can be arranged into linear patterns with 50 μm intervals or single droplet patterns containing only one or two cells [22]. In addition, droplet size can be controlled electronically to range from less than 1 to over 300 pL in volume with deposition rates from 1 to 10,000 droplets per second [23]. However, major drawbacks of jetting-based printing are its limited performance of 3D tissue construction. Unless cured rapidly, it is difficult to build up the 3D structure along the *Z*-axis with the jetting-based bioprinting techniques, and only low viscosity materials ($\sim$0.1 Pa/s) can be used [24]. Also, as cells are forced through the nozzle, shear stress induced during the printing process has a huge risk of damaging the cell membranes that can cause cell lysis [21]. Lastly, high cell concentrations (more than 10 million cells/mL) often result in nozzle clogging, and some instances may even alter the properties of the hydrogel greatly that it can hinder the proper cross-linking of the bioink [25,26].

Extrusion-based bioprinting

The most well-known and commercial 3D bioprinters are extrusion-based printers. Unlike jetting-based printing, extrusion-based printing uses an additive manufacturing mechanism that relies on fused deposition modeling, and the biomaterial is dispensed directly on the stage in a continuous string form rather than liquid droplets (Fig. 74.2B). The printer extrudes a 2D pattern designed by CAD/CAM software, and then each layer serves as the foundation for the next layer above it. These extrusion type printers mainly include a stage, a dispensing system, and a printing cartridge that are capable of movement in the *X*, *Y*, and *Z* axes. Three dispensing systems are widely utilized to extrude the biomaterial in the barrel for 3D bioprinting: (1) pneumatic-, (2) piston-, and (3) screw-based dispensing systems [4]. The pneumatic-based dispensing system allows accurate control over the air pressure to allow dispensing of the material with increased pressure need for more viscous materials [27]. The ultimate force of pneumatic systems is only limited by the air pressure capabilities of the system. On the other hand, mechanical dispensing systems use motor-derived piston or screw to provide more spatial control at the cost of reduced maximum force capabilities [4]. However, the rotating screw gear requires fine design to be used for bioprinting. Despite its advantages in dispensing high viscose material, the configuration of a screw can induce a high-pressure drop along the nozzle, which can potentially harm the loaded cells [9].

The main advantage of extrusion-based bioprinting is that can build 3D tissue architectures that can be implanted in vivo. For instance, Kang et al. used extrusion-based 3D printing for ear cartilage reconstruction (Fig. 74.2B) [1]. CT image of an ear was used for printing of the auricular implant with chondrocyte-laden hydrogel bioink, poly (ε-caprolactone) (PCL), and Pluronic F-127. In addition, the extrusion-based technique can use a wide range of biomaterials, including hydrogels, polymers, cell aggregates, and ceramics. Materials with viscosities ranging from 30 to greater than 6×10^7 mPa/s have all been successfully printed with extrusion-based printers providing a wide range of selection of biomaterials [28]. Another advantage of extrusion-based printing method is its ability to print bioink containing a high density of cells. However, one of the downsides is that an increase in pressure and nozzle gauge can induce high shear stress causing a decrease in the viability of cells. Therefore the size of the nozzle and level of pressure should be carefully selected to ensure high cell viability after printing. Another disadvantage of extrusion-based printing is its limitation in printing resolution and speed relative to other bioprinting techniques. For instance, nonbiological extrusion printers can print 5−200 μm resolution at linear speeds of 10−50 μm/s [29]. Using biomaterials and cells, the minimum resolution is generally over 100 μm which is lower than the resolution in other bioprinting methods [30].

Laser-assisted bioprinting

Laser-assisted bioprinting is a 3D printing method to shape and assemble bioink by laser-guidance direct writing [31]. In 1999 Odde et al. performed the direct writing of living cells (embryonic and chick spinal cord cells) [32]. It is operated by focusing a laser pulse toward an absorbing layer, typically gold or titanium, to generate high-pressure bubbles that propel cell-containing bioink toward a collector slide [4]. A standard laser-assisted printing system usually consists of a pulsed laser beam, a focusing lens, a donor slide, a "ribbon" that has transport support made from a laser-energy-absorbing layer, a donor substrate that has hydrogel or cellular material layer and a collector slide (Fig. 74.2C). The laser-assisted methods can deposit materials with viscosities ranging from

1 to 300 mPa/s and cell densities close to 10^8 cells/mL with resolutions close to a single cell per drop without significant effects on cell viability or function. There are many factors that affect printing resolution. Some of these factors include the energy delivered per unit area due to the laser, the surface tension, substrate wettability, the gap between the donor substrate and collector slide, and the thickness and viscosity of the biological layer [4].

Similar to jetting-based bioprinting, one of the reasons for using the laser-assisted technique is its ability to pattern cells in various designs. For instance, Guillotin et al. used alginate-based bioink with human endothelial cells (ECs) to print patterns of the Olympic rings and two concentric circles using laser-assisted bioprinting [33]. Similarly, Gaebel et al. printed cardiac patch made of human umbilical vein ECs (HUVECs) and human mesenchymal stem cells (hMSCs) using laser-induced forward transfer (LIFT) cell printing technique (Fig. 74.2C-i) [16]. Furthermore, Gruene et al. developed 3D tissue graft made of human adipose−derived stem cells (ASCs)−laden alginate hydrogel (Fig. 74.2C-ii) [15]. Another advantage of laser-assisted bioprinting method is that it is nozzle free. Therefore nozzle clogging issues often seen in jetting-based and extrusion-based bioprinting systems are avoided. However, there are also several disadvantages associated with the laser-assisted printing system. The major concern is its potential risk of damaging the cells caused by the thermal energy of the laser [33]. It can also be difficult to accurately target and position the cells due to the nature of the ribbon cell coating. Moreover, metallic residues may be present in the final construct due to the vaporization of the laser-absorbing layer. To reduce this contamination, there have been methods of using nonmetallic absorbing layers and altering the printing process so that an absorbing layer is not needed [34].

Laser-based stereolithography

On August 8, 1984, stereolithography (SLA) 3D printer was developed by Chuck Hull, which was the world's first 3D printer [35]. The SLA printing technique creates 3D objects by successively photo-curing thin layers of resin by a spatially controlled laser beam. The main components of a laser-based SLA 3D printer are a laser source, an X−Y scanning mirror, a vat (resin tank), photo-curable polymer resin, and a movable stage (Fig. 74.2D) [36]. Depending on the direction of fabrication, the printer has two approaches: bottom-up and top-down methods. Early developed SLA printers used the bottom-up approach where the printing stage lowers after the curing of the first layer to cover the topmost layer with unpolymerized resin. Another layer of resin is sequentially cured and the stage lowers again. The critical limitation of the bottom-up approach is that it requires a large vat of resin, which causes enormous consumption of materials and high expenditure. On the other hand, for the top-down approach, the light source is projected through a transparent film on the bottom of the vat filled with photo-polymers. The first layer is cured with light and is detached from the transparent film as the printing stage moves upward. Another layer of uncured photo-polymer fills in the gap between the first layer and the bottom of the vat. The second layer is printed on the bottom surface of the previous layer, and this process is repeated until the printing is over. The unpolymerized resin is removed by draining. The top-down approach uses a much smaller resin tank allowing a lower cost of material preparation. Due to this characteristic, many bioprinting studies with SLA technique use top-down approaches.

Digital light processing

Digital light processing (DLP) is another type of SLA. The major difference of DLP from laser-based SLA is that DLP uses a projection of ultraviolet (UV) light (or visible light) from a digital projector to flash a single image of the layer across the entire resin at once. One of the key components of DLP is a digital micromirror device (DMD) chip (Fig. 74.2E). DMD chip is composed of an array of reflective aluminum micromirrors that redirect incoming light from the UV source to project an image of a designed pattern or a layer of a 3D CAD model. The projection of an image that is composed of small square pixels called "voxels" passes through an optical lens and cures the photo-curable polymer resin [37]. To fabricate a high-resolution structure, setting up the parameters such as the curing time of each layer, layer thickness, and intensity of the UV light is critical. These parameters are highly dependent on the concentration and types of photopolymer and photo-initiator used for the resin.

There are many advantages of laser- and DLP-based SLA bioprinting techniques over extrusion-based methods. The SLA bioprinter has the ability to fabricate a complex 3D model with high resolution ($\sim$1.2 μm) [38]. Another advantage of SLA process is to precisely control the average energy dose to minimize the adverse effect on cells [17]. Chan et al. used SLA printer with both modified top-down and bottom-up methods to fabricate fibroblast-encapsulated 3D multilayer structure (Fig. 74.2D) [17]. The DLP bioprinter also can print an intricate structure with high resolution ($\sim$1 μm) and with fast printing speed ($\sim$30 min, mm^3/s) regardless of the layer's area and pattern [18]. Kim et al. printed a miniature of Eifel Tower with methacrylated silk fibroin bioink using DLP-based SLA printing (Fig. 74.2E-i) [18]. Moreover, the flexibility to fabricate complex 3D designs and integrate a variety of

functional elements including live cells, biomaterials, and nanoparticles can be achieved with these computer-aided, photo-curing-based techniques [39]. For instance, Lim et al. used MSCs-laden poly(vinyl alcohol) methacrylate (MA)/gelatin MA (GelMA) hydrogel to print complex tangled structure such as a woven chain mail (Fig. 74.2E-ii) [19]. Also, physical masks or molds are not needed in DLP 3D printing. However, the major downside of these SLA printing techniques is that there are limited biomaterials for the bioink that can be photo-cured [18]. Poly(ethylene glycol) (PEG) diacrylate (PEGDA), GelMA, Pluronic F127 DA, and hyaluronic acid (HA) MA are reported as potential biomaterials for DLP printing [40,41].

Hybrid and other techniques

Hybrid fabrication system is a combination of technologies that are individually practiced. Despite the rapid growth over two decades, the current 3D bioprinting techniques and systems fall short in integrating rigid and soft multifunctional components. In some instances the advantages of one technology might not be sufficient to meet the requirement of creating targeted functional tissue constructs. Merging technologies may overcome this limitation and improve the bioprinting process. The combination of technologies can be at the cellular level, bioink level, or on the bioprinter level. Tan et al. introduced a 3D bioprinting strategy by integrating conventional scaffold-based fabrication method and the cell-based bioprinting approach [42]. They explored the use of hydrogel encapsulated cell-laden microspheres as the bioink for 3D bioprinting. The hydrogel lubricates and glues the microspheres during printing and helps in fusing together after printing upon gelation. Kucukgul et al. developed computational algorithms to generate support structures of cylindrical cell aggregates for printing fully cell-based vascular structures [43]. Xu et al. proposed a combination of electrospinning and inkjet bioprinting techniques to develop layered cartilage constructs [44]. Combining the two different principles of electrospinning and bioprinting resulted in the fabrication of cartilage construct with appropriate cell function and mechanical properties. Shanjani et al. developed a new hybrid 3D bioprinting technology, called Hybprinter, by integrating soft and rigid components [45]. This technique employs DLP-based SLA component and molten material extrusion techniques. PEGDA was used as a soft hydrogel, and PCL was used for the scaffold's structural support. Mendoza-Buenrostro et al. reported a hybrid bioprinting technique for the fabrication of scaffolds with topography scales ranging from nanometers to millimeters [46]. Scaffolds were produced by extrusion printing PCL embedded with nanofibers.

Biomaterials as bioinks for three-dimensional bioprinting

Hydrogel-based bioinks for cell-based three-dimensional bioprinting

In bioprinting a hydrogel that can encapsulate and deliver tissue-specific cell types with bioactive molecules through the printing mechanisms is referred to as bioink. Generally, hydrogels are made from naturally derived or synthetically produced hydrogels that are biocompatible, biodegradable, and chemically or physically cross-linkable to maintain a user-defined structure that ultimately assists cell viability, proliferation, differentiation, and function [47]. Hydrogels are also highly moist and ideal for absorbing high levels of nutrients and oxygen, allowing cells to survive within the construct and diffuse waste. Due to these characteristics, hydrogel-based bioinks have been used in a variety of bioprinting techniques to directly deliver cells in the printed constructs.

The required properties of hydrogel-based bioinks

To ensure successful 3D bioprinting, printability of hydrogel-based bioink is critical. As the number of manufacturing techniques capable of bioprinting has increased over time, including jetting-, extrusion-, laser-assisted printings and SLA-based printing, the physical and rheological requirements for a feasible bioink vary upon printing methods [48]. Fig. 74.3 shows the schematic diagram of variables essential to 3D bioprinting strategy. Depending on the printing techniques used, hydrogels' material properties, cross-linking mechanisms, and printing parameters should all be carefully selected to improve the printability of bioinks.

In the extrusion-based bioprinting the required properties of hydrogel-based bioinks are (1) relatively sufficient viscosity to maintain homogenous cell suspension, (2) strong shear-thinning behavior to minimize cell damage, and (3) rapid cross-linking to build a 3D tissue architecture [3,49]. First, bioinks should have proper viscoelastic properties that allow them to have homogenous cell suspension and initial structural integrity to be printed in multiple layers before cross-linking. Second, bioinks should have strong shear thinning behavior, which is the non-Newtonian behavior of fluids meaning that viscosity decreases under shear strain [50]. The shear thinning behavior allows the otherwise stiff hydrogels injectable and minimizes cell damage during extrusion. Last, the rapid cross-linking of bioink is critical since most hydrogels cannot self-support upon layer-by-layer deposition [51]. Due to adverse effects of dense polymer matrices that can inhibit the remodeling and

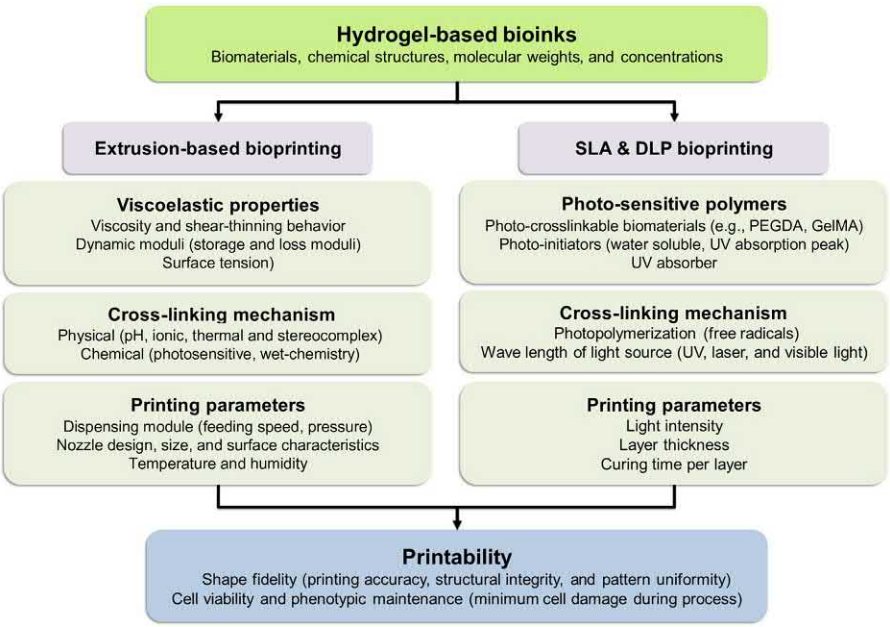

FIGURE 74.3 Schematic diagram of variables critical to 3D bioprinting strategy. The material properties, cross-linking mechanism, and printing parameters all needs to be carefully selected in hydrogel-based bioprinting. *3D*, Three-dimensional.

vascularization of cells, the traditional hydrogel precursors are low viscous solutions that are cross-linked either during or after the printing process [52]. Cross-linking before printing increases the shear stress on the cells, resulting in the high potential of cellular damage and nozzle clogging. Meanwhile, cross-linking after printing affects the resolution due to the spreading of bioink in the time between extrusion and cross-linking, which can lead to incomplete cross-linking in large multilayered constructs [4].

In the laser-based SLA and DLP bioprinting, the hydrogel-based bioinks are photopolymerized by a pattern of laser or projected UV light, respectively, to form 3D structure [18]. Therefore understanding of the photo-curing mechanism is essential. Briefly, a photo-initiator generates free radicals when absorbed with UV light (initiation). The free radicals abstract hydrogen from a double bond of polymer to generate new free radicals that abstract hydrogen from another polymer, and this process repeats to build a strong polymer network (propagation). Finally, two free radical species react with each other to create a stable, nonradical state (termination). Thus the hydrogel-based bioinks that are feasible for SLA and DLP must exhibit characteristics that are compatible with the lithographic process and which differ notably from the requirement of extrusion-based bioprinting [53]. Typically, GelMA and PEGDA are widely used photo-crosslinkable biomaterials in SLA and DLP bioprintings [54]. Also, the photo-initiator in the bioink needs to be carefully selected. The photo-initiator needs to be soluble to water, biocompatible, and have a wavelength of maximum absorbance that matches with the wavelength of light source used. Lastly, UV-absorber such as color dyes can also be added to avoid the overcuring of layers beyond the focal plane to enhance printing resolution.

Since the cell-based bioprinting aims to build a 3D tissue construct containing live cells, the cell viability after printing is one of the main criteria for printability of bioinks. For the cells to survive a biologically favorable microenvironment is required so that the cells can be well preserved not only during the printing process but also afterward in culture. In the hydrogel-based bioinks, the cell density, diffusion coefficient, temperature, and humidity can significantly affect the printability of the bioinks [55–57]. In addition, regardless of printing techniques, a sterile condition for cell printing must first be acquired to ensure high cell viability and prevent contamination after printing. The bioink and components of printer that directly contact with the cells must be sterilized before use.

Synthetic hydrogels

Synthetic hydrogels used as bioinks have low cytotoxicity, controlled biodegradability, and good mechanical properties; however, most of the synthetic hydrogels have low biological properties that minimally interact with cells. Pluronic F127, a thermosensitive hydrogel, undergoes a phase transition at room temperature and becomes a viscous substance [58]. When the concentration of Pluronic F127 is 25% w/v or more, it can be dispensed with high printability. Although high resolution of the printed structures can be achieved using Pluronic F127, the structure can be easily collapsed in the culture condition. To improve its mechanical stability, Pluronic F127 has been used chemically

modified as a photo-crosslinkable hydrogel [59]. In addition, Pluronic F127 hydrogel has been widely used as a sacrificial bioink to support the 3D architecture because it is easy to print uniformly and be immediately washed out once printing is complete [1].

PEG-based hydrogels are also widely used in 3D bioprinting because they can be chemically modified and functionalized to improve their biological and biomechanical properties by introducing various functional motifs attached to the terminal end of PEG [60] or combining with other hydrogels [41,61]. In order to improve the mechanical properties of PEG, the addition of DA of MA has been used for various applications. Thus photopolymerization of PEG-based hydrogels could achieve the tunable mechanical properties in the bioprinted constructs.

Naturally derived hydrogels

Natural hydrogels are classified into mainly proteins and polysaccharides. Most of them are present in the body, so they show high biological properties and do not cause a severe immune response. Collagen (mainly, type I) is the most abundant component of ECM, and it contains the cell-guiding chemical cues such as the cell adhesion peptide sequence, arginine−glycine−aspartic acid (RGD). Under the appropriate temperature and pH, a pure collagen solution physically forms a gel with properties dependent on the solution concentration. However, collagen itself has rarely been used as a bioink material due to low viscosity and poor mechanical stability. In order to overcome these limitations, the collagen has been mixed with various other hydrogels such as agarose, chitosan, fibrin, HA, and/or other materials [44,62−64]. On the other hand, Kim et al. determined collagen's rheological behaviors with various printing temperatures to improve the stability of the collagen-based bioinks without any additional hydrogels [65,66]. The results showed that the proper structural stability of printed collagen construct was achieved at 5°C−10°C for the printing nozzle and 35°C−37°C for the printing stage, followed by tannic acid cross-linking process. An approach for printing skin cell−containing collagen-based bioink from separate nozzles using an inkjet micro-valve dispensing method was reported [67]. In the printing process the collagen solution remained acidic and cooled. Multiple layers of cell-laden collagen bioink were printed and then treated with aerosolized sodium bicarbonate ($NaHCO_3$) to buffer the pH toward neutral for gelation. The results showed high cell viability at 1 day after printing for keratinocytes and fibroblasts, indicating the survival of cells and spatial control of the printing approach which is needed to offer a functional skin replacement.

Gelatin is a substance in which water-insoluble collagen is made soluble by high temperature or acid/base treatment. It forms a thermo-reversible hydrogel. Moreover, chemical modification of gelatin with unsaturated methyl MA results in GelMA, which can form covalently cross-linked hydrogels under UV exposure [51]. Recently, photo-crosslinkable GelMA is the most popular bioink material for cell-based bioprinting due to proper printability and tunable mechanical properties. GelMA has been used for printing a complex architecture, which contained various cell types and vasculature [68]. For instance, a cell-laden GelMA and sacrificial Pluronic F127 were dispensed and embedded within the GelMA block in predetermined 3D structure. After then, the printed structure was cross-linked by UV exposure. The sacrificial Pluronic F127 was removed at 4°C by the phase transition to create open microchannels within the GelMA block. Lastly, a suspension of HUVECs was seeded into the open microchannels. This approach allowed for the viable deposition of cells in 3D structure with a microvessel-like structure that was covered by ECs for the provision of nutrients to surrounding cells.

HA is the most abundant of the glycosaminoglycan (GAG) family, which has the repeating structure of glucuronic acid and *N*-acetyl-glucosamine disaccharide. HA has a high molecular weight and a large amount of branching that allow for intermolecular hydrogen bonding and high viscosity. Like other polysaccharides, HA can support cell survival but has low cell-binding motifs. Moreover, HA itself has very low structural integrity and shape fidelity after printing; therefore HA has been chemically modified for cross-linking or mixed with other hydrogels [69]. For example, Skardal et al. developed a bioink formulation combined with methacrylated HA and GelMA and photo-crosslinked by a two-step process, before and after extrusion, to form more compact firm constructs [61,70].

Fibrinogen, which is a glycoprotein, is reacted with thrombin to convert into fibrin network self-assembles [71]. Fibrin has many cell-binding motifs that allow the cell attachment and vulnerability to proteases for remodeling. Fibrin-based bioink has been used by LIFT-based printing process for a 3D multicellular array [72]. To improve the gel stability, HA was added to fibrinogen solution to print the arrays. Endothelial colony-forming cells (ECFCs) were printed along with ASCs in 3D patterns that a 9×9 array of ASC droplets were printed followed by an inset 8×8 array of ECFCs. These droplet arrays were printed onto a layer of fibrinogen−HA which was spray treated with thrombin−calcium chloride solution to induce the gelation. The cell-laden droplets were converted to fibrin-HA as they encountered the treated substrate with a residual thrombin solution. The results showed that ASCs initially migrated toward ECFCs without evidence of ECFC sprouting or migrating at all. Once ASCs contacted the ECFC aggregates, an explosion of ECFC network sprouts began to extend from the initial

droplet position and remained as stable networks for several weeks.

Alginate is a naturally derived anionic polysaccharide exhibiting gelation in the presence of divalent ions such as Ca^{2+} [73]. Alginate hydrogel has served as a cell delivery material for many tissue engineering and drug delivery applications due to ease of preparation and relatively good cell compatibility; however, the major drawback is the lack of mammalian enzymatic degradation, which limits tissue remodeling when implanted. In 3D bioprinting, alginate solution in 2%–4% (w/v) is extrudable and structurally stable after cross-linking process. In addition, it can be mixed with other materials to increase the printing resolution as a bioink. For example, the alginate solution mixed with cellulose nanofibers improved shear fluidization and the viscosity, resulting in high printing resolution. Then alginate was cross-linked with the divalent cation Ca^{2+} to stability the printed construct. In the early stage of cell-based bioprinting, a jetting printing setup was modified for 3D printing by printing of a Ca^{2+}solution into a reservoir of cardiac cells mixed with alginate solution [74].

Tissue-specific extracellular matrix–based hydrogels

Tissue-specific ECM–derived bioinks have been introduced for 3D bioprinting [75]. These ECM materials can either be obtained from cell-derived ECMs that are secreted during in vitro culture, or derived directly from native tissues through a decellularization process during which all the cellular components removed to avoid adverse immunological response [76–81]. To utilize the tissue-derived ECM materials as bioinks, the ECM-rich materials can be solubilized to reformulate as a gel type [82,83]. Importantly, the ECM provides a structural architecture that contains adhesion sites for cell surface receptors [84] and preserves normal tissue function by its tissue-specific mechanical and biochemical properties [85]. The interaction between cells and the surrounding ECM regulates a variety of physiological cellular processes, including motility, migration, invasion, and proliferation [86,87]. Moreover, the ECM regulates signal transduction pathways by binding to integrins or by modulating the activity of signaling molecules [88]. The ECM hydrogels are composed of the structural and functional molecules that characterize the native tissue ECM such as collagen, laminin, fibronectin, growth factors, GAGs, glycoproteins, and proteoglycans [89]. Thus bioinks derived from decellularized tissue-specific ECM can provide these same functions as naturally occurring ECM [90–92]. However, ECM-based hydrogel is inherently low viscous, exhibiting low shape fidelity and structural stability. Thus various attempts have been performed to enhance their chemical and physical properties in 3D bioprinting [93].

Biodegradable synthetic polymers for structure-based three-dimensional bioprinting

Synthetic polymers run some advantages for applications in tissue engineering and 3D bioprinting. These polymers can be synthesized with reproducible quality and fabricated into various structures with predetermined bulk/surface properties. Additional advantages include the capability to tailor the biomechanical properties and biodegradation kinetics for various biomedical applications. In bioprinting, synthetic polymers such as PCL, poly(lactide-*co*-glycolide) (PLGA) and poly(lactic acid) can provide the mechanical strength, thereby overcoming limitations of the hydrogel-based constructs on size, shape, and structural integrity [1]. For the extrusion method, melted thermoplastic polymers or polymer solutions with proper viscosity are needed. Therefore PCL is the most commonly available polymer for the extrusion-based bioprinting because of its low melting point of 60°C and high printability.

Unlike the extrusion-based bioprinting, SLA offers several benefits when compared to other printing techniques, most notably in the ability to print more complex architectures with high resolution. However, this printing technique requires photo-crosslinkable polymeric resins, which can be limiting for tissue engineering applications. A few of polymeric biomaterials has been adapted for use with SLA printers. For example, Dean et al. utilized poly (propylene fumarate) (PPF), which is photo-crosslinkable, for DLP printers [94,95]. The results showed that PPF was printed highly complex constructs with controlled chemical properties and porous architecture. Many research groups are exploring the synthesis of polymeric biomaterials for 3D bioprinting.

Scaffold-free cell printing

3D tissue structure can be printed using multicellular aggregates without supporting materials [96]. This method enables to dispense cell aggregates from a capillary to form 3D structure. Norotte et al. reported a scaffold-free cell printing method using multicellular spheroids consisting of smooth muscle cells (SMCs) and fibroblasts and agarose hydrogel for temporary support [97]. After printing the printed cell aggregates were fused and formed a small diameter vessel-like tube ranging from 0.9 to 2.5 mm in diameter. Li et al. fabricated vertical channels without the use of a supporting material by taking advantage of the gelation behavior of gelatin in combination with the cross-linking of alginate or fibrinogen [98]. Itoh et al. proposed a method to fabricate a scaffold-free vascular tube using the cell aggregates [99]. Predesigned 3D tubular structures were constructed with the cell aggregates consisting of ECs, SMCs, and fibroblasts. The multicellular aggregates self-organized and fused into a

tubular structure that was perfused with a bioreactor. In order to avoid the formation of droplets at the end of the nozzle due to surface tension, Ozler et al. developed a quantitative model to predict the success of cell aggregate extrusion [96]. This approach can be repeated for different cell types after obtaining their respective rheological properties. In addition, cell viability can be dependent on the compression ratio applied during the printing process. Thus it is necessary to first investigate the impact of compression on their survival rate and cellular functions.

Three-dimensional bioprinting in tissue engineering applications

Three-dimensional bioprinted vascular structures

A major limitation in the bioengineered tissue constructs is the lack of proper vascularization into the implanted constructs. Importantly, fully vascularized tissue constructs are required to attain long-term cell survival and tissue functions. 3D tissue constructs packed with metabolically active cells can rapidly be formed necrotic cores in the absence of a vascular network due to a limitation of the transport of nutrients and other physiologically relevant molecules toward and away from the tissue [100–102]. When a 3D tissue construct with cells is implanted, efficient mass transfer requires intact microvasculature to maintain the metabolic functions of cells deep inside the construct. Indeed, the ingrowth of the microvascular system into the implanted bioengineered tissue constructs in a timely manner is the key to success in clinical use [4]. Hence, many attempts have utilized 3D bioprinting as a promising technology to fabricate vascularized tissue constructs (Fig. 74.4) [68,97,103–105].

One of the earliest and simplest approaches to fabricate a vascularized tissue construct is to use a sacrificial component that acts as a structural role during printing and is later removed to create a hollow tunnel. For example, Miller et al. reported a vascular-casting approach with carbohydrate glass as the sacrificial template (Fig. 74.4A) [103]. They dispensed a cell-laden hydrogel into a mold with the lattice structure of carbohydrate glass which was removed after cross-linking of the hydrogel. Then HUVECs were injected into the generated lumen to form vascular networks. On the other hand, extrusion-based bioprinting technique has been also used to form a vascular construct. For instance, Kolesky et al. showed a method of fabricating 3D constructs completed with vasculature, including multiple cell types and ECM proteins (Fig. 74.4B) [68]. Coprinting two bioinks of HUVEC (red) and human neonatal dermal fibroblast cells (green)–laden GelMA formed 3D microvascular networks.

Although bioprinting technologies have evolved to a level of creating complex vascularized constructs carrying multiple cell types and ECM proteins, the reconnecting of the vascular structures to host circulatory system is still challenging. To address this, Lee et al. developed a novel bioprinting approach to creating a network from capillaries to large perfused vascular channels (Fig. 74.4C) [104]. The large channels were fabricated using 3D bioprinting and angiogenic sprouting of ECs from the edge of the large vessel was achieved through a natural maturation process. These printed constructs are often thin or hollow structures, so they are nourished by diffusion from host vasculature but not by anastomosing [106]. When the diffusion limit needed by engineered tissues exceeds 150–200 μm, a precise vascular network must be embedded into fabricated constructs, a feat that has not yet been accomplished [107,108]. Efforts to simplify the complex fabrication methods and to find new technologies for the bioprinting of vascular structures are currently in great need by tissue engineering as a whole.

There are also other vascularization techniques such as scaffold-free engineered tissue constructs and 4D bioprinting. First, the scaffold-free bioprinting avoids the limitation related to the foreign materials and exogenous scaffolds such as adverse host responses and infection [99]. Norotte et al. developed macrovascular tubular structures from multicellular cylinders using scaffold-free bioprinting (Fig. 74.4D) [97]. Double-layered vascular tubes similar to vessels were developed with human umbilical vein SMCs (green) and human skin fibroblasts (red), and H&E staining revealed a distinct boundary between the SMCs and fibroblast layers after 3 days of fusion. Another vascularization technique is a 4D bioprinting of self-folding tubes developed by Kirillova et al. (Fig. 74.4E) [105]. Thin films of methacrylated alginate and HA were printed and cross-linked with green visible light. Then the hydrogel films exhibited instant self-folding into tubes when immersed in water, phosphate-buffered saline (PBS), or cell culture media. The 4D bioprinting methods may allow the future development of reconfigurable tissue structure with controllable functionality and reactivity.

In vitro tissue models

Drug discovery is an inefficient process with a high failure rate and an extreme financial burden. Animal studies are not always indicative of the results in human trials, and the regulatory environment is becoming stricter as time progresses. In addition, from a moral standpoint, attempts should be made to reduce the number of animal studies conducted. In vitro studies, mostly 2D cell culture methods, are also severely limited. Drug response, gene expression, migration, morphology, and viability of cells

The construct shows three compartments consisting of the vascular lumen, EC lining, and the matrix encapsulated cells. Endothelialized channel walls and the intervessel junction surrounded by human fibroblasts. (B) The engineered tissue construct developed by Kolesky et al. [68]. Multilayers of channels lined with HUVEC (red) and HNDFs (green) formed 3D microvascular networks. (C) 3D bioprinted multiscale vascular systems performed by Lee et al. [104]. Fibrin-HUVEC cell mixture (green) was deposited in between the two vascular channels (red), and the integration of capillary network was observed at the border. (D) Scaffold-free, macrovascular tubular structures from multicellular cylinders by Norotte et al. [97]. Double-layered vascular tubes similar to vessels were developed with HUVSMCs (green) and HSFs (red), and H&E staining showed the distinct boundary between the smooth muscle cells and fibroblast layers after 3 days of fusion. (E) 4D biofabrication of self-folding tubes developed by Kirillova et al. [105]. Green visible light cross-linked methacrylated alginate and methacrylated HA hydrogel films exhibited instant self-folding into tubes when immersed in water, PBS, or cell culture media. *3D*, Three-dimensional; *EC*, endothelial cells; *HUVECs*, human umbilical vein ECs; *HA*, hyaluronic acid; *HNDFs*, human neonatal dermal fibroblast cells; *HUVSMCs*, human umbilical vein smooth muscle cells; *HSFs*, human skin fibroblasts.

have all been shown to differ between 2D and 3D environments. Recently, a large emphasis has been placed on creating in vitro 3D tissue models to overcome these limitations. Typically, this is done by suspending cells or organoids (or cell aggregates) in a 3D culture within a singular or entire array of microfluidic devices. Already, 3D in vitro assay systems have advanced immensely to a level in which living constructs can closely mimic the native tissue environment in a high-throughput platform. While several fabrication techniques have been used to develop these models, 3D bioprinting technologies are advantageous due to their low cost and efficiency, high throughput, excellent reproducibility, and the ability to create complex geometries. The major two areas to which 3D printed in vitro tissue models have been applied are cancer research and drug screening systems (Table 74.1).

Tumor models

3D bioprinting of cells as tumor models are helpful to study the interaction of immune and tumor cells and for the screening of new treatments [118]. Xu et al.

TABLE 74.1 Applications of bioprinting in vitro biological systems.

Tissue/ organ	Bioprinting method	Cell type	Encapsulation material	Testing	Outcomes	References
Tumor/ cancer	Pneumatic cell droplet patterning	Fibroblasts and ovarian cancer cells	Matrigel	Reproducibility and precision of cell density and spacing	Bioprinting methods showed improved performance compared to micropipette ejection	[109]
Tumor/ cancer	Temperature controlled, pneumatic extrusion	Hepatic carcinoma and mammary epithelial cells	Matrigel	Radiation shielding capabilities of the prodrug amifostine	Amifostine provided radioprotection to the cells, with the greatest benefit seen in the dual-cell model	[110]
Tumor/ cancer	Projection stereolithography (UV exposure)	HeLa and 10T1/2	PEGDA	The effect of channel width on tumor cell and 10 T1/2 migration and morphology	Tumor cells showed increased migration speed and less change in morphology with smaller channel sizes compared to 10 T1/2	[111]
Tumor/ cancer	Extrusion	HeLa	Gelatin–alginate–fibrinogen	Viability, proliferation, MMP expression, and chemoresistance versus 2D culture	3D cell culture increases cancer cell proliferation, MMP expression, and resistance to chemotherapy	[57]
Tumor/ cancer	Continuous 3D projection (with nonlinear exposure)	Breast cancer cells	PEG	Long-term culture and validation of breast cancer spheroids	Spheroids showed hypoxic cores and signs of necrosis, key features of tumor environment	[112]
Liver	Extrusion	Hepatocytes	Alginate	Validation of liver cell activity and metabolic performance	Cells were viable, proliferative, synthesized urea, and metabolized EFC to HFC	[113,114]
Bacterial infection	Inkjet	*Escherichia coli*	Alginate	Treatment of the *E. coli* with several common antibiotics	Similar results to the current low throughput, less reproducible, and more expensive methodologies	[115]
Brain	Extrusion and subsequent dissolution of sacrificial resin	Mouse brain ECs	Type 1 collagen microchannels	Model validation with transendothelial permeability measurements and hyperosmotic mannitol disruption test	Permeability decreased over 3 weeks of culture, and then recovered over 4 days after hyperosmotic mannitol disruption	[116]
Lung	Extrusion	ECs and epithelial cells	Matrigel	Cell viability, distribution, morphology, and permeability compared to manually placed cells	Printed constructs resulted in more homogenous cell distributions, proper cell morphologies, lower permeability, and similar viability	[117]

2D, Two-dimensional; 3D, three-dimensional; ECs, endothelial cells; EFC: 7-ethoxy-4-trifluoromethylcoumarin; HFC, 7-hydroxy-4-trifluoromethylcoumarin; MMP, matrix metalloproteinase; PEGDA, poly (ethylene glyocol) diacrylate; PEG, poly(ethylene glycol); UV, ultraviolet.

introduced a 3D in vitro cancer model using human fibroblasts and ovarian cancer cells on a Matrigel matrix, showing precise and reproducible control over cell density and spacing compared to manual ejection by micropipettes [109]. Snyder et al. also introduced a similar model in 2011 with human hepatic carcinoma cells and mammary epithelial cells. Cells and the microfluidic device were printed in order to test the radiation shielding of the prodrug amifostine. Radioprotective benefits for the liver were seen in the in vitro model [110]. Huang et al. examined tumor cell migration in a honeycomb structure with different channel widths (25, 45, and 120 μm) to mirror that of natural blood vessels [111]. HeLa and 10T1/2 cells were seeded within the device and were evaluated in the different channel sizes. HeLa cancer cells showed less morphological changes between channel sizes than 10T1/2 cells and also migrated at higher rates as channel size decreased. Also looking at bioprinted HeLa cells, Zhao et al. examined cell response after extrusion in a gelatin–alginate–fibrinogen hydrogel in comparison to a 2D culture model. Cells in the 3D model showed higher proliferation, matrix metalloproteinase expression, and chemoresistance [57]. Hribar et al. have used 3D projection printing to create concave PEG structures that form and maintain breast cancer spheroids for long-term culture [112]. The breast cancer spheroids exhibited necrotic, hypoxic cores that are key components of the tumor in vivo microenvironment.

Tissue-specific models

The number of in vitro drug screening systems has increased immensely both in quality and in quantity over the last decade, ranging from hepatic cells suspended in a microfluidic device to integrated, multiple-tissue, body-on-a-chip systems. Chang et al. used direct cell writing bioprinting to create a 3D micro-organ housed using soft lithographic micropatterning [113]. Alginate-encapsulated hepatocytes printed in the microfluidic device were viable, proliferated, and capable of synthesizing urea. This work was further investigated by infusing the hepatocyte containing a microfluidic device with 7-ethoxy-4-trifluoromethylcoumarin that was metabolized into 7-hydroxy-4-trifluoromethylcoumarin, mimicking the in vivo behavior of the liver [114]. Rodriguez-Devora et al. developed an inexpensive drug-screening platform via inkjet bioprinting deposition. *Escherichia coli* was printed in an alginate solution with different antibiotic droplets patterned on the cells, resulting in similar bacteria inhibition when compared to the current screening process [115]. An in vitro model of the blood–brain barrier has been developed by Kim et al. Mouse brain ECs were cultured within an array of type I collagen microchannels fabricated using microneedles on a 3D printed frame [116]. The model was validated by measurements of transendothelial permeability and a disruption experiment by hyperosmotic mannitol. In addition to the blood–brain barrier, an air–blood barrier has also been developed to model the lung. Horvath et al. developed a model by bioprinting epithelial cells and ECs separated by a basal membrane layer [117]. The bioprinted model was more reproducible and had thinner cell layers than which could be manufactured using traditional manual methods.

In addition to these already successful in vitro models, several areas for future work stand out in this new field. Work is in progress to incorporate an array of tissue types into the same drug-screening platform. Bioprinted in vitro models are also in good position to evaluate gene therapy techniques; however, standardized model systems/industry standards are needed to facilitate comparison across studies. The use of these in vitro models shows promise in increasing our understanding of biology, disease progression, organ cross talk, and many other areas as the field progress forward.

Three-dimensional bioprinted implantable tissue constructs

3D bioprinting has been utilized to fabricate constructs targeting nearly every tissue type in the body. While clinical implantation is still rare for this relatively new technology, there have been many successes in vitro and in vivo. Highly detailed, anatomically correct, and patient-specific tissue constructs have been fabricated for a number of tissues and organs (Table 74.2). A wide range of cells has been shown to maintain their viability, gene expression, and functional capabilities after the printing process. Various stem cells have demonstrated the ability to preserve their differentiation potential and also have been directed by various cues applied during the printing process [143,144]. This section will highlight a few of the tissue-specific applications that have been studied with bioprinting technologies.

Bone

Bone regeneration is a natural target application for bioprinting given the importance of anatomical structure to its in vivo functions. Conventional 3D printing technologies are already in use clinically as patient-specific metal implants [145]. Bioprinting offers a unique and promising alternative to bone grafting given the wide variety in anatomic location, defect size, and patient-specific morphology for bone pathologies [146,147]. Bioprinting's advantage is especially apparent for bone defects that also feature a significant cosmetic function such as in craniofacial reconstruction [148]. Fedorovich et al. printed a mixture of Matrigel and alginate hydrogels with endothelial

TABLE 74.2 Three-dimensional bioprinting technologies for tissue regeneration applications.

Tissue/organ	Testing model	Printing method	Cell type	Bioink	Outcomes	References
Bone	In vitro viability and differentiation studies	Extrusion	Endothelial progenitor and multipotent stromal cells	Matrigel and alginate hydrogels	Viability and differentiation capability were unaffected by the printing process, and the two distinct cell populations were maintained within a single scaffold	[119]
	In vitro differentiation studies	Inkjet	Primary muscle-derived stem cells	Fibrin	Incorporation of BMP-2 caused spatially controlled osteogenic lineage differentiation even in myogenic media conditions	[120]
	In situ bioprinting	Laser	Osteoblasts	Glycerol and *n*-Ha slurry	Successful in situ bioprinting into mouse calvarial defects with minimal side effects	[121]
	In vitro	Extrusion	—	PCL/ hydroxyapatite	Reconstructed from CT scans, anatomically accurate and supportive of physiological loads	[122]
	In vitro degradation, mechanical, and cytotoxicity	Laser	Fibroblasts	PPF	Scaffolds maintained their mechanical stability, and degradation products did not induce significant cell death	[123]
	In vitro and in vivo bone formation	Extrusion	Mesenchymal stromal cells	PCL/PLGA/β-TCP	Scaffolds which were decellularized after brief culture period induced a greater bone formation in vivo	[124]
Cardiac muscle	In vitro	Extrusion	Spheroids of HUVECs and cardiac cells	Type 1 collagen	Viable cells, fusion and beating at 70 h with early signs of vascularization	[125]
	In vitro	Inkjet	Cardiomyocytes	Alginate	Viability in thickness as high as 1 cm and contraction was observed at macro- and microscopic level	[74]
	In vivo cardiac infarct patch	Laser	HUVECs and human MSCs	Poly(ester urethane urea)	Increased function and vessel formation compared to cell only treatment 8 weeks postinfarct	[16]
	In vitro	Extrusion	Cardiac-derived cardiomyocyte progenitor cells	Alginate	Cells demonstrated viability, phenotypic cardiac expression, and the ability to migrate from the hydrogel	[126]
Cardiac valve	In vitro	Extrusion	Porcine aortic valve interstitial cells	PEGDA and alginate	Anatomical accuracy was confirmed, a range in mechanical properties was obtainable by varying the concentrations of the hydrogels	[10,30,127]
Cartilage	in vitro	Laser	MSCs	None	Good structural integrity and osteoblast and chondrogenic differentiation	[128]
	in vitro	Inkjet	Articular chondrocytes	PEGDMA	Similar mechanical and biochemical properties of native cartilage and good integration with surrounding tissue. FGF-2 and TGF-β1 synergistically improved GAG deposition	[129,130]
	In vitro and in vivo	Inkjet	Rabbit elastic chondrocytes	Fibrin–collagen	Combined PCL electrospinning and bioprinting technique facilitated type 2 collagen and GAG deposition with improved mechanical properties	[44]
	In vitro	Extrusion	Chondrocytes	Alginate	Biomimetic ear could translate sound waves into an electrical signal and coexist with viable chondrocytes	[131]
	In vitro	Extrusion	Chondrocytes and adipocytes	PCL and PEG (sacrificial) and alginate (encapsulation)	Chondrogenesis and adipogenesis confirmed by immunostaining	[132]

Skin	In situ bioprinting	Extrusion	Amniotic fluid-derived stem cells	Fibrin–collagen	Amniotic fluid derived stem cells outperformed both MSCs and acellular graft	[133]

	In vivo	Inkjet	Fibroblasts, keratinocytes, and microvascular endothelial cells	Collagen	10% improvement of wound contraction compared to allogeneic skin substitute	[136]
Bone–cartilage	In vitro and in vivo	Extrusion	MSCs and chondrocytes	Alginate	Distinct tissue regions were found after 21 days in culture and 6 weeks after subcutaneous implantation	[137]
	In vitro	Extrusion	Osteoblasts and chondrocytes	Type 1 collagen and HA	Cells showed better proliferation, migration, and function on hydrogels made from their native ECM and performed well in 14-day co-culture	[64]
Muscle–tendon	In vitro	Extrusion	Myoblasts amd 3T3 fibroblasts	PCL and PU	Cells were viable after a week in culture and scaffolds showed an appropriate trend in mechanical properties	[138]
Pancreas	In vivo	Extrusion	INS1E β/islets	Alginate and gelatin	Scaffolds were formed and embedded while maintaining cell viability & morphology	[139]
Adipose	In vitro	Laser	Adipose-derived stem cells	Alginate	Cells maintained viability, differentiation potential, and adipogenic gene expression after 10 days	[15]
Neural	In vivo	Extrusion	Bone marrow MSCs and Schwann cells	–	Grafts underperformed autograft controls, but provide a proof-of-concept for future work	[140]
	In vitro	Inkjet	Retinal ganglion cells and glia	–	Good cell viability and growth properties of cells was found after printing	[141]
	In vitro and in vivo	Laser	Neuronal, Schwann, and dorsal root ganglion cells	PEG	After three weeks, the nerve guide supported re-innervation across a 3 mm gap equal to that of an autograft	[142]

BMP-2, Bone morphogenic protein-2; β-TCP, beta-tricalcium phosphate; CT, computed tomography; ECM, extracellular matrix; FGF-2, fibroblast growth factor-2; GAG, glycosaminoglycan; HUVECs, human umbilical vein endothelial cells; HA, hyaluronic acid; MSCs, mesenchymal stromal cells; n-Ha, nano-hydroxyapatite; PCL, polycaprolactone; PLGA, poly(lactide-co-glycolide); PEGDA, poly(ethylene glycol) diacrylate; PEGDMA, poly(ethylene glycol) dimethacrylate; PEG, poly(ethylene glycol); PPF, poly(propylene fumarate); PU, polyurethane; TGF-β1, transforming growth factor beta-1.

progenitor cells and MSCs [119]. The constructs were implanted subcutaneously to immunodeficient mice. They were able to demonstrate that the incorporation of biphasic calcium phosphate microparticles caused the MSCs to differentiate into an osteogenic lineage and caused bone formation within 6 weeks after implantation. Phillippi et al. used the inkjet bioprinting to pattern bone morphogenic protein 2 on primary muscle-derived stem cells on fibrin-coated coverslips [120]. The stem cells differentiated into an osteogenic lineage even in myogenic differentiation media conditions. Keriquel et al. demonstrated in situ bioprinting by delivering nanoscale hydroxyapatite and osteoblasts into mouse calvarial defects with positive outcomes [121]. Using CT scanning, Yao et al. were able to print anatomically accurate, PCL/hydroxyapatite mandible scaffolds that supported physiological loads [122]. Wang et al. examined the degradation profile of printed PPF scaffolds as it pertained to pore size, porosity, and mechanical properties [123]. They also developed a novel test for cytotoxicity of the degradation products and determined the scaffolds to be suitable for bone tissue engineering applications. In order to incorporate biological materials with bioprinting technology, Pati et al. cultured MSCs on a printed PCL/PLGA/β-tricalcium phosphate (β-TCP) scaffold [124]. The cells deposited ECM during a brief culture period, after which the scaffold was decellularized. In vivo the ECM enriched scaffolds induced greater bone formation than unadorned scaffolds of the same composition.

Many limitations still exist including for large-sized defects and in high load-bearing applications. The lack of perfusion and neovascularization prevents large defects from being treated with bioprinting strategies, and further research in this area is needed [149]. In addition, the discovery of new bioprinting compatible materials and unique structural designs could increase the maximum load-bearing applications for these constructs. More work is also needed to closely match the degradation profiles of scaffolding materials with that of the bone remodeling rate. New bone formation is obstructed if the scaffolding material degrades too slowly, but the defect site is left without a load-bearing material if degradation occurs too quickly, damaging nearby tissue. Altogether, bone tissue is one of the more promising target tissue applications for bioprinting due to its many advantages relative to other tissue engineering strategies and the natural ability of bone to remodel in vivo.

Cartilage

Articular cartilage is imperative to reducing friction and absorbing compressive forces in load-bearing joints with little to no capacity for self-regeneration. Current cartilage tissue–engineering strategies are insufficient for reproducing tissue that is equivalent to healthy cartilage [150]. However, recently greater interest has been placed on the zonal differences found in cartilage matrix and cellular composition [151]. Bioprinting presents as an appealing tool for constructing stratified scaffolds, especially in patient-specific size and shape of individual lesions [152]. Gruene et al. used the LIFT to generate MSC grafts, showing good cell viability, density, and functionality [128]. MSCs were able to differentiate into osteoblasts and chondrocytes and the graft maintained good structural integrity in vitro. Cui et al. loaded chondrocytes into poly(ethylene glycol) dimethacrylate hydrogel and inkjet bioprinted them into an osteochondral plug [129]. The implant had mechanical and biochemical properties similar to native cartilage, and Safranin-O staining revealed good integration with surrounding cartilage tissue. The same group also used their experimental setup to investigate the effects of fibroblast growth factor 2 and transforming growth factor β1 on cartilage generation. Samples were cultured up to 4 weeks, and the highest GAG content was found for samples containing both growth factors, suggesting a synergistic effect between increased cell proliferation and increased chondrogenic phenotype expression [130]. To address some of the limitations of bioprinting, Xu et al. alternated between inkjet bioprinted layers of rabbit elastic chondrocytes suspended in a fibrin–collagen hydrogel and electrospun PCL [44]. The construct formed cartilage-like tissues in vitro and in vivo demonstrated by type II collagen and GAG deposition. In addition, the scaffolds with electrospun layers showed improved mechanical properties compared to scaffolds that were bioprinted only.

In particular, engineering the external ear has been a notably successful area of bioprinting cartilage tissue. The ear is almost completely avascular and aneural, has a complex geometry, and serves a largely aesthetic function which places a greater emphasis on individualizing each prosthetic to the specific patient. Mannoor et al. developed a bionic ear that can translate sound waves into an electrical output [131]. The scaffold was extrusion bioprinted with sodium alginate, silver nanoparticles, and chondrocytes in an ear-shaped geometry around the conductive, sound translating coil. Lee et al. extrusion printed PCL with PEG as a supporting sacrificial layer [132]. Chondrocytes and adipocytes were differentiated from adipose-derived stromal cells, encapsulated in alginate hydrogel, and dispensed into their respective regions. After 7 days in vitro culture, immunostaining analysis confirmed chondrogenesis and adipogenesis. Kang et al. also applied the extrusion-based bioprinting to fabricate a complex shape by making human-sized ear cartilage tissue construct (Fig. 74.5A) [1]. After implantation the printed ear shape was well maintained, with cartilage tissue formation upon gross examination. Histological

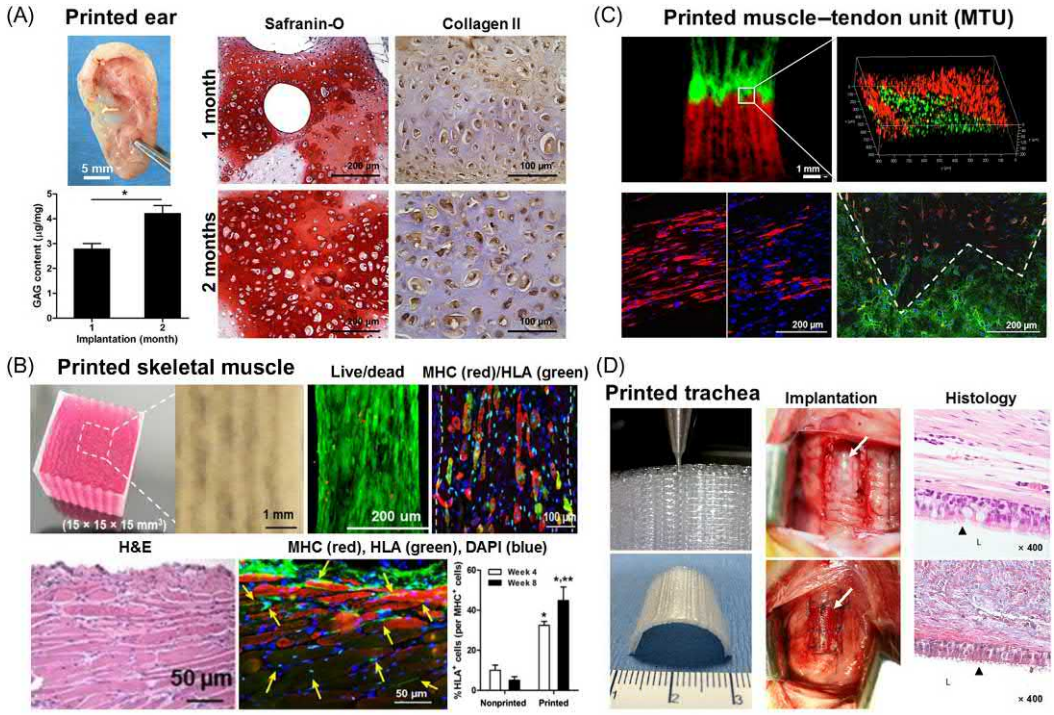

FIGURE 74.5 (A) Bioprinted ear construct: the shape was well maintained with substantial cartilage formation upon gross examination. Histological and immunohistochemical analyses showed the typical cartilage tissue formation [1]. (B) Bioprinted human skeletal muscle construct: the retrieved muscle constructs showed well-organized muscle fiber structures, vascularization, and host nerve integrity. The muscle force was recovered by up to 85% of native muscle at 8 weeks after implantation [153]. (C) Bioprinted MTU: fluorescently-labeled dual-cell printed MTU constructs (green: DiO-labeled C2C12 cells; red: DiI-labeled NIH/3T3 cells; yellow: interface region between green and red fluorescence) [138]. (D) Bioprinted tracheal construct: ingrowth of ciliary respiratory epithelium from the normal region was observed in the lumen of the bioprinted construct. Typical morphologies of respiratory mucosa and pseudocolumnar ciliary epithelium with goblet cells were well developed at 8 weeks after implantation (L: lumen) [154]. *MTU*, Muscle–tendon unit.

analyses showed the tissue formation of cartilage tissue as confirmed by GAG and collagen type II staining. Quantitatively, GAG content increased over time, reaching 20% of that of native ear GAG content at 2 months after implantation.

At this stage the next challenge for bioprinting as a means for cartilage regeneration is conducting translational studies. Very few in vivo studies have been conducted. Long-term stability of bioprinted cartilage constructs has yet to be demonstrated, and no studies have compared these strategies with practices currently used clinically. However, the research in cartilage bioprinting is growing exponentially and exhibiting many promising results for the future.

Skeletal muscle and tendon

The organized ultrastructure of skeletal muscle is required for muscle contraction and force generation [155]. Because 3D bioprinting mechanism enables to control of the spatial organization of cell-laden bioinks, Kim et al. were able to fabricate highly oriented muscle-like bundles for engineering skeletal muscle construct (Fig. 74.5B) [153]. A human muscle progenitor cell (hMPC)–laden hydrogel bioink was extruded with sacrificial acellular gelatin hydrogel bioink and a supporting PCL pillar. The printed hMPCs were longitudinally aligned along the printed pattern direction and showed high cell viability (over 90%) at 5 days in vitro. In the in vivo study where the printed muscle structures were subcutaneously implanted in athymic mice, the von Willebrand factor vessels and neurofilament nerves were observed at 2 weeks after implant. Furthermore, this bioprinted skeletal muscle construct maintained the tissue organization, followed by the tissue maturation and host nerve integration in rat tibialis anterior muscle defect model [153]. The results demonstrated that the 3D bioprinting was capable to produce promising structural and functional characteristics of skeletal muscle constructs in vitro and in vivo.

Tendon has a hierarchical architecture, and tenocytes are aligned along with dense collagen fibrous structure [156]. To mimic these structural characteristics of the tendon, an electrohydrodynamic jetting printing was introduced to generate a tubular-shape, multilayered tendon construct, having high porous, oriented microscale PCL fibers [157]. The cultured human tenocytes on the

bioprinted structure showed high cellular orientation, metabolism, and type I collagen expression. Importantly, 3D bioprinting technologies are particularly useful for composite tissue constructs like muscle–tendon. Merceron et al. used an integrated tissue and organ printing system to print four different components for the fabrication of a single integrated muscle–tendon unit (MTU) construct (Fig. 74.5C) [138]. The printed MTU construct comprised mechanically heterogeneous polymeric materials that were elastic (polyurethane, PU) on the muscle side and relatively stiff (PCL) on the tendon side, in addition to having a tissue-specific distribution of cells with C2C12 myoblasts on the muscle side and NIH/3T3 fibroblasts on the tendon side. The results showed that cells were printed with high cell viability and cellular orientation as well as increased musculotendinous junctional gene expression. It is demonstrated that 3D bioprinting technology enables a 3D heterogeneous tissue construction having region-specific biological and biomechanical characteristics.

Cardiac tissue and heart valves

The heart is a complex organ in both shape and tissue organization, both of which are difficult to replicate by other fabrication methods. The ability to spatially control the distribution of different cell types and growth factors makes bioprinting an attractive option for cardiac engineering, although only proof-of-concept successes have been accomplished thus far [158]. Jakab et al. were able to use extrusion-based bioprinting to pattern spheroids of HUVECs and cardiac cells on collagen [125]. The cells proved viable after the process, fused at 70 hours into a beating tissue, and showed early signs of forming vascularization. Using inkjet bioprinting, Xu et al. printed a half heart shape (with two connected ventricles) with cardiomyocytes encapsulated in an alginate hydrogel [74]. Cell viability was preserved in constructs as thick as 1 cm due to designed porosity within the structure, and contraction was observed in vitro at both microscopic and macroscopic levels. Instead of targeting whole heart reconstruction, Gaebel et al. developed a cardiac patch for regeneration after cardiac infarction [16]. Using LIFT bioprinting, HUVECs and human MSCs were patterned on polyester urethane urea and transplanted into the infarct zone. After 8 weeks, increased vessel formation and function were found compared to control treatment of bioprinted cells alone. A patch by Gaetani et al. used human cardiac-derived cardiomyocyte progenitor cells and extrusion bioprinted them in a sodium alginate mesh pattern [126]. They demonstrated cell viability, phenotypic expression of cardiac lineage, and the ability to migrate from the alginate, suggesting that bioprinting can be used for defined cardiac cell delivery. Wang et al. demonstrated the feasibility of 3D bioprinting to bioengineer a functional cardiac tissue construct that possesses a highly organized structure with unique physiological and biomechanical properties similar to native tissue [159].

Patients with heart valve failure must receive a replacement valve which can either be mechanical, require a lifetime of anticoagulant treatment, or biological, which typically fail within 10–20 years [160]. Bioprinting has gained momentum as a potential heart valve fabrication strategy to mimic the complex geometry and nonhomogenous material makeup, mechanical properties, and cell distributions which naturally occur in heart valves [160]. Hockaday et al. used a dual ionic and physical cross-linking hydrogel strategy by using PEGDA sodium alginate composite [10]. Printing accuracy of aortic valve root wall and tri-leaflets was confirmed via micro-CT scanning. By varying PEGDA and alginate concentrations, elastic moduli were found to range from 1.5 to 5.3 kPa. Porcine aortic valve interstitial cells were seeded and cultured on the scaffold for 21 days with nearly 100% viability. Later studies by the same group printed the cells directly within the hydrogel as opposed to seeding the scaffolds afterward, also with good geometric accuracy, cell viability, and mechanical properties [30,127]. While these studies are far removed from use in the clinic, they demonstrate that bioprinting technology is amenable to cardiac tissue regeneration and open the door for many future studies focused on improving the current methodology and outcomes.

Skin

Bioprinting is an excellent technology for the deposition of distinct layers and has been used in an attempt to mirror the layers of native skin, and research in this area has increased significantly recently. Skardal et al. performed directly in situ printing of amniotic fluid-derived stem cells suspended in the fibrin–collagen hydrogel [133]. In comparison to an acellular graft and an MSC graft, amniotic fluid-derived stem cells showed increased microvessel density and capillary diameter. Laser-assisted bioprinting has been used to embed fibroblasts and keratinocytes in collagen [134]. Histology revealed a high density of both cell types and the expression of laminin protein. The same group grafted their construct onto mice and reported early indicators of stratum corneum formation and blood vessels after 11 days [135]. Yanez et al. printed keratinocytes and fibroblasts in collagen as well but also included human microvascular ECs [136]. When implanted onto the backs of mice and compared to allogeneic skin substitute as a control, wound contraction improved by 10% and histological results appeared similar to that of normal skin. Sweat glands and hair follicles remain elusive, as does commercial and regulatory viability [161]. Nonetheless,

skin bioprinting has shown many encouraging successes, and the clinical bioprinting of skin appears to be an impending reality [42]. Very recently, Albanna et al. validated a mobile skin bioprinting system that provides rapid on-site management of extensive wounds. This system could facilitate the precise delivery of epidermal keratinocytes and dermal fibroblasts directly into a skin wound area, replicating the layered skin structure [162].

Other tissue types

Many other tissue types have been targeted with bioprinting technology, albeit to a lesser extent than those discussed thus far. This could be caused by a lesser clinical need, a higher difficulty of tissue engineering in general, or a poor matchup between the advantages of bioprinting and the necessary components for regenerating that tissue. Composite tissues are a major challenge facing regenerative medicine. No organ in the body is completely isolated, and many tissues such as tendons have specific and functional interfaces with other tissue types. Bioprinting is uniquely positioned to address this problem by spatially directing the placement of different cell types, growth factors, and biomaterials [163–165]. Fedorovich et al. extrusion bioprinted MSCs with hydroxyapatite, β-TCP, and biphasic calcium phosphate particles in alginate for one section of the scaffold and chondrocytes in alginate for the other [137]. Distinct tissue formation was found after 21 days in a mixture of osteogenic and chondrogenic media culture as well as after 6 weeks of subcutaneous incubation in vivo. Park et al. bioprinted osteoblasts in collagen I hydrogel and chondrocytes in HA hydrogel with good results after 14 days in vitro, in the process showing that the cells performed better on hydrogels made from their native ECM [64]. Finally, Merceron et al. targeted the MTU using PCL and 3T3 fibroblasts for the tendon zone and PU and myoblasts for the muscle zone [138]. The results showed that the cells were printed with good viability, begin developing into highly aligned morphology characteristic of muscle and tendon, and had increased muscle-tendon junction (MTJ)-associated gene expression during the culture.

Neural tissue has additionally been addressed by bioprinting. Owens et al. developed a nerve graft containing bone marrow MSCs and Schwann cells using the extrusion bioprinting [140]. The grafts were implanted for 10 months in a rat sciatic nerve injury model with autograft controls, concluding that that bioprinting was a promising approach to nerve grafting. Retinal ganglion cells and glia were piezoelectric inkjet bioprinted by Lorber et al., showing good cell viability and growth promoting properties in vitro [141]. Pateman et al. used a microsterolithographic technique to print a PEG-based nerve guidance channel for nerve repair [142]. At 3 weeks the nerve guidance was capable of supporting reinnervation across a 3-mm injury with similar results to that of an autograft in a common fibular nerve injury mouse model.

The trachea mainly comprises tightly stacked cartilage rings and respiratory mucosa in the luminal surface. Several synthetic implants have been used to reconstruct tissue defects [166–168]; however, these implants have been limited in their ability to mimic the tracheal functions biologically and biomechanically. Jung et al. developed a biomimetic tracheal construct using 3D bioprinting approach that could reconstruct a partial tracheal defect in a rabbit model (Fig. 74.5D) [154]. The printed tracheal PU constructs provided excellent structural characteristics. In the rabbit tracheal defect model, the printed PU constructs maintained the biomechanical function of the trachea, while the microscale porous architecture in the construct allowed the cellular infiltration for the biological integration with host tracheal tissue. Moreover, the printed PU scaffold provided a proper microenvironment to facilitate the resurfacing of the ciliated respiratory epithelium and the ingrowth of connective tissue with microvasculature.

Gruene et al. [15] laser bioprinted ASCs encapsulated in alginate-based bioink for adipose tissue engineering. They proved that the cells maintained their viability, differentiation ability, and adipogenic gene expression after 10 days in culture. Preliminary progress has also been made in several more complicated organs such as the intestine [169,170] and pancreas [139]. This section briefly examined the application of bioprinting to specific tissue types. Many studies were excluded due to space constraints and several tissue types, which have been explored via bioprinting, have not been covered here.

Conclusion and future perspectives

The principle of tissue engineering aims to build patient-tailored tissue constructs to reduce patient morbidity and mortality while improving quality of life. Currently, 3D bioprinting technologies combined with this principle hold great promise to achieve this goal. The focuses on replicating complex and heterogeneous tissue constructs continue to increase as 3D bioprinting technologies progress. Progression from single simple tissues, such as skin, bone, and cartilage, to organized contractile tissues, such as skeletal muscle and cardiac tissue, to composite tissues, such as osteochondral tissue and MTU, and finally to robust solid organs such as the kidney and heart are underway [2].

The clinically relevant workflow of 3D bioprinting requires multiple components that mainly include medical imaging, 3D CAD/CAM, 3D printing process, bioink materials, and translational cell source. Among those, various novel bioink systems have been developed for improving printability with high-resolution capability and

structural integrity. Advanced biomaterials, including hydrogels and polymers, that can serve as cell delivery bioinks and supporting structures but which also provide biological properties and mechanical and structural support, are required for 3D bioprinting. Moreover, advances in biomaterials depending on 3D bioprinting mechanisms are necessary for the long-term success in tissue engineering applications. Recently, an approach that utilizes the decellularized ECM can provide tissue-specific microenvironment to the cells. This decellularized ECM-based bioinks are still the closest biological microenvironment that mimics in vivo conditions; thus tissue-specific ECM-based bioinks are capable of providing critical cues for targeted cell engraftment, survival, and tissue formation.

There must be an increase in knowledge of biological, anatomical, and physiological aspects of complex tissues and organs. In particular, the development of in vitro 3D tissue models to study tissue- or organ-specific functions in the body will require a better understanding of morphological, structural, and functional units in tissues or organs. For clinical tissue engineering, the well-known limitation to build a large-scale tissue construct is vascularization in the construct. 3D bioprinting strategies have continued to overcome this limitation in various tissue engineering applications. A few groups have made progress toward printing vascularized tissue constructs; however, integrating functional microvascular structures into tissue- or organ-like constructs has not been accomplished. Approaches to utilize high porosity, angiogenic factors, and highly organized patterns of vascular cells by 3D bioprinting technologies may improve the principle of vascularization in the tissue-engineered constructs.

3D bioprinting technologies offer the opportunity to reconstruct the structural and ultimately the functional complexity of human tissues that incorporate multiple cell types, biomaterials, and bioactive molecules, resulting in sophisticated tissue constructs that have the potential to replace damaged or diseased human tissues and organs. Though there is much work to be accomplished to advance these technologies toward successful clinical translation, our efforts will constantly contribute to produce clinically applicable tissue constructs until 3D bioprinting strategy is able to improve the lives of patients. We envision that the bioprinted tissue constructs such as skin, bone, and cartilage have the great potential to be translated to clinical applications within a short period of time.

Abbreviations

2D	two-dimensional
3D	three-dimensional
ASCs	adipose-derived stem cells
β-TCP	beta-tricalcium phosphate
CAD	computer-aided design
CAM	computer-aided manufacturing
CT	computed tomography
DNA	deoxyribonucleic acid
ECM	extracellular matrix
FDA	US Food and Drug Administration
GAG	glycosaminoglycan
GelMA	gelatin methacrylate
HA	hyaluronic acid
HUVECs	human umbilical vein endothelial cells
HUVSMCs	human umbilical vein smooth muscle cells
LIFT	laser-induced forward transfer
MSCs	mesenchymal stem cells
PCL	poly(ε-caprolactone)
PEGDA	poly(ethylene glycol) diacrylate
PEGDMA	poly(ethylene glycol) dimethacrylate
PLGA	poly(lactide-*co*-glycolide)
PPF	poly(propylene fumarate)
UV	ultraviolet

Glossary

Bioprinting	The incorporation of biological materials into additive manufacturing techniques, either by directly depositing cells layer-by-layer or indirectly by 3D printing biologically active materials for later use in cellular applications.
Cross-linking	A chemical bond between two polymer chains which changes the overall properties of the material.
Electrospinning	A method for the production of fibers which utilized electrical forces to draw out nanoscale threads of melted polymer material.
Extracellular matrix	The environment secreted by cells which biochemically and structurally supports a cellular network.
Extrusion bioprinting	Direct contact bioprinting mechanism that relies on pressure or displacement to force material through the syringes.
Fused deposition modeling	An additive manufacturing technology which extrudes heated material layer by layer to create 3D structures.
High-throughput screening	Drug delivery process in which a lot of drugs or chemicals can be tested at a rapid pace.
Hybrid bioprinting	Utilizing multiple bioprinting mechanisms in one system to overcome the limitations of each mechanism.
Hydrogel	A polymeric, gel material in which the main component is water.
In situ bioprinting	Bioprinting directly in vivo such as onto a skin wound or into a bone defect; As opposed to bioprinting separately and then surgically placing a scaffold into a defect.
Jetting bioprinting	Originating from inkjet printers, this noncontact bioprinting mechanism uses pressure pulses to apply bioink in predetermined locations.

Laser-assisted bioprinting	Bioprinting mechanism that uses a focused laser to generate high-pressure bubbles that propel cell-containing material onto a substrate.
Microfluidic device	A device which is able to manipulate and control the flow of fluids on a microliter to picoliter scale.
Scaffold	The material which acts in place of the ECM, providing a physical, 3D environment for cells to attach, migrate, and proliferate.
Micropatterning	Precisely controlling the cellular microenvironment on a substrate for the purposes of studying cell behavior.
Perfusion	The process of oxygen and other vital nutrients being delivered from the bloodstream to tissues and cells.
Piezoelectric	A ceramic crystal which creates an electric charge in response to an applied mechanical stress.
Printability	The ability and usefulness of a particular material to be applied as a bioink.
Printing resolution	The smallest dimension which can be controlled by a particular bioprinting system.
Spheroid	A 3D conglomerate of cells, often organized into a sphere-shape.
Stereolithography	3D printing process in which liquid photopolymer is exposed above a perforated platform and then cross-linked by a UV laser forming the first layer. The platform then lowers exposing a new surface of liquid which the UV laser crosslinks to form layer two.
Structural stability	The ability of a printed construct to maintain its shape.

Introduction

Over the past decade, three-dimensional (3D) biofabrication has combined principles of 3D bioprinting and 3D bioassembly to replicate complex tissue structure and function [1]. Using new advancements in 3D printing technology, biomedical engineers can control the spatial positioning of biomaterials (natural, synthetic), biochemicals (drugs, growth factors), and/or living cells [induced pluripotent stem cells (iPSCs), mature-differentiated cells, embryonic stem cells, etc.]. As such, this approach enables the creation of precise tissue-engineered (TE) models for drug screening, studying human development, fabrication of functional implants to replace damaged tissue, and delivery of biomolecules with temporal and spatial cues to guide autologous tissue regeneration in vivo. These transformative tools have allowed researchers to develop 3D models that accurately depict the structure and function of normal and diseased tissues, resulting in more physiologically relevant behavior from the cell to the whole tissue level than traditional two-dimensional (2D) model systems.

2D cell culturing has been used for over a century to study cellular responses to biophysical and biochemical stimulation [2]. However, many of these cell responses differ in 2D culture than in vivo, making them poor-to-moderate platforms for various tissue models. To overcome this, 3D model platforms have been utilized that more accurately mimic the natural complex biophysical and biochemical stimuli cells experience in vivo. Studies have routinely demonstrated that cells in 3D culture differ morphologically and physically from cells cultured in 2D, which affects function, signaling, and gene expression [3–6]. Early evidence of this phenomenon was reported in 1989, when Dunn et al. demonstrated that hepatocytes cultured "sandwiched" between two layers of collagen gel maintained normal morphology and albumin secretion for at least 42 days, while hepatocytes cultured on a single collagen layer ceased albumin secretion within a week [7]. This early work and similar studies have motivated developing biomimetic 3D environments in order to preserve normal cellular function.

3D tissue models can be separated into two categories: (1) scaffold-based and (2) scaffold-free designs. Scaffolds serve as a biomimetic extracellular environment to provide chemical stimulation and/or mechanical support, in order to promote natural cellular interactions and organization. Scaffolds often consist of specially designed materials and are designed to degrade over time, coinciding with de novo extracellular matrix (ECM) production. These scaffolds can consist of one of more materials, in order to simultaneously provide a mechanically stable structure for handling and an environment which promotes cell adherence and migration. Cells can either be directly incorporated into the scaffold, or scaffolds can rely on the autologous cellular environment to migrate and differentiate within when implanted in vivo. Challenges with scaffold-based models include inhomogeneous distributions of cells within the scaffold and lack of gross complex tissue self-assembly. Scaffold-free models rely on self-assembly of cells into larger constructs with autologous ECM deposition for support. The building blocks of these constructs are often cell sheets, spheroids, and tissue strands and do not require complex fabrication

*. These authors contributed equally to this publication.

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00077-0

techniques, which are often utilized for scaffold-based models. For example, tissue strands can be formed by injecting a cell pellet into a microtubular capsule, allowing those cells to spontaneously adhere to one another and remodel via cadherin-mediated cell−cell interactions [8,9]. These strands can then be 3D printed to form TE constructs such as tissue patches. Scaffold-free models are limited by size (they often form a necrotic core due to inadequate nutrient diffusion) and have inadequate mechanical properties, leading to cell damage when handled [10]. Recently, synergistic methods combining scaffold-based and scaffold-free tissue models have been proposed, which may allow for more complex, mechanically stable TE constructs. Silva et al. reported the use of lockyballs—mechanically interlockable microscaffolds—in order to provide a sound mechanical structure, within which spontaneous tissue organization was allowed to occur [11]. Prefabricated human adipose stem cell spheroids were seeded into lockyballs and allowed to self-assemble and differentiate toward adipogenic, osteogenic, and chondrogenic lineages, effectively combining scaffold-based and scaffold-free approaches.

Native tissues are made up of a heterogeneous cell population consisting of fibroblasts, endothelial cells, and stem cell populations in addition to tissue-specific cells that cofunction to regulate ECM production, biochemical signaling, and overall tissue functionality. Traditional seeding of single or multiple types of cells on a scaffold is a simple approach; however, it is difficult to replicate the complex multicellular tissue composition that exists in vivo. Coculture platforms are of increasing interest as they provide both cell−cell (direct) and cytokine (indirect) interactions to occur, which result in more advanced stages of tissue formation [12]. Recent advances of 3D bioprinting now allow for precise spatial control over cellular deposition for both scaffold-based and scaffold-free tissue models. For example, Liu et al. demonstrated that hepatocytes alone will cease albumin and urea secretion after 2 weeks; however, secretion is protected when patterned with fibroblasts and endothelial cells in the same model even if not all cell types are in direct contact with one another [13]. Of particular interest is the patterning of endothelial cells within a construct to enhance vascularization [14] because as the engineered tissues grow, a necrotic core is likely to develop due to the diffusion limits of oxygen and nutrients to cells. Thus vascularized scaffolds would allow for larger and more clinically relevant engineered tissues to be fabricated.

3D biofabrication incorporates several powerful approaches to constructing complex tissue models. However, the appropriate choice of 3D bioprinting technology, biomaterials, and cells must be considered a priori in order to adequately represent the key mechanical, biochemical, and structural properties of the tissue of interest. The effective use of these tools has resulted in advanced 3D models of many tissue systems. In the following sections, we will discuss key factors involved in model design, and specific examples of how these techniques are applied to real-world situations.

Current methods of three-dimensional biofabrication

The most commonly used methods for 3D bioprinting include inkjet-based, extrusion-based, and light-assisted printing. All of these techniques have been used to either 3D print scaffolds onto which cells can be seeded or to directly encapsulate cells to form complex tissue models. The preprinted material is termed "bioink" and can consist of cells, biochemicals, and/or biomaterials, depending on the intended structure and printing method. Each of these methods has strengths and weaknesses that must be considered. Below, we will provide a detailed description, evaluation, and comparison of each of these techniques. In addition, these techniques are directly compared in Table 75.1.

Inkjet printing

The earliest forms of bioprinting systems were modified conventional desktop inkjet printers. Inkjet printers are able to deposit a very small volume (1−300 pL) of liquid onto a substrate through small nozzles. Inkjet bioprinters normally utilize a bioink consisting of cells in either culture medium or a cross-linkable hydrogel or can be acellular. Current inkjet-based bioprinters can print at speeds in the range of hundreds of millimeters per second and deposit hundreds of thousands of droplets per second, with a resolution as high as 50 μm [15]. The limit of resolution of inkjet printers relies both on the diameter of the nozzle and the viscosity of the bioink, thus reducing the diameter of the nozzle alone increases the likelihood of clogging. This limits the types of materials that are able to be printed using this method to low-viscosity (∼30 mPa s) or water-based materials [54]. There currently exist three different approaches to inkjet printing (Fig. 75.1):

1. *Thermal*—Thermal inject printing heats a small volume of the bioink (up to 300°C) for a matter of microseconds to vaporize the liquid and inflate an air bubble to force the ink out of the nozzle head. This method is most commonly used as it has the highest cell viability after printing, is user-friendly, and generally inexpensive [19].
2. *Piezoelectric*—Piezoelectric inkjet printing uses a mechanical pulse generated by a piezoelectric actuator. While no difference in viability of piezoelectric printed versus unprinted fibroblasts has been found,

TABLE 75.1 Comparison of different three-dimensional bioprinting techniques.

	Inkjet printing	Extrusion printing	DLP printing	TPP printing	References
Printing process	Serial (drop-by-drop)	Serial (line-by-line)	Parallel and continuous (projection-based)	Serial (dot-by-dot)	[19–25]
Printing speed	Medium (mm/s)	Slow (10–50 μm/s)	Fast (mm^3/s)	Medium (mm/s)	[26–29]
Resolution	<1 pL droplets; 50 μm wide	>5 μm	1 μm	~200 nm	[15,29–32]
Biomaterials	Low-viscosity suspensions of cells, biomolecules, growth factors	Polymers (natural/synthetic), plastics, cells, proteins	Polymers (natural/synthetic), cells, nanoparticles	Polymers (natural/synthetic), cells, nanoparticles	[15,31–35]
Biomaterial requirements	Low viscosity, rheopectic behavior, nonfibrous, rapid cross-linking	Shear thinning, low surface tension, low adhesion, rapid cross-linking, shape retention	Photopolymerizable, contain low-toxicity photo-initiators, stability, high mechanical strength	Photopolymerizable, contain low-toxicity photo-initiators, stability, high mechanical strength	[36]
Biomaterial viscosity	3.5–12 mPa s	30 to 6×10^7 mPa s	1–300 mPa s	1–300 mPa s	[15,34,37–39]
Mechanical integrity	Poor due to interfaces	Poor due to interfaces	Excellent due to scanningless and continuous printing	Poor due to interfaces	[17]
Cell viability	>85%	40%–80%	85%–95%	>85%	[40–43]
Compatible biomaterials	Thermo/pH/photosensitive	Thermo/photosensitive	Photosensitive	Photosensitive	[44–47]
Printer construction	Simple	Moderate	Complex	Complex	[21,23]
Advantages	Wide availability, low cost, ability to introduce concentration gradients	Many printable materials, scaffold-free fabrication, easy to print multiple materials simultaneously	Fast, nozzle free, no contact, precise control of geometry, precise control of mechanical properties, high cell viability	Nozzle free, highest fabrication resolution, single cell manipulation	[1,15,21,33,48–51]
Disadvantages	Limited vertical structure, susceptible to clogging, thermal/mechanical stress on cells	Low viability, critical timing of polymerization, requires matching material densities to preserve shape	Moderate capital cost, material waste, limited number of biomaterials	High capital cost, limited to small structures, material waste, limited number of biomaterials	[1,22,27,33,52,53]

there is a concern that the range of frequencies employed by these printers (15–25 kHz) can cause damage to the cell membrane and induce cell lysis [19,55].

3. *Electromagnetic*—Electromagnetic inkjet printing utilizes miniature solenoid valves to dispense fluid [56]. This method produces much larger drop volumes than other inkjet printing methods [57].

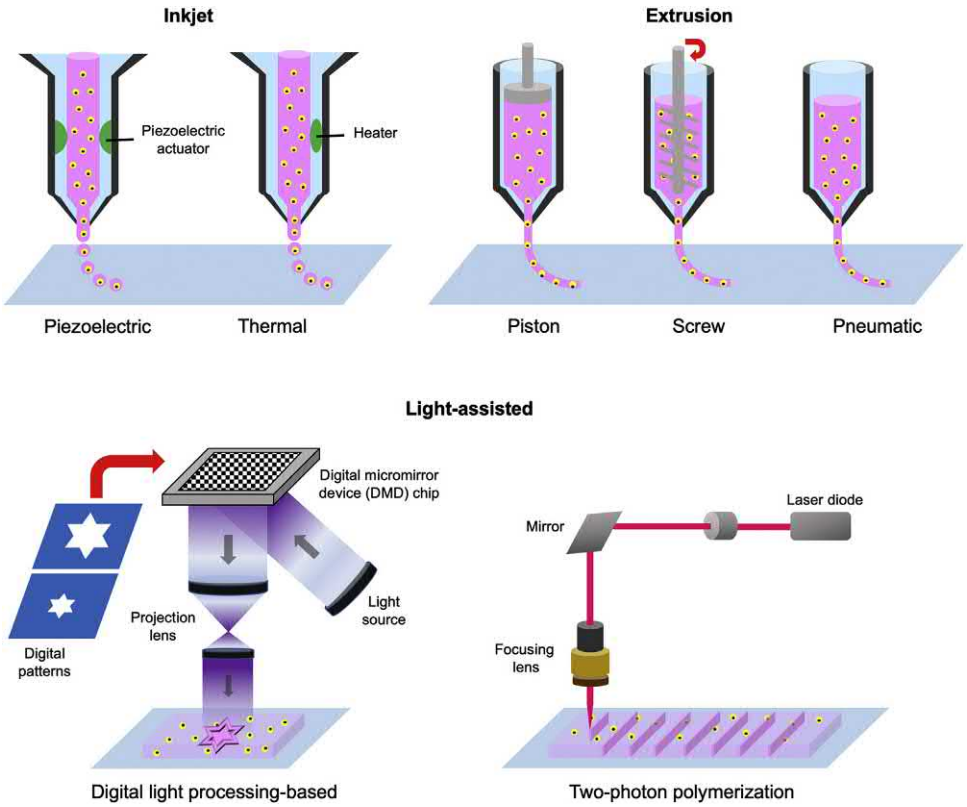

FIGURE 75.1 Schematic of different 3D bioprinting platforms.

While initially there was a lot of interest in inkjet bioprinting, there has been little development toward the fabrication of large tissue constructs. It is very difficult to layer low-viscosity liquid droplets on top of a solid surface with high fidelity. In addition, the deposition of cells results in high thermal or shear stress which can affect viability. While this method is cheap and flexible, challenges pertaining to bioink composition, resolution, layering, and printing speed must be resolved in order to build complex 3D models that other 3D bioprinting modalities are capable of.

Extrusion printing

Extrusion-based printers dispense bioink in a continuous manner at precise points in space. These bioprinters typically use piston-, screw-, or pneumatic-based controls to regulate the rate of bioink deposition, with linear actuators controlling the precise $x-y-z$ location of the nozzle or substrate (Fig. 75.1). The shape of the fabricated construct can be designed using traditional computer-aided design modeling software, which allows for designs inspired directly from computed tomography (CT) or magnetic resonance imaging (MRI) images.

A vast array of bioinks are available for use with this method including encapsulated cells, naturally derived polymers, synthetic hydrogels of varying viscosity, and sacrificial bioinks that can be washed away to leave voids. The viscosity of the bioinks available for extrusion printing is greater than that of inkjet printing, and allows for the fabrication of larger, mechanically stable structures. Certain bioinks can be thermally, chemically or photocrosslinked to form solid structures and increase handleability.

Several approaches have been taken in order to make models robust and complex, in order to more accurately replicate native tissue structure. These printers can be constructed with several nozzles, each containing a different bioink, which allows for multimaterial, multicellular constructs. This allows for both scaffold-based and scaffold-free tissue models to be fabricated using the same machine. In addition, coaxial printer heads allow for simultaneous bioprinting of a core bioink within a sheath bioink, which can be used to create microfibrous or hollow constructs.

There are a few limitations to extrusion-based 3D printing. Encapsulated cells undergo shear stress during extrusion, which limits cell viability. While extrusion-based 3D-printing allows for fabrication using more viscous mediums, these mediums often require more pressure, which affects cell viability more than the nozzle diameter, sometimes leading to worse cell viability than inkjet-based approaches [26]. While decreasing pressure

would increase cell viability, extrusion-based 3D bioprinting already has a very slow printing speed (10−50 μm/s). Typically, larger nozzle sizes are used which decreases resolution, but allows for overall larger structures to be fabricated. Therefore bioink viscosity, nozzle diameter, extrusion pressure, and printing speed must all be accounted for when fabricating cell-laden structures using this method. However, structures that do not require microscale features such as bone, cartilage, and skin can be easily fabricated using this method.

Light-assisted bioprinting

Light-assisted bioprinting is based on spatially controlling solidification of a liquid photopolymerizable material using light. This technique is of increasing interest in TE, as it allows for the encapsulation of cells with high viability, in addition to its rapid fabrication speeds, and high resolution, which altogether affords tight control over mechanical, physical, and chemical properties of the fabricated models. There are two main forms of light-assisted bioprinting: digital light processing (DLP)− and two-photon polymerization (TPP)−based bioprinting.

Digital light processing−based bioprinting

The basic components of a DLP-based bioprinting platform are a light source, a digital micromirror device (DMD) chip, a motorized computer-controlled stage, and a probe (Fig. 75.1). The light source (UV or visible) is reflected at the DMD chip, which contains 1−4 million micromirrors that can be rotated to be "on" or "off" using a simple binary mask. The light that is reflected off of the DMD chip passes through a series of optics into a solution of photopolymerizable biomaterials resulting in simultaneous printing of an entire plane of an optical pattern. By moving the stage or the light focal plane along the *z*-direction, complex patterns can be fabricated in 3D.

DLP-based bioprinters have several advantages over inkjet- and extrusion-based bioprinters, thus highlighting their versatility. Structures fabricated with DLP-based bioprinting are smooth and have higher mechanical integrity due to the lack of artificial interfaces between deposited materials that inherently exist in inkjet- and extrusion-based bioprinted constructs. Moreover, this method results in a significant time advantage and allows structures to be fabricated in a matter of seconds to minutes. The resolution of DLP-based printers is dependent upon the focal size of the reflected light beam and is usually on the order of a few microns. The stiffness of these structures can be modified by increasing power from the light source or by modifying the duration of exposure which affects the degree of polymerization of the fabricated structure. This can be used to create a single structure with multiple different stiffness profiles, which could more accurately depict models associated with pathology or disease. When printing cells, no shear forces are applied, resulting in higher cell viability than inkjet- or extrusion-based bioprinters. Taken together, DLP-based bioprinters can be used to fabricate complex 3D structures with fine features in a matter of seconds.

Two-photon polymerization−based bioprinting

TPP-based bioprinting utilizes a focused, near-infrared, femtosecond laser to polymerize a monomer solution (Fig. 75.1). Polymerization only occurs at the peak intensity area of the laser focal spot, where the energy is intensive enough to trigger nonlinear absorption of the femtosecond laser in the monomer solution and lead to photopolymerization for printing. This results in resolution below the diffraction limit and allows for high fidelity nanostructures with features less than 100 nm. 3D structures, including overhanging structures, can be fabricated by rastering through the monomer solution. The tradeoff of such a high-resolution printer is a decrease in the fabrication size and speed, although good cell viability is preserved. Similar to inkjet- and extrusion-based printers, since this is a noncontinuous printing process, fabricated structures have interfaces between photopolymerized parts, resulting in compromised mechanical integrity.

Both DLP- and TPP-based bioprinters suffer from few limitations. However, since no nozzles are used, the photopolymers typically reside in a reservoir from which the objects are printed and can result in wasted materials and increased cost. In addition, light-assisted printers utilize photopolymers, which must be chemically modified in order to facilitate 3D printing, thus limiting the number and type of materials which can be used.

Biomaterials for three-dimensional fabrication

Biomaterials are engineered substances that can be fabricated to interact with living biological systems either as therapeutics or diagnostics [58]. In order to fabricate physiologically relevant tissue models, it is necessary to closely mimic the natural physical and chemical properties of the tissue of interest. Therefore biomaterial selection is a crucial part of the design process and can govern which 3D fabrication methods may be used.

The biomaterials used in 3D bioprinting are often referred to as bioinks. These bioinks are most often hydrogels—a hydrophilic network consisting of cross-linked polymeric chains. Hydrogels can contain an aqueous solution of up to 1000 times its original weight [59]. The ability of hydrogels to absorb water arises from functional hydrophilic groups attached to their polymeric backbone and their ability to retain a structure is due to

the cross-links between their polymer chains [59]. Increasing cross-linking density increases the strength of a hydrogel, as well as decreasing the amount of water that can be absorbed. Due to its structure, the hydrogel typically retains high permeability to oxygen and nutrients, which makes it an attractive medium for 3D tissue scaffolds. 3D-printable biomaterials can be divided into two categories: (1) naturally derived and (2) synthetically derived. Many differences exist between the printability, biocompatibility, mechanical strength, and biochemical components of naturally and synthetically derived biomaterials. For a more detailed review of biomaterials used in 3D bioprinting, the reader is directed to the comprehensive reviews by Hospodiuk et al., Skardal and Atala, Parak et al., and Choudhury et al. [36,60–62].

Naturally derived biomaterials

Naturally derived bioinks that have been used for 3D tissue fabrication include collagen, gelatin, agarose, hyaluronic acid, silk proteins, chitosan, alginate, and decellularized ECM (dECM). Naturally derived biomaterials are an attractive bioink for 3D printing, as they contain the intrinsic biophysical and biochemical components of the native ECM. This results in increased cell adhesion, proliferation, differentiation, and migration. Structures made with naturally derived bioinks generally have high biocompatibility when integrated with native host tissues. The main detraction to naturally derived biomaterials is that they are often mechanically weak on their own and difficult to print with precision. Therefore naturally derived biomaterials are sometimes combined with synthetic biomaterials to form composites. In addition, as naturally derived biomaterials are derived from actual tissues, they are susceptible to batch-to-batch variability, which effects model consistency. Nearly all naturally derived bioinks are compatible with inkjet- and extrusion-based bioprinters but require chemical modification in order to be compatible with DLP- and TPP-based bioprinters. A list of commonly used naturally derived biomaterials and their uses can be found in Table 75.2.

Synthetically derived biomaterials

Synthetically derived biomaterials are often used for 3D tissue fabrication as they can be consistently produced and allow for easy control over mechanical properties, degradation rate, and printability. These materials can also be easily combined with nanoparticles in order to create functionalized scaffolds such as detoxification devices [113]. In addition, the backbones of these synthetic materials can be chemically modified to include cell-binding moieties such as RGD and YISGR in order to improve biocompatibility and cellular integration. A few of the most commonly used, synthetically derived biomaterials are poly(ethylene glycol) (PEG), Pluronic F-127, and poly(ε-caprolactone) (PCL). These materials are most commonly used as scaffolding materials due to their ease of printability and robust mechanical strength compared to naturally derived biomaterials.

PEG-based bioinks are among the most common hydrogels used in biomedical applications as they are nontoxic, nonimmunogenic, and have easily tunable mechanical properties via molecular weight modification. PEG alone has fairly poor mechanical properties, however, chemical addition of PEG diacrylate (PEGDA) or PEG methacrylate (PEGMA) groups facilitate photocrosslinking when in the presence of a photoinitiator, which results in increased mechanical strength. Therefore PEGDA and PEGMA are the most common forms of PEG used in 3D biofabrication. The addition of photopolymerizable groups allows the mechanical properties of PEG to be further tuned based on the duration and intensity of UV light exposure [103] wherein longer duration and higher light intensity increases stiffness. Due to its easy printability, fast photopolymerization (seconds), and relatively low cost, PEGDA and PEGMA are widely used in inkjet-, extrusion-, DLP-, and TPP-based printing. Common applications of PEGDA and PEGMA include cell encapsulation [114,115], biomimetic scaffold fabrication [102,103,107,108,116–118], and microfluidic devices [119–121].

Pluronic F-127 is a nontoxic poloxamer compound that undergoes reverse polymerization—increasing cross-linking with increasing temperature—and is compatible with extrusion-based bioprinting. Pluronic F-127 is also compatible with DLP- and TPP-based bioprinting after chemical modification [122,123] or combination with other photopolymerizable materials [124,125]. The temperature of cross-linking varies between 10°C and 40°C, depending on the molar mass, percentage of composites, and functionality [124,126]. This requires heating systems to be in place during the fabrication process, which, in combination with its relatively high viscosity, have precluded its use with inkjet-based bioprinters [36]. Pluronic F-127 has been used to encapsulate cells, although it typically degrades fairly quickly (within hours), making it more useful for cell delivery than as a long-term scaffold [127]. The rapid degradation time and reversible polymerization characteristics of Pluronic F-127 make it an attractive biomaterial for drug delivery and controlled release applications [128], as well as serving as a sacrificial bioink. Pluronic F-127 can be printed during the initial 3D fabrication process, only to be washed out after the construct acquires enough rigidity to retain shape [123,129–131]. This allows for the relatively simple construction of conduits or voids within a construct.

PCL is a thermoplastic commonly used with inkjet- and extrusion-based bioprinting platforms. PCL has a

TABLE 75.2 List of natural polymers commonly used for biofabrication.

	Collagen	Alginate	Hyaluronic acid	Matrigel
Printability	Moderate	Easy	Moderate	Moderate
Printer compatibility	Inkjet, extrusion, DLP	Inkjet, extrusion, DLP	Inkjet, extrusion, DLP, TPP	Extrusion
Cross-linking method	Thermo, pH, photo	Ionic (Ca^{2+}), photo	Chemical, photo	Thermo
Cross-linking speed	Seconds–1 h	Seconds	5–30 min	20 min–1 h
Chemical modification for photopolymerization (refs)	Methacrylation [63–65]	Methacrylation [66]	Methacrylation [67,68] Thiol(-ene) [60,69]	N/A
Advantages	Promotes cell adhesion and expansion, strong in vitro/in vivo biocompatibility, nonimmunogenic	High biocompatibility, cheap, nonimmunogenic, fast cross-linking time, generally low viscosity	Enhanced chondrogenesis/ osteogenesis, biocompatible, biodegradable, high solubility	Contains growth factors, facilitates cell growth/ adhesion
Disadvantages	Slow cross-linking time (0.5–1 h), nonhomogeneous cells distribution	Poor cell adhesion (no natural cell-adhesive moieties), slow degradation	Must be chemically modified, poor mechanical properties, slow cross-linking	Poor mechanical properties, must be combined with other materials
Common applications	Cell encapsulation, functionalize material surfaces	Composite bioinks, cell encapsulation, tubes, strands	Cell encapsulation, cell delivery, drug delivery, wound healing	Basement membrane, increase biocompatibility, promote cell growth

	Agarose	Fibrin	Decellularized ECM	Gelatin methacrylate
Printability	Easy	Easy	Moderate	Easy
Printer compatibility	Inkjet, extrusion	Inkjet, extrusion	Inkjet, extrusion, DLP	Inkjet, extrusion, DLP, TPP
Cross-linking method	Thermo	Fibrinogen + thrombin	Thermo	Thermo, photo
Cross-linking speed	Seconds–minutes	Seconds	Minutes	Seconds
Chemical modification for photopolymerization (refs)	N/A	N/A	Mix w/other photopolymerizable materials	Methacrylation
Advantages	Fast polymerization, thermally reversible cross-linking	Fast polymerization, highly adhesive, cell adherent, binds to growth factors	Contains native growth factors of target tissue, high cell adherence, high cell proliferation	Retains cell-binding motifs, fast polymerization, good cell viability, tunable mechanical properties
Disadvantages	No cell adherence proteins, poor mechanical properties tunable by concentration	Poor mechanical properties, difficult to control geometry	Poor mechanical properties, batch-to-batch variation, slow cross-linking time	Not as durable as synthetic polymers
Common applications	Cell encapsulation, structural support/ scaffolding	Adhesive, cell encapsulation, cell delivery	Incorporation with other materials for tissue-specific cellular response	Widely used, cell encapsulation, increasing biocompatibility
References	[91,94–98]	[60,99–101]	[102–106]	[107–112]

DLP, Digital light processing; *ECM*, extracellular matrix; *TPP*, two-photon polymerization.

relatively low melting temperature of 60°C [132] and is commonly used as a primary structural component in scaffolds [129]. PCL does not contain any natural peptide sequence motifs, so it is largely used in conjunction with other naturally derived polymers or functionalized materials to create composite structures [133,134]. As PCL is relatively stiff compared to other synthetic polymers, it is typically used in cartilage and bone tissue engineering [135,136].

Cell selection

A critical step in the design of 3D tissue models is the appropriate selection of cell sources as this directly influences the performance as well as accuracy and relevancy of the resulting model. Moreover, the cells chosen for the model must be able to replicate the key physiological characteristics of the normal or pathological states for the tissue of interest. Given these criteria, there are several cell sources available that can be classified as either primary cells, cell lines, or stem cell–derived cells. In the context of tissue biofabrication, it is also important that the cell source selected is capable of ex vivo expansion to meet the requirement of high cell numbers for bioprinting often ranging between 1×10^6 and 1×10^8 cells/mL depending on the application [137]. Reproducibility and consistency of the cells produced in terms of maintaining the desired phenotype and function are equally important postexpansion as well as during in vitro culture in a 3D format post fabrication. Other factors to consider also include the ability for the cells to survive the physical stressors brought upon during the bioprinting process as well as continued self-renewal thereafter to remodel the tissue construct and maintain appropriate cellular density in long-term culture.

Primary cells are terminally differentiated and have the quality of being a direct representation of the phenotype, maturation state, and functional features of the native tissue functional unit [138]. These cells are harvested from patient biopsies and have been reported to be used successfully for generating bioprinted liver, cartilage, and skin tissues [139–141]. However, because these cells need to be isolated, a major drawback is their limited availability as small samples can only be harvested at a time to avoid donor site morbidity and the procedures performed can be complex and invasive [142]. Furthermore, primary cell culture usage is further complicated by their limited capability for ex vivo culture as these cell types often lack in vitro proliferative capacity, are sensitive to culture conditions, prone to dedifferentiation, and susceptible to changes in phenotype expression over prolonged culture [142]. For the generation of reproducible tissue models, inherent donor-to-donor variability and risk of obtaining cells in a diseased state also poses a challenge for primary cells as this will affect the consistency in the functional response of the models.

To address the issues regarding primary cells, cell lines are a convenient substitute as they have been altered via viral transfection to be able to proliferate in vitro indefinitely by preventing normal cellular senescence, thus enabling large populations to be cultivated. To date, a plethora of cell lines have been established for several tissues including the immortalized normal adult kidney cell line human kidney−2 cells, human liver carcinoma cell line HepG2, human cervical cancer HeLa, mouse cardiac muscle cell line HL-1, and mouse fibroblast cell line 3T3 cells. While cell lines serve as important biological tools by offering several advantages such as ease of use, reproducibility, cost-effectiveness, unlimited supply, and circumventing ethical concerns regarding human and animal tissue use, it is important to recognize that although cell lines display functional features of primary cells they are not identical in behavior [143]. This is because cell lines have been genetically manipulated and serial passaging can result in variations of their native genotypic and phenotypic expression profiles, in addition to changes in response to different stimuli [143]. For example, it was found in a comparative study that using the human hepatoma cell lines, HepG2 and HepaRG cells, exhibited reduced sensitivity to drug toxicity compounds compared to primary human hepatocytes [144]. As such, these idealized cell types provide limited predictive value as they have poor resemblance to native primary cells, and it is imperative that the data collected from in vitro models produced from cell lines to be interpreted with caution.

More recently, the use of stem cell–derived cells originating from embryonic stem cells, pluripotent stem cells, or adult stem cells has gained popularity as a viable source due to their self-renewing properties and differentiation capacity into various functional cell types. Embryonic stem cells are totipotent thus enabling them to differentiate into specialized cell lineages derived from any of the three embryonic germ layers [145]. For instance, this includes plasticity to differentiate into cells of cardiac, neuronal, as well as hematopoietic origins. Embryonic stem cells can be cultured continuously for long periods of time in the undifferentiated state and are practical for generating large populations, thus enabling their potentiality to provide an unlimited number of any specialized cell type [145]. However, with ethical concerns regarding the use of human embryos in addition to risks of teratoma formation and allogenic origin, these factors may hinder their application for cell-based regenerative therapies [146]. In the last decade, techniques to generate iPSCs pioneered by Takahashi and Yamanaka resulted in a paradigm shift in the cell source landscape [147]. By introducing the four factors *Klf4*, *Sox2*, *Oct3/4*, and *Myc* this method enabled researchers to reprogram adult cells into iPSCs that

were capable of pluripotent differentiation and possess characteristics similar to embryonic stem cells with extensive self-renewal capacity [147]. Currently, a large range of protocols have been developed to produce specialized cell types from easily accessible human fibroblast, adipose-derived stem cell (ADSC), or peripheral blood cell sources into hepatocytes, neural stem cells (NSCs), pancreatic cells, and gastric epithelial cells [148]. The use of iPSCs also garners a significant advantage by not only overcoming the ethical concerns associated with embryonic stem cells but also enabling the possibility of patient-specific cell therapy for clinical applications. More specifically, cells can be obtained from patients to produce patient-specific tissue models for developing personalized medicine for the treatment of various rare diseases and elucidation of their associated pathological mechanisms. Finally, adult stem cells which can be autologously or allogeneically harvested from adult tissues such as adipose [149], bone [150], umbilical cord blood [151], and skin [152] have shown promise as a viable regenerative cell source in recent years. Unlike embryonic stem cells and iPSCs, adult stem cell populations are multipotent rendering them capable of differentiating into two or more cell types but are more limited in lineage plasticity. For instance, cells such as ADSCs and bone marrow–derived stem cells have been demonstrated to successfully differentiate toward the adipogenic, chondrogenic, and osteogenic lineages in vitro [153,154]. Although promising as an accessible cell source, adult stem cells are still met with challenges in terms of variability in self-renewal capacity, differentiation potency, donor-to-donor differences, as well as the steps taken in the isolation, identification, and purification of the multipotent stem cell population from the stroma [155]. As a result, many of these factors pose the same issues as primary cells by affecting their reproducibility and predictive capability which may compromise the quality of the final tissue model.

Three-dimensional tissue models for drug screening, disease modeling, therapeutics, and toxicology

In the following sections the application of 3D biofabricated constructs for in vitro disease modeling, high throughput drug testing platforms, and in vivo therapeutics will be discussed. Specifically, the implementation of various biofabrication strategies to recapitulate both normal and diseased brain, nerve, cancer, heart, liver, and vascularized tissue will be reviewed.

Brain and nerve tissue models

The brain is the most complex tissue in the body, consisting of numerous different cell types organized into intricate layers and compartments. Understanding the development, structure, and degenerative disorders which affect the brain is the main goal of neurobiology. Due to practical and ethical reasons, studying neural structure, development, and disease has been largely reliant on animal studies consisting of mainly rodent models. Brain structure and development vary greatly between animal and human models and thus has been a large motivation for the development of in vitro models of the human brain.

3D bioprinting neural structures present a number of challenges that are unique to accurately replicate brain structure and organization. This may partially contribute to the lack of successful 3D fabricated models in brain tissue compared to other more simplistic tissues. The human brain consists of roughly 86 billion neurons and 85 billion nonneuronal cells [156]. The nonneuronal cells, referred to as glial cells, include astrocytes, microglia, oligodendrocytes, endothelial cells, and pericytes [157]. Glial cells perform a wide spectrum of functions throughout the brain in order to maintain normal neuronal function. Damage to or imbalance of these cells leads to neurodegenerative disorders in vivo. Therefore in order to develop accurate in vitro models, the precise number and distribution of multiple cell types must be simultaneously accounted for, which is challenging but not impossible with 3D bioprinting.

The capacity to differentiate into multiple cell types and the self-renewal capacity of NSCs have made them attractive candidates for generating models of brain tissue. Using an extrusion-based printer, Gu et al. printed human NSCs differentiated in situ into a complex structure consisting of neurons, as well as astrocytes and oligodendrocytes [158]. Mature-fabricated models contained rounded soma and extensive neurite outgrowth, similar to native neuronal morphology. These models also exhibited bicuculline-induced increased calcium response, thus demonstrating that the differentiated neurons had formed into functional GABA receptors [159]. Hsieh et al. also utilized extrusion-based bioprinting to develop a unique polyurethane bioink containing NSC. When implanted into a zebrafish model of traumatic brain injury, the zebrafish recovered normal swimming ability and experienced reduced mortality [160].

Overall, 3D bioprinting brain tissue is still in its infancy compared to other methods of in vitro brain modeling. The most complex models of the brain are cerebral organoids. Cerebral organoids are a scaffold-free, human iPSC–derived “mini-brain” model, which contains various discrete, interdependent regions, fabricated using a hanging drop culture environment [161]. The culturing conditions promote self-organization and self-patterning of iPSCs into various brain regions without the use of exogenous patterning factors. Recently, these organoids

have been combined with poly (lactic-co-glycolic acid) (PLGA) microfilaments to enhance neuroectoderm formation and form a distinct cortical plate, which is considered the final step in corticogenesis [162]. These microfilament-engineered cerebral organoids formed distinct layers and had excellent neuronal organization compared to cerebral organoids alone (Fig. 75.2). A limitation of these models is that they do not contain microvasculature, which precludes the study of the blood–brain barrier (BBB). The BBB is a highly selective semipermeable membrane that regulates ion, molecule, and cell transfer from vasculature to the brain, and alterations in its function are involved in pathology and progression of disease [163]. To develop an in vitro model of the BBB, Nzou et al. utilized a hanging drop culture environment to develop an organoid model comprised of the six constituent cell types found within the cortex of the brain [164]. The resulting spheroids are capable of junction formation and selective permeation of ions, making this model attractive for testing a drug candidate's ability to cross the BBB.

Nerve injuries can be grossly classified into two general categories: (1) peripheral nerve injuries and (2) spinal cord injuries. In particular, peripheral nerve injuries

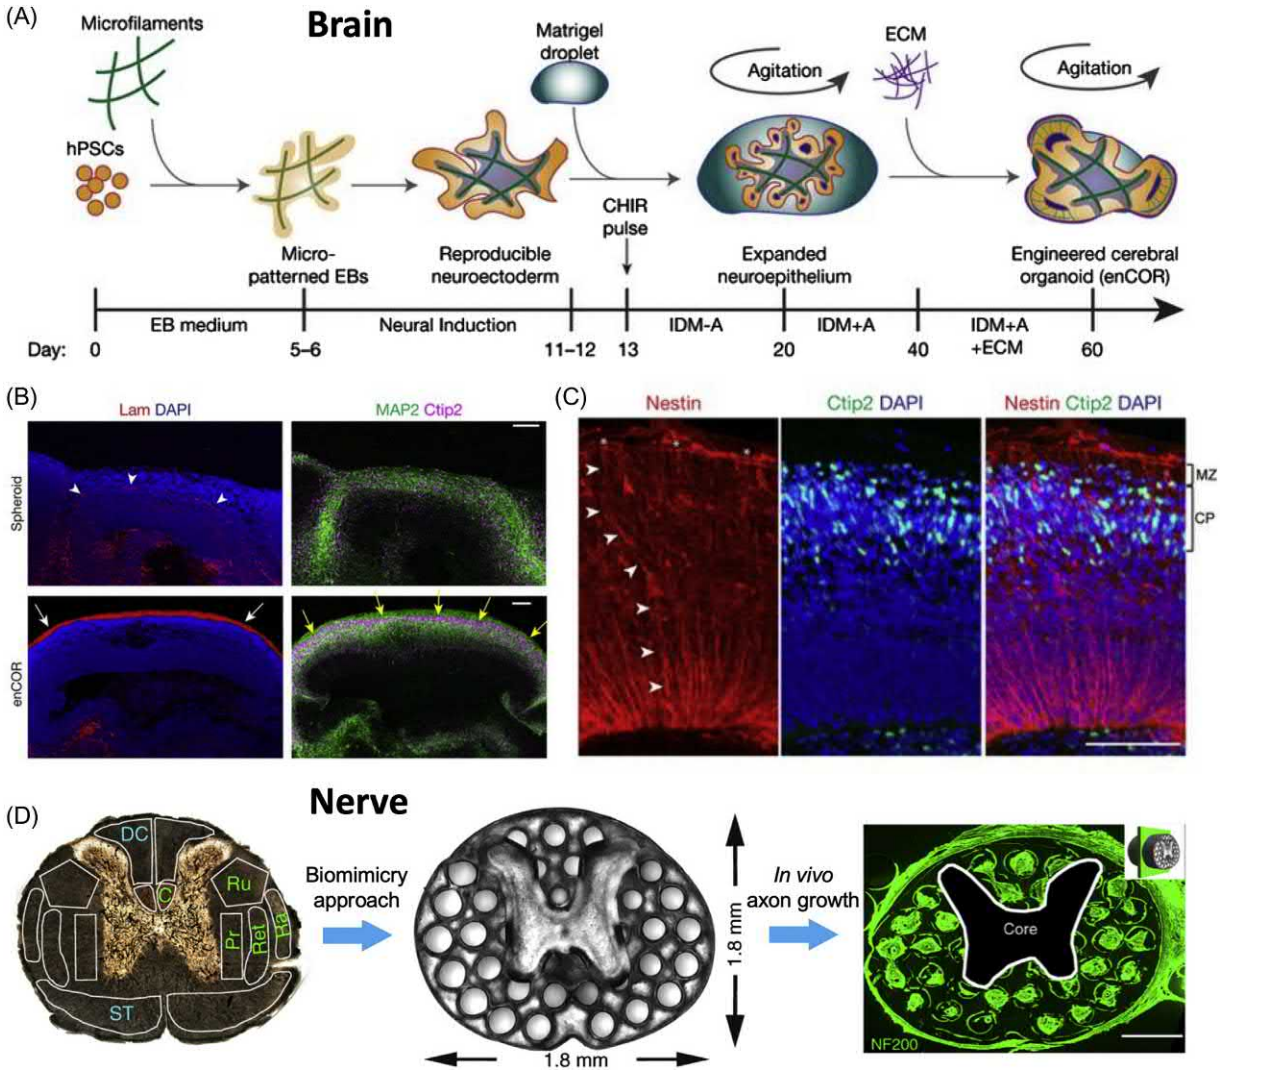

FIGURE 75.2 Brain and nerve tissue models. (A) Schematic of the method for generating the engineered cerebral organoids. (B) Immunohistochemical staining for laminin and the neuronal markers MAP2 and Ctip2 in engineered cerebral organoids. The organization of laminin, MAP2, and Ctip2 in the cerebral organoid containing microfilaments (bottom) is typical of the CP in vivo. (C) Nestin staining reveals long radial glia (*arrowhead*) organization that terminates outside the CP and MZ at the outside of the organoid. require approximately 200,000 surgeries annually in the United States [165,166]. Current clinical approaches to healing nerve injuries involve trying to suture the proximal and distal ends of the injury (<5 mm gap), or through autologous or cadaveric nerve transposition [167,168]. While autografts are the current gold standard, they require sacrificing nerve tissue from another part of the body and the resulting nerve may not actually fit the injury site [165]. This has motivated the development of peripheral nerve guides, to try to bridge the gap in a peripheral nerve injury [167,168]. Zhu et al. utilized a DLP-based 3D bioprinter to fabricate peripheral nerve guides with anatomically informed geometry [117]. In a rat injury model of peripheral nerve injury (sciatic transection) they were able to demonstrate improved functionality of motor and sensory function, as well as histological verification of nerve growth into the scaffold. Spinal cord injuries affect an estimated 285,000 people in the United States and have poorer outcomes and fewer surgical procedures available than peripheral nerve injuries [169]. Koffler et al. expanded upon the prior study and fabricated nerve guides for spinal cord injury repair using the same DLP-based 3D bioprinter [118]. The nerve guide geometry was informed by the anatomical structure of the spinal cord, and additionally included "neural relays" consisting of neural progenitor cells integrated into the scaffold (Fig. 75.2). In a rat spinal cord injury model (T3 spinal cord transection), implanted scaffolds were found to integrate with native injured host axons and significantly improve functional outcomes. Importantly, both of these studies demonstrated the capability to print human-sized scaffolds, as well as scaffolds with geometry extracted from MRI images. These patient-specific scaffolds hold promise for a future clinical translation of 3D bioprinting.

While 3D fabrication strategies for nerve are promising, complex models of 3D fabricated brain tissue still need to be developed. Brain tissue contains such a vast array of cells and has a unique microenvironment compared to the rest of the body. New biofabrication strategies must therefore focus on recapitulating the layered, complex organization of neural tissue in models that are capable of being handled.

Cancer models

Over 18 million new cases of cancer and over 9 million cancer-related deaths were estimated to have occurred in 2018 [170]. Despite its prevalence, the lack of understanding of tumorigenesis and metastases affects the ability to develop successful drugs to fight cancer. Currently, the percentage of cancer drugs that transition into successful clinical therapeutics is about 8% [171]. This is partially due to the lack of suitable in vitro and animal models for studying the complex tumor microenvironment (TME) in humans. While conventional 2D cancer models have yielded some promising results [172], they inadequately mimic the 3D TME [173,174]. This has given rise to the use of 3D bioprinting as a technique to fabricate in vitro cancer models to study tumor proliferation, metastasis, and drug response.

TME is highly complex, heterogeneous, and disease dependent, affecting cell proliferation and tumor characteristics. Zhao et al. utilized 3D extrusion-based printing to investigate differences in HeLa cell proliferation, matrix metalloproteinase (MMP) production, and chemoresistance in 2D planar culture versus 3D tumor modeling [175]. HeLa cells were found to have higher proliferation and formed spheroids in 3D compared to forming a monolayer in 2D culture. In addition, HeLa cells in 3D had higher MMP production and were more resistant to paclitaxel, a commonly used chemotherapy drug. Swaminathan et al. expanded upon this work to demonstrate that preformed spheroids prior to printing, demonstrated greater resistance to paclitaxel than individually printed cells in a breast cancer model [176]. The findings from these studies suggest that more biomimetic cell−cell and cell−matrix interactions may contribute to the differences in cancer cell behavior and function in 2D versus 3D microenvironments.

Tumor metastasis leads to 90% of cancer death and decreases 5-year survival rates. Therefore there has been much interest in evaluating how TME affects tumor metastasis in vitro. Using a DLP-based 3D printing platform, Soman et al. fabricated a scaffold with a log-pile architecture with tunable material properties [177]. The differences in cell migration in normal and TWIST oncogene−transformed breast endothelial cells were evaluated in 2D and 3D in scaffolds with soft or stiff substrates. They found that while no differences in cell migration were found in 2D between soft and stiff substrates, substantial differences were found between soft and stiff substrates for the cancer cells in 3D. This is important as it demonstrates that observations conducted in a 2D system cannot be directly extrapolated to 3D. Huang et al. further evaluated cancer metastasis utilizing a DLP-based bioprinter by fabricating a biomimetic microstructure with vasculature informed channel sizes (Fig. 75.3) [121]. The migration behavior of normal fibroblast (10T1/2) and HeLa cells was evaluated in channels with 25, 45, and 120 μm width. Channel width had no effect on average migratory speed of fibroblasts, but HeLa cell speed was found to significantly decrease with increasing channel width (Fig. 75.3). This suggests that the different responses of normal and cancerous cells to different geometric environments could be used as a tool to screen cancerous cells. These studies demonstrate how the 3D environment can drastically change the behavior

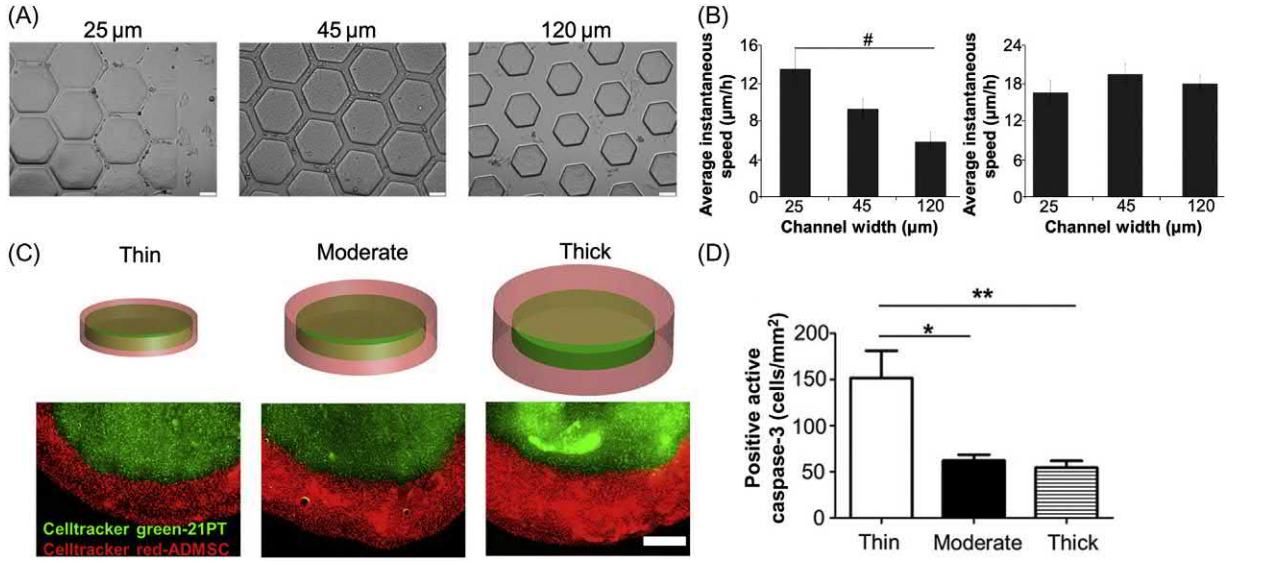

FIGURE 75.3 Cancer tissue models. (A) Optical microscope images of HeLa cells seeded on fabricated PEGDA microstructures. Scale bar = 100 μm. (B) Average instantaneous speed of HeLa cells (left) and 10T1/2 cells (right) cultured on microstructures. Channel width had a significant effect on instantaneous cell speed for cancer cells but not fibroblasts. (C) Bioprinted constructs consisting of primary breast cancer cells (21PT; *green*) and ADMSCs (*red*). Constructs were fabricated with thin, moderate, and thick layers of ADMSCs around the 21PT printed disk. Scale bar = 250 μm. (D) Density of Caspase-3 positive (apoptotic) 21PT cells in constructs with thin, moderate, and thick layers of ADMSCs after treatment with doxorubicin (chemotherapy drug). Increasing the amount of ADMSCs around 21PT cells decreases the sensitivity of 21PT cells to doxorubicin. *ADMSCs*, Adipose-derive mesenchymal stem/stromal cells; *PEGDA*, poly(ethylene glycol) diacrylate. *(A and B) Reproduced with permission from Springer Science + Business Media (2014) [121]; (C and D) reprinted (adapted) with permission from Heinrich MA, Bansal R, Lammers T, Zhang YS, Michel Schiffelers R, Prakash J. 3D-bioprinted mini-brain: a glioblastoma model to study cellular interactions and therapeutics. of cancer cell mobility and can be used to inform future studies investigating tumor metastasis.

Stroma tumor interactions have been increasingly identified as a key factor in treatment response to various drugs. In fact, stroma-induced drug resistance and stroma-induced synthetic lethality are linked to the TME with which tumor cells interact [178]. Wang et al. demonstrated that the addition of a layer of stromal cells around a disk of bioprinted breast cancer models decreased the breast cancer cell's sensitivity to a chemotherapy drug (doxorubicin) (Fig. 75.3) [179]. Further, the thicker the layer of stromal cells, the less breast cancer cell apoptosis was observed. This printing system consisted of multiple syringe extrusion-based printer, separate bioinks for each cell type, each encapsulated in a combination of methacrylated gelatin, hyaluronic acid, and gelatin. During the extrusion process, the construct had to be photo-crosslinked three separate times in order to fabricate a stable structure. Heinrich et al. recently utilized a similar setup in order to investigate the relationship between glioblastoma-associated macrophages and glioblastoma multiforme [180]. They printed a "mini-brain" consisting of a glioblastoma tumor surrounded by a large number of macrophages. They demonstrated that glioblastoma cells actively recruit macrophages and polarize them to have a more migratory phenotype. In addition, tumors cocultured with macrophages were found to have a much higher growth rate than tumors cultured alone. These studies demonstrate that the inclusion of stromal cells into the TME enhances clinical relevance of the models in vitro.

3D bioprinting of cancer models has the potential to provide insight into how the TME affects tumor development, behavior, metastasis, and invasion. Future works focusing on patient-specific cells have the potential to provide more insight on patient-specific as well as stage-specific behavior of various types of cancer. Further, 3D bioprinting patient-specific in vitro tumor models has the tremendous potential to screen drugs which may or may not be effective, potentially resolving the disease faster and improving patient outcomes. However, additional work is needed to develop the materials and cell sources in order to create repeatable, physiologically relevant tumor models.

Heart tissue models

Worldwide, cardiovascular diseases (CVD) are a major cause of morbidity and mortality [181]. Myocardial infarction (MI) and valvular heart disease (VHD) are some of the main forms of CVD. In the United States, an estimated 720,000 people experience a new MI with 335,000 having a recurrent MI annually [181] and an

estimated 2.5% of the population are thought to have VHD [182]. As cardiac muscle has limited capacity for self-repair, current treatment strategies include grafting diseased tissues or inserting artificial prostheses to attempt to restore function [183]. However, each of these approaches is complicated by their own respective disadvantages which include lack of donor tissue, immune rejection, anticoagulation therapy, and limited durability [184]. These factors have driven a large amount of resources to develop predictive preclinical platforms for cardiac drug testing, as well as durable patient-specific therapies to treat CVD and physical models for presurgical planning [185,186].

Current models of 3D cardiac tissue focus around seeding cells atop, or encapsulating cells within a hydrogel-based scaffold [52,187], then utilizing 3D aligned cultures [188], mechanical stretching [189], or electrical pacing [189,190] to promote mature cardiomyocyte phenotypes. However, by using 3D printing, it is possible to achieve mature aligned cardiomyocytes without any external stimulus. For instance, Liu et al. employed a DLP-based printer to directly print human iPSC–derived cardiomyocytes into aligned patterned slabs suspended between two pillars [191]. While both slabs and aligned cardiomyocytes exhibited spontaneous synchronous beating, cardiomyocytes printed in slabs beat without directional preference, whereas aligned cardiomyocytes beat along the direction of the patterning (Fig. 75.4). Furthermore, the deflection of pillar structures in which the cardiomyocytes were printed onto enabled analysis of cardiac force generation and drug response in a high throughput manner [116]. These studies demonstrate the ability to rapidly fabricate in vitro cardiac models, capable of supporting rapid drug testing. Some drugs may disproportionately benefit or harm certain genotypes, ethnicities, sexes, and ages [192]. Since the cardiomyocytes used in this platform are derived from human iPSCs, this allows for in vitro drug testing for all potential patient populations.

During MI, reduced blood flow to the heart results in ischemia and subsequently leads to large necrotic patches of heart tissue. TE cardiac patches are designed to mimic the native ECM and provide mechanical support as well as delivery of cells to the area of MI. For example, Jang et al. utilized a dual nozzle, extrusion-based printer to fabricate a prevascularized stem cell patch [193]. Both cardiac progenitor cells (CPCs) and mesenchymal stem cells (MSCs) were printed in a dECM bioink containing vascular endothelial growth factor (VEGF), and cultured for 5 days. Using a standardized model of MI in a rat, implants were surgically implanted before sacrifice at up to 56 days' postinjury. Patterned patches were found to increase ejection fraction and decrease fibrosis compared to patches consisting of simply mixed CPCs and MSCs.

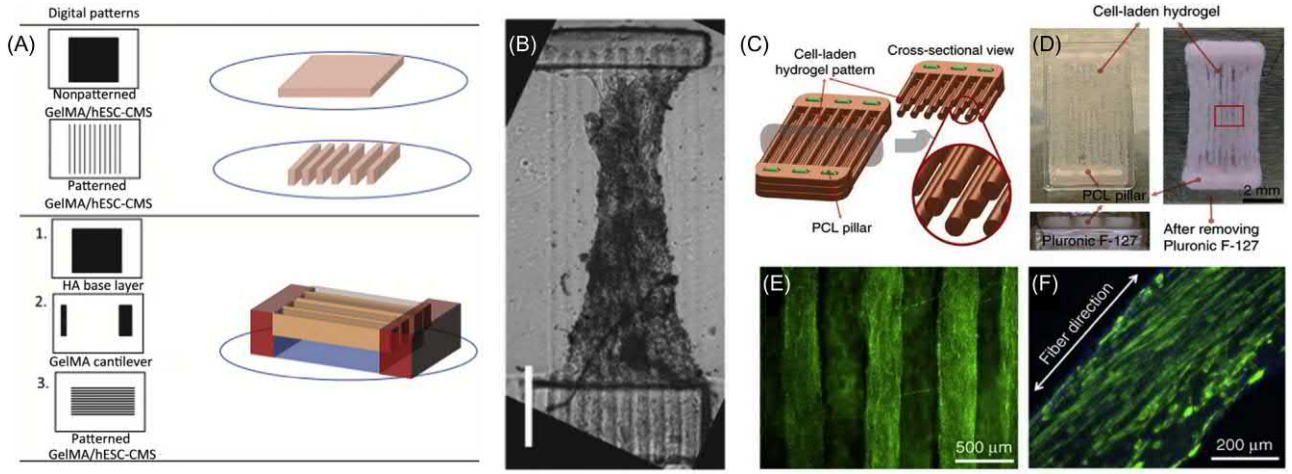

FIGURE 75.4 Heart tissue models. (A) *Top:* Two sets of digital patterns including a slab and aligned patterns for encapsulated cell printing with a DLP-based bioprinter. *Bottom:* The masks for the multilayer pattern to produce 3D scaffolds. First, a hyaluronic acid base layer is printed; second, a gelatin methacrylate cantilever system; and third, parallel lines of hESC-CMs. (B) Optical image of the resulting patterned hESC-CMs printed in the force gauge scaffold after culture for 21 days. Scale bar = 500 μm. (C) Designed fiber bundle structure for muscle organization. PCL pillars (*green*) were used to maintain the structure and to induce the compaction phenomenon for cell alignment. (D) 3D patterning outcome of designed muscle organization (left) before and (after) removing the sacrificial material (Pluronic F-127). The printed construct was cross-linked with thrombin solution to induce gelation of fibrinogen and the uncross-linked sacrificial material was removed by dissolving with cold medium. (E) The Live/Dead staining of the encapsulated cells in the fiber structure indicates high cell viability after the printing process (*green*: live cells; *red*: dead cells). (F) Immunofluorescent staining for myosin heavy chain of the 3D printed muscle organization after 7 days of differentiation. Furthermore, revascularization of the damaged myocardium was observed. These results demonstrate that an organized 3D bioprinted scaffold can not only improve cardiac function via mechanical support but also promote neovascularization of the damaged tissue.

Cardiac valves play a major role in the proper functioning of the cardiovascular system by ensuring proper blood flow through the four chambers of the heart. In severe cases of VHD, valves must be surgically replaced. There is increased interest in developing a TE heart valve rather than relying on mechanical prosthetics, donor supplied allografts, or porcine/bovine xenografts. Since cardiac valves have highly specific geometry integral to proper function, 3D bioprinting has been sought as an attractive fabrication method. Hockaday et al. used an extrusion-based 3D bioprinter to fabricate a biocompatible heterogeneous valve with flexible leaflets and a rigid root [194]. Duan et al. implemented a similar model using extrusion-based 3D bioprinting and incorporated valvular interstitial cells and smooth muscle cells encapsulated in a combination of methacrylated hyaluronic acid and methacrylated gelatin rather than a synthetic polymer [195]. Further work by van der Valk et al. sought to use a similar approach by encapsulating valvular interstitial cells in order to develop an in vitro model of calcific aortic valve disease (CAVD), the most prevalent form of VHD [196]. Microdissection and careful mechanical testing of a cadaveric human ventricle with CAVD was performed to accurately model the disease progression. Mechanical properties of the fabricated construct were varied by modulating the ratios of the main constituents of their bioink [gelatin methacrylate (GelMA) and methacrylated hyaluronic acid]. The resulting multilayered 3D construct recapitulated the layer-specific mechanical properties of the dissected valve and provided a novel 3D model for studying CAVD.

Overall, 3D bioprinting is a promising technique for the fabrication of in vitro cardiac models to in vivo cardiac therapies. A common thread between successful platforms is the importance of cellular alignment and mechanical properties of the scaffolds, which are integral features of the heart architecture. These features are not only integral factors to consider in cardiac muscle but in skeletal muscle as well. 3D fabrication of skeletal muscle models for in vitro disease modeling and in vivo muscle repair consistently demonstrates that fiber alignment during the initial formation of a scaffold leads to organized muscle tissue with superior functional outcomes (Fig. 75.4) [129,197]. In tissues such as cardiac and skeletal muscle, where aligned cellular organization is essential for normal tissue function, 3D printing is a key tool for fabricating physiologically accurate tissues.

Liver tissue models

Liver is a densely populated organ composed of approximately 120 million cells/gram in humans and is made up of mainly hepatocytes as well as several tissue-specific cell types including Kupffer cells, epithelial cells, stromal cells, and sinusoidal endothelial cells [198]. These cells are arranged into highly organized hexagonal hepatic lobule functional units. Within each hepatic lobule, hepatocytes are situated into plates that radiate in an outward direction from the central vein with portal triads located at each vertex composed of the hepatic arteriole, portal venule, and bile duct. Venous blood and arterial blood enter through the portal vein and hepatic artery, respectively, and flow through the sinusoidal regions and drain into the central vein of each hepatic lobule.

Since liver is a major site for drug adsorption, distribution, metabolism, and excretion there is a critical need for novel liver tissue models as tools to more accurately predict drug metabolism, pharmacokinetics, and hepatotoxicity for the development of potential new therapies. Namely, this demand has largely driven strong motivation in the pharmaceutical industry for the development of better liver models for drug-induced liver injury (DILI) as this is a major cause for drug failure resulting in liver transplantation or morbidity in patients [199]. To address this issue, it was recently shown that a 3D bioprinted liver tissue using patient-derived primary hepatocytes and nonparenchymal endothelial and hepatic stellate cells were suitable as a multicellular model for DILI [139]. Using a scaffold-free assembly process of cellular spheroids, Nguyen et al. patterned the different cells types using an extrusion-based bioprinter into a microarchitecture composed of several compartments filled with hepatocytes and surrounded by nonparenchymal cells (Fig. 75.5). Using this bioprinted liver, they demonstrated that the printed tissue was capable of maintaining long-term function over 4 weeks in culture including albumin secretion and expression of drug-induced enzyme activities of cytochrome P450s [139]. In particular, it was shown that model was sensitive to trovafloxacin dose-dependent toxicity at clinically relevant doses, which is normally undetected in standard in vitro systems [200]. Similarly, Ma et al. developed a complex heterogeneous liver tissue model that uniquely replicates the physiological microarchitecture and microscale features of the hexagonal lobule unit for drug screening [108]. In this work, a DLP-based 3D bioprinter was employed to pattern human iPSC–derived hepatic progenitor cells (iPSC-HPCs) within a GelMA matrix, as well as human umbilical vein endothelial cells (HUVECs) combined with ADSCs in a GelMA and glycidyl methacrylate hyaluronic acid (GMHA) matrix to serve as the supporting cell population to form a triculture 3D liver model as shown in Fig. 75.5.

Compared to 2D monolayer controls as well as iPSC-HPC only bioprinted liver constructs, Ma et al. demonstrated improved metabolic activity with regards to increased albumin and urea secretion over time in the triculture system over 19 days in culture. Maturation state also increased in the triculture system as characterized by a significantly higher expression of albumin (*ALB*), transthyretin (*TTR*), hepatocyte nuclear factor 4 alpha (*HNF4α*) along with a downregulation of the early marker alpha fetal protein (*AFP*) [108]. When treated with the hepatotoxic drug, rifampicin, CYP expression levels (i.e., *CYP2C9*, *CYP2C19*, and *CYP3A4*) significantly increased in the triculture model compared to untreated controls, while no observed significant increase was detected in the 2D monolayer and bioprinted iPSC-HPC only groups. These results suggest that the triculture model provided a suitable environment for drug induction potential of iPSC-HPCs in vitro.

The pathological mechanisms of liver fibrogenesis have also been largely studied as this condition develops over time in many types of chronic liver diseases and is a consequence of an imbalance in the reparative process following injury. As such, this results in changes in the liver tissue matrix due to an abnormal overproduction of

fibrillar collagen that disrupts normal liver microarchitecture, as well as the production of inflammatory cytokines and growth factors, which altogether deteriorates normal liver function [201]. Modeling liver fibrosis in vitro is challenging to recapitulate since the process in vivo is complex and involves multiple interactions between both resident cells as well as recruited cells. Since macrophages play an important role in liver fibrogenesis, Norona et al. aimed to further elucidate the role of Kupffer cells, which are specialized macrophages located in the liver sinusoids and involved in homeostatic functionality [202], following drug-induced fibrogenesis in a 3D bioprinted liver model [203]. Using a NovoGen Bioprinter platform (Organovo, San Diego, CA) a scaffold-free, two-compartment tissue geometry was produced comprising of hepatic stellate cells and endothelial cells within the border regions while primary human hepatocytes were positioned within the compartments in the presence or absence of Kupffer cells [203]. Over 28 days in culture, the liver tissues were treated with TGF-β1 and methotrexate to induce fibrotic injury. Interestingly, levels of lactate dehydrogenase activity, which was used as a general biomarker of cytotoxic response over the treatment period, was reduced in the liver tissue containing Kupffer cells for both TGF-β1 and methotrexate [203]. Furthermore, the release of miR-122, which was used as a specific hepatocyte injury biomarker, verified that the early onset of injury in response to TGF-β1 was delayed in the Kupffer cell containing model compared to the standard model without Kupffer cells [203]. On the other hand, miR-122 levels were also delayed in the methotrexate treated samples during initial exposure; however, the overall levels increased relative to the standard model across the treatment period. While both drugs resulted in similar biochemical responses, gene expression profiling further elucidated that Kupffer cells played an important role on baseline tissue function and the varied responses these cells have on different drug compounds [203]. Specifically, it was hypothesized that TGF-β1 acts after hepatocyte injury occurs during the intermediate stages of the response while methotrexate acts upstream by instigating hepatocyte injury prior to downstream fibrotic events [203]. In a different examination, a platform for studying the effects of pathologically relevant 3D matrix stiffness on hepatocellular carcinoma (HCC) progression and invasion was developed by Ma et al. (Fig. 75.5) [103]. Here, a 3D liver construct composed of decellularized porcine liver ECM and GelMA was developed such that the mechanical properties of the engineered liver tissue were precisely tuned to recapitulate varying stages of fibrotic liver conditions ranging from physiologically relevant softer than normal (0.5 kPa), normal (5 kPa), and cirrhotic (15 kPa) moduli [103]. Next, encapsulated HepG2 cells within the bioprinted scaffold were measured to evaluate their growth and invasiveness over 7 days. The results demonstrated characteristic restricted growth and upregulation of invasive markers of these cancer cells under cirrhotic stiffness compared to healthy stiffness controls, which confirmed the validity of the tissue model. This work affirms the feasibility of using 3D bioprinting to study HCC growth and invasion in a pathological mechanical environment.

Overall, these advanced engineered liver tissues highlight their potential use as more reliable, sensitive, and predictive models for improving the drug screening process. However, many of these 3D liver models are still in early development and limited in terms of their application in high throughput arrangements accustomed in the pharmaceutical industry. Moreover, to ensure the efficacy of future 3D liver models, they will need to satisfy the following criteria: (1) demonstrate significant advantage over conventional models such as 2D cultured hepatocytes, (2) exhibit long-term maintenance of normal function and phenotype as well as drug-metabolizing enzyme activities to enable prolonged in vitro hepatotoxicity testing, and (3) produce measurable outcomes in response to the development of DILI such as changes in mitochondrial function and the formation of reactive oxygen species [204].

Vascular tissue models

Adequate vascularization is critical for long-term survival by facilitating the delivery of oxygen and nutrients to cells within thick constructs to overcome diffusion limitations and is an essential element for realizing the potential of constructing full-scale tissues and organs [205]. With the development of complex tissue model systems, the incorporation of functional vascular networks is important as they play a key role in several biological processes including wound repair, progression of cancer and tumor pathologies, developmental angiogenesis, as well as aiding in graft implantation and integration into the host tissues [206–209]. To date, methods to produce vasculature in vitro can be divided into several strategies: (1) via the incorporation of proangiogenic growth factors (e.g., VEGF, basic fibroblast growth factor, and epidermal growth factor) to stimulate de novo vessel formation, (2) use of sacrificial materials for the construction of hollow microchannels, (3) use of microfluidic systems, or (4) patterning of encapsulated endothelial cell populations [210]. However, engineering functional blood vessels at multiple length scales within a construct ranging from small capillaries to large arteries has been a challenge in the field due to limitations in biofabrication technologies.

Recently, the flexibility and resolution offered by advanced 3D bioprinting platforms have enabled the production of vascular networks possessing complex

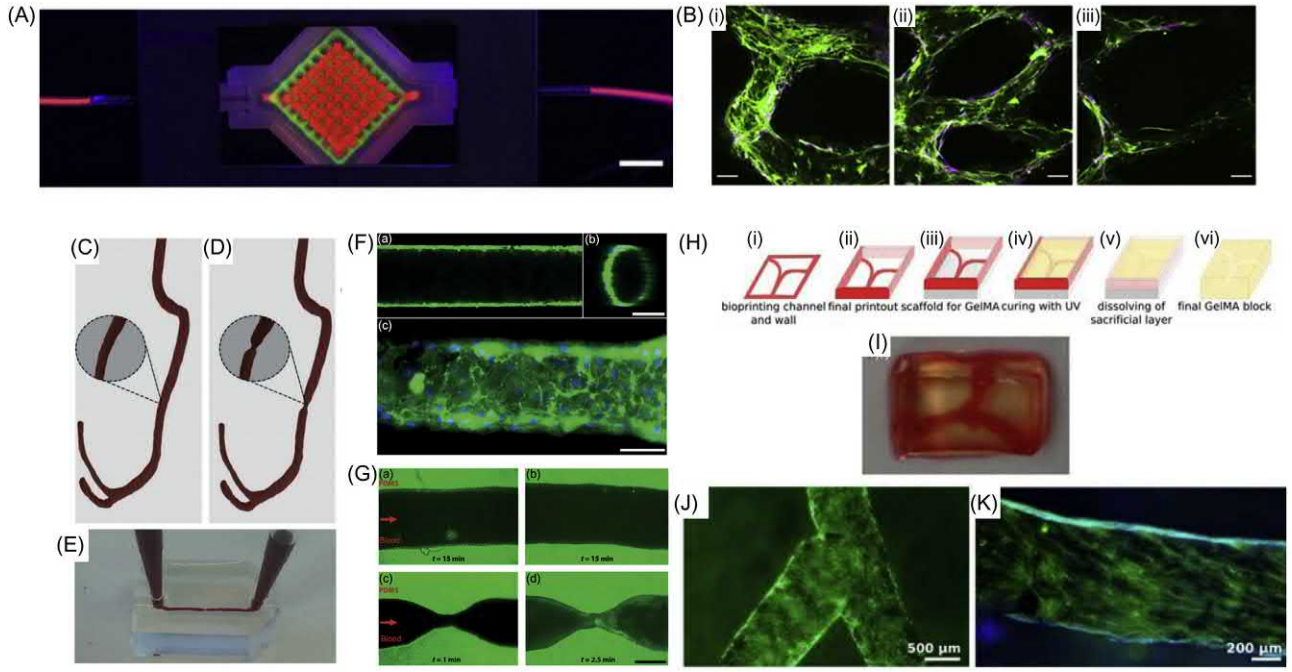

FIGURE 75.6 Vascular tissue models. (A) Image of an extrusion printed vascularized tissue contained in a perfusion chamber. Scale bar = 5 mm. (B) Fluorescent images of direct DLP-based 3D bioprinted prevascularized tissues showing stained HUVECs (*green*, CD31) and supportive mesenchymal stem cells (*purple*, alpha-smooth muscle actin) of varying widths (i–iii) ranging 50–250 μm. Scale bar = 100 μm. (C and D) Schematic of 3D printed health and stenotic vascular models, as well as (E) an image of the PDMS chip containing the vascular microchannels. (F) Confocal images of HUVECs stained with *F*-actin (*green*) and nuclei (*blue*) lining the interior microchannel walls. Scale bar = 200 μm (top and side view) and 50 μm (confluent interior). (G) Microfluidic device with healthy geometry before (top left) and after 15 minutes of blood perfusion (top right) demonstrates no evidence of platelet aggregation. A microfluidic device with stenotic geometry after 1 minute (bottom left) and 2.5 minutes (bottom right) of blood perfusion demonstrates thrombosis at the apex of the stenosis. Scale bar = 200 μm. (H) Schematic of an extrusion 3D bioprinting process to form a vascularized hydrogel thrombosis model as shown in (I). (J) Images of endothelialization within bifurcated microchannels showing (K) a confluent monolayer of CD31 (*green*) and nuclei (*blue*) stained HUVECs along the walls. *3D*, Three-dimensional; *DLP*, digital light processing; *HUVECs*, human umbilical vein endothelial cells; *PDMS*, polydimethylsiloxane. *Reproduced with permission from (A) National Academy of Sciences, ©2016 [130]; (B) Elsevier (2017) [107]; (C–F) The Royal Society of Chemistry (RSC) (2017) [218]; and (H–K) PubMed Central (PMC) (2016) [219].*

geometries over traditional approaches by way of sacrificial, spheroid-based, core–shell extrusion, and light-based printing techniques. For instance, using sacrificial biomaterials that can be evacuated to produce intricate microchannel networks and subsequently populated with endothelial cells is a simple and effective technique to create functional vessels. Using this approach, Kolesky et al. employed an extrusion-based bioprinter and formed intricate networks with a fugitive ink composed of Pluronic F-127, which was subsequently cast with a soft gelatin–fibrinogen matrix containing human neonatal dermal fibroblasts (Fig. 75.6) [130]. Following removal of the Pluronic F-127, the resulting open microchannels, approximately 400–500 μm in diameter, were seeded with HUVECs into a confluent monolayer and it was demonstrated that the perfused tissue chip was capable of supporting a tissue thickness of 1 cm for at least 6 weeks in culture [130]. In another approach, Norotte et al. utilized a scaffold-free bioprinting method that relies on the self-assembly of patterned cell spheroids to maximize direct cell–cell interactions and achieve high cellular density found in native vessels [211]. This was demonstrated by depositing spheroids of Chinese hamster ovary cells and human skin fibroblasts (HSFs) onto supporting agarose rod molds. After 5–7 days in culture to allow for cell fusion, the spheroids assembled into hollow vessels measuring 900 μm in diameter with a wall thickness of 300 μm [211]. However, issues regarding spheroid scalability, long fusion durations, and homogeneity of the final vessel upon spheroid fusion limit the use of this approach for building larger structures. As such, this group demonstrated a more efficient technique via the extrusion of multicellular cylinders composed of human umbilical vein smooth muscle cells and HSFs onto agarose rod molds, which enabled fusion to complete within 2–4 days resulting in branched tube structures with double-layered walls [211]. While promising, spatial resolution remains a challenge using this approach since it is restricted by the spheroid size or micropipette tip diameters (i.e., 300 or 500 μm). Furthermore, a direct method to construct vasculature that circumvents the multiple steps and time involved in sacrificial and spheroid-based

printing strategies would enable a more rapid, streamlined, and scalable fabrication approach. To address this challenge, Jia et al. developed a technique to directly print perfusable vascular constructs using an extrusion bioprinter fitted with a trilayered coaxial nozzle to deposit a blend bioink composed of sodium alginate, GelMA, and 4-arm PEG-tetra-acrylate (PEGTA) [212]. Ionic crosslinking of the alginate component was first induced via the simultaneous delivery of calcium ions in the core channel and ambient spray in the outer ring of the print nozzle to ensure temporary mechanical stability during the extrusion process. Afterward, the GelMA and PEGTA components were UV photopolymerized to permanently stabilize the final construct. By varying the nozzle internal and external needle sizes, different combinations of diameters (i.e., outer = 500−1500 μm, inner = 400−1000 μm) and wall thicknesses (i.e., 60−280 μm) were achieved using this technique in addition to being able to readily form various designs and geometries of perfusable networks. Furthermore, it was demonstrated that coencapsulated HUVECs and human MSCs within the blend bioink provided an optimal microenvironment for the cell viability, proliferation, and spreading to form perfusable constructs resembling native vasculature after 21 days in culture [212]. However, the ability to form multiscale vasculature structures in a continuous single step using this approach remains difficult as it will involve physically interchanging different nozzle sizes throughout the printing process. One strategy is to utilize light-based printing that does not involve physical contact during fabrication and instead works by projecting a series of digital patterns onto a photopolymerizable reservoir to quickly form vasculature structures in a direct manner. Zhu et al. demonstrated this technique by rapidly constructing complex hierarchal branched networks by using a microscale continuous optical bioprinting platform to encapsulate HUVECs and supportive C3H/10T1/2 cells within a GelMA and GM-HA blend prepolymer (Fig. 75.6) [107]. Meanwhile, the areas surrounding the printed vasculature networks were printed with a GelMA bioink embedded with HepG2 to form a heterogeneous tissue construct. Intricate vessel structures with microchannel widths ranging between 50 and 250 μm were readily fabricated and over time the endothelial cell population remodeled the hydrogel to form lumen-like structures after 1 week in culture [107]. In vivo implantation into a subcutaneous mouse model of the prevascularized tissues also revealed integration and anastomosis to the host circulation after 2 weeks compared to nonprevascularized controls [107].

With the promising application of 3D bioprinting technologies to engineer vascularized tissues, several studies have also utilized the flexibility of 3D bioprinters to create models to better understand the mechanisms of vascular pathogenesis and disorders. In particular, thrombosis has been linked as a major contributor and cause for global disability and mortality due to its association as an underlying factor for cardiovascular disorders [213,214]. For instance, venous thromboembolism, in the form of deep vein thrombosis or pulmonary embolism, is a prevalent medical condition that results in a blood clot occurring in the vein and affects 1 out of 1000 adults annually in the United States [215]. This condition derives from patient risk factors such as age, obesity, surgery, genetic factors, trauma, cancer, and immobility that can lead to chronic pain, tissue swelling, formation of venous ulcers, and in severe cases lung collapse resulting in heart failure [216]. Similarly, arterial thrombosis is also a leading cause of death in the United States due to occlusions caused by clots or arterial plaque that when left untreated, can manifest into a host of secondary health complications including stroke, heart attack, and critical limb ischemia [217]. Due to its prevalence, there is a need for models of thrombosis that accurately recapitulates the vessel geometries, local flow patterns, as well as underlying cellular interactions to develop better future treatment options. Recently, Costa et al. used a stereolithography-based 3D printer to create a replica of a miniaturized coronary artery model based on CT angiography (CTA) (Fig. 75.6) [218]. Using this approach, they were able to produce polydimethylsiloxane microfluidic chips of healthy and stenotic coronary arteries that were seeded with a monolayer of HUVECs and perfused with human whole blood containing fluorescently labeled platelets [218]. Under physiologically relevant arterial shear rates, it was demonstrated that thrombosis occurred within the stenotic geometries after 2.5 minutes of perfusion but not in the healthy controls as expected. Computational fluid dynamics further confirmed the validity of their scaled microfluidic model geometries to closely correlated to the original CTA scale geometries under the selected flow velocity profiles and shear rate distributions used in this study for both the healthy and stenotic conditions [218]. This work highlights several advancements regarding the ability to recapitulate real vessel architectures possessing smooth walls to elucidate factors affecting hemodynamics. In particular, changes in fluidic velocity gradients, increased shear rates, platelet formation in the recirculation zone, and activation of the intrinsic coagulation pathway within stenotic vessel geometries were probable root causes of thrombosis in their model [218]. In another study of thrombosis, Zhang et al. examined the pathology of fibrosis within vessels by using an extrusion-based 3D printer to create hollow bifurcated microchannels within a GelMA hydrogel via the removal of sacrificial Pluronic F-127 (Fig. 75.6) [219]. To evaluate the migration of fibroblasts in exacerbating the formation of a fibrotic clot due to a damaged endothelium three groups were tested:

(1) microchannels lined with HUVECs and no fibroblasts in the GelMA matrix as a negative control, (2) HUVECs lined microchannels with fibroblasts in the GelMA matrix to serve as a normal vessel control, and (3) fibroblasts in the GelMA matrix with no HUVECs lining the microchannels to simulate the damaged endothelium [219]. Thrombosis was induced by administering $CaCl_2$ into human whole blood which was then perfused into the microchannels for each group and allowed to culture for 2 weeks. Interestingly, as expected there was no visible staining of collagen I present within the clot in both the negative control and normal vessel control due to the absence of fibroblasts and barrier formed by the endothelium, respectively. In contrast, the group simulating the damaged endothelium had significant invasion of fibroblasts found in the regions of the thrombus along with deposition of collagen I secreted by the cells, which is a representative of the in vivo setting [219]. Overall, these realistic models hold great potential to serve as physiologically relevant platforms for studying the mechanisms of thrombus formation as well as other vascular disorders by being able to closely mimic the native vascular microenvironment.

Conclusion and future directions

Over the years, 3D bioprinting has surfaced as a flexible biofabrication tool that enables the creation of complex tissue model systems to better recapitulate the native microenvironment. In particular, the successful outcome of engineered tissue models relies on several key factors including mechanical properties (i.e., stiff/soft and elastic/brittle), biochemical composition (ECM components, growth factors, etc.), and complexity of the final tissue (cell source, multiple cell types, shape, and organization). Taken together, careful consideration of these factors can influence which method of 3D bioprinting is best suited for a specific tissue application. To date, a growing variety of engineered tissues have been successfully produced using a range of different 3D bioprinting modalities to serve as models for improving diagnostic and therapeutic outcomes including nerve, cancer, heart, liver, and vascularized tissues as highlighted above. While these advanced tissue models represent a step closer to physiologically relevant tissue platforms, many challenges remain regarding their maturation state, multicellular complexity, and scalability for high throughput manufacturing.

With the emergence of complex 3D tissue models, the trend toward the selection of stem cell–derived cells, particularly iPSCs, has gained popularity in terms of their practicality in research and translational advantages. While promising, it is important to recognize that the relevancy and performance of tissue models composed of these cell types are highly dependent on the efficacy of the protocols employed to control differentiation and maturation toward the desired lineage in vitro. Specialized cell types differentiated from iPSCs are not equivalent in their maturation state as primary cells and are considered immature with resemblance more similar to fetal cells of the native tissue. As such, the successful use of stem cell–derived cells hinges on new methods to facilitate their differentiation pathway to achieve mature adult phenotypes and functionalities in order to more accurately extrapolate data for disease processes observed in adult tissues and organs. In another aspect the multicellular population inherent in native tissues comprised of both parenchymal and nonparenchymal cell types is critical in the design of physiologically relevant tissue models. Simplistic 3D tissue models contain a homogenous population comprised of a single cell type representing the functional unit of the tissue or organ. However, growing evidence in recent literature has shown that supportive nonparenchymal cells play a critical role in overall tissue function [108,203]. As such, future designs will need to continue to recapitulate tissue or organ cellular heterogeneity to build toward improved engineered tissue models that possess greater relevancy to native behavior that will increase their efficacy. Finally, reliable and reproducible manufacturing methods will be an essential factor for the scalability of 3D bioprinted tissue models in high throughput applications. This is necessary as future tissue models will need to be produced in a manner that is able to interface directly with existing commercial platforms accustomed in industry, such as for drug screening and diagnostics, without compromising performance, consistency, and predictive value. Considering these factors is an important step toward achieving the full potential of 3D tissue models for use in the development of new therapies and elucidating pathological mechanisms. Nonetheless, technological advancements in 3D bioprinting continue to play a critical role in defining new directions and possibilities for realizing the production of tissue or organ substitutes in both research and clinical applications.

Introduction

Until very recently, experimental models for human physiology have been limited to animal models and two-dimensional (2D) cell culture systems that have not proven to be reliable for accurately modeling human pathology or predicting drug efficacy or safety. There is a considerable need for a much more accurate in vitro representation of human biology for disease modeling, drug development, and determination of drug safety [1,2]. Preclinical animal models have represented the cornerstone of biomedical research for centuries. These animal models have been instrumental in a plethora of discoveries across virtually all areas of science [3]. However, it has become clear that animal models have significant limitations due to phenotypic differences in physiology as compared to humans. This is especially critical for the assessment of toxic side effects of drugs that might target the liver, and other organs, due to differences in enzyme isotype expression profiles between humans and animals; often resulting in significant differences in drug metabolism, efficacy, and toxicity.

2D cultures of transformed or primary cells have also been used extensively as models of human biology. These in vitro models do normally use human cells; however, the genotype of cell lines is, by definition, altered from the natural state. Primary cells isolated from cadaveric tissues can undergo dramatic phenotype changes when cultured on a rigid plastic substrate. These changes occur as cells attempt to adapt to a radically new environment that lacks many of the physical and biochemical features of native tissue [4,5]. Some of the most prominent features of the normal cellular microenvironment lacking in static 2D culture are cell/cell and cell/matrix interactions, the stiffness of the cell substrate, and the lack of an interstitium to facilitate appropriate autocrine and paracrine signaling [4,6,7]. The latter of these also results in the inability to accurately model drug diffusion kinetics resulting in erroneous estimations of threshold doses for efficacy or toxicity [6,7].

Recently, more advanced in vitro models have been developed that incorporate many of the basic principles of tissue engineering. These include creating a three-dimensional (3D) cell structure containing multiple cell types within a supportive biomaterial scaffold that has appropriate mechanical properties. In combination with advanced microfluidic and microelectronic technologies, these in vitro models demonstrate many of the functional properties of normal human tissue and organs. For example, liver models exhibit normal metabolic activity, skeletal and cardiac muscle constructs contract in a physiologically normal manner, lung organoids "breath," and gut/vessel/brain microvasculature constructs maintain normal barrier functionality [8,9].

"Body-on-a-chip" devices that recapitulate 3D tissue architectures and physiological fluid flow conditions are much more supportive of normal cell function than static 2D culture [10]. These engineered platforms can include sophisticated hardware systems with the potential for scaled-up automated production that increase the potential for high-throughput experimentation and screening of test compounds. These models deliver much more sophisticated cellular interactions and responses while providing user control over physical factors such as fluid shear stress and mechanical stresses. Microfabrication techniques based on a variety of technologies have resulted in

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00078-2

the development of microscale fluidic systems with predictable fluid dynamics throughout the entire fluid circuit [11]. Tissues and organoids can be immobilized at specific locations within platform microreactors using advanced hydrogel biomaterials. These materials provide a proper microenvironment and anchor the cellular constructs within the fluidic circuit for long-term culture. A variety of iterations upon these basic concepts are currently being utilized by laboratories around the world [12–14]. In addition to modeling normal human physiology, a variety of on-chip disease models have also been investigated [13].

The current and most pressing challenge in advancing the body-on-a-chip field is the integration of multiple tissue types within a common microfluidic circuit. Such systems represent a major step toward in vitro modeling of human physiology at the organism level. Ideally, these systems would recapitulate the interdependent and interrelated functions of all tissues and organs within the human body. The microfluidic circuit connecting organoid microreactor chambers allows for fluid flow across each organoid type in a sequence in much the same way that the vasculature delivers blood sequentially to the organs within the body [8]. Drugs, metabolites, and soluble molecular factors would be transported to downstream tissue model types in a physiologically relevant sequence. These advanced body-on-a-chip platforms would be ideal for testing newly developed drugs and determining potential toxic side effects in humans. Furthermore, integrated body-on-a-chip platforms would offer tremendous benefits for pharmacological studies aimed at determining the specific effects and toxic thresholds for newly developed drugs, allowing for better prediction of appropriate doses for human trials. In this chapter, we highlight a variety of body-on-a-chip systems for applications such as drug screening and disease modeling and look to the future of multiorganoid body-on-a-chip systems and applications in personalized precision medicine.

Advanced in vitro modeling systems—progression from two-dimensional to three-dimensional models

The development of novel drugs that are safe and effective in humans has been slowed by the lack of accurate models for human physiology. Animal models, used extensively in preclinical drug studies, are traditionally regarded as the gold standard for establishing drug safety. However, animal models do not accurately reflect human drug metabolism and often yield results not predictive of results in humans. As discussed earlier, conventional in vitro 2D model systems lack many of the environmental questions required for the long-term maintenance of cell viability and cellular function [4,15]. In addition, drug distribution and cellular drug bioavailability are completely nonphysiological in traditional cell culture, and drug doses that are effective in 2D are often ineffective when scaled to patients [6,7].

Recently, an appreciation has developed for applying basic principles of tissue engineering to in vitro models. A myriad of studies have demonstrated that 3D cell culture consistently outperforms 2D cultures in many aspects, including maintenance of in vivo function, including metabolism of drugs and toxins [16]. The current drug development pipeline (Fig. 76.1A) does not yet include advanced 3D models for human physiology, and countless discrepancies between in vitro drug screening and clinical performance continue to be identified [17]. As an example, it has recently been demonstrated that metastatic colon carcinoma cells adopted an epithelial appearance in 2D tissue culture. However, when transitioned to a 3D form factor, the cancer cells adopted a morphology that more closely resembled malignant cells, in vivo [18]. Observations such as these raise the question, why is there not greater momentum to include advanced 3D models into the clinical translational pipeline?

Tissue engineering technologies have evolved to the point that microengineered tissue constructs can better mimic the architecture, cellular diversity, and function of in vivo tissue. In vitro models incorporating principles of tissue engineering can often be maintained in viable states and preserve physiologically relevant levels of function for periods of time that greatly exceed those possible in 2D. It is generally assumed that tissue engineering technologies, including construct geometry, cellular scaffolds/substrates, mechanical properties of the microenvironment, and cellular diversity, all contribute to the increased function of in vitro physiological models. Oxygenation is seen as a limiting factor in the construction of 3D tissue models. When these constructs become larger, an oxygen gradient develops across the cellular model, which can lead to heterogenous phenotypic changes across the construct. However, oxygen gradients exist within organs and tissues, in vivo. As such, so long these gradients and their effects are characterized, they may actually increase the reliability of the model. When 3D models become too large, insufficient oxygen diffusion to the core of the construct can result in cellular necrosis. This may only be prevented by limiting the size of the constructs, or by incorporating a channel system, through which the cellular model may be perfused.

An area in which the use of 3D cell culture systems has seen significant growth is in basic research. Academic science in particular is beginning to embrace 3D models. However, 2D cell culture has been an established technology for many decades and will certainly remain a widely used tool for many years to come. 2D cell culture is easy and inexpensive in comparison to 3D culture systems. Implementing 3D systems in a lab can be complicated

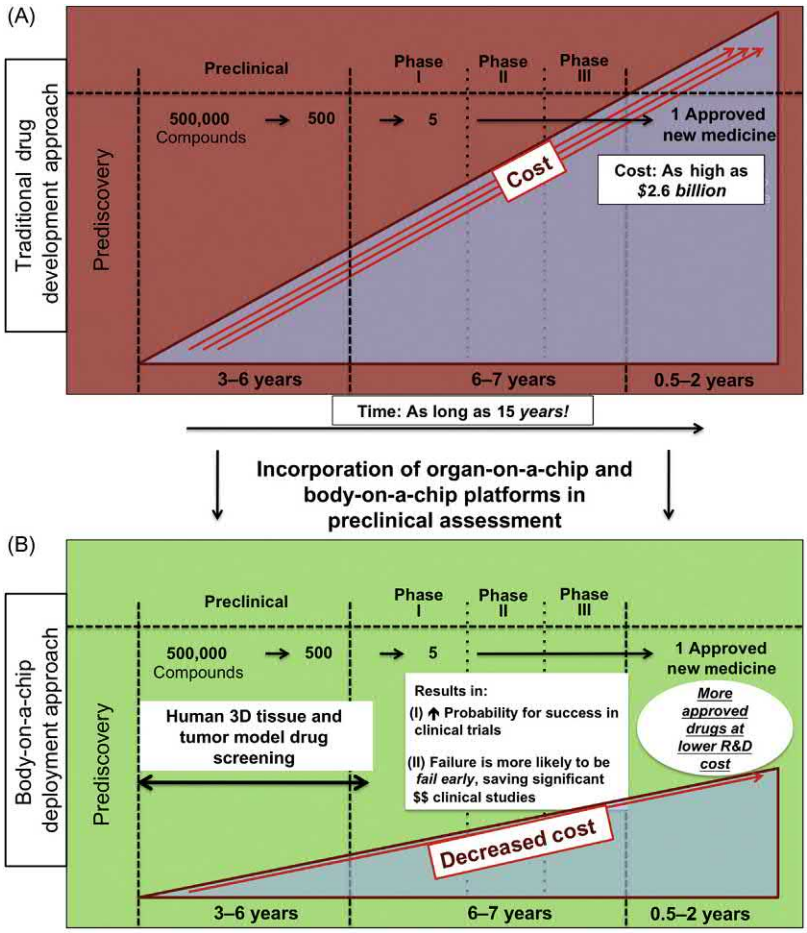

FIGURE 76.1 Potential improvements in the drug development pipeline as a result of deployment of organ-on-a-chip and body-on-a-chip technologies into pharmaceutical research and development. (A) The current drug development pipeline requires many years and multiple billions of dollars to bring a drug to market. (B) Plugging in human-based biofabricated on-a-chip platforms into preclinical stages can potentially drastically improve the efficiency of the drug development pipeline.

and require training in several new technologies, including biomaterial development and biofabrication techniques. After the initial learning curve has been overcome, several challenges persist. Processes regarded as trivial in 2D culture, such as cell harvest and cell passage, can be quite difficult and in some cases impossible in current 3D culture systems. For example, if cells are cultured within a 3D hydrogel, the substrate must be dissolved in order to harvest the cells. Some biomaterials support cell retrieval by building in features that allow for easy liquification of the substrate for cell harvest [19]. Most semisolid substrates still require enzymatic dissolution that can be quite damaging to the cells, and result in significant reduction in viability. In addition, a majority of the cell imaging techniques were developed for 2D cell cultures. These techniques were designed to image cells across a narrow focal plane. In 3D, cells also must be imaged across the *Z*-axis. Consequently, high-quality imaging in 3D may only be obtained by fluorescence imaging that may be activated within a specific plane of space. These techniques, including confocal or macro-confocal microscopy, require expensive equipment that many laboratories do not have access to. In addition, several assays routinely used to characterize cells in culture are significantly more difficult to perform on 3D models or require significant adaptation for application to 3D models. Finally, some materials used in body-on-chip systems, particularly polydimethylsiloxane, are prone to fouling and drug and protein adsorption. However, new materials for device hardware are being developed to solve this problem.

After considering all things, 3D systems represent a better strategy for modeling normal human physiology, as compared to 2D cell culture [16]. These 3D platforms have an immense potential to improve several aspects of biomedicine. In particular, 3D models may accelerate drug candidate evaluation and reduce the number of toxic compounds that make their way deep into the translational pipeline—decreasing development costs and increasing success rates of clinical trials (Fig. 76.1B).

Organ-on-a-chip technologies and their applications

In recent years, advances in tissue engineering [20], biomaterials [21], and micro-biofabrication [22] have allowed for the development of fabricated tissue analogs that reflect native tissue function to a degree that was not possible just a few years ago. A wide variety of advanced

human in vitro models have been developed and validated for modeling the effects of drugs and toxins [14,23–25]. Advances in molecular genetics and tissue engineering technologies have also allowed for the development of 3D models of human diseases [13,26–28]. Technologies adjacent to tissue engineering, such as microfabrication, and microfluidics, have augmented 3D cell models by providing precisely controllable fluid flow, in-line biosensing and platform miniaturization for high-throughput testing. These organ-on-a-chip systems vary widely in design and cover a wide range of tissue types. Some of these systems have already proven beneficial in drug discovery [12] and are beginning to show promise for improving the efficiency of the clinical translation pipeline. The following represent just a few examples of microengineered tissue models, including, liver, vasculature, lung, and tumor. However, it should be noted that there are many variations of these systems, as well as many additional models for virtually any tissue type.

Microengineering and biofabrication

The cellular component of a body-on-a-chip model may be considered the fundamental core of the construct. However, including a physiological composition of cell types alone does not guarantee recapitulation of normal cellular function. An additional component of the cellular microenvironment that must be considered is the extracellular matrix (ECM). As described previously, the cellular microenvironment has a direct effect on cell phenotype. Therefore it is important to include as many components of the normal cellular microenvironment in an in vitro model system as possible. Several strategies have been developed to include both the structural and biochemical aspects of the cellular microenvironment in advanced 3D model systems.

The technique of micropatterning refers to the precise deposition of bioregulatory molecules within a cell culture substrate. Micropatterning can be accomplished by a variety of methods including (1) microcontact printing, wherein a stamp, coated with a pattern of ECM proteins, is pressed against a solid substrate; (2) photo-patterning using ultraviolet light projected through a photomask to catalyze adherence of ECM proteins in a predetermined pattern; and (3) laser-patterning, where laser light is used to mediate protein binding to a substrate in any desired pattern with very high resolution [29].

Many bioregulatory components of the ECM can be distributed in a controlled manner by using micropatterning techniques. For instance, deposition of discrete units of ECM cell proteins that restrict cell spreading induces apoptosis in bovine adrenal capillary cells, while simultaneously maintaining the differentiation state of epidermal keratinocytes. Conversely, micropatterning of ECM proteins that induce cell spreading promoted the proliferation of both the bovine adrenal capillary cells and epidermal keratinocytes. These experiments demonstrate a clear link between the local ECM composition of a cell substrate, cell cycle, and cell differentiation potential [30,31]. This concept is further supported by another study where mesenchymal stem cells grown on small micropatterned patches that restrict cell spreading promoted adipogenic differentiation, whereas micropatterning of factors that induce cell spreading promoted osteogenic differentiation. These studies also showed that modulation of cell shape was sufficient to induce the expression of the signaling proteins Rac1 and *N*-cadherin, which govern cell lineage specification [32,33]. Micropatterning represents a powerful tool for precisely controlling protein composition of the cellular microenvironment within a cell culture substrate. By patterning the biochemical properties of a cell substrate, the phenotype of cells within that substrate may also be patterned. This opens the potential for controlling cellular microarchitecture within the construct. Micropatterning has a wide variety of applications in advanced in vitro modeling and will become increasingly utilized for fine-tuning the cellular arrangement within these systems.

The micropatterning technologies described earlier are most appropriately used to control the cellular microenvironment in a 2D plane. Bioprinting provides a method for doing the same in a 3D space. Bioprinting involves the layer-by-layer deposition of structural material, cells, and bioregulatory factors in a controlled manner. Current bioprinting technologies allow for the fabrication of complex cellularized 3D constructs that may include components of the ECM, including both intrinsic and bound bioregulatory.

Bioprinting technologies are highly customizable across a wide range of both resolution and physical characteristics. Applications requiring a more rigid structure can be printed using biomaterials with high mechanical stiffness. For stiffnesses beyond those that are compatible with a specific printing modality, methods for cross-linking structural components of the biomaterial subsequent to bioprinting have been developed. As an example, very rigid dental implants have been bioprinted from polycaprolactone and hydroxyapatite [34]. On the other end of the stiffness spectrum, soft tissues, such as vascular grafts, have been printed using very low stiffness poly(ethylene glycol) hydrogels [35]. With increasing resolution and speed of modern bioprinters, the structures that may be fabricated are becoming highly complex. The ability to precisely pattern the cellular, structural, and biochemical microarchitectures of tissues will most certainly increase the fidelity and function of bioprinted 3D cell models.

Several 3D cell models have already been fabricated using bioprinting technology. Liver constructs that

include multiple liver cell types within a supportive hydrogel have been generated using microextrusion technology. These constructs demonstrated exceptionally high functionality and viability over the long term [36]. Skin analogs have also been created using a laser bioprinting technology. This technique allowed for layered deposition of different cell types within the engineered skin. The resulting constructs were implanted into rodent dermal wounds and demonstrated robust neovascularization, differentiation of mature keratinocytes, and generation of a normal dermal basal lamina—all hallmarks of native skin [37].

3D printing may still be considered an emerging field. Logistical obstacles continue to limit the potential for whole organ biofabrication. However, the speed, reproducibility, and scalability of bioprinting make it an ideal fabrication technology for body-on-a-chip modeling. 3D printing can be used to generate an industrial-scale volume of constructs with low run-to-run variability and the complex architecture required for high fidelity modeling.

Liver-on-a-chip

Early tissue-on-a-chip devices were designed to promote cell aggregation, thereby creating 3D cell structures. For example, microwells with a convergent geometry were designed to funnel cells together into a compact structure. Based on the microwell geometry, liver cells could be formed into either spherical or cylindrical constructs. These 3D constructs maintained much better cellular function than 2D controls [38,39]. In another example, spheroids were created within an array of channels connecting inverted pyramid-shaped microwells, allowing for the delivery of cells and test compound to multiple chambers, simultaneously. This integration of microfluidics with an array of microwells greatly increased the throughput potential for experimentation using 3D constructs [40].

In recent years, liver-on-a-chip devices have become much more complex. Currently, they may employee controlled fluid flow for addressing nutrient circulation, drug administration, sample collection, and integration with other tissue types. The latter will be discussed in detail later in this chapter. In one such liver-on-a-chip, hydrogels were used to encapsulate HepG2 hepatoma cells with NIH-3T3 fibroblasts. These arrays of 3D organoids demonstrated increased liver function, as compared to 2D controls, and produced an appropriate toxic response to acetaminophen [41]. In other experiments a versatile photopolymerizable hyaluronic acid biopolymer system was used for in situ photo-patterning of HepG2 cells to generate 3D liver constructs. The constructs were formed in parallel channel fluidic devices that were fabricated by soft lithography and molded PDMS. This system was used for toxicity screening by administering multiple alcohol concentrations within each chip. The expected dose response was seen for both viability and cellular function [14]. Current efforts within our group are focused on the miniaturization of these types of systems, to further increase throughput. Miniaturization and microfabrication approaches can be employed to generate more intricate biological microarchitecture, perhaps at a high enough resolution to model capillary structures. Precise layering of hepatocytes and endothelial cells within microfluidic circuits may be used to generate structures with the resolution required for modeling sinusoid-like structures [42]. Another approach for generating biologically relevant microarchitecture involves mating synthetic and biological components. As an example, using a semiporous membrane to separate two adjacent chambers may be used to partition human hepatocytes from sinusoidal endothelial cells. Such a design was shown to generate higher levels of albumin and urea, as compared to traditional hepatocyte cultures, and demonstrated another strategy for recapitulating normal microarchitecture to increase cell function [43].

Vessel-on-a-chip

The term “microfluidics” carries with it the assumption of controlled fluid routing. Thus microfluidic devices are effective for modeling vascular networks. Drugs are generally either introduced directly into the blood stream or enter the blood stream shortly after oral or pulmonary intake. Microfluidics are used to model the trafficking of compounds and metabolites within a body on a chip platform. A substantial number of vascular fluidic devices have been developed, including both straight channel devices [44,45] and devices with more complex, branching geometries [46,47]. A major feature of the vasculature is to form a barrier between the circulation and the tissue interstitium at the capillary bed. Many microfluidic systems have been designed to model transendothelial delivery of test compounds to a target tissue. As an example, two perpendicular channels that cross at a single point were constructed with a semipermeable membrane colonized by endothelial cells positioned at the point where the two channels cross. Fluorescently labeled albumin was introduced into one channel and transport through the endothelial monolayer that was quantified by laser excitation of the fluorophore in the other channel [48]. In another example an endothelialized construct was designed with a mechanism that allowed for the control of shear stress experienced by the endothelial cells. The device was used to determine the effect of fluid shear on nanoparticle translocation across the endothelial monolayer. These studies were intended to define the ability of fluid shear to influence pharmacokinetics and drug

biodistribution [49]. Other microfluidic devices with integrated vasculatures have been developed to determine how the atomic structure of drugs and nanoparticles can influence the rate of translocation across the capillary bed [50]. The integration of vascular function in organ-on-a-chip microfluidic design would seem to offer great promise in providing more accurate modeling of drug pharmacology in next generation in vitro cell platforms.

Lung-on-a-chip

The lungs, which represent a fluid/air interface between the in vivo and ex vivo environments, serve as a port of entry for drugs, toxins, pathogens, and other xenobiotic compounds. Accurate modeling of the alveoli in organ-on-a-chip systems is an important component of modeling the effects of compounds that enter the circulation through the lung. Significant advancements in the on-chip modeling of lung tissue have been realized over the past decade [51]. Many of these lung constructs consist of lung epithelial cells and endothelial cells situated on opposing surfaces of a semipermeable membrane. The cellularized membrane forms a barrier that can model transport of aerosols or vapors from the gaseous alveolar compartment into the aqueous circulatory compartment. Contact of the alveolar epithelial with air in the alveolar compartment has the added advantage of promoting normal cellular function and maintenance of the mature differentiation state. In more complex models, multiple independent pneumatic channels were incorporated into the design. Cyclic deformation of the pneumatic channel walls paired with controlled shear within the fluid channel promoted exceptional cell morphology and function [52,53]. These advanced models have proven to be quite valuable for modeling several lung pathologies, including inflammation, pulmonary edema, mucus plug rupture, alveolar epithelial cell damage, and have also improved the reliability of drug screening [54–57]. While planar air/fluid interface models have shown incredible promise for modeling normal exchange across the alveoli and certain pulmonary disease states, it is worth noting that more simple, acinar lung organoids may be sufficient for screening drug toxicity of compounds delivered orally or directly into the circulation.

Heart-on-a-chip

Current models for cardiac tissue are generally quite straightforward in design. The heart's sole function in the human body is to drive the circulation of blood, and a majority of the in vitro cardiac models are designed around modeling this function. Simple monolayer cultures of human cardiomyocytes will spontaneously beat in culture when grown on Matrigel [58]. Sheets of human cardiomyocytes may be layered to produce 3D cardiac constructs that retain the ability to contract in synchrony [59]. These planar construct designs are sufficient for modeling the heart's beating action but are not ideal for modeling 3D mechanics such as contractile force. 3D cardiac constructs consisting of human cardiomyocytes embedded in ring-shaped collagen hydrogel structures have been shown to self-organize into a circumferentially aligned architecture that supports physiologically relevant action potential propagation [60]. These types of constructs have been integrated into microfluidic circuits to form dynamic, contractile heart-on-a-chip systems [61–65].

Cancer-on-a-chip

In addition to modeling normal tissue such as liver and heart, excellent models for tumor tissue have also been developed. These models have been integrated into microfluidic platforms to form tumor-on-a-chip devices capable of modeling both tumor growth and metastasis. The microenvironments of tumors are often very complex and may vary significantly from tumor to tumor. In addition, the malignant properties of the cells within the tumor are often reliant upon the nature of the stroma. The physical and biochemical characteristics of 3D tumor models can be controlled using microfluidic and microfabrication techniques. Tumor models derived from a patient's tumor sample can be used for determining effective chemotherapeutic agent selection and determining an optimal dose on a patient-by-patient basis [66,67].

Recent advancements in tumor-on-a-chip modeling include the development of integrated hardware for monitoring the tumor tissue. These include advanced imaging technologies and onboard molecular assays, which provide detailed characterization of tumor behavior, on-chip. The microscale of these types of models has been shown to significantly influence cell metabolism. This results from the bioavailability of oxygen within these platforms. Studies have demonstrated that microfluidic systems provided greater access to oxygen, as compared to standard 2D culture systems. This increased oxygen level results in increased Krebs cycle activity and decreased expression of hypoxia-regulated factor-1 [68]. Constant perfusion of with oxygenated media provides a better model for a normal tumor microenvironment.

A device has also been designed with multiple drug gradient generators and parallel cell culture chambers to facilitate multidose high-throughput drug screens. This system has been paired with automated cell labeling and high content imaging, on-chip [69]. Another tumor model design includes microscale bioreactors that contain hepatocytes, nonparenchymal cells, and breast cancer cells and is intended to simulate the liver microenvironment.

The device also contains oxygen sensors, micropumps for controlling nutrient distribution, and real-time sampling capabilities [70]. This device was used to demonstrate that breast tumor cells will spontaneously become dormant when placed within the microenvironment of the liver. This effect was suspected to result from the cytokine profile created by the presence of hepatic cells within the liver portion of the construct. Breast cancer has also been studied using a system that includes models for both the ductal and lobular components of breast tissue [71,72]. This system is intended to model the interaction between these two microanotomical compartments during tumor initiation and progression. In another device, HCT-116 colon carcinoma cells and HepG2 hepatoma cells were encapsulated in Matrigel in separate chambers. Myeloblasts were embedded in alginate gels within an additional chamber in order to simulate bone marrow. Using this platform, the cytotoxic effects of the 5-fluorouracil (5-FU) prodrug Tegafur could be determined for each cell type. Interestingly, using 3D tumor organoids, the liver constructs were able to metabolize Tegafur to 5-FU, resulting in cell death within the other two tumor organoid types. Tumor models arranged in 2D were unable to metabolize the prodrug to its activated form [73].

Lung tumor models have also been developed in microfluidic devices. Human nonsmall cell lung cancer in both 2D and 3D cell model configurations were evaluated for sensitivity to several common chemotherapeutic agents [74]. In another example, lung cancer spherical constructs were formed from cell lines or derived from patient lung tumor biopsies, both with and without the addition of the associated pericyte population. Each of these constructs was tested for susceptibility to the drug cisplatin. Systems that included the pericyte population demonstrated higher levels of chemoresistance to the anticancer drug, indicating the importance of, including all relevant cell types from within the tumor when developing a tumor model [75]. These examples of tumor-on-a-chip models demonstrate the benefits of 3D design and advanced microfluidic technologies for cancer research and selection of an effective drug and dose for a specific patient.

Body-on-a-chip: integrated multiorgan systems and future applications

While body-on-a-chip technologies are relatively new, they have already demonstrated exceptional promise for applications in research and drug development. Recently, systems of increased biological complexity have been developed that feature multiple engineered tissue types integrated within a single platform [76–79]. These multitissue models [80] have demonstrated greatly increased potential for modeling physiology at the organism level, as compared to single tissue models. Until recently, these integrated platforms utilized cell lines and animal cells [73,81] More recent systems have begun to use human primary cells. These models have required the development of more advanced cell substrates and microfluidic devices to support the viability and function of human primary cells. There have been several notable studies demonstrating complex human multitissue systems. In one such system a four-tissue circuit was developed in a pumpless microfluidic perfusion platform, housing 2D cultured liver, cardiac, skeletal muscle, and neuron, all integrated within a single microfluidic circuit. This platform was designed as a screening tool for determining cell toxicity in experiments using doxorubicin, atorvastatin, valproic acid, acetaminophen, and *N*-acetyl-*m*-aminophenol [82]. The pumpless concept has also been employed in a dual-tissue gut/liver system, including transepithelial electrical resistance sensors, for monitoring gut epithelial barrier function [83]. In another study a multitissue microfluidic model was developed with integrated intestine, skin, liver, and kidney tissues. In this system function, appropriate gene expression, and viability were maintained for 28 days [77]. These examples represent important steps towards modeling the complex, multitissue responses and interactions that occur within a living organism.

The importance of multiorganoid integration

In vitro models that accurately recapitulate human tissue function are still quite rare. Even fewer are designed to model multiple tissues within a single integrated platform. Such models offer clear benefits in determining drug toxicity, as toxic responses often involve multiple tissue types. In addition, integrated multitissue models have the potential to increase function of the individual tissues to an even higher level, as endocrine and other molecular signals produced by various organs would condition the media with a more normal repertoire of supportive factors. With respect to drugs, effects in off-target tissues can be as important as effects at the intended target site. If undetected, detrimental secondary effects can lead to failure of expensive clinical trials, or withdrawal from commercial or clinical.

Multiorganoid platforms are also useful for disease modeling. Cancer metastasis, in which malignant tumor cells migrate to a secondary site, may be modeled in multiorganoid platforms. While useful for many applications, single-organoid models have limited ability to model these types of physiologically significant events. Here we describe several examples of multiorganoid platforms that demonstrate the importance of these systems.

Cancer

As described earlier, cancer metastasis is a disease process that may only be modeled in a multiorganoid system. When a tumor becomes metastatic, certain cells within the tumor gain the ability to penetrate the endothelium and enter the circulatory or lymphatic systems. They may then migrate to a distant tissue and reenter tissue at a distant secondary site. Few in vitro systems have been developed that are able to accurately model this process. One system has demonstrated that it is possible to model the metastatic process, in vitro. This metastasis-on-a-chip platform was designed to allow tracking of the migrating metastatic tumor cells from a bioengineered colon model to a bioengineered liver model within a simple recirculating microfluidic device (Fig. 76.2A). It was shown that metastatic colorectal cancer cells were able to migrate out of the colon tumor model into the microfluidic circuit and engraft in the downstream liver model. Conversely, a nonmetastatic colorectal cancer cell type continued to grow at the primary site but never migrated to the liver [84].

Tumor metastasis-on-a-chip platforms, as previously described, may comprise multiple organoids that allow for tumor cells to metastasizes from a primary location to a secondary site. On-a-chip devices have also been designed to assess certain discrete aspects of metastasis. For example, a recently developed system includes a microfluidic device that can model the process by which multicellular tumor aggregates migrate through both a collagen matrix and an endothelial cell layer [85]. Another device includes and endothelial cell layer that partitions a microfluidic circuit from a chamber that houses a 3D bone construct. This system allows modeling of the extravasation of metastatic tumor cells from the vasculature into bone [86,87]. Other recently developed models include a system for assessing the effects of interstitial pressure on cell migration [88], and a system for screening antiangiogenic drugs [89]. These systems illustrate the potential benefits that on-a-chip cancer technologies are capable of delivering. However, few platforms model both the primary and metastatic sites, as well as the barrier structures that separate these locations, such as basement membranes, blood, ECM, and endothelium. By including circulating flow through a system containing multiple organoids, modeling the migration of cells from the primary tumor into a downstream target tissue may be accomplished. The results of these systems have been very similar to what is seen clinically. For example, these systems have demonstrated colorectal cancer cells preferentially engrafting into liver constructs, a well-known target tissue for colorectal metastases [84]. These examples represent several components of the metastatic process that have been modeled in multiorganoid systems, and future studies will likely rely upon these types of platforms to uncover other factors that influence metastasis.

Drug testing/toxicology

As has been discussed throughout this chapter, a major area of interest within the body-on-a-chip field is the determination of drug safety. Multitissue type models offer particular benefits for these types of studies. For example, 5-FU is one of many common chemotherapy agents employed in treating colorectal cancer.

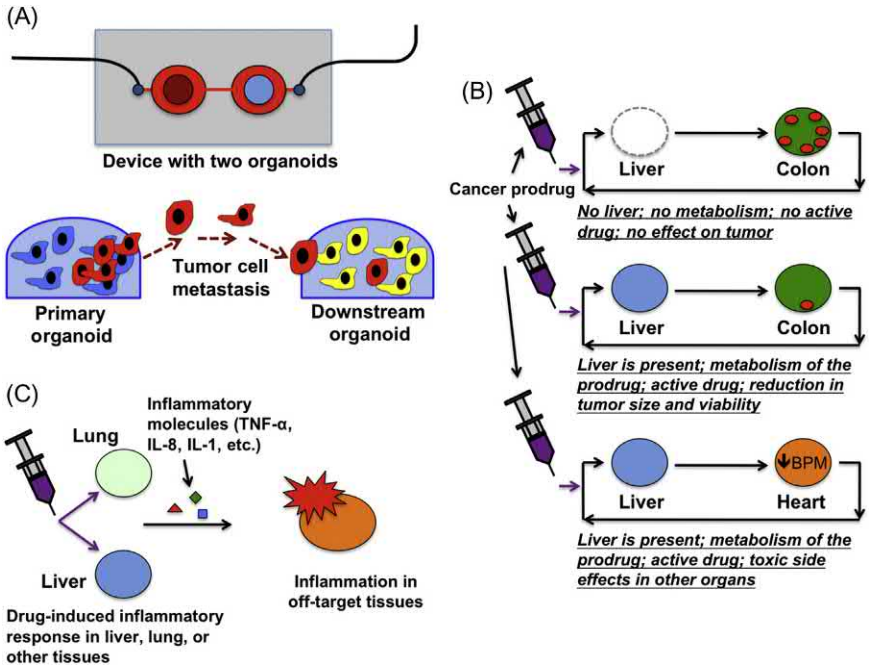

FIGURE 76.2 Examples of multiorgan interactions that cannot be modeled with single-organoid systems. (A) Migration and metastasis of tumor cells from one organ or organoid site to another, demonstrated in vitro in a metastasis-on-a-chip device in which colorectal carcinoma metastasizes from the colon to the liver. (B) Reliance of a prodrug therapy such as the anticancer 5-fluorouracil prodrug Tegafur on liver metabolism to activate the drug to generate a positive effect by successfully targeting tumor cells. (C) Inflammatory molecules secreted from organs such as the liver and lung upon drug injury can cause detrimental inflammatory responses and cell injury in downstream tissues.

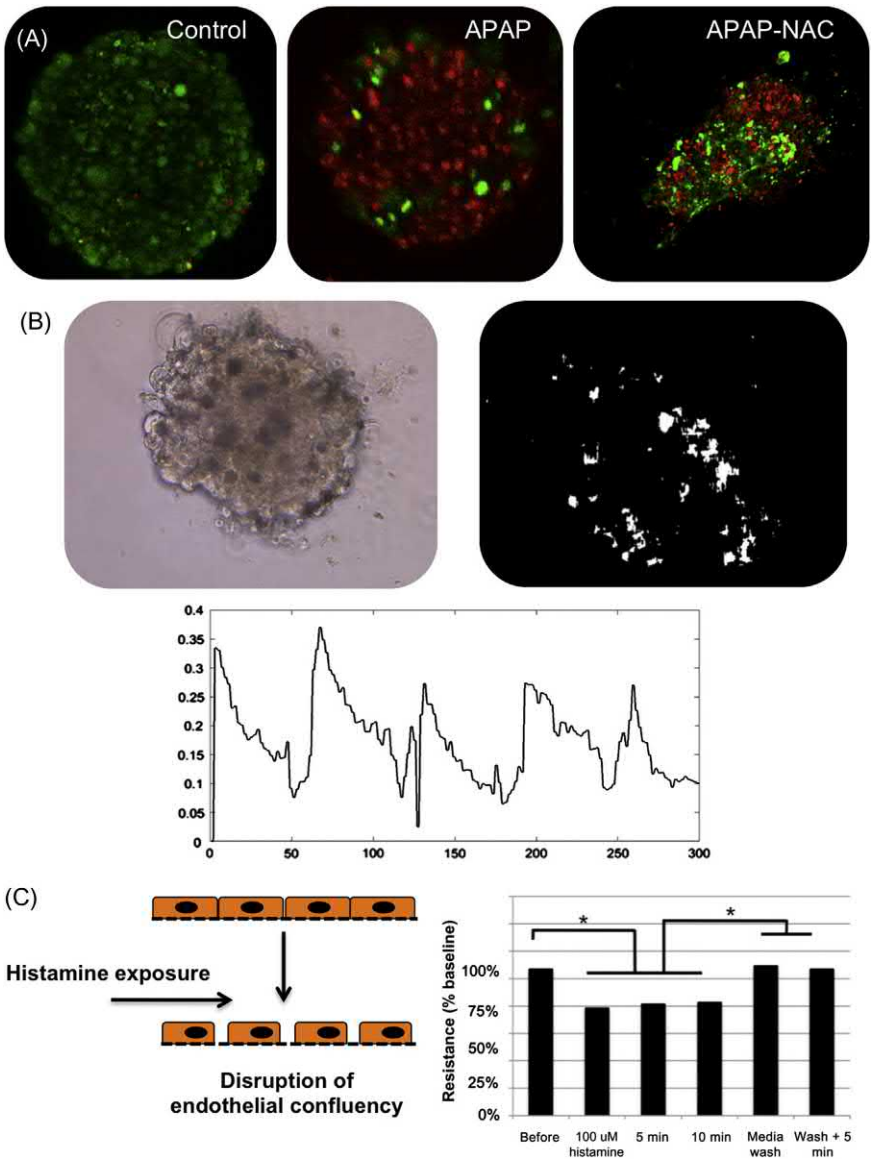

FIGURE 76.3 Highly functional organoids for a multiorganoid body-on-a-chip platform. (A) acetaminophen (APAP) toxicity in liver organoids and reduction in toxicity by *N*-acetyl-L-cysteine (NAC). (B) Cardiac organoids remain viable long-term and support transport of fluorescent dyes [lucifer yellow (*yellow stain*) and fluorescein (*green stain*)] through interconnected ion channels suggesting high levels of cell−cell communication. (C) Beating analysis of cardiac organoids: an onboard camera captures video of beating organoids, after which beating rates are calculated by quantifying pixel movement, generating beat plots. (D) Vascular endothelium devices respond to changes in endothelium integrity as measured by a transendothelium electrical resistance sensor. *NAC*, *N*-Acetyl-L-cysteine.

Unfortunately, 5-FU can induce a variety of detrimental side effects in patients, including cell damage in the gastrointestinal tract. To reduce toxicity, several prodrugs have been developed, such as Tegafur. Tegafur and other prodrugs are inactive in the administered form. The prodrug is metabolically activated by the liver to the active drug, 5-FU. Consequently, without including a functional liver model in the system, no active drug would be produced and experimental results would be irrelevant. By including a functional liver construct, along with intended target tumor cells and potential off-target tissues that may experience toxicity, a more complete understanding of the benefits and risks associated with administration of these types of drugs may be determined (Fig. 76.2B).

In another example, 3D cardiac and liver constructs were used to screen drugs and toxins. By employing a mini-microscope with custom-written software to analyze cardiac beating kinetics, precise determination of beat frequency and amplitude can be recorded [64]. These systems were used to screen a panel of environmental toxins and a set of drugs that were recalled from the market due to unanticipated toxicity in human patients (Fig. 76.3). Fig. 76.4 highlights some of these studies, where the dual-organoid systems were able to model these toxicities. In addition, the integration of different microengineered tissue types into a single system allows for screening studies that can identify unanticipated toxicities (Fig. 76.2C) [90].

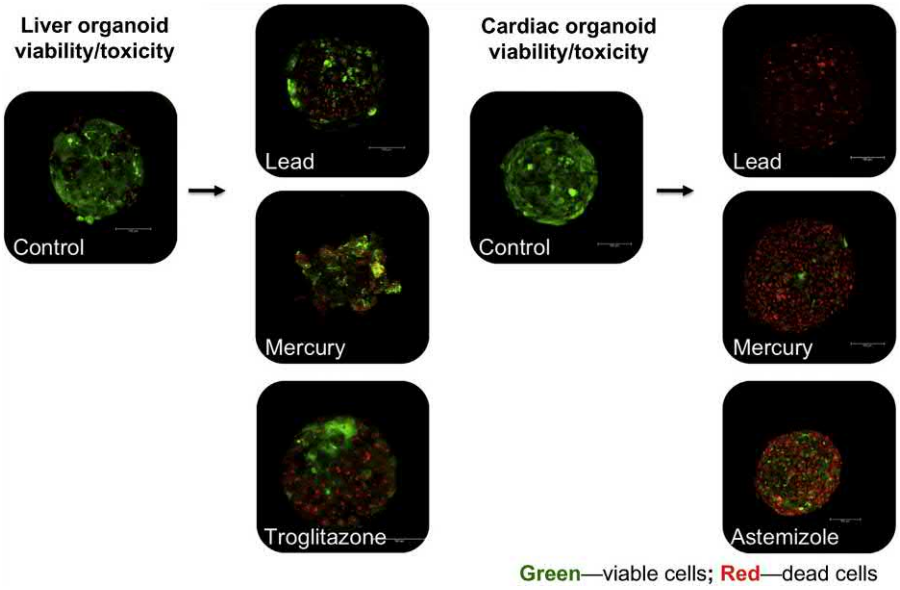

FIGURE 76.4 Drug and toxicology screening in liver and cardiac organoids. LIVE/DEAD stains show the presence of dead cells (*red*) after treatment with lead, mercury, troglitazone, or astemizole.

Additional disease modeling

Research on human pathologies other than cancer may also benefit from the capabilities of multiorganoid systems. There are many drugs and diseases that are known to cause inflammation. For example, large doses of the very common analgesic acetaminophen cause significant inflammation and toxicity in the liver. Other drugs, such as chemotherapeutics like bleomycin, cause inflammation, toxicity, and irreversible fibrosis in the lungs or other organs. In most of these cases, toxicity and apoptosis lead to the release of proinflammatory cytokines such as TNF-α and interleukin-1 into the circulation. These molecules can cause a series of downstream responses, including recruitment of inflammatory cells, activation of fibroblasts, and changes in vascular protein expression and permeability (Fig. 76.4C). Integrated multiorganoid model systems with integrated vasculatures can model responses across multiple organs and capture physiologically relevant effects that would be missed in single tissue models.

Cutting edge body-on-a-chip: the first highly functional multiorganoid systems

As described previously, there is a paucity of truly integrated multiorganoid platforms that are able to accurately model and test the complex responses to drugs, toxins, and disease across a range of human tissue types. However, progress is being made, primarily within the last several years.

The Ex vivo Console of Human Organoids platform

This system represents an advanced, modular multitissue integrated body-on-a-chip system for use in drug development, and toxicology screening. The multiorganoid body-on-a-chip platform is named Ex vivo Console of Human Organoids (ECHO). This platform was initially developed to include four engineered tissues representing liver, cardiac, vascular, and lung, which were integrated into a single system that provides real-time monitoring of physiological responses to toxic agents and pharmaceuticals.

Using the ECHO platform, a comprehensive set of data providing characterization of each organoid has been developed. In general, the 3D models are contained within platform microreactors using tissue type−specific supportive hydrogels. The result is an array of tissue equivalents suspended in a substrate containing tissue-specific ECM [36,91]. Liver models are fabricated using liver ECM-derived hydrogels that help maintain viability and function in vitro for over 4 weeks [91] Productions of key liver markers (e.g., albumin, multiple CYPs, epithelial cell−cell adhesion markers, dipeptidyl peptidase IV, and OST-α) been confirmed and are stable over a month. These models respond to toxins such as acetaminophen (APAP) at appropriate doses and in a dose-dependent manner. The models also respond to the clinical countermeasure for APAP intoxication, *N*-acetyl-L-cysteine by demonstrating reduced toxicity (Fig. 76.4A). Cardiac models also remain viable for 4 weeks, and beyond. These models demonstrate transport of fluorescent dye molecules among cells within the organoids, indicating a high degree of cell−cell communication. The constructs beat spontaneously and change their beating rates appropriately in response to a variety of drugs. These kinetics are captured using an onboard camera system [92,93] and custom software for analysis (Fig. 76.4B). In addition, an engineered vasculature has been incorporated into the

platform. The vessel model responds to agents such as histamine by disruption of the endothelial cell monolayer (Fig. 76.4C). This results in increased transendothelial transfer of larger MW molecules that are normally sequestered within the microfluidic circuit.

Several integrated, multitissue type studies have been performed using the ECHO platform. Experiments, including integrated liver, cardiac, and endothelial modules, have been performed in these microfluidic devices (Fig. 76.5A and B) under a common medium. These systems have demonstrated long-term viability, and produced multitissue responses to drugs in a manner that largely mimics the responses that would be expected in an experimental animal, or even in a human. For example, Fig. 76.5C describes the effects of propranolol and epinephrine on the cardiac model, both with and without integrated liver in the microfluidic circuit. Epinephrine induces an increase in beating rate in cardiomyocytes. Without liver, propranolol, a beta-blocker, blocks the β1- and β2-adrenergic receptors, preventing cardiac beat rate increase following epinephrine administration. However, in the integrated system that includes the liver model, propranolol is metabolized to an inactive form, resulting in the recovery of much of the epinephrine-induced increase in beat rate. To our knowledge, these experiments are the first interdependent in vitro multitissue type studies that

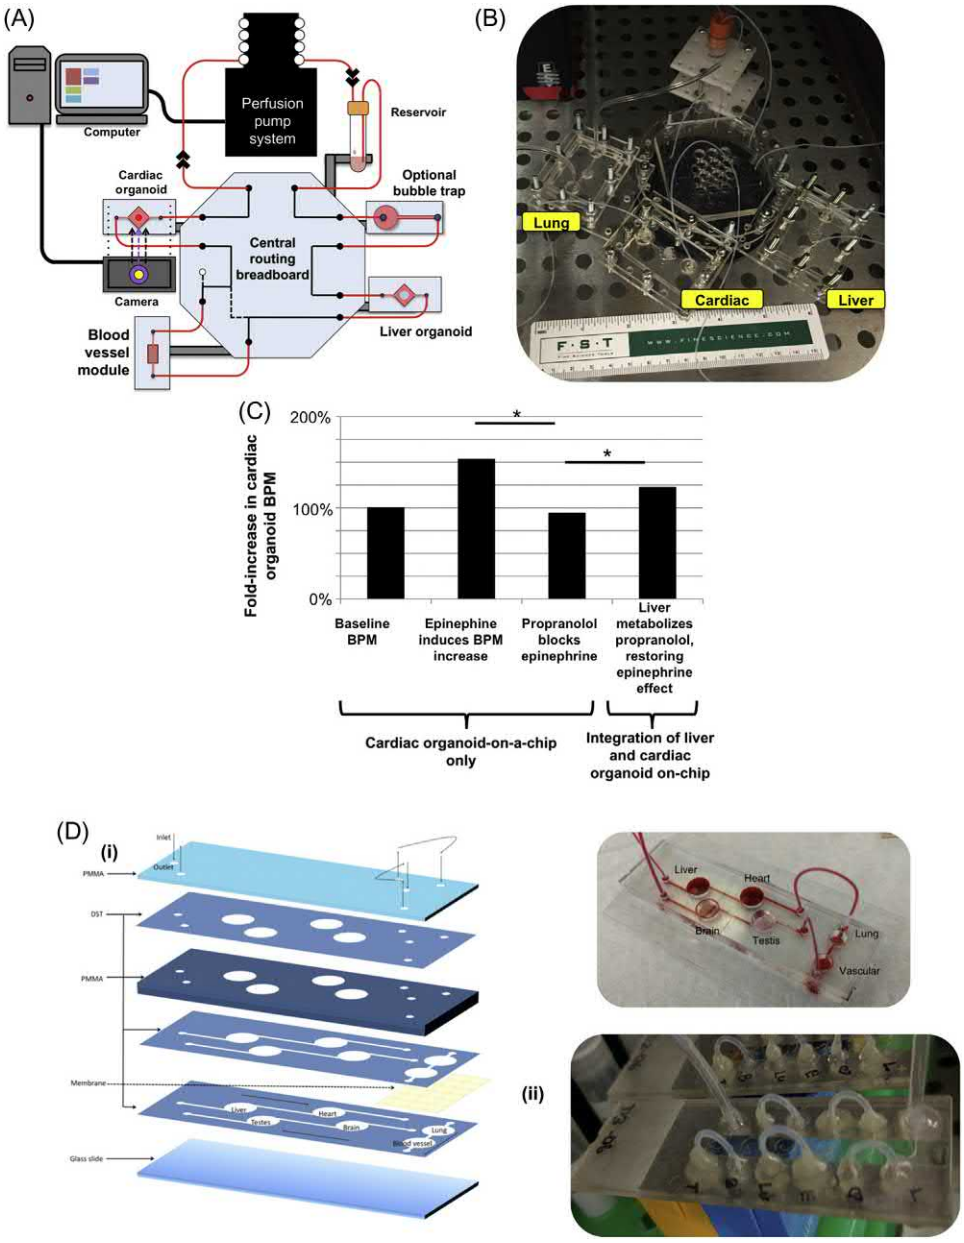

FIGURE 76.5 A multiorganoid body-on-a-chip. (A) A depiction of a liver, cardiac, and vascular organoid-containing body-on-a-chip platform. (B) A photograph of the three-organoid system. (C) Description of the effects of propranolol and epinephrine on cardiac organoids, with or without liver organoids, illustrating the importance of multiorganoid systems. Without liver, propranolol, a beta-blocker, blocks cardiac beating increases by epinephrine. However, with both organoids present, propranolol is metabolized by the liver organoid resulting in a measurable epinephrine-induced increase in beating rates. (D) (i and ii) Future body-on-a-chip platforms for increased capabilities for linking multiple organoids within a single circulatory system.

have been performed successfully in a single, integrated system.

The ECHO platform has also been used to screening drugs that were withdrawn from market due to unanticipated toxicities. Due to the lack of accurate models for predicting drug toxicity, many drugs have passed through preclinical studies and clinical trials, received FDA approval and remained on the commercial market for years, before being recalled for causing unanticipated toxic effects in humans. Approximately 90% of these drugs that have been removed from market result from toxicity in the liver and heart. A panel of these drugs has been tested in the ECHO platform. These include the drug troglitazone (Rezulin), an antidiabetic and antiinflammatory that was recalled for causing liver failure, and mibefradil, an ion channel blocker that was recalled for having fatal interactions with other drugs, including antibiotics. In the ECHO platform, troglitazone and mibefradil both demonstrated liver toxicity. The drug rofecoxib (Vioxx) is an NSAID that was recalled for causing serious vascular pathologies such as heart attack, stroke, skin reactions, and gastrointestinal bleeding. Astemizole, an antipsychotic that caused slowing of potassium channels, torsade de pointes, and QT prolongation; as well as terodiline, a drug for bladder incontinence that caused QT prolongation were tested in ECHO and showed functional changes and loss in viability among several cell types within the platform. The anticancer drug 5-FU and isoproterenol, a beta-adrenergic agonist, both of which are known to induce cardiac toxicity were evaluated in ECHO. Each of these drugs result in dose-dependent cell death within the cardiac constructs. Using the onboard camera, beating effects were observed to decrease in a dose-dependent manner as well. Notably, effects on beat kinetics were detected at doses well below the toxic threshold. This is an important point, as drugs withdrawn from the market for cardiac toxicity are generally not withdrawn for overt toxicity, but rather for causing arrhythmias.

Other body-on-a-chip programs

The ATHENA (Advanced Tissue-engineered Human Ectypal Network Analyzer) program has designed a miliscale multiorganoid system, and a program sponsored by the Defense Advanced Research Projects Agency (DARPA) has sponsored a 10-organoid project [94].

These projects have stressed aspects of microphysiological systems that are somewhat different than ECHO. Specifically, the ATHENA program, based out of Los Alamos National Laboratories, has developed a system comprised four organs—liver, heart, lung, and kidney [95]. These models are three orders of magnitude larger than the ECHO models. This scale allows for more relevant mechanical testing and the system fluid volume is sufficient for collecting samples that may be analyzed using standard clinical diagnostic equipment. The DARPA program, based out of Harvard's Wyss Institute, is working a collection of 10 models, including representations of endocrine, gastrointestinal, immune, musculoskeletal, and reproductive tissues [96].

In addition, the National Institutes of Health are supporting a major organ-on-a-chip program through the National Center for Advancing Translational Science, the National Institute for Biomedical Imaging and Bioengineering, the National Cancer Institute, *Eunice Kennedy Shriver* National Institute of Child Health and Human Development, National Institute of Environmental Health Sciences, NIH Common Fund, and NIH Office of Research on Women's Health. The NIH initiative differs in that the funding is distributed among a variety of individual research laboratories and developing models for a wide range of tissue types [97]. The program stresses derivation of models from iPSCs, and many of the constructs developed by members of this program are nuanced and sophisticated. However, the potential for integrating these models into a multiorganoid has yet to be accomplished.

Organ-on-a-chip systems for personalized precision medicine

There is an increasing interest in developing in vitro models for personalized medicine. This is an unmet clinical need, as finding the most effect drug and dose for a specific patient is often a trial and error procedure. With personalized organoid models (Fig. 76.6A and B), therapies can be screened on a patient's own cells in a 3D tissue model system. For example, accurate prediction of a patient's tumor progression and response to therapy is one of the most challenging aspects of oncology. Prescribed treatments are often made based on the general success rate of a drug within a population, not on the specific response that may be expected within an individual patient. Recently, the concept of precision, or personalized, medicine has evolved to address these problems by using the patient's genetic profile to identify "drugable" targets for treatment [98–100]. However, in real-world practice, the results of this approach do not achieve the desired goals [101]. Following identification of key mutations through genetic profiling, physicians are still left with an array of drug options, with no concrete direction regarding potential side effects or the level of expected effectiveness. As such, there is a clear need to develop tools that can help predict the response of individual patients to drugs [102,103]. Current efforts are focused on the development of multiorganoid platforms that contain patient-specific tumor models in which therapeutic strategies are selected based on empirical results generated in the patient's on normal and malignant cells. Such systems

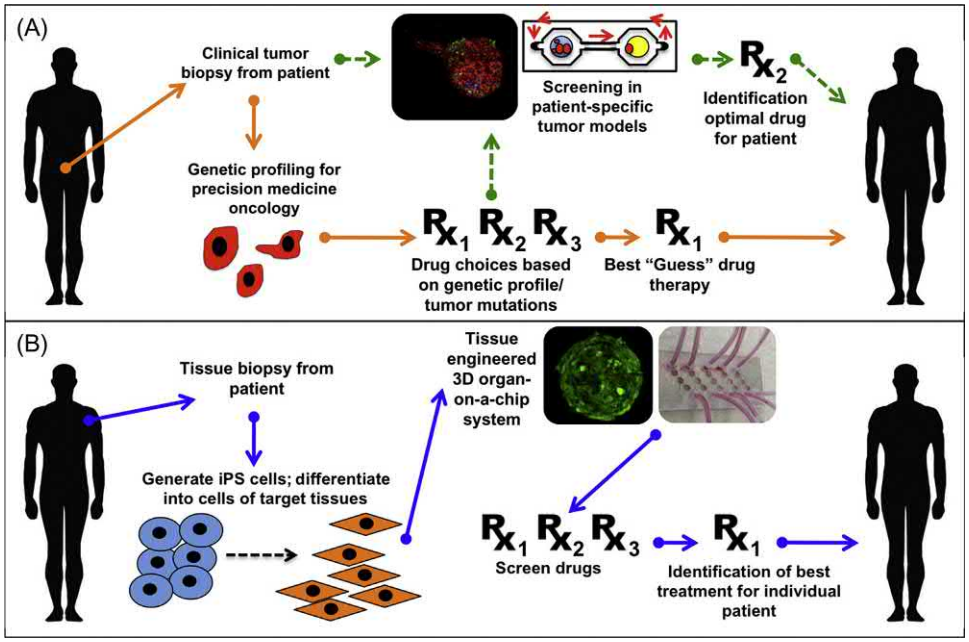

FIGURE 76.6 Employing biofabricated tissues in personalized medicine. (A) In personalized precision medicine for cancer patients (*red arrows*), currently a potential list of drugs are determined based on mutations found in the tumor genetic profile, from which best guess therapies are prescribed. In the future, cells from tumor biopsies could be used to create in vitro tumor models specific to a given patient (*green arrows*). Potentially effective drug therapies can then be screened in the models, thereby identifying the optimal drug therapy for that patient, both in terms safety and most effectiveness. (B) In genetic diseases, cells can be harvested from alternative tissues, such as skin, translated into induced pluripotent stem cells, differentiated into cells of the tissue of interest (e.g., lung or heart), and bioengineered into 3D organoids and organoid-on-a-chip systems, after which generic and genome-specific drug therapies can be screened for the original patient. *3D*, Three-dimensional.

may also indicate tissues to which metastatic cells may potentially migrate [84]. Taken together, these advanced 3D patient-specific models may allow clinicians to provide accurate prognoses regarding tumor progression and metastases and develop individually targeted treatment plans, personalized to each patient's tumor. As iPSC technology continues to evolve, it will likely be possible to generate an array of patient-specific tissue models that could provide information on the sensitivity of these tissues to specific treatment regimens. This would allow for the selection of an agent that spares healthy tissues while maximizing the killing of malignant cells. A final idea to consider is that the greatly reduced scale of these tumor models allows for the assessment of therapeutic efficacy against the small stem cell populations that are driving the bulk of the tumor, so long as these cells are captured within the model.

Conclusion and perspectives

While the benefits of multitissue type model systems are quite clear, there remain several challenges for their acceptance and widespread deployment for drug development and personalized medicine. Currently, most single cell type systems, do a respectable job at mimicking certain aspects of in vivo physiology and are quite amenable to high-throughput drug screening. The few single- and multitissue type models that include multiple cell types within each model provide a much better representation for human physiology, but they have not yet been optimized for high throughput [104]. As such, these more complex systems are best suited for evaluating drugs that are in the later stages of development. Many groups are actively developing strategies for multiorganoid systems and automating their production [14]. Significant reduction of size, automated fabrication, improved onboard biosensing and in-line diagnostic technology would greatly increase the throughput potential for multiorganoid platforms across all potential applications [92,93,105,106]. Another perceived challenge for the development of advanced, multiorganoid, platforms is the requirement of a common cell medium to support a wide variety of cell phenotypes. Typically, human primary cells and iPSC-derived cells require complex, highly specialized media formulations that are tailored to each specific cell type. Surprisingly, there is growing evidence that 3D cell constructs are intrinsically supported and much less reliant on complexed media supplements or serum. This has been demonstrated in the maintenance of a variety of cell types in human cancer models [18,84] using serum-free medium and customized hydrogen substrates [36,91,107]. Even more remarkable is the ECHO platform described earlier

in this chapter. In this platform, up to six organoid types, each containing up to five human primary cell types each have been maintained under a serum-free, common medium for at least a month with minimal loss in viability or function. It is likely that the constructs themselves produce the autocrine and paracrine factors that are required for long-term viability and function. The compact architecture, scant interstitial space between cells, and normal ECM proteins would allow these factors to become concentrated within each organoid and diminish reliance on exogenous factors delivered through the medium. Multiorganoid body-on-a-chip technology is advancing at a rapid pace and is likely to soon be deployed for drug screening [10]. These platforms have significant utility in many areas and will dramatically change the way that precision medicine, cancer modeling, and drug development are performed.

Introduction

Tissue engineering (TE) systems (TESs) are defined as devices and accessories that enable the culture of engineered tissues for regenerative medical, diagnostic, or research purposes. These systems range in complexity, from a tissue culture plate in an incubator to TE bioreactor systems. This chapter will focus primarily on the monitoring and control in TE bioreactor systems. TE bioreactors are related to, but different from, industrial-scale fermenters. They are primarily used to mimic a physiological environment on a laboratory scale and to thus regulate temperature, pO_2, pCO_2, pH, nutrient concentrations, and osmotic environment. In some cases, they provide biologically relevant stimuli such as growth factors or mechanical input according to defined protocols.

Monitoring in a TES can be done at several levels: intracellular, extracellular/tissue, and environmental (Fig. 77.1). Cellular monitoring involves mostly fluorescence, bioluminescence, and other "imaging" modalities. Tissue monitoring may require microprobes (e.g., needle probes for O_2) and specialized hardware for measuring mechanical properties. Environmental monitoring can be very comprehensive and include most of the biomolecules, for example, oxygen, glucose, proteins, metabolites, and proteins in the culture medium.

Monitoring and control in TE bioreactors can be important for two main reasons (Fig. 77.2). The first is to ensure homeostasis of a selected parameter; this is common to most TES. Parameters that must be monitored in most cases include pH, pO_2, nutrient transport, waste removal, and temperature. Thermostatic control of the reactor temperature within defined limits is an elementary example. In such a case the variable that is monitored and the variable that is controlled are the same. In other cases the controlled variable can be used to indirectly manipulate the tissue. For example, glucose levels can be monitored and controlled to indirectly manipulate tissue growth.

The second reason for monitoring and control is the large (and still poorly understood) inter- and intra-donor variability in the performance of the cellular component. This variability affects critical TE parameters, such as the magnitude and time course of responses to growth factor treatment, tissue metabolic rates (and hence sensitivity to mass-transport limitations). This is particularly well-documented for mesenchymal stem cell (MSC)-based TE but also affects other cell types [1–3]. For cartilage TE, for example, this ultimately defines the composition, physical properties, and the timing of accrual of the extracellular matrix (ECM) [4]. It should be noted that failure in any one of these leads to an inadequate product [5,6].

A practical requirement of TE is to understand and predict process failures. Thus if issues are caught early during the development of the tissue, one can intervene either to address the issues or to decide to abandon a preparation to avoid implant failure and unnecessary costs. Nondestructive technologies with predictive skill are needed for monitoring engineered tissue during development. The monitoring should include key quality parameters for the end product, should be feasible in real- or near-real time, and should not compromise the prospects for implantation [6–8]. This is an interdisciplinary undertaking, which requires expertise in subject areas such as molecular and cell biology, biomedical, chemical, mechanical, and electrical engineering, advanced imaging, and computer modeling [6,8].

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00079-4

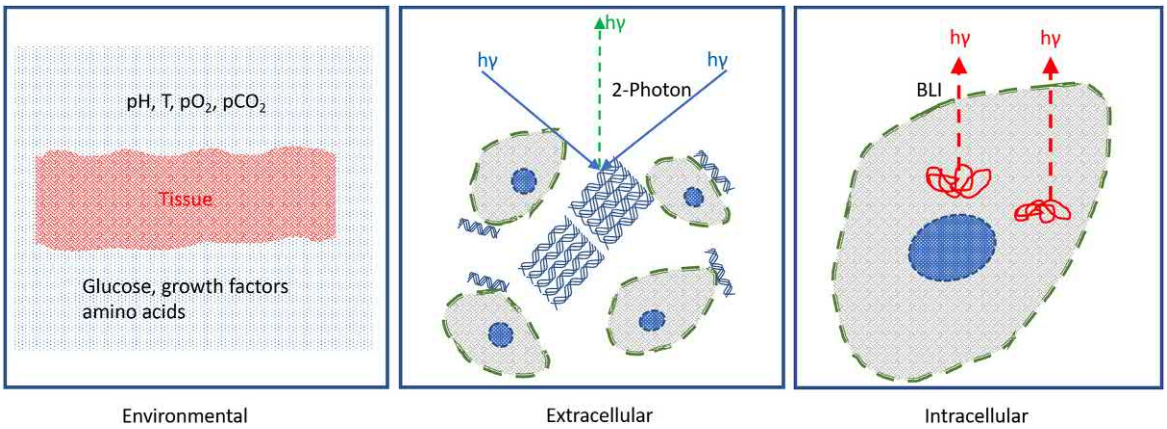

FIGURE 77.1 Levels of monitoring and control in TES. At the environmental level (*left panel*), pH, T, pO_2, pCO_2 are controlled along with monitoring of biomolecules glucose, growth factors, and amino acids. At the extracellular or tissue level (*center panel*), ECM deposition can be monitored using two-photon microscopy, ultrasound, or OCT. At the intracellular level (*right panel*), reporter-based systems can be used to monitor gene expression. *ECM*, Extracellular matrix; OCT, optical coherence tomography; *TES*, tissue engineering system.

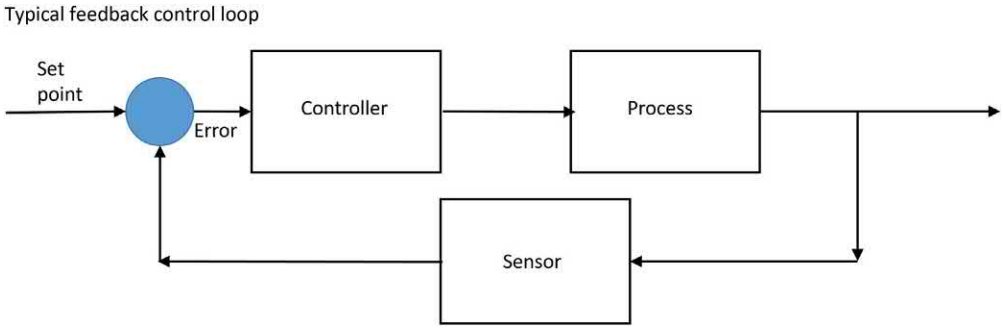

FIGURE 77.2 General flowchart for monitoring and control. In a conventional feedback control system the process variable (temperature as an example) is measured and compared to a set point, and a control action is performed to correct any error between the measurement and the set point. For many TES, monitoring of additional variables (compressive modulus) can be carried out without performing any action to correct any error between the measurement and the desired set point (release criteria). This is primarily due to two reasons: (1) we do not know the set point, (2) even if we do, we do not know what corrective action can be taken to address the error. *TES*, Tissue engineering system.

On the control side, currently, corrective actions based upon feedback for environmental parameters are probably the closest to being implemented. Thus temperature control is a mature technology, or for another simple example, glucose depletion can be counteracted by supplying more glucose (Fig. 77.2). Implementations will be discussed below. On the other hand, monitoring of emerging properties of the developing tissue may, at this point, only result in go/no-go decisions for the particular piece of tissue. In many cases, this is because we do not yet know what parameters to "tweak" to effect a correction.

A major challenge in monitoring and control of TES is that there is often no direct relationship between the parameters that are controlled, and the outcomes that are important for release criteria. This is partly due to a lack of knowledge regarding release criteria for any specific tissue, but more importantly due to inferior knowledge connecting tissue function to controllable parameters. For example, the compressive modulus of TE cartilage tissue may be related to glucose levels in the culture medium, but we do not yet understand the exact nature of the relationship. Consequently, at this point, we are not able to control the outcome of a TE exercise with respect to the release criteria, rather we focus on parameters that are considered critical to growth, differentiation, or maintenance of engineered tissue.

Current state-of-the-art

General environmental monitoring and real-time control

In most TES, there are key variables of the system that are always monitored and controlled. These include temperature, pH, and pO_2. The set points for these are based on standard (and sometimes historical) physiological values and not tissue-specific: for example, in a MSC-based cartilage TESs, temperature is set at 37°C though it

is well-known that in humans, both the bone marrow and knee joints have slightly reduced temperatures (~35°C) [9]. The list of controlled variables may include TES-specific variables such as mechanical strain for mechanically stimulated cartilage constructs (e.g., shear [10,11], compression [12], perfusion, hydrostatic load [13,14], or combinations thereof). While many other variables can be monitored, it is often difficult to control them. More importantly, currently, there is little understanding of how controlling such variables will affect the engineered tissue outcomes.

Temperature: Usually, a 37°C physiological set point is desired. This can be achieved by housing the TES in a commercial incubator or, in stand-alone systems, by using a heater and thermostatic control. In the former case, it should be noted that actuator systems associated with the TES (e.g., pumps, stirrers, etc.) can introduce excess heat if they are also enclosed in the incubator.

pH: In most TES a physiological pH set point of about 7.2−7.4 is desired, although for differentiating tissue, this value may be different. Culture medium pH is a good indicator of cell metabolism. Thus, in a perfusion bioreactor, pH is a qualitative proxy for nutrient availability/depletion. Most culture media have a pH indicator, for example, phenol red but quantitative measurement of pH requires sensors. pH sensors can be based on electrochemical or colorimetric methods [15]. As with every sensor-based system, fouling is a major concern, which limits long-term monitoring, especially in electrochemical sensors. In a typical bioreactor (fermenter) pH is controlled using acid/base injection. However, in a TES, pH control is more complicated and may be achieved by modulating buffered medium flow rate and to some extent by dissolved CO_2 content if a CO_2/bicarbonate buffer system is used.

Carbon dioxide: Control is primarily to maintain the buffering capacity of bicarbonate-based medium. If TES is housed in a commercial incubator, CO_2 produced by the tissue may not be a big issue. In self-contained bioreactors, CO_2 control should be built into the design using a dissolved CO_2 probe or a pH probe (as stated previously).

Oxygen: All mammalian tissues require oxygen for survival and function. The amount of oxygen required by the tissues, however, depends greatly on the state (e.g., differentiation) and type of the tissue. In vivo, oxygen delivery is primarily dependent on the transport resistance to oxygen and not on thermodynamic limitations (due to high oxygen carrying capacity). However, in vitro, oxygen transport to engineered tissues is greatly affected by both: the very low oxygen carrying capacity of culture medium and transport resistance of engineered tissues lacking a vascular network. Oxygen measurements of culture medium can easily be performed using oxygen probes. While oxygen reduction reaction−based probes (e.g., Clark electrode sensor) are popular, they are prone to error when oxygen levels are low. In such cases an optode-based sensor (e.g., ruthenium-based oxygen sensors) is superior and more accurate. Even though oxygen measurements using such probes are straight-forward, calculating oxygen uptake requirements of the tissue, is not. This is because often oxygen measurements are prone to leaks from atmospheric oxygen, and due to diffusional transport within and very near the tissue, oxygen values can drop precipitously near the tissue.

Control of O_2 can be achieved by changing the oxygen content in the culture medium (thermodynamic consideration) or by increasing medium flow rate (transport consideration). Both suffer from tissue-dependent limitations. In a metabolically active TES, even at the maximum thermodynamic limits, we may not be able to control oxygen content in culture medium for large tissues. This is because cells and tissues can be sensitive to shear caused by the flow conditions. In addition, medium washout can be a problem as paracrine signaling is considerably reduced under high flow conditions, though this can be ameliorated by recirculating the culture medium.

In TES the growth, differentiation or maintenance of the tissue is strongly dependent on the biochemical environment surrounding the cells and tissue. This biochemical environment comprises exogenous biomolecules such as oxygen, glucose, amino acids, proteins (e.g., growth factors), and endogenous cell-secreted biomolecules such as metabolites (e.g., lactate), amino acids, and proteins (e.g., ECMs and growth factors) biomolecules. While most researchers use a constant initial biochemical environment-defined exclusively by exogenous biomolecules, cell-based variability (e.g., donor-to-donor variability) and exposure to endogenous biomolecules produced during tissue culture have been shown to critically affect the dynamics of the TE process. This variability results in signature changes in metabolite or cytokine uptake/production rates, which can be measured through continuous monitoring of the biochemical environment. Later we discuss the various types of biomolecular measurements that can be beneficial for monitoring tissue quality.

Glucose is an important nutrient required by all tissues. In TES, only the glucose levels of the supply culture medium are set. These set values are not always determined as optimal based on the tissue requirements; rather, they are based on experiments done with small-scale tissue constructs in conditions that maybe quite different from the reactor conditions. In addition, for differentiating tissues, these supply medium levels may change with time as the metabolism of the differentiated cell phenotype is likely different from the progenitor cell metabolism. Glucose can be easily monitored through off-line measurements made using enzymatic electrochemical sensors [16]. Continuous glucose monitoring is improving

due to recent developments in glucose sensors (nonenzymatic) that have been a primary developed for diabetic monitoring/control [17,18].

Lactate is a key waste product of cellular metabolism, especially, glycolysis. Large levels of lactate in the cell culture medium signify oxygen-independent Adenosine Triphosphate (ATP) production. While this may be due to oxygen deficiency in the TES, it can also be an indication of dominant cellular metabolism. It has been shown that for chondrogenesis of human MSCs, lactate secretion is a good indicator of the quality of the tissue, even in the presence of oxygen [16]. Lactate measurements are obtained typically off-line using enzymatic and electrochemical/colorimetric methods [16]. Continuous lactate monitoring maybe possible using lactate oxidase–based sensors; however, long-term (days to weeks) use of such sensors in a TES has not been well-established.

Amino acids are key building blocks of proteins. Uptake and secretion of amino acids can be indicators of the degree of protein metabolism of the tissue. These can be crucial in connective TE as the primary functions of such tissue often require protein synthesis, often at levels considerably higher than the progenitor cell type (e.g., MSCs) from which the tissue is engineered. Amino acid monitoring requires tools such as LC/MS and therefore is done off-line using samples collected from the TES.

Uptake and secretion of proteins occur during the culture of any tissue construct. Proteins are used in the culture medium, typically, for signaling purposes. In the early days of tissue culture, fetal bovine serum's presence in culture medium was ubiquitous. However, due to concerns of disease transmission and serum batch-to-batch variability, more serum-free media are available now. An advantage of a serum-free defined culture medium is that it is easier to monitor proteins uptake/secretion. While proteins are not used to continuously monitor the tissue quality—primarily due to high cost of detection and measurement-secretion and uptake/binding of proteins can be very important in predicting tissue quality. For example, during epidermal differentiation in a skin TES, keratinocyte differentiation-associated protein (Kdap) secretion is a key indicator of differentiation [19]. Similarly, secreted phospholipases A2 (sPLA2) are found in the culture medium of differentiating keratinocytes [20].

While proteins in culture medium can be quantitated using ELISA or proteomic methods (e.g., mass spectrometry), reporter-based systems (see *Reporter Based gene expression Imaging*) can be used to monitor gene expression at the cellular level. In addition to ELISA, aptamer-based protein monitoring can be a powerful method, but it is not as widely available.

Tissue-level monitoring

At the tissue level, parameters such as ECM proteins, structure and organization, and mechanical properties of the tissue can be monitored. Strategies to controlling these parameters have not been developed yet.

Extracellular matrix structure

Noncontact, nondestructive insights into the structure of the ECM in tissues can be derived from acoustic parameters. In the example of cartilage, acoustic anisotropy of the tissue has been linked to the orientation of the ECM [21]. In cartilage TE, this anisotropy would be a desirable emerging property of the ECM and could be used to control, for example, directional mechanical stimulation.

Extracellular matrix amount/levels

Second harmonic generation using multiphoton microscopy allows the identification of ECM molecules, specifically collagen, in live unstained tissue in real-time, noninvasively and nondestructively [22,23]. Parameters such as collagen deposition per cell can be acquired. In combination with measurements of AA depletion (e.g., pro/hyp) in the medium, this could provide a useful feedback for controlling the medium composition.

In addition, in in vitro chondrogenesis, it is known that (particularly early on) a substantial fraction of newly synthesized ECM molecules are released into the culture medium [24,25]. This opens the opportunity for analysis of the synthesis profile [25].

Mechanical properties

For many TE constructs, matching the mechanical properties of the engineered tissue to the target tissue is a critical consideration. Techniques that evaluate the tissue in a nondestructive fashion could serve to evaluate tissue maturation and to inform decisions as to the maturity of the tissue, or to the trajectory of development (go/no-go decisions). Ultrasound elastography can be used to map strain fields through the tissue and, through modeling, can be used to determine local mechanical properties [26–32]. This can be valuable for determining whether the tissue is developing uniformly through its thickness. Other acoustic properties, such as speed of sound, reflection coefficient, frequency-dependent reflection coefficient, integrated reflection coefficient, ultrasonic roughness index, attenuation, and apparent integrated backscatter, can all be determined and provided for characterization of the tissue nondestructively [33–40].

Ultrasound

Ultrasound elastography is showing potential for evaluating the properties of TE cartilage noninvasively/nondestructively. In this case, light compression can be applied to the developing tissue in a bioreactor using an ultrasound transducer, and time shifts in returning signals (corresponding to internal displacements in the tissue) can be used to calculate internal strain fields [41].

Optical coherence tomography

Optical coherence tomography (OCT) has the potential to be a valuable technology for in vitro evaluation of engineered tissues [42]. Depth of penetration is small at a few mm but is sufficient for many some tissues. Axial resolution of OCT is better than ultrasound by one to two orders of magnitude. OCT has been used to evaluate cartilage arthroscopically in situ and in tissue explants; it is sensitive to ECM collagen orientation and fibrillation [42–51]. The speckle pattern in OCT images suggests that this approach could be coupled with elastography to determine internal deformation and mechanical properties of tissues [52].

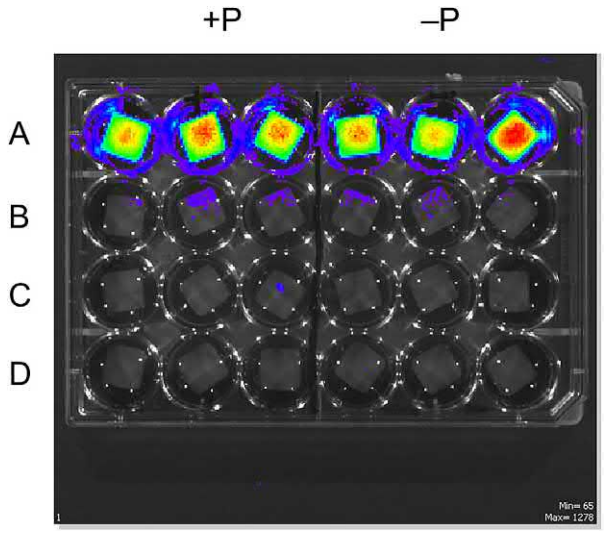

FIGURE 77.3 Example monitoring cells: non-invasively monitoring osteocalcin promoter activity in human MSCs using a luciferase-based reporter construct. Cells were seeded on different bone-implant substrate configurations *A–D*, with or without oxygen plasma etching (*+P, −P*). Two days after seeding, a decision can be made on which substrate to use going forward. Configuration A outperformed the other configurations for osteogenic differentiation support (cell numbers were identical across groups) plasma etching had very little effect. Constructs remain viable after this assay. *MSC*, Mesenchymal stem cell.

Cell-level monitoring

At the cell level, parameters such as gene expression or miRNA levels can be monitored. As discussed previously, strategies to controlling these parameters have not been developed yet.

Reporter-based gene expression imaging

Reporter gene–based measurements or bioluminescent imaging can be used to track molecular and cellular events (Fig. 77.3) [53]. In the context of monitoring and control in TES, event-specific or tissue-specific reporter gene constructs can be used. From a monitoring perspective the advantage of these approaches is that destructive sampling can be avoided and longitudinal imaging can be used to follow the evolution of the tissue over time. Imaging of the whole TE construct or sampling and quantitative analysis of the bioreactor medium (in the case of secreted reporters) can be done [54]. At this point, no automated controls have been implemented to respond to fluctuations in this type of signal in real time. However, capturing such changes can lead to the decision to proceed, or to modify or discontinue growth of particular samples.

In the example of tissue cartilage, reporter gene constructs with Col2 promoter-driven luciferase have been developed [55] to track chondrogenic differentiation [56]. Similarly, the promoter for the transcription factor Sox 9, a master regulator of MSC chondrogenic differentiation, and aggrecan, an ECM component, have been developed into reporter systems for use during TE chondrogenesis [54,56–60]. During the later stages of cartilage formation the expression of proteases and proteinases [e.g., matrix metallopeptidases (MMPs) and tissue inhibitors of MMPs (TIMPs)] that are involved in cartilage remodeling can signal differentiation past the optimal point for articular cartilage [61]. MMP-13 promoter-driven reporters for imaging MMP-13 are available [62–65], as are reporters driven by the TIMP3 promoter [66,67].

An alternate, potentially much simpler approach is to use noncoding RNAs (e.g., miRNA)—responsive reporter constructs to track pathway regulation [68,69].

Tissue-specific

Below, we describe some tissue-specific considerations for control and monitoring.

Cartilage monitoring and real-time control

Cartilage TESs involve bioreactor culture of constructs larger than a few millimeters. Fig. 77.4 shows a disk-shaped cartilage construct (12 mm diameter × 3 mm thickness) cultured in a perfusion bioreactor. The bioreactor consists of a transparent membrane made of fluorinated ethylene propylene membrane that allows free exchange of oxygen and carbon dioxide between the

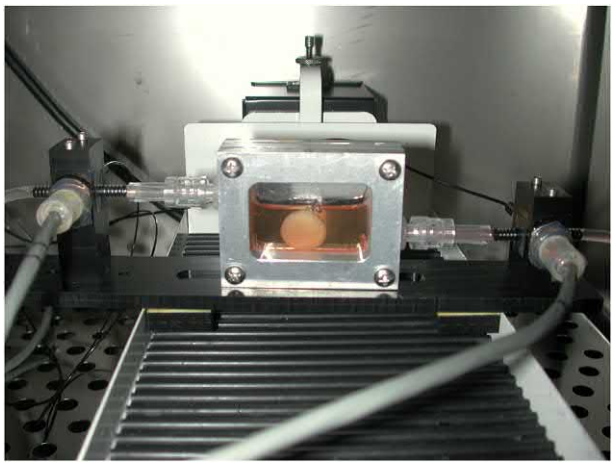

FIGURE 77.4 Cartilage environment monitoring and control. Tissue engineered cartilage construct in a perfusion bioreactor culture. Fiber optic pH sensors sense the color change of the pH indicator dye phenol red in the medium between the inlet (*right*) and the outlet (*left*) of the bioreactor.

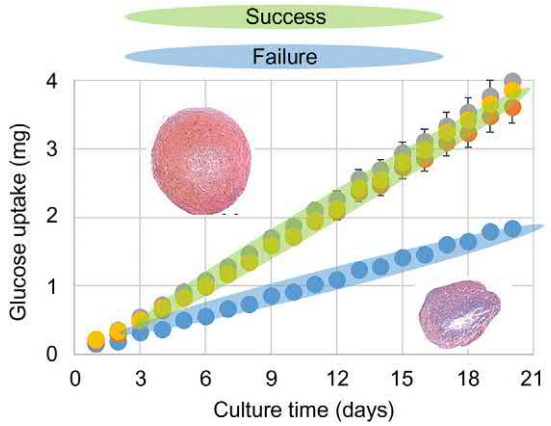

FIGURE 77.5 Glucose uptake as a proxy go/no-go decision maker. Glucose uptake measured over time for different culture conditions. Higher glucose uptake led to improved cartilage ECM as determined by the Safranin-O staining of the histological sections (*inserts*). Even as early as day 3, glucose uptake of a failed culture condition is significantly lower than that of the successful conditions. *ECM*, Extracellular matrix.

culture medium and the incubator environment in which the reactor is housed. In this bioreactor, pH was monitored using probes at the inlet and outlet using a colorimetric method.

Glucose monitoring in an MSC-based cartilage system can be used to make decisions on success/failure of the culture. Fig. 77.5 shows glucose uptake measured over time for different culture conditions. Higher glucose uptake led to improved cartilage ECM as determined by the Safranin-O staining of the histological sections (inserts). While control of glucose maybe achieved by increased flow or higher glucose concentration in the medium, continuous monitoring is still essential to make go/no-go decisions.

Skin

Skin equivalents, a.k.a., reconstructed epidermis are emerging for use in drug testing and possibly for burn coverage. Large-scale skin engineering will require bioreactors. Early attempts at growing keratinocytes on perfusion bioreactors were largely run without tissue-derived feedback [70]. Standard environmental parameters, temperature, CO_2, and medium flow rate are controlled as described previously. It should be noted that most of the skin culture in the literature is done at constant 37°C. It is, however, known that skin temperature is generally lower than that and experiences circadian and exertion-dependent fluctuations [71]. It may be useful to mimic these conditions in skin TES going forward. There will also likely be the need to culture the skin constructs at an air−liquid interface, as this is required for the maturation of the epithelial layer that recreate the barrier function.

For vascularized skin graft constructs, perfusion pressure is controlled. A physiological pressure profile including systolic and diastolic pressures can be provided [72]. Emergent barrier function of the skin equivalent can be monitored nondestructively during tissue maturation by impedance spectroscopy [73].

Although not traditional TE, in vitro expansion of skin grafts to increase the available coverage is being developed. Here tension is applied to skin explants and, stretch magnitude and rate are monitored, and controlled increases in area in the range of 110%−180% have been achieved [74,75].

Cartilage and skin are probably the most investigated tissues for TE and regenerative medicine. Other tissues are being considered; some relevant markers at the cell, tissue, and environmental levels are shown in Table 77.1.

Concluding remarks

TES comprises a complex ecosystem of cells, scaffolds, and medium to produce a piece of tissue for study or implantation. Active monitoring and control are indispensable for optimal tissue production. The monitoring side includes traditional cell culture environment variables that not only apply to most cell types and tissues but also to a wide variety of variables such as mechanical stimulation that are specific to the tissue of interest or its intended function. On the control side, homeostasis or programmed profiles of the common environmental variables are well understood, but for the more tissue-specific variables, the current state-of-the-art may only allow for

TABLE 77.1 Tissue type and monitored/controlled variables.

TES type	Intracellular	Extracellular/tissue level		Environmental	Other	References
		ECM proteins	Mechanical			
Cartilage	Sox9, RUNX2	Type 2 collagen	Compressive and shear loading	Physiological pH, T, pO_2[a], pCO_2		
Skin	Involucrin, keratin profiles, transglutaminase	Type 1 collagen, fibronectin	Tensile loading	Physiological pH, T, pO2, pCO2	Air–liquid Culture	
Bone	Osteocalcin, RUNX2	Type 1 collagen, alkaline phosphatase	Compressive loading, tensile loading	Physiological pH, T, pO_2, pCO_2		
Heart valves	MMPs and TIMPs, α-SMA	Type 1 collagen, elastin	Stretch, flexure, flow, pressure cycling	Physiological pH, T, pO_2, pCO_2		[76,77]

Chapter 78

Biomanufacturing for regenerative medicine

Joshua G. Hunsberger[1] and Darren H.M. Hickerson[2]

[1]Regenerative Medicine Manufacturing Society, Winston-Salem, NC, United States, [2]Wake Forest Institute for Regenerative Medicine, Winston-Salem, NC, United States

This chapter entitled will cover the current landscape of biomanufacturing where we will highlight current technology and areas where biomanufacturing is established and biomanufacturing is seeking to mature. We will also consider current workflows for biomanufacturing and what are some of the top challenges are that need to be addressed. Platform technologies that are enabling biomanufacturing will be highlighted, as well as covering the regulatory challenges and looking toward the future.

Current landscape of biomanufacturing

Biomanufacturing encompasses the scale-up of processes that permit the consistent production of biological products at a commercial scale. Our specific focus in this chapter is biomanufacturing for cell therapies and tissue engineering applications fundamental to regenerative medicine. Current technology for biomanufacturing is still being developed, but we can focus on areas that are well established and will review some of them later. Many of these other areas of manufacturing have processes that could be adapted to biomanufacturing and assist with bringing this relatively young field to a higher level of maturity within a short period of time. There is no need to reinvent the wheel. Rather, rapid progress can be made by adapting and reconfiguring these manufacturing processes from other fields to biomanufacturing.

For example, automobile manufacturing is well developed. We would like to highlight an automobile production process management system from HITACHI [1] and draw parallels to biomanufacturing where many of these processes could be adapted. The sequencer accurately drafts production sequence plans for automobile manufacturing. Similar production sequence plans could be generated for biomanufacturing clinical products. Airlocation controls the storage of complete automobile yards on a real-time basis. This parallels having on-demand biomanufactured products in a warehouse or tissue bank that could communicate in real-time between the manufacturers, hospitals, clinicians, and patients when a clinical product is available. POP controls the production instructions and result collection for the manufacturing sublines. A parallel with biomanufacturing is that this system could be used to collect real-time data from the biomanufacturing of a clinical product to ensure product quality attributes. Unit processing controls the casting, forging, and processing processes for unit products in a lot production system where this could aid biomanufacturing processes by layering in a quality control process for raw materials that could be used in manufacturing the clinical product. Unit assembly controls the assembly and inspection process for unit products in a mixed-low production system. A parallel here to biomanufacturing is that this system could provide quality assurance as the product is assembled, expanded, matured, and packaged for delivery/storage. NXAUTO is a software package that supports the automobile manufacturing process. This could be assimilated into the biomanufacturing management system as a software package that would integrate the different biomanufacturing processes while also providing in-line sensing quality controls in real time to optimize the manufacturing process to produce a clinical product with the quality attributes of identity, strength, quality, purity, and potency needed to ensure safety and efficacy.

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00080-0

Antibody manufacturing is also well developed. Monocolonal antibodies are a major class of biopharmaceutical products. Traditional large-scale manufacturing processes using stirred tank bioreactors for the growth of Chinese hamster ovary cells often require large initial investments and ongoing production costs. Molecular farming is an alternative method for using plants for large-scale production of biopharmaceuticals. Molecular farming has been demonstrated to be safe, scalable, and capable of reducing manufacturing costs [2]. This may be a technology that can be applied to biomanufacturing of regenerative medicine–based products. For instance, one potential cost advantage could be achieved by accumulating recombinant proteins in seeds for long-term protein stability without the need of the cold chain. Interested readers who would like to learn more about advantages and disadvantages of molecular farming are encouraged to consult this review on the current state-of-the-art in plant-based antibody production systems [2].

Vaccine manufacturing is advancing with new production methods that can produce vaccines more efficiently [3]. These new production methods can take processes that used to take 6–36 months to produce, package, and deliver high-quality vaccines and reduce their production time significantly. One solution that GE Healthcare Life Sciences is implementing to speed production is the development of turnkey facilities, out-of-the-box manufacturing platforms. Companies are also finding ways to accelerate vaccine development in emerging economies. One example is from Millipore Sigma, approach of which is to support companies in emerging economies in various ways such as assisting with streamlining manufacturing processes or sharing expertise. This act of corporate social responsibility will help in advancing the global vaccine industry. This lesson of corporate social responsibility can also be applied to biomanufacturing where regenerative medicine products need to be available also for emerging economies.

Chimeric antigen receptor (CAR) T is a cell therapy approach to treat cancer. While we will not address the entire clinical manufacturing process of CAR T cells here, interested readers should seek these reviews [4,5]. CAR T cell therapy is quite effective in treating acute lympoblastic leukemia [6–8]. However, manufacturing clinical-grade CAR T cells under current good manufacturing practices (cGMPs) to enable widespread use of this therapy is still a challenge and one that biomanufacturing will share as well. There is need to develop platform technologies that are efficient and cost manageable to support commercialization. These platform technologies will be implemented along the entire manufacturing process of CAR Ts, which generally speaking include the following steps: (1) apheresis collection, (2) apheresis product wash/fractionation, (3) T-cell selection, (4) T-cell activation, (5) gene transfer, (6) T-cell expansion, (7) T-cell formulation, (8) T-cell cryopreservation, and (9) infusion to patient [4]. In addition to these manufacturing processes there is also an in-process and quality control testing performed throughout the entire manufacturing process.

The field would like to take the manufacturing processes developed for the areas previously mentioned and apply them to cell therapies, personalized medicine, and tissue engineering. In the following section, we will consider current workflows for biomanufacturing for regenerative medicine that would benefit greatly from the more developed manufacturing processes highlighted earlier for automobile manufacturing, for instance.

Highlighting current workflows for biomanufacturing

In this section, we will briefly highlight three common workflows envisioned for biomanufacturing clinical products (Table 78.1). These include (1) allogeneic, (2) autologous, and (3) xenogenic workflows. Many perspective articles have been written that go into additional detail on these workflows, and interested readers are encouraged to consult these reviews [9–14]. An allogeneic workflow would consist of taking a donor's cells (tissue acquisition), isolating those cells, expanding them, harvesting them, bioprinting or seeding them on a scaffold (for a tissue-engineered product), packaging the cells (or tissue-engineered product), and then shipping or cryopreserving the cells (or tissue-engineered product) before they are administered to the patient. Along this workflow is integrated in-line testing to assist with ensuring quality, safety, and efficacy of the cells or tissue-engineered product. Autologous workflows are similar but would use patient's own cells to produce the cell therapy or tissue-engineered product. This will call for a manufacturing process that can be mobile and decentralized and set up at primary care facilities or will incorporate a rapid two-direction shipping model for raw material and final product. Xenogenic workflows are similar to allogeneic workflows but will engineer nonhuman cells or tissue raw materials to be manufactured into a clinical cell therapy or tissue-engineered product.

Current challenges in biomanufacturing for regenerative medicine

The current challenges in biomanufacturing for regenerative medicine are many, but we would like to highlight some of the top challenges, which are summarized in Table 78.2. These include the high costs of biomanufacturing a clinical product. One study done in the United

TABLE 78.1 Manufacturing workflows for regenerative medicine.

	Allogeneic workflows	Autologous workflows	Xenogenic workflows
Overview	This workflow enables true off-the-shelf products where the cell- or TERM-based product is derived from a human source that is not the patient	This is a patient centric workflow that develops a cell- or TERM-based product from a patient's own cells	This workflow enables off-the-shelf products where the cell- or TERM-based product is derived from a nonhuman source
Approach	Cells or tissues are acquired, isolated, expanded, harvested, and bioprinted	Cells or tissues are acquired, isolated, expanded, harvested, and bioprinted	Cells or tissues are acquired, isolated, expanded, harvested, and bioprinted
Therapeutic potential	Off-the-shelf products will be favorable for commercial potential. Potential concerns with immune rejection will need to be addressed	Novel manufacturing processes will need to be developed to take these patient derived therapies and expand them in parallel to a commercial size that is cost manageable	Xenogenic products will be off-the-shelf and favorable for commercial potential. Additional tests will be needed to ensure product safety since cells will be genetically engineered and from a nonhuman source

TERM, Tissue-engineered regenerative medicine.

TABLE 78.2 Current challenges in biomanufacturing and potential solutions.

Current challenge	Description of challenge	Potential solutions
High cost	Very limited cost data to begin with, but the costs for cell therapy and tissue-engineered organs to manufacture under cGMP conditions for a clinical product are very high and will be difficult to make these treatments widely available	Development of universal, defined media for cell manufacturing. Development of a universal bioink for 3D bioprinting
Insufficient automation	Many of the biomanufacturing processes are performed manually and are not fully automated	Develop fully automated processes for biomanufacturing that can be used with multiple cell types for cell therapies or tissue-engineered products
Underdeveloped QC	There is need especially for in-line sensing quality control that is nondestructive	Develop nondestructive in-line sensing technology that can be integrated into automated processes to ensure quality attributes of the biomanufactured clinical product
Lack of sufficient standardization	One specific gap is the standardization of ancillary materials for biomanufacturing	Development of standardized criteria and documentation to ensure consistency and quality for all ancillary materials used in biomanufacturing processes
Lack of modular systems	Currently there are no modular systems that can be configured for biomanufacturing	Develop modular universal bioreactors for expanding and maturing cells and bioengineered tissues and organs

cGMP, Current good manufacturing practices; *QC*, quality control.

Kingdom provided cost data for a stem cell–based tissue-engineered airway transplant ranging from $174,420 to $740,500 for three patients treated [15]. This study provides some of the first cost data really documenting the expense behind bioengineering an organ. Some solutions to combat these high costs are listed in Table 78.2 and are also addressed in a perspective article cited here [16]. Insufficient automation is another challenge where many biomanufacturing processes are still performed manually. Another challenge is having underdeveloped quality control metrics and in-line sensing systems. There is specific need for real-time data that could be gathered throughout

the manufacturing process and done so in a nondestructive manner. Standardization is another gap. In particular, there is great need to standardize ancillary materials that are used in biomanufacturing. Ancillary materials are the raw materials used during the biomanufacturing process for the cell therapy or tissue-engineered product, but they are not intended to be part of the final product. Many considerations have been made on ancillary materials and how they could affect the clinical product and patient safety [17]. There is also a gap in technology in creating configurable modular systems for biomanufacturing. These could be modular bioreactor systems for cell expansion or any other subsystems that could accommodate different cell types and biomanufacturing processes. One could imagine plug-and-play modules that could be connected together to build out an end-to-end biomanufacturing process for any cell or tissue-engineered product. In the next section, we will consider some platform technologies that will enable biomanufacturing.

Current platform technologies enabling biomanufacturing

Media development for biomanufacturing is a platform technology that is being advanced. The Food and Drug Administration (FDA) provided a nice perspective on mesenchymal stem cell (MSC)-based characterization for clinical trials [18], where they reviewed four parameters that could affect product characteristics in manufacturing MSCs, which included (1) fetal bovine serum (FBS), (2) atmospheric oxygen, (3) cryopreservation of the final product, and (4) cell banking (working or master cell banks). Developing a defined media that avoids the use of FBS would address one of these critical parameters which the FDA remarks over 80% of regulatory submissions on investigational new drug (IND) applications for MSCs use FBS in their manufacturing process [18]. Removing FBS from media formulations will increase the consistency of the product and reduce variance from different manufacturing lots. Interested readers who want to learn more about considerations for serum replacements should consult this review [19]. Some commercial suppliers are developing serum-free media and also an industry-driven consortium effort is making progress on developing a serum-free defined media to support clinical cell manufacturing [20].

Another platform technology that will enable biomanufacturing is bioprinting. 3D printing technology has the potential to decrease production time by enabling same day production and shipping [21]. Potentially, a product that would normally take a month to go through design modification phase now only takes 7 days. As an analogous case study, for Ford to create a brand new mold every time they wanted to test a new part of their engines takes 4−6 months and tens of thousands of dollars. Ford can now produce these molds in just 4 days with costs amounting to only $4000. Perhaps we will find ways for 3D printing technology to provide similar benefits to biomanufacturing with enabling innovation to occur more rapidly with introduction of new bioprinted scaffolds or bioprinted organoids or 3D printing novel bioreactors or 3D printing connectors that could all optimize performance and function of the new regenerative medicine clinical product. Essentially 3D printing manufacturing facilities could innovate new technologies on the fly and test them out in a rapid fashion. Another advance in 3D bioprinting is the development of tunable bioinks that can be used across different bioprinting platforms. Many commercial entities are working on designing these bioinks, and an industry-driven consortium effort is also making progress on the development of a tunable bioink for 3D printing that would have applications in both tissue engineering and also personalized medicine [20].

Next-generation biomanufacturing platform systems do not currently exist in their entity, but there are components that do exist. These biomanufacturing platforms consist of scale-up systems, quality control systems, and automation. For scale-up systems, these would include bioreactors that could be used to expand different cells of interest under controlled and monitored conditions. They could also be envisioned to accommodate maturation of cells and priming of tissues and bioengineered organs to be ready for physiological demands. For a more comprehensive review of the current and future states of bioreactors, readers are encouraged to consult this review [22]. Quality control systems need to be used throughout the entire manufacturing process and can provide a report card on the quality attributes of the cells, tissues, or bioengineered organs being biomanufactured. These quality control systems could incorporate real-time monitoring of pH, lactate, glucose, and other attributes as well as designing omic (genomics, proteomics, and metabolomics) assays for more comprehensive profiling. There is some progress toward automation for cell therapies [22,23]. The robotic technology to fully automate biomanufacturing processes currently exists, but defining and standardizing these processes for each clinical product is still a challenge. Also automation will have to be thought about differently based on allogeneic (off-the-shelf products) versus autologous (patient specific) workflows. Artificial intelligence (AI) can also be integrated into automation and will be one of the most disruptive platform technologies for biomanufacturing. AI could be used for smart maintenance to reduce unplanned downtime and maximize productivity. It could also be used to alert manufacturing teams of emerging production faults that could lead to quality

issues with a product. AI could also be used as a personal assistant to perform routine functions and provide teams with sound recommendations [24].

Collectively, these platform technologies will all enable biomanufacturing. In the following section, we will consider regulatory challenges for biomanufacturing.

Regulatory challenges for biomanufacturing

In their structural complexity and heterogeneous mechanisms of action, tissue-engineered products represent a paradigm shift from conventional drugs and devices. While they may be constructed of multiple cellular, biochemical, and structural components, their function is more like a graft or organ transplant than a drug or device. And rather than a daily dose to alleviate symptoms, a tissue-engineered organ often promises a cure in one dose.

Thus a primary challenge for biomanufacturing of tissue-engineered products is one of regulatory categorizations. Internationally, the International Conference on Harmonization, the World Health Organization, and various national and international agencies or coalitions such as European Union legislate or guide regulatory compliance and categorization. In the United States, and addressed primarily in this chapter, the US FDA regulates drugs, biologics, and devices differently. A tissue-engineered organ, which may contain cells, growth factors, and a biomaterial scaffold, is considered a combination product, consisting of a biologic and drug component (cells and/or growth factors, for example) and device (biomaterial scaffold). Which FDA center regulates the product and whether an IND or investigational device exemption (IDE) application is required depends on the primary mode of action of the product: whether the device portion or the drug portion has the most important role in intended efficacy (for more information, see Ref. [25]). Generally speaking, tissue-engineered therapies have required INDs and clinical trials according to the Public Health Service (PHS) Act section 351. Meanwhile, certain minimally manipulated, homologous use products may not require INDs or clinical trials according to PHS Act 361. In additional to PHS regulation, most biologics are also regulated under the Federal Food, Drug, and Cosmetic Act [FD&C Act, Code of Federal Regulations Title 21, or 21 CFR (Codes of Federal Regulation)] since they are categorized as drugs.

The FDA's Center for Biologics Evaluation and Research regulates biologics, which include everything from vaccines to tissue-engineered organs. Meanwhile, the FDA's Center for Drug Evaluation and Research regulates other biological products more biochemical in nature such as monoclonal antibodies and growth factors used for therapeutic applications (for more information, see Ref. [26]). Thus the regulatory pathway for a specific tissue-engineered product may not always be straightforward, and final categorization may take communication with the FDA to determine.

The 21st Century Cures Act of 2016 [27] was designed to help accelerate moving from innovation to the clinic more efficiently. This included a new regenerative medicine advanced therapy (RMAT) designation that allowed for an expedited development pathway if (1) it is a non-361 regenerative medicine therapy; (2) it is intended to treat a serious life-threatening disease or condition; and (3) "preliminary clinical evidence" indicates potential to address an unmet medical need for the target condition [28]. The FDA released a suite of four guidance documents in 2017 to clarify its position on minimally manipulated, homologous use biologics and RMAT designation (see the first four guidance documents in the list next).

The tissue therapy biomanufacturing community was hoping the abovementioned developments in regulatory pathway would include a broadening of therapeutics that would fall under PHS Act 361 or the benefits of RMAT designation, thus lightening the regulatory and financial pathways to market. This has generally not been the case for the most innovative tissue-engineered products, as the homologous use definition is very narrowly defined for 361 classification and prior clinical evidence is required for RMAT designation. First in human applications do not apply.

A major focus of the FDA in recent IND filings has been the requirement for biocompatibility testing. Every new application or change in formulation adds about 50,000−100,000 USD and about 6−18 months to the IND approval process. While identical materials, or materials from different vendors, are already approved, there is little tolerance for justification of equivalence instead of testing in a climate that is highly risk-averse and lawsuit-prone.

While there are numerous clinical trials in progress, to date there is only one stem cell therapy approved by the FDA: the use of cord blood for hematopoietic regeneration; bone marrow is also used for similar applications but is not currently regulated by the FDA [29]. As of 2015, about 11 regenerative medicine or tissue-engineered products had reached the market approved by the FDA; see Table 78.3 [30]. Of the biologics and cell-based devices, three used autologous and three used allogeneic cell sources. The majority of tissue-engineered organs use autologous cells seeded on a synthetic or biological scaffold material. In 2016 the FDA approved the first tissue-engineered autologous cellularized scaffold product for the repair of cartilage defects in the knee of adult patients: Maci, by Vericel Corporation, is composed of cultured chondrocytes on a porcine collagen membrane

TABLE 78.3 Regenerative medicine products approved as of 2015 [30].

Product	Category	Biological agent/application	Biologics source
lViv	Biologics	Fibroblasts/improving nasolabial fold appearance	Autologous
Carticel	Biologics	Chondrocytes/cartilage defects from acute or repetitive trauma	Autologous
Apligraf, GINTUIT	Biologics	Cultured keratinocytes and fibroblasts in bovine collagen/topical mucogingival conditions, leg and diabetic foot ulcers	Allogeneic
Cord blood	Biologics	Hematopoietic stem and progenitor cells/hematopoietic and immunological reconstitution	Allogeneic
Dermagraft	Cell-based medical devices	Fibroblasts/diabetic foot ulcer	Allogeneic
Celution	Cell-based medical devices	Cell extraction/adipose stem cells	Autologous
GEM 125	Biopharmaceuticals	PDGF-BB, tricalcium phosphate/periodontal defects	Allogeneic
Regranex	Biopharmaceuticals	PDGF-BB/lower extremity diabetic ulcers	Allogeneic
Infuse; Inductos	Biopharmaceuticals	BMP-2/tibia fracture; lower spine fusion	Allogeneic
Osteogenic protein-1	Biopharmaceuticals	BMP-7/tibia nonunion	Allogeneic

[31]. The Armed Forces Institute of Regenerative Medicine (AFIRM) grants awarded by the department of defense since about 2011 have committed more than 75M USD for military population–targeted regenerative medicine applications, including extremity repair, craniomaxillofacial reconstruction, skin injury and burn repair, composite vascular allotransplantation and immunomodulation, and genitourinary repair and lower abdomen reconstruction [32]. With the limited number of approved tissue-engineered products on the market, this was an ambitious push to move more of these into the investigational sphere with potential for broader application in traumatic injury and degenerative condition repair for the general population in the near future.

The hope is that with continued innovation and FDA guidance, these few products that have been approved will set precedence for the safety and efficacy of regenerative medicine products and the pathways to investigational approval and market approval will be accelerated.

Food and Drug Administration guidance documents

In the United States, the CFRs are the laws to follow for regulatory compliance. To help apply these in tissue engineering and regenerative medicine products, the FDA offers various nonbinding guidance documents. Where compliance requires adherence to standards or specifications set by other organizations such as the International Organization for Standardization (ISO), United States Pharmacopeia, the PHS, and the National Institute of Standards and Technology, those documents will generally cite those sources. Specifically which CFRs and guidance documents will apply depends on the categorization and phase of clinical trial or licensure, as briefly discussed previously. Representative CFRs and guidance documents that may apply in tissue engineering and regenerative medicine are discussed in Table 78.4.

These regulations begin to provide the framework on how biomanufactured clinical products will be regulated. From these important documents, biomanufacturing processes can be developed to ensure a smooth transition through the regulatory approval process. In Table 78.5 a list of representative nonbinding guidance documents provided by the FDA is given.

These important guidance documents provided by the FDA serve to provide direction and recommendations for industry in numerous critical areas, including considerations for human cells, tissues, and cellular and tissue-based products; expedited programs for regenerative medicine therapies for serious conditions; and how to properly control and validate electronic recordkeeping systems. The more direction that is provided, the better industry can develop biomanufacturing processes in compliance with federal regulations to enable mass production of safe and effective regenerative medicine–based clinical products.

TABLE 78.4 Representative US regulations governing current good manufacturing practices (cGMPs), good tissue practices (GTPs), or related tissue processing requirements.

- 21 CFR 312: Investigational New Drug Application
- 21 CFR 812: Investigational Device Exemptions
- 9 CFR 113.53: Requirements for ingredients of animal origin used for production of biologics
- 21 CFR 4: cGMP requirements applicable to combination products (and see 21 CFR 3)
- 21 CFR 11: Electronic Records; Electronic Signatures
- 21 CFR 210: cGMP in Manufacturing, Processing, Packing, or Holding of Drugs; General
- 21 CFR 211: cGMP for Finished Pharmaceuticals
- 21 CFR Parts 600 through 680: Other applicable regulations for biological products
- 21 CFR 820: Quality System Regulation
- 21 CFR Part 1271: Human cell, tissue, and cellular and tissue-based products (HCT/Ps)
- Section 351 of the PHS Act (42 U.S.C. 262): Drugs, devices, and/or biological products requiring clinical trials
- Section 361 of the PHS Act (42 U.S.C. 264): Human Cells, Tissues, and Cellular and Tissue-Based Products (HCT/Ps) meeting certain minimally manipulated and homologous use criteria

CFR, Codes of Federal Regulation; *PHS*, Public Health Service.

Creating standards

Quite often, compliance in regenerative medicine, particularly tissue engineering, is an interpretive art since the CFRs and guidance documents do not have a special category for those technologies. Cells are still considered "drugs" and "biologics" can be anything from vaccines to tissue-engineered bladders, so determining improperly which regulations apply can lead down expensive and time-consuming wrong directions when applying related similar prior experience or the first apparently related guidance document. Some areas where greater guidance for tissue engineering would be helpful are discussed, as the problems seen in one setting are not directly related to another.

Stem cell–based therapies have a history of safety concerns, primarily with direct mutagenesis or genetic plasticity. Both human embryonic stem cells (hESCs) and induced pluripotent stem cells (iPSCs) have history of teratoma formation; MSCs may be associated with undesired differentiation, and their otherwise advantageous immune suppressive and angiogenesis properties may also indirectly promote metastasis [33]. The FDA has concerns that immortalized cell substrates in vaccine production could cause cancer in recipients [34,35]. The concern logically extends to tissue-engineered products. However, it is difficult to apply a direct genetic test for abnormalities since autologous, somatic cell populations may already naturally contain varying levels of donor age–dependent aneuploidies in a wide range of abundance; for example, nullisomy Y may occur naturally in men in about 10%–73% of cells [36–39]. While some karyotyping studies showed increases in gross aneuploidy in culture from early to late passages [40], others showed decreases, indicating selection against chromosomal aberrations in culture rather than proliferation [41]. This, combined with similar results in other studies, indicates that there is little evidence that karyotypic drift in culture of MSCs or differentiated somatic cells contributes to mutagenesis as seen in hESCs and iPSCs, and supports that these abnormal cells are typically reduced or eliminated in culture [42–44]. Since tissue-engineered products generally use differentiation pathway–dedicated stem cells or somatic cells, the mutagenesis risk appears largely mitigated in these products. Nevertheless, the clinical significance of the karyotypic variations previously noted when delivered in an allograft or autologous cell or tissue therapy product is widely unknown and unstudied. There is currently no requirement by the FDA to conduct karyotypic analysis of tissue-engineered products or as part of a panel of suggested safety testing for general biologics produced by aseptic processing. Some additional guidance and updated information by the FDA in this regard specific to the various categories of tissue engineering and cell therapy applications would be helpful.

Virtually all INDs are returned with an instruction to develop potency assays prior to later phase trials. This can be difficult since the elements defining the potency of an organ (or even a cell) are complex and heterogeneous. Some advanced guidance in what has constituted adequate potency assays for tissue-engineered products would be helpful.

Some common reagents and components are generally considered to be averse to inclusion in cell-based final products. Phenol red is an example; while there is no specific restriction to its use, and phenol red is used as a pharmaceutical, some prior work has indicated that it should be removed, and so organizations go to great lengths (and great cost) to remove it from all cell expansion products. Some clear guidance or standards on safe amounts of phenol red and other common reagents would be helpful.

The future: envisioned advanced biomanufacturing

Biomanufacturing of tissue-engineered organs or organ subcomponents is currently a very manual, hands-on process. The ideal would be completely closed, automated systems. The typical product requires suspending a biomaterial scaffold in a bioreactor, sterilizing it, then reopening the system to rehydrate it, seed cells on it, and mature it. While parts of the process can be performed in closed systems, and technology exists, there currently exist no commercially available systems to either fully automate or fully close production of a tissue-engineered organ from cell expansion through final product formulation.

Closed-modular biomanufacturing systems

As a replacement for the most common system (an open clean room with manual operators), the fully closed organ production system can be developed with or without automation. First, a system without automation can be a modular system that connects specialized ISO5, HEPA-filtered enclosures for all incubations and critical equipment, such as cell sorters and centrifuges. Manipulations can be performed manually via glove boxes or mechanical pass-through manipulators or robotics. The product would be moved to various locations within the modular system for specific parts of the process, but it would not leave the enclosure until final product was prepared and in its clinical delivery containment and closure vessel. The entire system would be sterilized by ethylene oxide or another system such as plasma phase H_2O_2 (Sterrad.

In this model, cell expansion systems could use conventional 2D flasks or could incorporate 3D technologies, including carrier beads or automated fiber systems such as the Terumo Quantum. The system, like standard clean rooms and equipment, would have to be monitored and controlled for temperature, humidity, CO_2, ongoing functionality of equipment when not directly observed by operators, etc. Consumables would need to be loaded into the system prior to sterilization (if compatible with resterilization), and all systems and consumables would need to be validated for sterilization method. This system would be relatively easy to construct with existing technology, given enough financial and time commitment to design and build for one dedicated purpose at a time.

As a second-tier technology, a fully automated system could be developed. These systems could be designed to place all critical components within it and then press the

green button to produce a tissue-engineered organ in a few weeks. While all technology exists to do this even today, the integration of technology has not been attempted. For example, the Quantum cell expansion system exists, but it does not inherently monitor critical culture condition indicators such as glucose and lactate levels. The fully automated system would need to not only do that but also make decisions based on the readings, and carry out the actions necessary for expansion and production. For this to work the process itself would have to be highly standardized and characterized, and the automation system would need to integrate chemistry systems, optical monitoring, digital image transformation with software algorithm interpretation, macro- and microfluidic controls, robotics, and automation of any specialized equipment such as cell sorters.

Off-the-shelf products

A critical step in the scale-up of tissue-engineered organs is mass production. This is most easily accomplished by a decrease in the personalized medicine nature of these products through standardization of more universally compatible products. This can be done through immune-modulated allograft-based products, or production of a suite of off-the-shelf products compatible with a spectrum of human leucocyte antigen (HLA) types. Entire organs, or critical components, can be cryopreserved, thawed, reconstituted, combined, and prepared as final products, ideally with the automated systems described earlier, and ideally within a few hours of a physician placing the prescription. Only in one of these off-the-shelf modes can these products truly meet the high demand and perpetual shortage of organ donations available for transplant.

Preservation advances

Currently, long-term storage requires cryopreservation or lyophilization. Both of these can drastically change the physical structure of tissue-engineered organs, scaffolds, cells, or other subcomponents. Future cryopreservation or stabilized cold storage (nonfrozen, liquid storage) would ideally be DMSO free and should maintain the inherent shapes and structures of the tissue-engineered organs or subcomponents. Researchers have studied the biochemical hibernation mechanisms of larger mammals and smaller organisms that can survive under desiccation or freezing conditions for seasons or even years; these natural coping and preservation mechanisms will someday be harnessed to allow long-term preservation of large tissue-engineered organs or organ subcomponents.

Synthetic biology advances

As chemistry, rheology, and biocompatibility advances continue to be made in bioprinting, better, more customized scaffolds and scaffold materials are currently being developed. The groundwork for making on-demand scaffolds has already been prepared. Organ structures, bones, and support structures can be bioprinted from patient MRI or CT scans. To make this a reality for patient treatment, standardization of production methods and development of more robust, sterile, and reliable bioprinting technology are needed.

A key requirement of 3D biological structures is vascularization. Current technology employing decellularization of entire organ structures retains blood vessel structure at the capillary level, awaiting autologous recellularization. These structures could be mass produced from standard forms or could be replicated on demand by bioprinting. Alternatively, advances in angiogenesis using specialized MSCs could be employed as a hybrid technology with bulk scaffold structures.

Cell banking advances

For mass production and off-the-shelf products, banking and storage systems will need to be optimized. In addition to improvement of biological material stabilization for long-term storage noted above, banking systems will need to be updated to handle the large amount of banking that will be needed and to fit the custom, large organ or tissue shapes that need preservation. The standard vials used in cell banking will no longer work. Bag systems will need to be widely employed to maintain system closure. Importantly, reliable and automated, optically or RF coded labeling and retrieval systems will need to be employed. The cryopreservation freezers themselves will need to be redesigned to geometrically better handle the volume of materials in unusual sizes and shapes—rectangular boxes in round freezers may no longer be practical.

Medical applications for biomanufacturing in regenerative medicine

We next wanted to highlight case examples for medical applications for biomanufacturing. To do this, we have highlighted current products in the cell therapy and tissue engineering clinical trial pathway at Wake Forest Institute for Regenerative Medicine (WFIRM) (Table 78.6).

These case examples highlight where the next-generation of health care is going to provide personalized medicine, on-demand tissues and organs, and even innovative treatments for our wounded warriors.

The AFIRM grants took a major leap forward in providing a prime source of funding for tissue engineering

TABLE 78.6 Case examples of regenerative medicine therapies advancing at an academic clinical center.

Regenerative medicine therapies in clinical trial pipeline at WFIRM
• Tissue-engineered corpus cavernosum for repair of damaged penile tissue
• Tissue-engineered urethra for repair of strictures or other damage
• Tissue-engineered internal anal sphincters for repair of fecal incontinence
• Tissue-engineered vagina for restoration of normal function from congenital defects or traumatic injury
• Tissue-engineered bladder for repair and reconstruction following damaged or disease
• Volumetric muscle repair and replacement from injury or disease, beginning with tissue-engineered muscle repair for cleft lip
• Would healing using amniotic membrane powder
• Testicular tissue banking prior to ablative chemo therapy or radiation therapy for future restoration of fertility
• Muscle progenitor cell implant for repair of stress urinary incontinence
• Bioprinted skin
• Tissue-engineered intestine
• Bioprinted nasal septum
• Fetal placental and amniotic fluid stem cell master cell banks to be used for a broad spectrum of autologous applications, including wound healing, gene therapy for hemophilia, necrotizing enterocolitis, erectile dysfunction, abdominal adhesions following surgery, and neonatal lung damage

WFIRM, Wake Forest Institute for Regenerative Medicine.

applications geared toward repair of battlefield injuries at a time when there were no tissue-engineered organs on the market. The grants provided invaluable funding and advancements to the field of tissue engineering and have moved a half dozen or more tissue-engineered organs from the lab bench to the doorstep of first in human clinical trials at WFIRM alone. A prime focus of WFIRM's tissue-engineered products has been genitourinary repair, a key need in an era when battlefield armor and medicine have been able to save so many lives, while roadside bombs leave targeted lower limb and pelvic floor injuries in high numbers in young men and women in prime marriage and child bearing age. The restoration of their ability to bear children, in addition to the cosmetic and functional repair for normal sexual, urinary and fecal function in general, restores these soldiers not only in their physical functionality, but also in their self-confidence and sense of wholeness as well.

While battlefield injuries will unfortunately always be a reality and a potent motivator for public funding to honor this specific and deserving population, the natural extension of this work is that the general population will always have a need for these technologies as well. Automobile, gunshot, construction, and untold other types of accidents leave similar injuries in average citizens every day. Moreover, the potential to offer off-the-shelf engineered organs to replace the need for cadaveric organ transplants is one of the holy grails of the future of medicine. Many of these technologies exist in incipient form today and can be brought to fruition through continued major financial investment from interested organizations; by participation by the regulatory agencies in guiding the regulatory framework to streamline development and clinical testing of these products; and through investment of time and resources by companies willing to develop the enabling technologies for automation, closed systems, and mass production.

Space exploration

This technology is often called "science fiction become science fact" by people who realize how advanced the technology currently is and how close it is to making major changes in the face of medicine. This technology may be absolutely necessary as the next phase of science fiction moves closer to science fact: extended space exploration. Plans are in development in the United States for long-term colonies to be established on both the Moon and Mars. While many people may be willing to take on the risk for the sake of adventure, many others will be less willing to sacrifice themselves for the cause by dying of treatable conditions while on these colonies until all medical capabilities and populations are developed to replicate all medical support present on the Earth. Tissue engineering technologies offer one mechanism to treat major medical conditions with limited population resources, such as cadaveric donors for organ transplants. Bioprinters and modular tissue engineering labs could be placed both on space stations and Moon and Mars colonies. All of the battlefield injury repairs currently under development for tissue-engineered therapies would be candidates for the types of injuries one may face in the rugged early phases of colony development. And the longer people spend on those colonies, the more likely the population will face the needs for organ transplantation, including kidney, lung, heart, and bladder.

Part Twentytwo

Clinical experience

Chapter 79

Tissue-engineered skin products

Jonathan Mansbridge
California Way, Woodside, California, United States

Introduction

Skin tissue engineering was perceived as the simplest tissue engineering application and was the first to be explored. The culture of fibroblasts, derived from skin biopsies, was established early. The cells were comparatively easy to grow and were used to develop many basic tissue culture techniques. The culture of keratinocytes was achieved by Rheinwald and Green in the late 1970s [1], and using a different system, by Liu and Karasek [2]. Skin biology was second only to immunology in the application of the techniques of molecular and cell biology to medical problems, which has led to great advances in the understanding of the physiology of skin. Examples of methods that have been applied include the use of classical techniques of molecular and cell biology and transgenic animals.

The skin acts as a barrier between internal structures and the external environment. In the 1980s it was realized that the skin, in addition to acting as a barrier, also has significant interaction with both the innate and the adaptive immune systems [3,4]. It is thus much more than a passive barrier and actively recruits defensive mechanisms to protect against infection, colonization by microorganisms, and other external noxious entities.

With a long history of development, tissue-engineered skin substitutes have achieved market exposure and have some of the most extensive experiences with the application of such products in a therapeutic setting. From its inception in 1979 [5], engineered skin was seen as potentially a clinical product and trials started in the 1980s. Preclinical testing was inaugurated and demonstrated that fibroblasts were apparently not rejected and persisted for a considerable period in experimental animals [6–8]. This led to human clinical trials in the late 1980s and early 1990s. Tissue-engineered skin products first gained regulatory approval and appeared on the market in 1997. The first was TransCyte (Advanced Tissue Sciences, which was a nonviable burn product produced by tissue engineering techniques). It was followed by Apligraf (Organogenesis) in 1998, the first tissue-engineered, viable, organotypic product, Dermagraft in 2000 and Orcell in 2001. At the same time, many applications of such products for in vitro testing applications and models of skin physiology were developed.

Much of the discussion in this article is based on experience with Dermagraft and TransCyte. Both products have a similar basis in growth of fibroblasts on three-dimensional (3D) scaffolds. The systems, however, differ substantially in detail.

Dermagraft is grown on 2 in. × 3 in. sheets of a knitted polylactide/glycolide scaffold under static conditions in a bag bioreactor. Following seeding, the cultures are refed with medium every few days until harvest after about 2 weeks. Initially, the fibroblasts proliferate rapidly, much as in monolayer, but as they become confluent, at about 8–10 days, they lay down increasing amounts of extracellular matrix and form a dermis-like structure. At harvest, medium is replaced with cryoprotectant, the bioreactor is welded closed without exposure of the product to the environment, boxed, and frozen under controlled conditions. Dermagraft is stored below −65°C for up to 6 months. During the first month, sterility and analytical testing is performed and the paperwork completed to allow release of the product by the quality assurance department. On thawing, which is performed by the end user, the cells of Dermagraft show 50%–80% viability.

TransCyte was grown using a similar process on two 5 in. by 7 in. sheets of a knitted nylon (nondegradable) scaffold with a silastic backing in a hard bioreactor with a continuous flow of medium. This system has advantages in the ease of taking samples of the medium for analysis and in slightly superior cell growth but it adds considerably to the complexity of the system. At harvest the cultures were rinsed, the bioreactors sealed from the system by welding, packaged, and frozen without any precautions

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00081-2

taken to maintain viability so that the final product was not alive.

The 3D structures formed by the cells under these conditions consist of cells embedded in extracellular matrix that they, themselves, have secreted. It comprises a complex series of molecules. The process of secretion may be thought of as formation of a foreign body capsule in vitro.

Types of therapeutic tissue-engineered skin products

The development of the manufacture of tissue-engineered skin has taken two fundamentally different approaches using alternative methods for the 3D culture of fibroblasts and a third that has intermediate characteristics. One is the use of fibroblasts suspended in collagen gel, in which the gel acts as a substrate for the growth of keratinocytes and forms a structure that has some resemblance to human skin. The second involves culture on a 3D nonbiologically derived, polymeric scaffold. Fibroblasts are responsive to signals from their environment and respond in quite different ways to the two types of culture. In a third system, fibroblasts are grown on a collagen sponge in serum-containing medium. Since collagen adsorbs fibronectin and vitronectin, this system initially shows cell adhesion to both collagen and fibronectin and vitronectin and the cultures show intermediate properties. A fourth approach, using 3D printing methods, will not be discussed as it is a fundamentally different approach that is not scaleable using the concepts discussed here.

In collagen gel suspension, fibroblasts are surrounded by collagen and respond through $\alpha_1\beta_1$ and $\alpha_2\beta_1$ integrins, which are collagen receptors, by becoming quiescent and nonproliferative [9]. Characteristically, the collagen gel is contracted by the fibroblasts to less than 10% of its original volume in about 20 hours, through the $\alpha_1\beta_1$ integrin. At the same time, many genes, notably those for collagen type I and proliferation, are repressed [10] and the cells show mechanosensitivity [11], also mediated through the $\alpha_1\beta_1$ integrin [9]. If the gels are mechanically stressed, usually by preventing contraction with a ring, many genes, including collagen type I and proliferation related genes, are somewhat induced relative to contracting gel fibroblasts, although not to the level of monolayer fibroblasts [11]. The cells also show a substantial upregulation of genes associated with inflammation such as the genes for IL-1, IL-6, and cyclooxygenase [12].

When grown on scaffolds, fibroblasts proliferate rapidly and then deposit large amounts of extracellular matrix. Initially, the conditions on the scaffold are not dissimilar from monolayer culture. The scaffold adsorbs proteins from serum, which is a component of the medium still used for fibroblast culture. The adsorbed proteins include fibronectin and vitronectin as in monolayer culture [13]. However, as the cells reach higher densities and the fibroblasts cease to proliferate, they proceed to lay down extracellular matrix at rates approaching their own weight per day. The matrix is loose connective tissue, much like the provisional matrix of granulation tissue. The cells are clearly very active and induce several genes, among the most notable of which are neutrophil chemoattractant chemokines, CXCL1, CXCL5, CXCL6, and CXCL8 (gro-α, ENA-78, GCP-2, and IL-8, respectively). They also induce the expression of IL-6 and IL-11. The conclusion from these observations is that the fibroblasts act to recruit neutrophil granulocyte components of the innate immune system, which is important in responding to the most likely type of environmental insult to which the dermis is liable, physical injury followed by bacterial colonization.

Components of tissue-engineered skin grafts as related to function

Scaffold

Several types of scaffold have been employed for tissue-engineered skin implants. They include collagen gels, knitted polylactate/glycolate (PLGA) or nylon fabrics, and collagen sponges. As discussed earlier, the scaffold has profound effects on gene expression and the function of the fibroblasts.

The Dermagraft and TransCyte processes used scaffolds obtained as finished commercial products from other companies, which already had regulatory approval. While this simplified the development of the products, it ultimately proved an expensive decision. A solution to this is to obtain a second source of raw material that is not a finished product and establish its equivalence.

A further point here is that, while the use of already approved products as scaffolds may be an easy initial path, the available materials may not be ideal for the particular application envisaged. There remains a need to expand the range of scaffolds available for commercial tissue engineering. As an example, enzymatically, rather than spontaneously, degrading scaffolds may be more suitable for tissue engineering applications, allowing control of the degradation process.

An interesting direction is the development of scaffolds incorporating a vascular capability. Revascularization of skin substitutes is a limitation in their application and the ability to be perfused by the host circulatory system would be a major advance. Scaffold with this type of capability may be made by decellularizing a perfused tissue or organ and then using the remaining extracellular matrix structure as a scaffold [14].

Keratinocytes

Keratinocytes generate the impervious surface of the skin (the stratum corneum) and also have been thought of as having a major role in defense against microbial colonization as activators of immune responses. As a consequence, keratinocytes have been included either alone or in combination with other components in many skin implants [15]. Their role in forming a physical barrier is important, but they also have the ability to produce antimicrobial peptides, such as β-defensin, psoriasin, and cathelicidin [16,17] and a wide variety of cytokines capable of activating immune responses [18,19]. The epidermis contains antigen presenting cells that are capable of activating T lymphocytes under suitable conditions to both cell-mediated and humoral adaptive responses. This is largely a function of Langerhans cells, but it is possible that the keratinocytes also take part under special conditions. It has been argued that the application of a keratinocyte-containing bag to a wound, permeable to proteins but not to cells, may be beneficial without incorporation of the cells into the patient (United States Patent 5972332).

It is notable that the keratinocytes show a higher expression of the fibroblast stimulating platelet-derived growth factor (PDGF) A chain gene than do fibroblasts. This may constitute part of the secretion of reciprocal paracrine growth factors by the epidermis and the dermis [20]. Such a pathway has been described by Fusenig, involving IL-1α secretion by keratinocytes, which stimulates secretion of FGF-7 (keratinocyte growth factor 1) and granulocyte-macrophage stimulating factor that promotes keratinocyte proliferation [21]. Such interactions may well be of importance during wound repair when proliferation of both types of cells is important [22].

In practice, allogeneic keratinocytes in skin implants appear to remain for some weeks and then disappear. This has been attributed to immunological rejection, but this is not clear as keratinocytes, cultured to the numbers required for a skin implant, consist almost entirely of transiently amplifying cells that follow a differentiation pathway that leads to a modified form of apoptosis. They may, thus, be expected to be lost from the implant without the intervention of the immune system.

An approach that has been explored for increasing the coverage and survival of grafted epidermis is to mix allogeneic with autologous keratinocytes. This permits a comparatively small number of autologous keratinocytes, without extensive expansion, to cover a large area [23]. The allogeneic cells provide initial coverage, while the autologous population, which retains stem-like cells, provides a persistent surface. Most of the allogeneic cells are eventually lost, but the epidermis remains.

An alternative application of keratinocytes to wounds by spraying has been explored. The cells survive the experience, and the technique provides a very simple and convenient way of applying them [24]. It is possible to envisage a system spraying largely allogeneic keratinocytes together with a fresh autologous keratinocyte suspension isolated intraoperatively from skin or scalp [25].

Fibroblasts

Fibroblasts are the major producers of extracellular matrix, discussed in the following section. They are not antigen presenting cells and have been regarded as not having a major role in interactions with the immune system. However, their ability to secrete neutrophil attractant chemokines, CXCL-1, CXCL-4, CXCL-5, and CXCL-8, and the cytokines IL-6 and IL-11, discussed later, suggests that they may have a more important role in activating innate immune responses.

Fibroblasts do not appear to produce significant quantities of defensins, cathelicidin, or other antimicrobial peptides. Their major antimicrobial activity appears to be through recruiting neutrophils.

Extracellular matrix

Fibroblasts express a large array of extracellular matrix genes. Transcripts giving the 30 highest signals on Illumina expression arrays are listed in Table 79.1. Expressed genes represent collagen types 1, 3, 5, 6; proteoglycans (decorin, lumican); thrombospondins; fibulins; fibronectin; tenascin C; metalloprotease inhibitors; lysyl oxidase; tissue factor inhibitor; and secreted protein, acidic, cysteine-rich. They also include matrix-bound growth factors, such as FGF-2 and TGF-β. The matrix includes multiple kinds of integrin ligands, including those for integrins $\alpha_1\beta_1$, $\alpha_2\beta_1$, $\alpha_3\beta_1$, $\alpha_4\beta_1$, $\alpha_5\beta_1$, $\alpha_6\beta_1$, $\alpha_v\beta_1$, $\alpha_7\beta_1$, $\alpha_6\beta_4$, and proteins that are known to modify adhesion. It provides complex stimulation that, since it is secreted by fibroblasts, is presumably appropriate for cell migration. In systems where fibroblasts are cast in collagen gels, the initial signal is through the $\alpha_1\beta_1$ and $\alpha_2\beta_1$ integrin and that remains the dominant stimulus until the cells elaborate other signaling molecules such as $\alpha_6\beta_4$.

Subcutaneous fat

Subcutaneous fat has received little attention thus far in the engineering of skin. However, it has been shown to undergo major structural changes during the hair cycle in the mouse and is a highly vascular organ. Fat-derived stem cells have been used successfully in the production of skin substitutes and may provide advantages over fibroblasts [26].

TABLE 79.1 Extracellular matrix proteins secreted by fibroblasts in three-dimensional culture, as a percentage of the protein giving the highest signal on an Illumina expression array [secreted protein, acidic, cysteine-rich (SPARC)].

Extracellular matrix protein	Signal as percent of SPARC (%)
Collagen, type I, alpha 1	18.83
Collagen, type I, alpha 2	36.51
Collagen, type III, alpha 1	30.96

Laminin, gamma 1	12.91

Components of the immune system

Inclusion of Langerhans cells has been accomplished in test systems but has not been applied to therapeutic products. As they are antigen presenting cells, they would have to be autologous (see later), and thus their inclusion would not be suitable for a scaleable manufacturing system,

Melanocytes

Other cells of the epidermis have been incorporated into test systems and have also been considered for transplant into epidermal tissue—engineered therapeutic products. An example is the inclusion of melanocytes as a treatment for vitiligo, which is a clinical problem in countries such as India. Systems, including melanocytes, have been used

extensively in test systems for ultraviolet radiation protective preparations.

Adnexal structures

The self-assembly of hair follicles and their use as a therapeutic product is discussed later in this chapter. Inclusion of sweat glands has been explored, but they have not yet been included in tissue-engineered constructs. The early fear that patients treated with cultured keratinocyte allografts might have problems with temperature control has not eventuated.

Commercial production of tissue-engineered skin products

Commercial production of tissue-engineered skin products takes place in a precisely controlled and highly regulated environment, which imposes many constraints if the process is to be successful. These will be discussed under a series of headings, dealing with physical constraints, such as bioreactor design, growth system design, cell sources, and with broader considerations of the nature of preclinical and clinical assessment, government regulation, reimbursement, and the market place. It is central to a commercial enterprise that it ultimately make a profit if it is to be successful. Since tissue engineering is inherently an expensive undertaking, minimizing costs at all stages is essential.

Regulation

Regulation of tissue-engineered products by the Food and Drug Administration (FDA) or other regulatory authorities has taken a long time to develop. Since commercial products have only been available for less than 20 years and they are very different from other medical products, establishing a regulatory pathway has been complex. Tissue-engineered skin substitutes do not fit readily into any of the standard FDA categories; for drugs, the Center for Drug Evaluation and Research (CDER); for biologics, the Center for Biologics Evaluation and Research (CBER); or for devices, the Center for Devices and Radiological Health (CDRH). Classification is important as requirements, criteria and guidelines differ substantially between the centers. Skin implants were originally considered as dermal or skin replacements and classified as devices. As it became evident that growth factor activity played a part in their mode of action, considerations appropriate to biologics played an increasing role. There is now within FDA an Office of Combination Products responsible for assembling reviewers from different FDA centers to form a team to review such products. While tissue-engineered skin substitutes generally have more biochemical activity than would be expected of a pure device, they do not fit easily as a biologic. For instance, the concept of "dose" is not straightforward. If a component of the activity of these materials is through secretion of growth factors, growth factor production would seem to be a reasonable release criterion. However, unlike a purified growth factor preparation, these products are living, and the secretion of growth factors may vary depending on conditions. The cells adjust their cytokine output to the environment in the wound bed. It may be possible to devise conditions under which secretion of a growth factor is maximal and determine output under those conditions. For instance, vascular endothelial growth factor (VEGF) might be measured under optimal PDGF stimulation. However, this has not been explored and to avoid such problems, a "dose" of Dermagraft has been defined as a piece.

Also, at this stage, the composition of tissue-engineered skin can only be determined to a limited extent. Usually, it is desirable that a biologic contains well-defined constituents, including an active ingredient at a known dose and excipients. Thus far, studied components of skin implants have included those that are known, and, to some degree understood, from other work. There is no comprehensive identification of constituents, and several that appear on expression arrays, such as lumican and collagen type 6, which are prominent, have received inadequate attention.

However, despite these difficulties, the FDA is placing increasing emphasis on the biological aspects of skin substitutes and overseeing them as biologics and as drugs.

Product development

Development of a commercial product should start with a product concept from which a design requirements document is developed. As an example, Table 79.2 shows the product concepts for Dermagraft and TransCyte. The product is then developed to meet the design requirements by a series of hierarchical, more and more detailed design processes that ultimately comprise the design master file. The requirements can be divided into groups: in each concept, the first statement is concerned with the therapeutic purpose of the product, the next three describe intrinsic characteristics of the product, and the last three are concerned with practical issues of importance to the final user. All these factors need to be considered from the earliest stages of development.

Overall concept

The initial application for Dermagraft was a dermal replacement for burn patients. Initial clinical application indicated that it provided little benefit and was slightly

TABLE 79.2 Design concepts for Dermagraft and TransCyte.

deleterious. As trials for chronic wound applications progressed, and it became evident that it was efficacious, the concept of Dermagraft as a cytokine source replaced the notion of a dermal replacement.

TransCyte, a replacement for cadaveric skin for covering third-degree burns after debridement, was seen as a means to overcome problems with rejection and potentially with disease transmission.

Allogeneic cell source

The second item in both product concepts was that the products would be allogeneic. The decision whether a product will be allogeneic or autologous is fundamental to the entire development process. While not impossible, the development of a commercially successful (profitable), autologous, tissue-engineered product is very difficult. It requires separate, independent, tissue culture suites (hood, incubator, centrifuge, microscope, and air conditioning), which will be occupied by the product for a single individual for the entire period of culture. It is a service industry, with complex logistics and high cost. As an alternative, it would be possible, in principle, to construct an automatic machine that would accept a patient's tissue and produce the tissue-engineered construct in the hospital with minimal intervention. The advantages of an autologous process from a commercial point of view is the comparatively low requirement for safety testing and the lack of immunological rejection by the patient.

Allogeneic tissue engineering has advantages in using only one tissue culture facility per product type, allowing economies of scale and straightforward logistics. The major disadvantages are the very large amount of safety testing required for the master cell banks (MCBs) and the potential for immunological rejection. The first of these disadvantages is ameliorated by the infrequency of making MCBs. In the case of Dermagraft and TransCyte, a single MCB was used for more than 20 years, so the investment could be amortized over a long period. Required testing is determined by regulatory authorities and may be increased from time to time as new risks become known. It includes testing of the donor and, in the case of fibroblasts, the donor's mother for major human pathogens (human immunodeficiency virus, hepatitis, cytomegalovirus, etc.). The cells isolated from the donor are tested for the major human pathogens, xenogeneic pathogens (which might be introduced from the reagents used in tissue culture), karyotype, identity (isoenzyme, variable number of tandem repeats, single nucleotide polymorphisms, etc.), tumorigenicity, latent viruses, etc. This is tested both on the initial MCB and again on cells reisolated from final product (the end-of-production cell bank).

Viability of product and avoidance of a final sterile fill

The viability of the product depends on its intended function and differs for Dermagraft and TransCyte. As discussed later, to package sterile material is a matter of some difficulty and it was decided, in this case, to avoid the issue. The bioreactor in which the tissue was grown was designed to form part of the final packaging.

Shelf life

Extended stasis preservation is important for commercial products, including tissue-engineered products. It allows time for quality control (QC) testing, for off-the-shelf availability, and for distribution. In addition, the Dermagraft and TransCyte processes take 12 weeks from thawing a vial from the manufacturer's working cell bank (MWCB), cell expansion, 3D growth, and QC testing. The difficulty of predicting the market so far ahead so as to minimize waste is greatly aided by extended shelf life.

This was achieved through cryopreservation at −70°C. Other systems for long-term stabilization of tissue-engineered constructs have been explored with varying degrees of success, including trehalose, DMSO, and 3-*O*-methyl glucose [27−29].

Size, user convenience

The remaining items in the product concept are related to convenience of use by the physician applying the product. This is an important item for a commercial product and needs much work in focus groups and thought. Thawing the product is already a major issue, requiring time and, in the case of TransCyte, careful estimation of the amount required to avoid wasting expensive material or having to wait for a piece to be thawed. The Dermagraft bioreactor was designed so that it would open easily and the tissue would be positioned so as to be easily rinsed prior to use, through the use of a *Z*-weld that attached opposite sides of the scaffold to opposite walls of the bioreactor. The bioreactor is translucent to aid in marking out the piece to be cut out for implantation.

The manufacture of Dermagraft and TransCyte

Overall schemata for the manufacture of Dermagraft and TransCyte are illustrated in Fig. 79.1. As can be seen, as much of the two processes as possible are identical. This economizes resources and reduces cost. In this case the MCB, MWCB, the cell expansion process, and much of the release testing are all in common. In addition, the clean room facility, all its ancillary equipment and monitoring are the same.

Cells

Several times per week, fibroblasts used in manufacture are recovered from liquid nitrogen storage (the MWCB) and expanded in roller bottles from fifth to eighth passage. This is a conventional procedure but may not be ideal. Fibroblasts for Apligraf are expanded on beads in a mixed bioreactor. It has become evident that the proliferation of fibroblasts is improved at low oxygen (2%−6%) [30], and, at this oxygen concentration, the development of a senescent phenotype may be reduced [31−33]. A tank bioreactor lends itself to active control of parameters such as oxygen tension and pH and is worth exploring before a system gets fixed by regulation. The cells should ideally be grown just to the beginning of stationary phase. Further incubation seems to be slightly deleterious.

Expansion of fibroblasts for Dermagraft and TransCyte manufacture was performed in roller bottles. These are well established for the production of large numbers of cells under ambient conditions. Various other systems have been devised that may provide superior performance and greater control of the conditions of growth [34,35].

Medium

The Dermagraft and TransCyte systems are grown in Dulbecco's-modified Eagle medium, supplemented with 10% calf serum, nonessential amino acids, and glutamine. All tissue culture beyond initial cell isolation from the foreskin is free of added antimicrobial agents, such as antibiotics. Antimicrobial agents might hide otherwise significant contamination, which might only become evident in therapeutic application.

With the increased concern with the transmission of prion diseases, there has been great interest in developing serum-free systems. While serum-free media are available

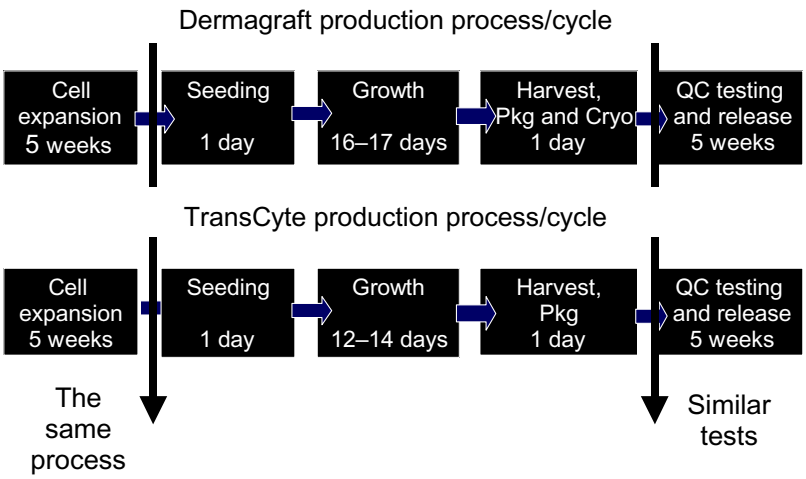

FIGURE 79.1 Overall comparison of the Dermagraft and TransCyte processes.

for keratinocytes, it has been found difficult to achieve such systems for fibroblasts. Serum-free fibroblasts media are commercially available, but while these have been successful in the research laboratory, transferring them to scaled-up systems and manufacturing has proved elusive. The major issue is that the cells do not grow to the extent required apparently because they acquire a senescent phenotype comparatively early in the expansion process. It has long been established that serial subculture of fibroblasts leads to senescence after about 60−80 population doublings. While this can be attained in serum-containing medium, experiences with serum-free media have indicated a life span of about nine doublings. Since Dermagraft is made at about the 28th generation, which is about 10 doublings from the MWCB, 19 from the MCB, and because implanted fibroblasts should not be too close to senescence, serum-free media do not provide sufficient proliferation potential.

The alternative solution to serum-free medium is to take extreme caution in the source and treatment of serum. By regulation, all materials used in manufacture must be traceable to their sources, but in addition, bovine serum is obtained only from countries that are free from bovine spongiform encephalopathy, which include Australia and New Zealand, from closed herds with a known pedigree history that includes no animals from outside the country. Serum is also irradiated sufficiently to eliminate possible viral contamination.

Bioreactor design

Many of the considerations of bioreactor design involve questions of mass transport, conditions under which cells are able to grow and so forth, much as in noncommercial tissue engineering systems. A second series of considerations deals with the large-scale production process. These include ease of scale-up, ease of handling, minimal footprint, and maximal automation. In addition, the use of the product by a community not experienced with products of this type is also important. This leads to an emphasis on features to make the product easy for the end user to work with and apply.

The bioreactor used for the growth of Dermagraft consists of a bag with eight cavities welded into it, each of which contains a sheet of the scaffold. Such bags are attached in groups of 12 to manifolds, with a solid support, for cell, medium or cryopreservative addition, to form a system. Several systems may be connected and all fed at the same time to form a lot, which is the unit of manufacture. The bag reactors, systems, and even lots may be assembled under clean, but not necessarily sterile conditions and sterilized by 25−43 Grays gamma radiation prior to seeding. From this point the process only requires nine sterile connections and is substantially automatic.

The TransCyte bioreactor systems are similarly assembled under clean conditions, complete with all associated tubing, and attached in groups of 12 to a manifold to form a system. This entire assembly is then sterilized by gamma radiation as described previously. Several systems can then be connected to form a lot. In this case the inlets to each bioreactor are individually passed through a peristaltic pump to provide even flow. (Attempts to use constrictions to control flow were found to be inferior.) Again, as with the Dermagraft system, once set up and seeded, the TransCyte system is substantially automatic.

Automation in tissue engineering systems is an important feature. Apart from reducing labor costs, automation greatly reduces the number of errors that have to be investigated, requiring time, effort, and cost. While operator errors are generally less serious than machine failures, they are much more numerous and still require individual investigation. Backup systems can be installed to minimize the impact of machine failure.

The Dermagraft and TransCyte production processes

The production of Dermagraft and TransCyte started with the cryopreserved MCB that was stored at passage three in liquid nitrogen. About four times per year, cells were taken from this bank and expanded in roller bottles to fifth passage when they were stored again as the MWCB. This was tested to ensure identity to the MCB. Several times per week, cells were taken from the MWCB and expanded to eighth passage in roller bottles when they were seeded to the 3D bioreactors. This process was conventional, large-scale tissue culture. It used batch feeding and exposed the cells frequently to atmospheric oxygen. As discussed elsewhere in this article, fibroblasts grow better and senesce less rapidly in a lower oxygen environment.

On seeding, the bioreactors were manipulated to ensure even distribution of the cells. In the case of Dermagraft, the bioreactors were rolled; in the case of TransCyte, each side was seeded successively under static conditions. The medium was replaced 1 day after seeding and then the cells fed every 2−4 days until harvest.

The time of harvest was determined from the glucose metabolism of the cultures. In the case of TransCyte, glucose consumption and lactate production were determined daily and interpreted as notional adenosine triphosphate (ATP) turnover, assuming a P:O ratio for mitochondrial oxidative phosphorylation of 3. The resulting values were correlated with the performance of the system relative to release specifications and appropriate target values

selected. In the case of Dermagraft, there was a concern that lactate release from the degradation of the scaffold might interfere with the ATP turnover estimation, so the time of harvest was determined on cumulative glucose utilization alone.

At the harvest of Dermagraft, medium was replaced by a cryopreservative solution that consisted of 10% dimethylsulfoxide in phosphate buffered saline, supplemented with calf serum, and the individual pieces of Dermagraft sealed, removed from the surrounding bag, packaged, cooled slowly at a rate that fell within design parameters, and frozen. It was then stored in a freezer set to −75°C. The time between cryopreservative addition was at least 4 hours and was validated to a 12 hours delay. This time interval did not appear to affect the viability of the cells and it was conjectured that it allowed induction and synthesis of stress proteins in response to the high osmotic pressure.

Release specifications

The release specifications included sterility (bacterial, fungal, mycoplasma, and endotoxin) as well as analytical criteria that ensure consistency of the product. Dermagraft used four analytical release criteria, 3-(4,5-dimethylthiazol-2-yl)-2-5-diphenyltetrazolium bromide (MTT) reductase activity before freezing (in-process MTT) and after thawing, collagen content by Direct Red binding [36] and DNA content. MTT reductase was used to determine the metabolic activity of the product, collagen as a surrogate for the amount of extracellular matrix, and DNA content was used to establish adequate cellular content. MTT reduction was an assay that was established early in the development of Dermagraft. Since then, several other substrates measuring essentially the same activity have been developed, several of which are less toxic to the cells than MTT and can be used repeatedly. It would be wise in the development of a new product to examine these early and select a method carefully. MTT reductase is frequently viewed as measuring mitochondrial activity. However, 70% of the activity is extramitochondrial [37] and it is better regarded as a general measure of cellular activity. The MTT reductase assay was originally developed to evaluate toxicity or cell proliferation, where values obtained after treatment were compared with pretreatment control values. In determining the metabolic activity of tissue-engineered products, this is not possible and a great deal of fruitless effort has been expended in trying to obtain a standard for the MTT assay. MTT determination before and after cryopreservation might be interpreted in the same manner as in toxicity assays. However, changes occur in the viability and metabolic activity of cells for up to 3 days after cryopreservation, due to necrosis, apoptosis, and repair; so the MTT values for tissue-engineered products are better regarded as independent absolute determinations rather than relative values.

In the case of TransCyte the microbiological criteria and the collagen and DNA determinations are similar to those for Dermagraft. However, as the cells are nonviable in the final TransCyte product, there is no MTT determination. Determination of MTT reductase prior to final freezing (in-process MTT) was replaced by release specifications applied to ATP consumption as described earlier.

Definition of specifications was initially within three standard deviations of the process performance. In the case of MTT, it was evident during the clinical trial that the specifications needed to be refined, requiring a mid-trial correction and ultimately an additional clinical trial.

Distribution and cryopreservation

The use of −70°C cryostorage for Dermagraft was a compromise between an ideal solution and practicality and turned out to have several benefits. If the goal was 100% cell viability and indefinite shelf life, the ideal solution was likely to have been storage at liquid nitrogen temperatures, probably using a vitrification procedure in which high concentrations of cryoprotectant and very rapid cooling is used to achieve the formation of a glass with minimal ice crystallization. While the technical difficulties of achieving sufficiently rapid cooling of a therapeutically useful structure and problems with the brittleness of plastics at low temperatures can probably be overcome, the method would still entail transport at liquid nitrogen temperatures and safety issues. Cryopreservation at dry ice temperatures provided adequate shelf life and allowed shipping in a container capable of maintaining −65°C for 4 days. This allowed distribution throughout the world and would generally permit 2−3 days leeway for patient and physician scheduling at the site of use. If a center had a −70°C freezer, storage at this temperature would allow much longer shelf life at the treatment site.

In addition to logistical advantages, the induction of stress proteins by the cryopreservation procedure [38], combined with the suboptimal viability recovery meant that necrotic cell debris, including heat shock proteins, was released from lysed cells. Such proteins activate macrophages through CD91 and Toll-like receptors [39]. While such necrotic products are likely not to be scarce in a chronic wound, this property may have contributed to the efficacy of Dermagraft.

While discussing cryopreservation, an important point that has received little attention is the thawing process. In the case of Apligraf the thawing protocol involved multiple solution replacements, requiring a procedure of several hours, which was performed at the company. This provided shelf life, but not off-the-shelf convenience, and

required additional resources from the company. Therefore the procedure was not continued. In the case of Dermagraft, thawing was performed in the physician's office, out of the control of the company.

During the controlled freezing process, after the majority of the osmotic water removal has occurred, the cell contents reach a eutectic and freeze. While most of the intracellular material forms a glassy state, small ice nuclei may be formed. The slow growth of these nuclei during −70°C storage is probably what limited the shelf life of Dermagraft.

During thawing, conditions arise that allow the growth of ice crystals, which enlarge and, if they become big enough, kill the cells. It is important to take the cells through this stage as rapidly as possible to minimize ice crystal growth. So rapid thawing, straight from the −70°C storage is critical. The procedure that was adopted for Dermagraft involved a thawing tub with a thermometer, which could be filled with warm water from the tap, or a water bath at 37°C. A few seconds of exposure of frozen Dermagraft unprotected in ambient air was sufficient to reduce viability drastically. It may be noted here that the viability of Dermagraft could probably been improved be decreasing the amount of cryoprotectant in the final product, reducing its heat requirement, and thus allowing more rapid thawing.

Problems with commercial culture for tissue engineering

In large-scale tissue culture, procedures are followed that differ from those found in a research laboratory. As a result, problems have arisen from time to time that have no counterpart in culture on a smaller scale. Frequently, it is difficult to establish the cause unequivocally because of the scale and cost of the experiments that would be required. When such a problem occurs, it is usual to assemble all those with potentially valuable ideas, analyze the incident with respect to changes in procedure (new batches of medium or other raw materials, newly implemented changes, etc.), and prioritize possible solutions. Usually the most likely and cheapest suggestions are explored first. These tend to be implemented more or less at the same time and immediately. This means that, when the problem ceases, as it usually does, it is very difficult to determine which suggestion solved it. At best, the solution relies on a plausible rationale.

Examples of the causes of such occurrences include light damage to medium and deterioration of cell banks. It has been known for many years that medium is light sensitive and will degrade if left exposed to daylight or fluorescent light. However, such an event is never seen in the research laboratory, as medium is normally stored in a refrigerator in the dark and exposed to light for short periods. In commercial operation, it is sometimes necessary to make up medium a few weeks in advance and store it in a cold room. If the lights in the cold room are fluorescent and are left on, deterioration of medium will be observed. Indeed, the Dermagraft plant was illuminated with yellow light to avoid such problems.

In a research laboratory, cell stocks frozen in liquid nitrogen are manipulated rarely, a few times per year. In commercial-scale tissue engineering, vials from the MWCB are required several times per week. While one or two vials are identified and removed, the remainder of the cell bank stock taken out of cryostorage is warming up. We noticed that, after some years of this, the fibroblasts could be shown to demonstrate a decreased life span. This was attributed to ice recrystallization during periodic warming to perhaps −120°C to −90°C during recovery of other vials. It is, thus, necessary to store the MCB independently of the MWCB and to devise a method of recovering selected vials with minimal disturbance to other vials.

Clinical trials

The design and implementation of clinical trials is specialized and beyond the scope of this discussion. The process requires a great deal of time and expense. In the case of the CDRH division of the FDA, the initial trial is a pilot or feasibility trail, equivalent to a Phase I trial in the CBER or CDER. This consists of a small number of patients (6−20) per treatment regime and is primarily concerned with safety. Any information obtained on efficacy in a trail of this magnitude is unlikely to be statistically significant but may provide useful information on the size and variability of the therapeutic effect that is valuable in design of the subsequent, pivotal trial.

The pivotal trials (equivalent to Phase III trials in biologics and devices) involve much larger numbers of patients (50−500 in the case of devices), which is determined by a sample size calculation, based on the results from the pilot trial, to give about 80% probability of a significant result ($P < .05$) if one exists. Recently, it has been suggested that the threshold value of P should be reduced to .005 to reduce the number of false successes, which can lead to much further development expense before the product definitively fails.

Trials with chronic wounds take about 2 years or more to complete. The design phase, deciding on protocols, obtaining institutional approval for multiple centers and preliminaries to the recruitment of patients is likely to take at least 6 months. The actual trial involves screening many more patients than will actually take part in the trial, as many fail to conform to exclusion criteria, which reduce irrelevant and interfering factors, established in the

design phase. With a trial involving a 12-week follow-up period, most should be completed within 18 months to 2 years. There is then a period of 6 months while the data are checked, discrepancies resolved and the results of the trial evaluated. This period could be shortened substantially by logging the patient outcomes to an internet site and checking them online as they are generated.

The design of the clinical trial should be conducted in close consultation with the relevant regulatory authorities. It is critically important that all aspects should be thoroughly discussed and agreed beforehand. In the case of Dermagraft, failure to follow advice from the FDA precisely led to considerable delay and additional expense.

Considerations in the selection of clinical trials include the size and value of the potential market, the expected efficacy of the product, and the difficulty of completing the trials. Five major areas of chronic wounds include venous stasis ulcers, diabetic foot ulcers, arterial ulcers, pressure (decubitus) ulcers, and all other chronic wounds. Of these, venous stasis ulcers represent the largest market. Diabetic ulcers are a valuable market, as, while smaller in number, the consequence of failure to heal such an ulcer is limb amputation, an expensive and seriously debilitating procedure. It is very difficult to perform a trial on decubitus ulcers, as the patients are frequently elderly, infirm and may need approval from a guardian. Such trials are very arduous, may be difficult to complete and are best undertaken by a specialized group with well-developed access to such patients. In no cases does the treatment of chronic wounds with skin implants address the underlying cause of the ulcer, which lies in venous insufficiency, metabolic abnormalities, reduced arterial supply, or repeated ischemia. This is particularly evident in ulcers caused by arterial insufficiency. While the angiogenic activity implant may be capable of improving vascularity in the region of the wound, little may be gained if blood supply to the limb is inadequate.

The pivotal clinical trial for Dermagraft for diabetic ulcers was initiated in 1994. Dermagraft gave a statistically significant increase in healing of 19.1% that was similar to results obtained in similar trials with other products. These data were used in combination with mechanism of action and clinical instruction to support the clinical use of Dermagraft commercially. Since then, it has grown to a several $100 M/year business.

The indications for which the product may be marketed (its labeling) are strictly limited by the clinical trials and new trials are required to extend them. However, in certain categories, there may be insufficient patients to support both a clinical trial and a commercial market. Examples are monogenetic congenital diseases, where, although the conditions may be very distressing, the entire population may number in the hundreds or a few thousand. An example in the chronic wound field is epidermolysis bullosa (EB). For such diseases the FDA has a category, humanitarian device exemption (HDE), which allows much reduced clinical testing. It does, however, require institutional review board approval from each institution where it will be used. In the case of dermal implants, such a route has been used for Apligraf and Orcell for all genetic forms of EB, and for Dermagraft for the dystrophic forms of EB. The category, "all other chronic wounds" includes many miscellaneous conditions, such as pyoderma gangrenosum and necrobiosis lipoidica diabeticorum, for which there is too small a patient population to perform a trial, but it would be expected to benefit from treatment with Dermagraft or TransCyte. The HDE pathway may not be appropriate or available. However, since the FDA does not regulate the practice of medicine, some approach to these patients may be obtained through off-label use, although this cannot be formally promoted by the manufacturer.

Immunological properties of tissue-engineered skin

Immunological rejection of tissue-engineered products remains a controversial question. As was clearly established by Medawar in the 1940s, allogeneic transplants of whole live organs invariably cause immunological reactions that lead to rejection [40]. However, experience with some cultured cells and tissue-engineered constructs indicates that, in some cases, no clinically significant rejection occurs. At this point, some hundreds of thousands of patients have been implanted with Dermagraft, in many cases several times to the same patient, without a single example of immunological rejection and experience with Apligraf has been similar. The fibroblasts from Dermagraft have been found to persist in the wound site for 6 months and survival for about a month has been obtained with Apligraf [41].

There are two major pathways of transplant rejection, direct and indirect. The direct pathway involves recognition of donor histocompatability antigens (HLA) by the host immune system leading to acute rejection over about 2 weeks. This involves both HLA, of which Class II molecules, such as HLA-DR, are the most important and also costimulatory molecules on the transplant, CD40 and the CD80 group. These molecules are not normally expressed by fibroblasts. However, in monolayer tissue culture, the presence of γ-interferon, which may be present in chronic wounds, will cause induction of HLA-DR, CD-40 and genes involved with the physiological function of Class II HLA (antigen presentation). In contrast, in 3D culture, many of the cells show a selective response to γ-interferon, which excludes induction of these molecules [42]. The indirect pathway of rejection involves display

of transplant antigenic peptides by host antigen presenting cells (macrophages, tissue dendritic cells, and endothelial cells). This gives rise to chronic rejection which may cause destruction of the transplant over many months. While it cannot be excluded that this may occur, Dermagraft fibroblasts have been detected at 6 months from the time of implantation, and no clinical evidence for chronic rejection has been observed.

Acute rejection is primarily an attack on the endothelial cells of the vascular system, which are antigen presenting cells and do express the component of the antigen presentation system (HLA Class II, CD40, CD80). It is possible that the lack of rejection of tissue-engineered skin products is related to the absence of such cells. Indeed, adding antigen presenting cells (in this case, B lymphocytes) to a tissue-engineered construct has restored susceptibility to immunological rejection [43].

Commercial success

There are many contributors to the commercial success of a product. They include a satisfactory clinical trial, a good rationale for the performance of the product, convenience in use, a reasonable price, adequate reimbursement from third-party payers, sensitivity to complaints, and efficient distribution. Some of these require long-term effort and must be initiated early in the development process.

New products frequently find themselves selling into a conservative and skeptical market that arises from the hype that is involved in developing and funding the product. The first requirement in overcoming this view is a satisfactory clinical trial. This process is determined by regulatory bodies. The major criteria for the American authorities (FDA) are safety and efficacy. Unless the product's safety and efficacy is extraordinary, clinical results need to be backed up by a mechanism of action that, while it may not be fully established, must provide a logical reason for using the product. In the case of Dermagraft, this has led to a great deal of fundamental wound healing research.

Equally important is the convenience of use, cost, and process for reimbursement of the physician applying it. Convenience of use and cost are functions of bioreactor and process design, and company structure, which are discussed elsewhere. Third-party reimbursement and health economics are major and specialized subjects that are outside the scope of this article. However, a major component of establishing satisfactory reimbursement in the United States involves the Center for Medicare and Medicaid Services (CMS). Government authorities with similar responsibilities are involved in other countries. Their criteria, in contrast to the FDA, are reasonableness and effectiveness/cost ratio. Both the FDA-type and CMS-type criteria have to be met for a product to be successful.

Following introduction into the market, products approved under CDER are tracked. Adverse events, new toxicities, and complaints that might affect the use of the product have to be reported. However, performance has not been. It may, however, become a regulatory requirement to confirm safety, efficacy, and cost-effectiveness with a larger patient population than possible in a clinical trial. It is also valuable to the manufacturer because, while anecdotes of positive clinical experience may be heartening, they do not provide objective quantitative data. This was not performed in the cases of Dermagraft or TransCyte, making it difficult to assess the actual performance of the product in clinical use.

Mechanism of action

Understanding the mechanism of action of a product required some understanding of the underlying pathology of the disease the product is intended to treat. Wound healing, and particularly the etiology and maintenance of chronic wounds, was poorly understood during the development of Dermagraft and TransCyte. Many phenomena have been observed, particularly, in chronic wounds. The problem is sorting out how they relate to one another, which are etiological, and which are symptomatic; the difference between cause and response. The problem was less acute in the case of TransCyte as the product was only designed as a temporary covering for third-degree burns.

Changes from normal skin observed in chronic wounds include lack of keratinocyte migration, capillary cuffing, protease activity, abnormalities in macrophage activation, diminished vascular supply, and senescence in fibroblasts [44]. In developing a rationale for the action of Dermagraft, the first aspects considered were vascular supply and keratinocyte migration. Much study was undertaken on the angiogenic activities of Dermagraft and it was shown that the tissue produced VEGF and hepatocyte growth factor. It was also shown to be angiogenic in the chick chorioallantoic membrane assay and to increase blood supply to diabetic ulcers in patients in vivo using laser-Doppler techniques. Thus a case could be made that one mode of action was through its angiogenic effect.

The high protease activity of chronic wounds was combined with the lack of keratinocyte migration to hypothesize that the extracellular matrix in a chronic wound was degraded to the extent that the migration substrate was lacking. Indeed it was demonstrated that fibronectin was degraded by neutrophil elastase [45]. This led to work on the properties of Dermagraft and TransCyte as substrates for keratinocyte migration.

During comprehensive surveys of genes induced by 3D culture, it was found that the most highly upregulated gene was IL-8. Other ELR CXC chemokines were also highly induced. This led to studies of the secretion of these proteins and to changes in their production that might relate to the etiology of chronic wounds and the possible role of Dermagraft. It was found that Dermagraft secretes IL-8, sometimes in large quantities although the secretion was extremely variable. Monolayer fibroblasts also secrete CXCL-1, CXCL-5, and CXCL-6 that are all chemoattractive for neutrophils and activate them to a bactericidal phenotype. At the same time, it was observed that bacterial products (lipopolysaccharide) inhibit keratinocyte migration. This led to the hypothesis that a major function of fibroblasts in a wound context is the recruitment of neutrophil leukocytes to destroy colonizing bacteria and that failure of this system in chronic wounds results in the establishment of bacterial contamination that leads to failure of reepithelialization. It is known that fibroblasts in chronic wounds display a senescence-like phenotype [46] that grows slowly and is unresponsive to growth factors. The condition is probably related to stress-induced premature senescence caused by ischemia reperfusion injury, metabolic abnormality, extravasated red cells, and the inflammatory conditions of the chronic wound. It has been found that, although the senescent fibroblast phenotype is generally inflammatory, the production of CXCL-1, CXCL-5, CXCL-6, and CXCL-8 decline in senescent fibroblasts. Thus in chronic wounds, decline in the ability of the fibroblasts to recruit and activate neutrophils allows wound colonization by bacteria and failure of keratinocyte migration to close the wound. Chronic wounds seem to involve an arrest of normal healing at about the stage of neutrophil immigration. On this hypothesis a major role of Dermagraft is to provide nonsenescent fibroblasts that are able to respond to the presence of bacteria with appropriate secretion of neutrophil chemoattractant chemokines.

In the case of TransCyte the formation of a foreign body capsule–like material in vitro leads to lack of ingrowth of the scaffold into the wound through a host foreign body reaction, and, thus, comparative ease of removal. The ability of TransCyte to reduce the pain of second-degree burns is common to many occlusive dressings.

A remarkable feature of dermal implants is that they do not appear to have led to an increase in infection. Indeed the general experience has been a slight reduction in infections. Preparations, including keratinocytes, show secretion of antimicrobial peptides, but this is not known to be the case for fibroblasts. The most likely explanation is a combination of fibroblasts secretion of neutrophil chemoattractant CXC chemokines and the provision of an extracellular matrix substrate for leukocyte migration.

Future developments

The major direction of development in skin products is toward simpler, possibly nonviable systems. Inclusion of live cells in a product entails many issues such as the use of allogeneic cells, cryopreservation, distribution, inconvenience to the customer (for instance, the thawing procedure), and many manufacturing problems. Hence, studies were initiated to explore the possibility that a possibly less effective but substantially less expensive product could be developed. This is a direction that has also been explored by companies in the field.

It is a general principle that value is likely to be obtained by exploiting a technology base as far as possible. A major product of fibroblasts is collagen, in this case human. As a nonviable product, human collagen has been extracted from the extracellular matrix laid down by fibroblasts in 3D culture and used, by injection, for the treatment of wrinkles.

An alternative to cryopreservation that has been explored is the possibility of storage by desiccation. Many natural systems, such as plant seeds, tardigrades, *Artemia*, and yeast have developed the ability to survive desiccation and, in that state may be able to survive extreme conditions of temperature, vacuum, radiation, and time [47]. Many factors appear to be involved in this ability [48], but one that has attracted attention is trehalose, which is a disaccharide (1,1,α,α diglucose) that is produced in large quantities by many desiccation-resistant organisms. It was found that TransCyte could be dried at room temperature in the presence of trehalose, irradiated to 25–40 Grays to provide terminal sterilization and would recover its structure and wound adhesion on rehydration. Similar results could be obtained by careful lyophilization. While some success has been obtained in the retention of viability of human cells in the desiccated state, it is not yet possible to obtain the shelf life (at least 1 month and preferably at least 6 months) required for a tissue engineering application. It is also questionable whether the radiation treatment possible with a nonviable product would be appropriate with living cells. In this case an aseptic drying and packaging system would have to be devised.

Thus far, the therapeutic applications of skin tissue engineering have encompassed acute and chronic wounds and comprise dermal components alone or dermal components with epidermal structures. In the future, it is likely that adnexal structures will be added. Remarkable success in this direction has been achieved with hair follicles [49], where it has been found that, in a mouse system, hair follicle-inducing cells can be cultured so that they retain their properties and, mixed with hair follicle-derived keratinocytes, will on injection form a hair. Similar results have also been achieved with human cells. The

remarkable feature of this system is that the entire organ, hair follicle, sebaceous gland, and erector pili muscle is formed. This constitutes one of the few examples of true organogenesis observed using adult cells. We may also expect the increased use of induced stem cells.

Conclusion

Experience with the commercial production of tissue-engineered skin has developed many principles that are important beyond the simple development of a tissue-engineered product. Most of these are based on well-known concepts used in other manufacturing processes, as applied to tissue engineering. They include

1. optimized cryostorage of MCBs with minimal access
2. intermediate storage of expanded cell banks (MWCB)
3. use of allogeneic cells
4. bioreactors that permit scale-up and minimize footprint
5. minimal aseptic connections
6. maximal automation, to minimize errors
7. avoidance of aseptic fill, so that the bioreactor forms part of the final package
8. bioreactor designed for end user convenience
9. cryostorage

While it may not be possible to incorporate all of these principles into the manufacture of a tissue-engineered product, as many as possible should be used. The major problem with such products in the market place is cost, and all these principles are directed toward reducing cost. Some, such as the use of allogeneic cells, may be difficult to implement. While experience with fibroblasts indicates that immunological rejection is not a major issue, this is not known for other cells. The possible use of allogeneic cells should, however, be checked, preferably in animals other than mice, because the advantages for a commercial product are great. Optimal cryostorage is a compromise between ideal tissue survival and other factors, such as ease of distribution.

Chapter 80

Tissue-engineered cartilage products

Henning Madry
Center of Experimental Orthopaedics, Saarland University, Homburg, Germany

Introduction

The articular cartilage provides an extremely smooth surface, which significantly reduce the friction between the ends of articulating bones. Individual diseases affecting the cartilage include traumatic chondral defects, osteochondritis dissecans (OCD), osteonecrosis (ON), and osteoarthritis (OA), which are profoundly different in their origin. Articular cartilage defects caused by trauma, OCD, and ON are potentially severe pathologies because they may induce (secondary) OA. Of importance, OA is a heterogeneous disorder, caused by special biomechanical, genetic, metabolic, and inflammatory events affecting all structures of the joint, including the articular cartilage, subchondral bone, menisci, and synovial membrane. Thus the usually ill-defined large OA cartilage lesions should not be confused with the often well demarcated, circumscribed chondral defects, as only the latter are amenable to regenerative cartilage repair techniques.

After early preclinical experiments—such as transplantation of autologous chondrocytes isolated from nasal septal cartilage of rabbits into muscle, where new cartilage is formed [1], and transplantation of autologous epiphyseal and articular chondrocytes into damaged joint surfaces of rabbits [2]—and studies in the laboratory of Daniel Grande providing evidence that the repair tissue in cartilage defects is based on the transplanted cells using autoradiography [3], autologous chondrocyte implantation (ACI) was first performed by Lars Peterson in patients in 1987 and published together with Mats Brittberg in 1994 as the first clinical tissue engineering application. ACI is a two-stage surgical procedure characterized by a first step of initial (arthroscopic) cartilage removal, cell isolation, and expansion, and the second step of subsequent implantation. While the initial technique of transplantation involved injecting a cell suspension under an autologous periosteal flap retrieved from the ipsilateral proximal tibia, it has seen significant advances that have further strengthened the clinical process of ACI through modern biotechnological innovations, for example, by applying biomaterials as cell carriers. However, the basic principles of ACI continue to involve the removal of cartilage, chondrocyte isolation, and expansion in the laboratory, and the subsequent reimplantation into the cartilage lesion. The goal of ACI, as for all surgical procedures, is to achieve a high degree of articular cartilage repair. In this sense, ACI continues to reflect the very principles of tissue engineering, as defined by Robert Langer and Joseph Vacanti in 1993 as "an interdisciplinary field that applies the principles of engineering and the life sciences toward the development of biological substitutes that restore, maintain, or improve tissue function."

Supported by the technical advances, ACI has clinically and scientifically established itself in recent years. For example, there are currently long-term results with follow-up periods up to 20 years after implantation, and the number of high-quality controlled prospective randomized studies has increased significantly, also against the background of the regulatory requirements, resulting in an increased scientific proof of the effectiveness of the method. Also, the recent cost-effectiveness assessment by the National Institute for Health and Care Excellence (NICE) in Great Britain concluded to strongly recommend ACI as an option for treating symptomatic articular cartilage defects of the knee for defect sizes above 2 cm^2.

Cartilage defects, osteoarthritis, and reconstructive surgical options

Cartilage defects pathophysiology

By definition, cartilage defects involve a disturbance of the structural continuity of the articular cartilage. Chondral defects are restricted to the articular cartilage and are classified either as partial- or full-thickness

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00082-4

chondral defects based on their depth. Osteochondral defects also disrupt the structural integrity of the subchondral bone, representing an extension of the purely chondral defects, for example, as a result of an osteochondral fracture. Chondral defects are only sparsely repopulated by cells which are migrating from the synovial membrane. The spontaneous repair of osteochondral defects is much more efficient, because mesenchymal stem cells (MSCs) from the bone marrow (BM) compartment (BM-MSCs) initiate a significant reparative response. There are several factors affecting repair, among which patient age, defect localization, and size. In general, spontaneous repair of cartilage defects decreases with increasing defect size. Another factor that plays a role in the natural history of (osteo)chondral defects is an unicompartimental increase in joint contact forces, as occurring, for example, in the medial tibiofemoral compartment in patients with axial malalignment of the lower extremity, as it may accelerate degeneration.

Surgical treatment options for articular cartilage defects

The multitude of surgical interventions aiming either to replace the damaged (osteo)chondral tissue or to induce repair attest to the unsolved clinical problem of true cartilage regeneration. Marrow-stimulation techniques establish a communication between the cartilage defect and cells from the subchondral BM either by focal perforation of the subchondral bone plate with awls (microfracture), drill bits (subchondral drilling), or by a generalized abrasion of the subchondral bone plate with burrs (abrasion arthroplasty) [4]. BM from the subchondral compartment fills the defect and a three-dimensional (3D) BM clot containing mobilized pluripotent MSC forms. These stem cells are undergoing chondrogenic differentiation, resulting in the formation of a fibrocartilaginous repair tissue. For larger defect areas, clinical evidence suggests that a sufficient defect repair by this strategy is insufficient. Osteochondral autografts and allografts involve the transplantation of osteochondral tissue into areas of cartilage damage. They are chiefly indicated for small osteochondral defects such as resulting from OD. For larger defects areas, multiple osteochondral cylinders may have to be used, preferentially as osteochondral allografts because of the increasing donor-site morbidity when harvesting osteochondral autografts.

Tissue-engineered cartilage products for orthopedic reconstruction

Tissue engineering of cartilage is based on seeding chondrocytes in or onto biodegradable scaffolds for defect repair. For cartilage repair, the engineered construct is nearly exclusively used to repair focal defects of the articular cartilage. In addition to articular cartilage reconstructive applications, engineered cartilage can principally be also used in head and neck reconstruction, for example, treating defects in the auricle, nose, and trachea. For articular cartilage repair, both a sufficient horizontal and vertical integration with the underlying subchondral bone and adjacent native articular cartilage are specifically challenging. Ideally, the mechanical properties of the engineered construct should be similar to those of the adjacent cartilage in order to prevent perifocal OA. At the time of implantation, however, they are usually inferior, relying on the in situ maturation of the implant over time. Moreover, the scaffold needs to provide an environment that guarantees chondrogenic stability of the implanted chondrocytes. Although it is recommended that such an implant should also survive in an inflammatory environment, significant clinical inflammation is clinically absent as this represents a contraindication, similar to OA or arthritis such as rheumatoid arthritis (RA). Despite significant advances, however, no engineered construct is capable to completely mimic the structure and properties of the native articular cartilage. As cartilage defects occur in different sizes and are often irregular in shape, the transplanted construct needs to be either robust enough to sustain a trimming in the operation room to be implanted in a defect specific shape or to adapt itself to the defect.

Cells for tissue-engineered cartilage repair

Chondrocytes are the logical choice for tissue-engineered cartilage repair since they represent the resident cell population and are consequently capable of proliferation and cartilage-specific extracellular matrix (ECM) production and deposition. The first step in tissue-engineered cartilage repair is the biopsy of cartilaginous tissue containing chondrocytes. It is usually performed arthroscopically. Cartilage biopsies are taken from within the knee joint, even if the engineered transplant is implanted in other joints such as hip or ankle. In contrast, the use of cartilage fragments or material from debridement does not meet the requirements for a standardized collection process and is therefore discouraged. As such a biopsy represents by definition a secondary injury within the joint, other sources for chondrocytes such as rib, auricular or nasal cartilage, or allogeneic chondrocytes have been explored. Nasoseptal chondrocytes can be harvested by nasal biopsy and are currently evaluated in clinical trials for articular cartilage repair in the knee joint. Since these are heterotopic nonarticular chondrocytes, structural clinical data on the repair tissue are mandatory. Future efforts to increase their potential

include strategies reducing possible dedifferentiation and applying chondrocytes from OA cartilage.

Adult MSCs from BM, adipose tissue, adipose tissue, muscle, synovium, periosteum, perichondrium, and other sources have chondrogenic differentiation ability, thus appearing as an alternative. Nevertheless, also MSCs pose several challenges, including relatively low cell numbers within the donor tissue, the need for characterization and chondrogenic differentiation which in vitro takes several weeks, the similar instability of the differentiated chondrogenic phenotype, and unanswered question of differentiation into other lineages such as osteoblasts within a cartilage defect in vivo. Interestingly, cartilaginous constructs engineered in vitro from BM-derived MSCs have been shown to be dissimilar in their epigenetic signature to constructs from primary chondrocytes that are almost identical to autologous articular cartilage, necessitating future investigation [5].

Scaffolds for clinical tissue-engineered cartilage repair

An ideal scaffold for articular cartilage repair must provide a favorable 3D environment for the maintenance of the differentiated chondrocyte phenotype. It needs to enable attachment both of implanted chondrocytes and cells migrating into the defect. The scaffold must allow the diffusion of nutrients and chondrogenic factors as well as allow the removal of cellular waste products. It should be biodegradable, ranging from an initially biomechanically strong support which is reduced over time in a rate paralleling ECM deposition and tissue remodeling. An abundance of natural, synthetic, or hybrid scaffold materials have been developed and tested for tissue engineering of cartilage in vitro, and in animal models in vivo. As only a few have successfully found entry into clinical applications, a focus is placed on such materials (Table 80.1).

From a surgical standpoint, an application via an arthroscopic procedure would be desirable. Solid scaffolds are attractive because their initial mechanical stability immediately upon implantation makes them potentially interesting to treat large cartilage defects. Currently, the majority of scaffold materials in clinical applications are based on solid materials. However, hydrogel scaffolds are ideal candidates for implantation by minimally invasive arthroscopic surgery. They can be tailored to exhibit similar mechanical, but also swelling, and lubricating behavior as articular cartilage. Also, hydrogels allow the seeded chondrocytes to retain their differentiated chondrogenic phenotype characterized by a spherical morphology. Remarkably, also decellularized cartilage has been studied as a suitable basis for tissue-engineered repair because of the correct assembly of the ECM macromolecules and its good mechanical properties, although the process of cellular population is not as efficient as for preseeded or porous scaffolds.

Collagen scaffolds

Collagen scaffolds are of either natural or synthetic origin, or hybrids. Natural scaffolds such as type-I collagen are currently the most widely used to repair cartilage in clinical applications. Although type-I collagen is associated with the fibrocartilaginous phenotype of the cartilaginous repair tissue, it often shows a mixed morphology containing both types-I and -II collagens. Type-III collagen functions in the healing response of cartilage damage as a covalent modifier to add cohesion to a weakened type-II collagen network. Most of the commonly used type-I/III collagen membranes are derived from animals. The collagen molecules in these scaffolds are cross-linked to strengthen the fibrils, stabilize their structure, extend resorption time, and enhance biocompatibility. Commercially available type-I/III collagen membranes for applications in articular cartilage repair usually comprise a bilayer structure. The layer facing the synovia (and the opposing cartilage) is compact and has a smooth surface with a low porosity. The other (inner) layer is more porous and has a spongy 3D appearance. While

TABLE 80.1 Overview of scaffolds for clinical tissue-engineered cartilage repair.

Material	Structure of the three-dimensional network	Example of commercial products
Type-I/III collagen	Solid scaffold	MACI, Novocart 3D
Type-I collagen (atelocollagen)	Hydrogel	Koken Atelocollagen Implant
Hyaluronic acid	Solid scaffold	Hyalograft C
Hyaluronic acid	Hydrogel	CARTISTEM
Albumin and hyaluronic acid	Hydrogel	Novocart Inject
PGA, PLA, and polydioxanone	Solid scaffold	BioSeed C
Fibrin	Hydrogel	Chondron
Agarose and alginate	Hydrogel	Cartipatch

Note that not all commercial products (e.g., Hyalograft C) are currently available. Only scaffolds that have been used in conjunction with cells are shown.
PGA, polyglycolic acid; *PLA*, polylactic acid.

most type-I/III collagen products are solid scaffold membranes, type-I collagen (atelocollagen) is also used as hydrogel scaffold for ACI. Type-II collagen is the principal molecular component of cartilage and plays a key role in maintaining chondrocyte function. Not as easy available as type-I collagen, recombinant human type-II collagen has been experimentally used in vitro and in vivo for tissue engineering. Although comparative studies revealed the superiority of type-II collagen for chondrocyte phenotypic stability versus type-I collagen, hydrogels based on type-I collagen (as also alginate and agarose) also allow to maintain the chondrocytic phenotype. As these collagens are rapidly remodeled in vivo, their main task is to provide a temporary matrix within the cartilage defect to support the transplanted cells, rather than acting as a structural matrix that is present for a long time. Other cartilage-specific collagens such as types-VI, IX, X, XI, XII, and XIV found little use in tissue engineering approaches so far.

Hyaluronan

Hyaluronan (or hyaluronic acid) is a naturally occurring glycosaminoglycan (GAG). Hyaluronan is an important component of the articular cartilage ECM. It also acts to lubricate the articular cartilage surfaces in synovial joints. In addition, hyaluronan binds to the aggrecan molecules in the ECM, forming larger aggregate structures. It has been used for cell delivery both as a solid scaffold or hydrogel.

Synthetic polymers

Synthetic polyesters such as poly(lactide acid) (PLA), poly(glycolid acid) (PGA), and their poly(lactide-*co*-glycolide) (PLGA) copolymers are the most often used biodegradable polymers. Devices made of PLGA combine good mechanical properties and defined degradation according to the specific tissue requirements. They can be easily extruded into fibrous or open lattice structures, ideally supporting cell attachment, and have been extensively used to engineer cartilage in vitro and in vivo. Self-assembling peptides are another versatile class of materials capable of providing a microenvironment to enhance chondrogenesis. These peptides are able to self-assemble into stable hydrogels at low peptide concentrations but have not been tested in clinical settings.

Agarose and alginate

Both agarose and alginate are natural carbohydrate polymers that are manufactured from marine algae. Agarose is a linear polymer based on a disaccharide consisting of made up of D-galactose and 3,6-anhydro-L-galactopyranose. Alginate is a linear copolymer with homopolymeric blocks of β-D-mannuronate and α-L-guluronate at different concentrations. Both polymers provide a 3D environment for chondrocytes, supporting their differentiated phenotype and have been applied for tissue engineering purposes. They may be combined with other materials, such as chitosan. Although translational studies attest to the potential value of agarose- or alginate-based hydrogels for chondrocyte delivery into cartilage defects, clinical applications have been rare [6].

Scaffold-free three-dimensional systems

Scaffold-free 3D systems have also found entry into clinical applications, consisting of chondrocytes as spheroids. The chondrocytes are cultivated in culture plates where they cannot adhere and consequently start to aggregate into a round high-density structure, mimicking the cell condensation observed during the embryonic development of cartilage. Inside the spheroids, the chondrocytes display a round cell shape. As the synthesis and deposition of ECM by the chondrocytes continues within the spheroids, the chondrocytes progressively encapsulate themselves within a self-synthesized ECM. The ECM is composed of types-I and -II collagens, GAGs, and aggrecan, comparable to an early chondrogenic phenotype. Interestingly, more type-I collagens is deposited near the surface of the spheroids, where the cells have an elongated shape. The chondrocytes in the spheroids express chondrogenic growth factors, which are insulin-like growth factor I, transforming growth factor beta, bone morphogenetic proteins-2 and -4, and platelet-derived growth factor. Such growth factor expression is important for the success of all ACI technologies as this suggests a continuing paracrine effect of the transplanted cells within the cartilaginous repair tissue in vivo.

Bioreactors for tissue-engineered cartilage repair

Considering the fact that the phenotypic stability of articular chondrocytes can be supported by using specific environmental factors such as 3D culture, low oxygen tension, and mechanical stimuli, bioreactors represent a logical choice for their cultivation for clinical protocols. Culture of chondrocytes in 3D bioreactors has long been a powerful tool to enhance the structural and functional properties of tissue-engineered cartilage. Such constructs, cultivated in rotating bioreactor systems, are characterized by a more uniform cell seeding, increased cell numbers, and enhanced ECM deposition compared to static cultivation systems. Such increased structure properties directly translate to increased load-bearing capacities and stiffness by the tissue-engineered cartilage. Yet no current clinically available protocol does apply these advances. Nevertheless, it

may be speculated that in the future such bioreactor-based strategies will find also applications in commercial manufacturing strategies for chondrocyte implantation.

Clinical nomenclature of scaffold-based techniques

Clinical generations of autologous chondrocyte implantation

The clinical nomenclature of ACI generations reflects the evolution of the technique. It spans from the use of a periosteal flap to biomaterial scaffolds that are preseeded with cells. The initial first-generation ACI procedure as proposed by Grande, Peterson, and Brittberg is based on the inoculation of a cell suspension containing expanded autologous chondrocytes into the hollow space that is created by covering the previously prepared cartilage defect with a biological membrane of autologous periosteum removed from the ipsilateral proximal tibia. The first generation of ACI focused on safe and effective cell application. Harvesting of the flap was challenging and time-consuming, but most importantly the spatial distribution of the implanted cells was irregular. As undesired effects such as hypertrophy of the periosteal graft and failures were noted [7], biomaterial scaffolds were introduced as substitutes for the periosteal flap, leading to "second-generation" and "third-generation" ACI. Second-generation ACI uses a biomaterial scaffold (mainly a type-I/III collagen membrane) as a cover of the defect where the cell suspension is injected in vivo in the operation room in a similar fashion than when using the periosteal cover. Third-generation ACI further applies the principles of tissue engineering as the expanded chondrocytes are already seeded into the 3D biomaterial scaffold before implantation, allowing the cells to settle down and attach on the scaffold fibers ex vivo, thereby avoiding the asymmetric cell distribution following injection of the cell suspension into a possible oblique defect base in vivo. Cell quality was optimized by characterization, minimally invasive application, focusing on a purely autologous setting without foreign material, and modifying the environment and biomaterials. Thus the nature of the structural template for chondrocyte implantation evolved from a purely biological membrane to a preseeded resorbable biomaterial that, in most cases, is a solid membrane but may also constitute a hydrogel scaffold.

Acellular, scaffold-based products

The importance of this scaffold evolution is also reflected in the clinical advent of the concepts of acellular, scaffold-based products, which chiefly aim to combine biomaterial scaffolds with marrow stimulation. Of note, these so-called matrix-augmented BM stimulation techniques do not use ex vivo cultivated chondrocytes as in the ACI procedure, and the abbreviation "AMIC" of the (trademark-protected) term "autologous matrix-induced chondrogenesis" may not be confused with MACI, another (trademark-protected) term referring to an ACI product based on a porcine type-I/III collagen membrane. Of surgical technical importance, ACI never includes the penetration of the subchondral bone plate (i.e., microfracture) which is mandatory for matrix-augmented BM stimulation techniques. A large variety of such products is on the market, including BST Cargel (chitosan), CaReS-1S (rat type-I/III collagen), Cartimaix (porcine type-I/III collagen), Chondrofiller (rat type-I/III collagen), Chondro-Gide (porcine type-I/III collagen), Chondrotissue (synthetic PGA and hyaluronic acid), Hyalofast (hyaluronic acid), and Novocart Basic (bovine type-I/III collagen) [8]. Although such matrix-augmented BM stimulation techniques appear to be clinically safe, there is a paucity of high-quality, randomized long-term controlled studies testing them versus established procedures such as microfracture or ACI especially for the knee, making it difficult to recommend joint-specific indications for this, from a biomaterial standpoint, interesting technique [9]. However, such a sole biomaterial implantation appears especially attractive as an off-the-shelf therapeutic option, serving the demand of more economical solutions for cartilage repair although caution has to be applied based on their lack of long-term clinical data. In any case, such acellular membranes may be used in salvage procedures after failed previous attempts at cartilage repair to cover large defects when ACI is contraindicated or not available.

Particulated autologous or allogenic articular cartilage

Other commercially available products involve the implantation of the natural cartilage ECM with chondrocytes in the form of particulated articular cartilage from either autograft or juvenile allograft donors, among which Cartilage Autograft Implantation System (CAIS), DeNovo Natural Tissue (NT) Graft (DeNovo NT), and Particulated Juvenile Allograft Cartilage (PJAC) neither use isolated and expanded chondrocytes nor a 3D biomaterial scaffold, with the exception of the fibrin glue that may be used to attach these cartilage fragments to the defect [10,11].

Commercial autologous chondrocyte implantation products

MACI (Vericel, Cambridge, MA, United States)

The MACI product involves the established method in which autologous chondrocytes are expanded in monolayer culture after initial enzymatic digestion. Several

days before implantation they are seeded onto on a resorbable type-I/III collagen membrane (Chondro-Gide, Geistlich, Wolhusen, Switzerland). The MACI implant represents a cellular sheet, consisting of autologous cultured chondrocytes at a density of about 500,000 cells per cm^2.

ChondroCelect (TiGenix, Leuven, Belgium)

The product ChondroCelect (TiGenix, Leuven, Belgium) was the first cartilage cell product approved as advanced therapy medicinal product (ATMP). The initial idea was, at the molecular level, to assess efficacy through the characterization of marker genes associated with chondrogenic performance which led to the term of "characterized chondrocyte implantation" of the product. Nevertheless, the technique and the surgical application are not different from the first and second-generation ACI products. Even though the initial approval was submitted and granted for the combination with an autologous periosteal flap, a porcine type-I/III collagen membrane was recommended. The innovation of the product has to be seen in the field of cell biology: The chondrocytes cartilage cells are characterized in vitro in terms of chondrogenic potency. Yet, it should be noted that other manufacturers are also obliged to perform an analysis of chondrogenic markers as a prerequisite for the detection of the quality of the product, and the characterization of chondrocyte marker gene expression did not have a clinical consequence. From a clinical point of view, a structural superiority after 1 year in direct comparison with microfracture, a functionally better treatment result after 2 years, and in the subgroup of patients with a short symptom duration, a superiority after 5 years all have been demonstrated.

Spherox (Co.don, Berlin, Germany)

Spherox represents the concept of a scaffold-free 3D system, including spheroids of autologous chondrocytes within their ECM. The chondrocyte cultivation takes place in two steps: after isolation of the chondrocytes, their propagation is performed first in monolayer culture using autologous patient serum and growth factor-free medium. Subsequently, the cells are transferred into a 3D culture as spheroids. Already in this phase of cultivation, the chondrocytes produce and deposit an ECM. A spheroid contains approximately 200,000 cells and measures about 300−600 μm in diameter at the time of implantation. They are directly applied either arthroscopically or via arthrotomy to the subchondral bone plate (about 10−70 spheroids/cm^2 defect) in a dry environment where they adhere to the host within about 20 minutes and obtain a flattened shape. The adhesion and subsequent in situ remodeling are considered crucial steps for its integration into the defect. It consists of an initial fixation phase by cell mediated adhesion to the host subchondral bone, continuous integration via migration of the transplanted chondrocytes along the irregular surface of the subchondral bone plate and spheroid remodeling. A biomaterial coverage or fixation is not required, supporting the minimally invasive application.

Novocart 3D (Tetec, Reutlingen, Germany)

The product Novocart 3D represents a classic representative of matrix-associated ACI using a biphasic biomaterial. Novocart 3D is distributed since the end of 2003. Here, the articular chondrocytes are already preoperatively seeded in a type-I/III collagen-based biphasic matrix in a density of 0.75 to 4.0×10^6 cells/cm^2 matrix. The bovine biphasic matrix consists of a covering membrane and an underlying collagen sponge, whose interconnecting pores allow a homogeneous 3D cell distribution. Implantation of Novocart 3D typically requires a (mini) arthrotomy to allow secure fixation of the support membrane with sutures to the surrounding cartilage. For defects where stable edge walls cannot be created, resorbable pins are an alternative.

BioSeed C (Biotissue, Geneva, Switzerland)

The product BioSeed C represents one of the first representatives of the so-called third generation of ACI, which combines in vitro the expanded chondrocytes with a synthetic polymer-based biomaterial as a carrier for before transplantation. It is distributed since 2002. For cell seeding, a porous fleece based on PGA, PLA, and polydioxanone, on which chondrocytes are suspended in fibrin glue, is used. The material can be tailored according to the defect size. The fleece is fixated with sutures to the surrounding cartilage, or with transosseous sutures or arthroscopic darts. It should be noted that this product has not yet initiated a central approval by the European Admission Office (EMA) in the sense of initiating a registration study.

Novocart Inject (Tetec, Reutlingen, Germany)

The product Novocart Inject pursues a technically different approach as cells are applied in a hydrogel in contract to nearly all other approaches which are based on solid scaffolds. Novocart Inject is an injectable, chondrocyte-containing hydrogel on the basis of albumin and hyaluronic acid that polymerizes in the defect after being combined with a biocompatible cross-linker similar to fibrin glue. Novocart Inject also reaches defect locations that are difficult to address. It can be applied using arthroscopic techniques in a dry environment, or by mini-arthrotomy. Registration trials are already initiated for Novocart Inject and the first patients were enrolled in 2018.

Chondron (Sewon Cellontech, Seoul, Korea)

Chondron is a technique based on the transplantation of in vitro cultured autologous chondrocytes which are embedded in fibrin glue as hydrogel scaffold and then implanted into the cartilage defect. Case series without control groups have been reported [12].

Cartipatch (Tissue Bank of France, Génie Tissulaire, Lyon, France)

Cartipatch is a solid agarose/alginate hydrogel scaffold containing autologous chondrocytes. Following monolayer culture for 3 weeks, cells are placed in the hydrogel matrix to produce cylindrical hydrogel grafts of 10, 14, and 18 mm in diameter. A multicenter randomized controlled trial reported significantly inferior functional outcomes compared to mosaicplasty for isolated focal osteochondral defects of the femur at 2 years postoperatively [6].

CARTISTEM (Medipost, Seongnam, Korea)

CARTISTEM is the first allogeneic stem cell product for the treatment of knee cartilage defects in patients including ICRS grade IV OA lesions approved in South Korea. It is based on allogeneic human umbilical cord blood (hUCB)−derived MSCs (hUCB-MSCs) given at a dosage of 2.5×10^6 cells/500 μL/cm^2 cartilage defect area. The stem cell−based medicinal product is a composite of culture-expanded allogeneic hUCB-MSCs and a hyaluronic acid hydrogel. hUCB is collected from umbilical veins at the time of neonatal delivery, stored in a cord blood bank, and isolated and characterized hUCB-MSCs are cultivated in medium supplemented with 10% fetal bovine serum, maintained in monolayer culture for approximately 2 weeks and resuspended in a hyaluronic acid hydrogel when reaching 80% confluence. Using a standard arthroscopic procedure followed by a mini-arthrotomy, the cartilage defect is first treated with prograde subchondral multiple drill holes (5 mm in diameter, 5 mm deep, approximately 2−3 mm apart). Next, the allogeneic hUCB-MSCs/hydrogel composite is implanted in each of the drill holes [13].

JACC stands for a product based on isolated autologous chondrocytes that are cultured in a 3D atelocollagen gel environment [Japan Tissue Engineering Co, Ltd. (J-TEC) autologous cultured cartilage (JACC) system]. Following cell isolation, the cells are mixed with an atelocollagen solution containing 3% type-I collagen. The final cell density per the hydrogel depends on the size of the cartilage defect. The cultured hydrogel is applied to the defect and covered with a flap of periosteum harvested from the femoral condyle.

Clinical application of autologous chondrocyte implantation in reconstructive articular cartilage surgery

Indications for autologous chondrocyte implantation

The value of ACI lies primarily in the treatment of large, symptomatic, full thickness focal non-OA chondral or osteochondral defects in the knee joint in patients ≤ 50 years. For cartilage defects in children and adolescents, ACI is not primarily recommended due to their good intrinsic repair capacity. There is a high degree of agreement in international guidelines and recommendations, reflecting the limited success of BM stimulating techniques for large-area cartilage damage. A structural superiority of the repair tissue following ACI has been shown in prospective randomized studies. Through sequential international recommendations, the indications for ACI have been refined, especially the lower limit of defect size, for which an ACI is recommended, especially in young and physically active patients. ACI is currently indicated for primary defects with areas above 2.5 cm^2. For other patients, there is a consensus of treating defects with areas above 3.0 cm^2 with ACI. Another indication is defects of all sizes in the same age group, in which previous cartilage-repairing measures failed. The cartilage of the corresponding articular surface may be damaged up to a maximum of II in the International Cartilage Regeneration & Joint Preservation Society (ICRS) classification (excluding ICRS grades III or IV; ICRS Cartilage Injury Evaluation Package 2000). A reduction of the total ipsilateral meniscus volume of a maximum of one third is permitted. It is important to recognize that a physiological leg axis must be present or possibly created, since analyses of failed cases revealed local overload based on untreated axial malalignment as the most commonly recognized reason (in 56% cases) for failed surgical index procedures such as microfractures or osteochondral transplantations. For example, in the cases of patients with focal cartilage lesions that are located in the medial femoral condyle with accompanying varus deformities of >5 degrees, there is general consensus to realign such deformities together when performing an ACI either in a one- or two-staged scenario. The evidence for the upper ankle or hip joint is much lower, and for other joints (glenohumeral) only a few case reports exist.

Contraindications

ACI is not indicated for the treatment of advanced OA [Kellgren−Lawrence (K−L) grade 3 or 4]. Other specific contraindications include conditions such as hypersensitivity

to products of porcine or bovine origin and inflammatory arthritis including RA.

Surgical steps

The first step of the surgical procedure is the strict examination of the knee joint, which needs to be performed arthroscopically in analogy to the current international recommendations. If the indication for ACI is confirmed intraoperatively, the arthroscopic procedure for the biopsy of cartilaginous tissue can directly follow. The most common method is the removal of three defined narrow osteochondral cylinders using small hollow punches from regions of normal cartilage. The superolateral or superomedial trochlea and the superior border of the intercondylar fossa are suitable locations. By definition, this removal process represents the first step in the manufacture of a drug within the context of "ATMP" and is thus subject to regulation. Such regulation includes a standardized collection process for the removal of cartilage, the examination of the donor suitability, careful documentation of the biopsy process, regular instructions of the responsible persons, and fulfillment of structural and hygienic conditions, together with documentation and filing of all documents for 30 years after collection.

After submitting the osteochondral cylinders in cell culture medium to an approved laboratory by express delivery, the enzymatic digestion of the cartilage which has been separated from the subchondral bone and the primary monolayer culture of the isolated articular chondrocytes in a clean room laboratory are carried out. Subsequently, the monolayer expansion of the chondrocytes takes place in the context of a standardized proprietary expansion protocol of the cooperating company and the production of the final product. This period varies depending on the manufacturer between about 3 and 8 weeks. It is not influenced by the surgical demands, solely depending on the manufacturing process. The possibility of an interim cryopreservation of the chondrocytes makes it possible to adapt the time of transplantation to the needs of the patient. This option is offered by most commercial ACI suppliers.

Following cell expansion, chondrocytes are seeded into the biomaterial scaffold, which will be implanted in most cases. This is performed either in the laboratory some days before implantation or a cell suspension is being delivered directly to the operation theater where the suspended chondrocytes are seeded into the biomaterial immediately before implantation. As an alternative, 3D spherical aggregates of chondrocytes obtained in a similar fashion may be implanted without the use of a scaffold into defects.

Implantation of the ACI product may be performed as open surgery (arthrotomy) or arthroscopically, chiefly depending on the type of product (Fig. 80.1). In most cases, an arthrotomy is needed. A meticulous surgical technique has to be applied. After defect identification, the careful debridement of the diseased cartilage tissue represents the first surgical step. In contrast to marrow-stimulation techniques, the integrity of the subchondral bone plate is preserved. During debridement, all diseased cartilage tissue ultimately has to be removed, resulting in stable and vertical defect walls surrounded by healthy and vital cartilage and a subchondral bone plate lamella free from residual calcified cartilage tissue, avoiding bleeding from the subchondral bone, as in vitro studies show a negative influence of blood on the regeneration capacity. The technique of implantation and fixation is product-dependent. In general, the supporting membrane is accurately adapted to the geometry of the defect, implanted and firmly fixed (Fig. 80.2). For fixation, it may be anchored to the adjacent cartilage using single interrupted sutures (e.g., USP 6-0) or with resorbable pins or fibrin glue (Fig. 80.3). Erosion of the subchondral bone plate is tolerable up to a depth of the bony lesion of about 5 mm. Deeper osteochondral defects should be recontoured by filling with autologous cancellous bone. This "sandwich technique" is a useful option for large osteochondral defects based on osteochondritis dissecans (OD), where there is no possibility of fragment replication.

Clinical results of autologous chondrocyte implantation

Overview

A large clinical body of therapeutic evidence already exists for ACI (Fig. 80.4). Long-term studies with a

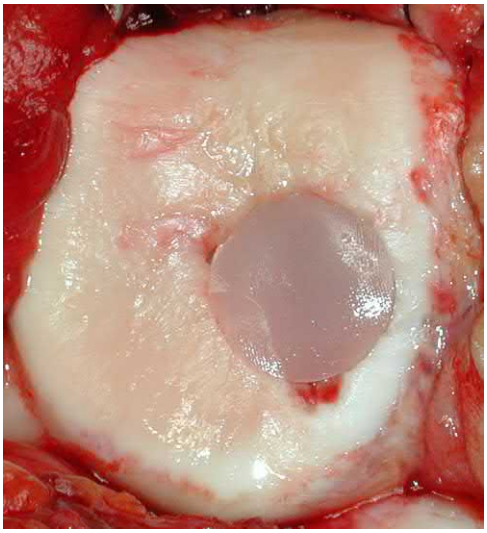

FIGURE 80.2 After meticulous defect preparation, the membrane supporting the chondrocytes in this third-generation ACI product is accurately adapted to the geometry of the defect and implanted. *ACI*, Autologous chondrocyte implantation.

follow-up of up to 20 years, specific information on typical complications, together with meta-analyses of several thousand patients on its clinical results and the important possibility of returning to sports for the younger patient population that mainly benefits from the intervention, all showing relatively good outcome parameters. Most importantly, a significant number of data from prospective randomized clinical trials (RCTs) have refined the indications for ACI, especially within the context of the regulatory steps as required for approval of ACI as a drug. Most of these very valuable studies have been designed for ethical reasons as "noninferiority studies,"

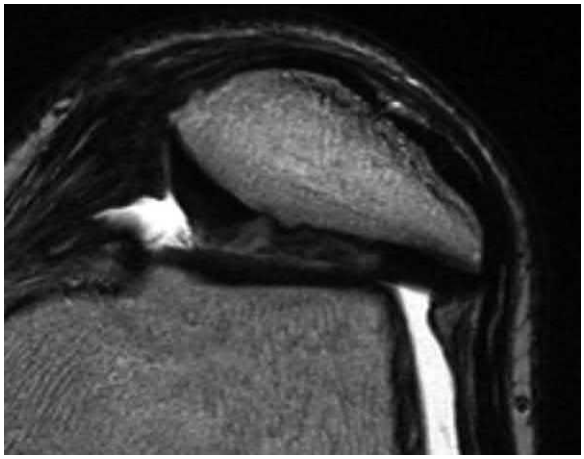

FIGURE 80.4 MRI of the femoropatellar joint of the case after 1 year. Note the complete filling of the defect with a repair tissue, its relatively good integration to the adjacent articular cartilage and the subchondral bone, the irregular subchondral bone plate and the structural differences of the repair tissue compared to the adjacent cartilage.

thus the control group represents another form of surgical therapy, which is in the most of the cases an arthroscopic microfracture. However, in the context of these studies, it has to be kept in mind that most of these studies comparing arthroscopic microfracture with ACI are studying patients with defect sizes that are rather small, thus often not meeting the indications for ACI, which are chondral defects larger than $2.5-3.0\,cm^2$ (marrow stimulation is indicated for defects smaller than $2.5-3.0\,cm^2$). As the defect size is an essential criterion, a direct comparability with microfracturing for larger defects has not been performed to date. The fact that most long-term RCTs are based on defects sizes not higher than $4.0\,cm^2$ and involve first-generation ACI suggests that more high-quality clinical evidence is needed for a satisfactory answer as to whether recent techniques of ACI show superior clinical outcomes in long-term follow-up compared with microfracture. Nevertheless, meta-analyses of the second and third generations of ACI (i.e., the currently marketed products) show the evidence of superiority of ACI in individual studies at the structural (histology) and clinical levels.

Data from prospective randomized clinical trials

Knutsen et al. reported a long-term follow-up at 15 years of a randomized multicenter trial (level I) comparing first-generation ACI with microfracture. The 80 patients had cartilage defects mainly in the femoral condyles, and the defect sizes ranged from 1.4 to $11.2\,cm^2$. At 15 years, the clinical data from this important trial showed significant clinical improvements compared with baseline (clinical scores and pain) and no significant differences between both treatment groups. Failures were noted in

both groups (ACI; $n = 17$, microfracture; $n = 13$), and sometimes total knee replacements were needed (ACI; $n = 6$, microfracture; $n = 3$), without significant differences between them. Of note, about 50% of the surviving patients in both groups had radiographic evidence of early OA (e.g., a K−L grade of ≥ 2) without significant differences between the groups, showing that the problem of delaying OA has not been solved [14]. Although this clinical trial applying a first-generation technique did not show superiority of ACI versus marrow stimulation, there is a strong consensus in the international clinical cartilage repair community that ACI is beneficial to treat either large lesions or as a rescue technique following failed other previous repair strategies. A recent systematic review of 5-year outcomes comparing microfracture versus ACI for articular cartilage lesions in the knee showed that patients undergoing microfracture or first/third-generation ACI can be expected to experience improvements in clinical outcomes at midterm to long-term follow-up without any significant difference between the groups [15].

Long-term results of autologous chondrocyte implantation

In addition to evidence-based prospective studies, long-term results for the treatment of cartilage defects in the knee joint with ACI are now available. Although these represent uncontrolled studies and thus cannot provide any statements about a direct superiority of the method over other treatment options, they may serve as a general proof of the long-term efficacy of the surgical method. At a mean follow-up of 10.9 ± 1.1 years, first-generation ACI led to satisfying clinical results (patient satisfaction, reduction of pain, and improvement in knee function). Nevertheless, full restoration of knee function cannot be achieved. Interestingly, the level of structural cartilage repair as assessed using MRI did not correlate with the long-term clinical outcomes [16]. A 20-year follow-up of first-generation ACI showed satisfactory survival rates and significant clinical improvements [17].

Clinical factors affecting the clinical outcomes of autologous chondrocyte implantation

Several factors affect the clinical success of ACI besides defect size, among which depth of lesion, anatomic defect location, and patient age and occupation. Deep osteochondral defects are challenging, such as occurring after OCD or avascular necrosis, because patients suffering from these lesions have a high risk of OA if the articular congruence is not restored. Here, ACI is combined with autologous bone grafting, termed "sandwich" technique. Treating symptomatic deep osteochondral lesions in the knee was significantly better in the ACI sandwich group than in comparison with autologous bone grafting alone in terms of survival rate at a mean follow-up of 16 years. Especially no significant OA progression from preoperatively to a mean of 5 years postoperatively was seen in the ACI sandwich group based on K−L grading [18]. Since patients with cartilage damage are typically young with high levels of activity, the rate of return to exercise and the intensity with which sport can be performed again after surgery is a relevant parameter for evaluating different therapies. Return to low- and moderate-intensity levels of sport appears realistic in the majority of cases, whereas the likelihood of returning to activities with high stress applied on the knee joint is low. Neither defect location nor size appears to significantly influence postoperative sports activity or return-to-work rates [19]. Meta-analyzes based on a significant number of included cases reveal the highest rates of return to sport postoperatively if defects were treated with autologous osteochondral transplantation or ACI, while the best rate was observed in terms of the intensity of postoperative exercise capability in ACI. Yet, autologous osteochondral transplantation and microfracture (usually indicated for smaller defects) allow for a faster return to sports activity in direct comparison to ACI, although clinical performance of microfracture appears to be inferior. However, it has to be kept in mind that that postoperative sport ability is a very heterogeneous parameter, as recent data shows differences in terms of sports ability depending on the desired intensity and scope. Most importantly, the ability to return to sports and the intensity of sports do not correlate with the structural quality of the repair tissue in the postoperative course. The premorbid level of sporting and recreational activities in general cannot be achieved as shown at 11 years after first-generation ACI. Also, MRI data do not correlate with long-term sporting activity [20]. Data on anatomic defect location usually indicate that defects in the femoral condyles show superior outcomes than patellofemoral defects. Recent information from a prospective cohort of patients indicates that second-generation ACI for patellofemoral lesions successfully allowed returning to work in the majority of patients of moderate to very heavy occupational demand with significantly decreased knee pain at 2- [7] and 4-year follow-ups, adding to the evidence that ACI is a valuable cartilage repair technique for patellofemoral lesions [21]. In contrast to other cartilage repair techniques, patients 40 years and older do not have an inferior outcome up to 2 years after ACI for isolated cartilage defects when compared with younger patients [22].

From a clinical and scientific point of view, ACI has established itself in the treatment of large cartilage damage to the knee joint. The data on ACI in other joints are much more reduced in scope and value compared to the knee joint. For example, ACI is more commonly performed in the hip joint and the upper ankle joint, but the proof of its efficacy in other joint-based controlled randomized studies is still pending. Open questions are the

optimal cell dose needed for optimal morphological repair after ACI [23], and the lack of correlation between cartilage repair tissue ultrastructure and clinical or qualitative MRI outcomes [24]. Finally, it remains to be seen whether other cell sources such as MSCs are capable of achieving similarly effective MRI scores and qualitative histological and clinical outcomes [25].

Introduction

Bone is both a tissue and an organ. Bone defects can result from congenital anomalies, trauma, metabolic diseases, infections, and tumor removal [1,2]. Bone deficiencies represent formidable clinical challenges and have inspired creative scientific approaches for repair and regeneration. Bone tissue engineering remains one of the most robustly pursued fields in tissue engineering.

Contrasting to several other skeletal tissues, bone has certain intrinsic regenerative capabilities for self-repair. However, numerous bone defects do not heal and have been termed "critical size bone defects" and require surgical interventions [3,4]. For example, the clinical management of a critical diaphyseal defect, a large discontinuity in bone that cannot spontaneously regenerate, continues to be a major challenge. The two available treatment options are limb salvage or amputation, leading to disability [1,2]. These clinical scenarios can be complicated further by infections and/or nonunion fibrosis. Moreover, these problems and the high morbidity and associated costs of care are not limited to the civilian population but represent a major concern in the ever-increasing nonlethal combat casualties [5]. The treatment of diaphyseal bone defects has advanced over the years from amputation to reconstruction with bone grafts (vascularized, cancellous, autologous, allograft) to distraction osteogenesis with Ilizarov devices to the emergent translational possibilities of tissue engineering and regenerative medicine [6].

Similarly, oral cancer is a major reason for mandibulectomy and maxillectomy, and major neurosurgical procedures typically involve craniotomy. In vivo bone formation is a major challenge in various craniofacial reconstructions and dental procedures that involve jawbone [7,8]. Currently, major mandibular defects can be repaired with an autologous vascularized bone from a variety of donor sites, including fibula, scapula, iliac crest, or rib. A major disadvantage of this technique is that harvesting these grafts always creates a skeletal defect at the donor site and induces significant secondary morbidity. Other therapeutic options, including allografts, xenogenic tissue grafts, synthetic materials, or prosthesis, unfortunately do not yield consistent and efficient regenerative repair and are fraught with complications [9]. Significant progress in tissue engineering could yield more favorable outcomes than current clinical approaches used to repair craniofacial defects.

Conventional bone tissue engineering strategies: cells, scaffolds, and biofactors

Regenerative medicine approaches based on engineering cells and biomaterial scaffolds into "spare part" tissues promise to shape the future of reconstructive surgery and organ transplantation. To date, the use of growing *functional* engineered tissues in vitro for subsequent implantation into tissue defects in vivo remains experimental, despite some early clinical successes [10]. In this approach, combinations of cells and bioactive molecules are seeded onto three-dimensional (3D) biomaterial scaffolds [11–15]

Cells can be retrieved from a variety of sources, including embryonic stem cells, postnatal and adult stem/progenitor cells, or the most recently discovered induced pluripotent stem cells. The common approach in engineered tissue regeneration has been to isolate cells from tissue biopsies or aspirates, manipulate them, and reintroduce them into the host [14]. For bone regeneration,

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00083-6

multiple cell sources have been investigated, including fresh bone marrow aspirates [9]; purified, culture-expanded bone marrow mesenchymal stem/progenitor cells [15], osteoblasts and cells that have been modified genetically to express osteogenic factors such as rhBMP [16], umbilical cord blood cells [17], adipose-derived stem/progenitor cells [18], or embryonic stem cells [19]. Perceived advantages and disadvantages of these cell sources in bone tissue engineering have recently been reviewed [8].

One of the pivotal challenges of cell transplantation is the cost and complexity associated with the development of experimental strategies into regulatory approved products. Intraoperative cell processing, while immune from regulatory approval, can only serve as a *point-of-care* service for one patient at a time. Once the cells are manipulated off site, regulatory approval is automatically required. Cell transplantation has encountered a number of barriers toward clinical translation, including potential immune rejection for nonautologous cells, pathogen transmission, potential tumorigenesis, costs associated with packaging, storage and shipping, shelf life and reluctance of physicians, and insurance in clinical adoption [8]. Cell survival in the host is also an unsettled issue, regardless of the cell source, and there is debate on whether the transplanted cells are regenerative per se or simply act as a pleiotropic source of factors and signals, especially in their ability to regulate inflammation [20]. These barriers will continue to be challenges for the implementation of engineered bone as a clinical treatment in foreseeable future. An alternative paradigm is to activate endogenous stem cells to participate in bone regeneration. A case in point is periosteal progenitor cells that are activated by injury and play an indispensable role in fracture repair [21,22]. Whether simple mobilization and homing of endogenous stem cells to the defect site will suffice for regeneration and have advantages over exogenous cell transplantation remains to be proven.

The assembly of the cells into the required 3D form of the bone defect requires a scaffolding biomaterial that delivers and retains the cells, and potentially stimulates and guides their induction of tissue regeneration. The minimum requirements of biomaterial scaffolds in addition to sustenance of *form* (3D shape and size) include *fixation* (securing the attachment to the host bone and minimization micro-motion), *function* (establishment of temporary or permanent mechanical load bearing), and *formation* (provision of appropriate porosity for mass transport, revascularization, osteoinduction, and osteoconduction) [23]. Additional biocompatibility characteristics must also be met in biomaterial scaffolds, including the lack of immunogenicity and toxicity. Furthermore, scaffolds can be enhanced by surface functionalizing to elicit affinity to cell binding and interactive modulation of the cells' response and can be designed for localized, controlled delivery of various bioactive molecules.

Scaffolds can derive from native tissues and biological polymers and/or synthetic polymers and can be fabricated using a variety of conventional techniques (reviewed in [24]). Among these techniques, solid freeform fabrication offers distinct advantages in enabling exquisite control of the scaffold form and internal architecture based on medical image-guided 3D modeling of the bone defect [25]. Recently, 3D bioprinting has been enabled by the commercial availability of low temperature, high resolution, multiinjector 3D-printing systems, which were originally developed for rapid prototyping applications. This technology has been successfully adapted for bone tissue engineering with biocompatible and osteoinductive calcium phosphate powder and biocompatible binder system for computed tomography (CT)-guided 3D printing of patient-specific scaffolds [26]. The multiinjector capabilities of a *colored* 3D printer potentially allow the embedding of combinations of biofactors and molecules within the scaffold with spatial control, which can be attractive in scenarios that might require spatiotemporal control over release kinetics. However, a recent review of scaffolds for bone tissue engineering has painted a bleak picture for translational progress of the field [23], which remains riddled with technical challenges of designing, manufacturing, and functionalizing scaffolds, regulatory approval barriers, business challenges related to meeting identifying niche markets and generating large initial investments necessary to sustain the business through the long-drawn-out regulatory process, and intellectual property life cycle issues that must protect the product long enough beyond the regulatory process to recoup the investment and make these products commercially viable.

Delivery of molecules and/or scaffolds to augment endogenous bone regeneration

Delivery of biofactors and molecules can alter cell signaling in the defect milieu and has been shown to influence the outcome of regeneration. A popular paradigm in tissue engineering suggests that reactivating developmental factors and signaling might be necessary for true regeneration of the lost adult tissue [27]. However, it is unclear whether the complex developmental signaling gradients and cascades need to or can be replicated faithfully in postnatal tissue repair. Regardless, our understanding of the developmental biology of the musculoskeletal system, and more specifically endochondral and intramembranous bone formation in the embryo, provides us with a plethora of information about factors, which when applied individually can enhance bone regeneration. This latter, a simpler approach is preferable for therapeutic translation.

A case in point has been the discovery of bone morphogenetic proteins (BMP) that were discovered by Marshall Urist and touted for their osteoinductive properties [28–30].

Basic science studies using transgenic mice in which individual BMPs have been selectively knocked out from the limb skeleton have identified BMP-2 as a critical factor in the innate regenerative capacity of bone [31]. The combination of recombinant human BMP-2 on an absorbable collagen sponge (ACS) carrier has been one of the most studied systems in preclinical and clinical investigations and represents one of the most significant therapeutic orthopedic discoveries [32]. With supporting level 1 clinical trial data, rhBMP-2/ACS (INFUSE Bone Graft) is commercially available, at the time of this writing, for three Food and Drug Administration (FDA)-approved clinical indications, including spinal fusion, open tibial fractures with an intermedullary (IM) nail fixation, and oral and maxillofacial augmentation (sinus augmentations and alveolar ridge augmentations for defects associated with extraction sockets) [32]. However, the efficacy of INFUSE Bone Grafts requires supraphysiological concentrations of BMP-2, and numerous adverse events have been filed at the FDA and reported in the literature in approved indications and off-label uses [33,34]. Therefore the identification of effective doses of BMP-2 (and perhaps other osteogenic and vasculogenic factors) for the regeneration of critical bone defects, preferably with tolerable and subclinical side effects, remains a common challenge for tissue regeneration community.

An exciting prospect has been the discovery of the therapeutic value of systemic hormones such as parathyroid hormone in fracture repair [35–38] and tissue engineering of critical diaphyseal defects in preclinical models [39–41]. This systemic delivery approach might overcome the challenges associated with local delivery but remains to be clinically validated.

To sum, each of the individual components of the conventional tissue-engineering triad (cells, scaffolds, and biofactors) brings unique sets of challenges. Optimization of these *composite* constructs into *functional* tissue substitutes is typically performed empirically in the laboratory ex vivo using cell and tissue culture models and in vivo using preclinical animal models. However, this approach has faced difficult barriers to translation from the bench to the bedside. A three-component medical product would have at least 3^n_i possible combinations of independent variables (where n_i is the number of possible variables associated with the ith component of the three-component product), which makes the feasibility of testing the experimental matrix in a comprehensive investigation impossible. This has limited advances in the field to only incremental discoveries, despite exciting developments and breakthrough technologies that have been reported in small animal and preclinical models. The regulatory requirements of the multicomponent bone regeneration products have hindered and continue to slow down clinical translation. Nevertheless, innovative *point-of-care* regenerative approaches guided by the tissue engineering paradigm have been reported in the clinical literature with remarkable early successes.

Biomaterials development and three-dimensional printing

Clinical successes and opportunities in regenerative repair of diaphyseal defects

Segmental diaphyseal defects are common in long bone in scenarios involving tumor resection, trauma, and

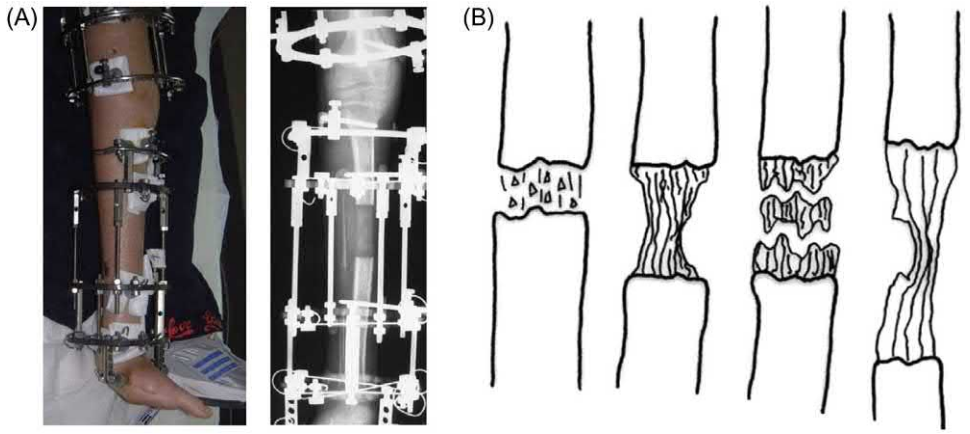

FIGURE 81.1 Bone regeneration using distraction osteogenesis.
(A) Typical distraction osteogenesis hardware (frame and rings) is shown. (B) Distraction osteogenesis proceeds in stages, the first of which is the *latency* stage during which the injury and repair process initiates and fracture callus forms, followed by the *distraction* stage in which the bone is gradually distracted through the osteotomy site at a rate of approximately 1 mm/day resulting in a fibrous interzone composed of mesenchymal progenitors. The interzone eventually revascularizes, and the cells differentiate and form regenerate bone through intramembranous and endochondral ossification. Finally, in the *consolidation* stage, the immature bone that formed in the defect is remodeled into lamellar bone. *Reproduced with permission from Catagni MA, Radwan M, Lovisetti L, Guerreschi F., Elmoghazy NA. Limb lengthening and deformity correction by the Ilizarov technique in type III fibular hemimelia: an alternative to amputation. Clin Orthop Relat Res 2011;469(4):1175–80.*

debridement following infections or atrophic nonunions. Previously, substantial bone defects have required amputation. In the 1960s an innovative technique for in vivo bone regeneration was developed in Russia by Ilizarov [42–44]. In the late 1980s this technique, referred to as distraction osteogenesis, was extended into Western Europe and the United States. Distraction osteogenesis is a process in which a bone is gradually separated at an osteotomy site. The bone on either end of the osteotomy is stabilized with an external fixation device (Fig. 81.1A). The regeneration of bone involves three stages [45]. The initial stage is termed latency and consists of a 5- to 10-day period during which the injury and repair process initiates and fracture callus forms. During the second, or distraction phase, the bone is gradually distracted through the osteotomy site at a rate of approximately 1 mm/day. Separation of the bone results in a repetitive tensile force in the distraction gap between the bone segments. In the center of the distraction a fibrous interzone composed of mesenchymal progenitors forms, while at each of the osteotomy surfaces bone the tissue is revascularized, and the cells differentiate and form regenerate bone through intramembranous and endochondral ossification. The final phase of the process is termed "consolidation" in which the immature bone formed in the defect is remodeled into lamellar bone (Fig. 81.1B).

Distraction osteogenesis has been used successfully to reconstruct limb defects resulting from tumor, trauma, infection, and developmental diseases [46–48]. The approach is also frequently used for the treatment of craniofacial defects [49]. The process of bone formation in distraction osteogenesis is dependent upon the mechanical stimulation of the healing bone callus that is generated by the tensile forces resulting from the daily separation of the bone fragments [45,50]. The tensile force results in the release of cytokines and growth factors that stimulate the proliferation and differentiation of mesenchymal stem cell progenitors and lead to angiogenesis and revascularization of the tissue. Growth factors associated with distraction osteogenesis include BMPs, vascular endothelial growth factor (VEGF), fibroblast growth factor (FGF), and Wnt signaling factors [51–53]. Thus distraction osteogenesis includes the various features associated with the successful engineering of regenerate bone: stabilization of the skeleton, mechanical stimulation, recruitment and stimulation of stem cell populations, angiogenesis, and bone incorporation and remodeling.

Despite these advantages, distraction osteogenesis is not an ideal approach to regenerate bone. While effective, distraction osteogenesis has a high complication rate. The stabilization of the bone with an external frame connected to pins or wires inserted into the bone is associated with pin tract infections in nearly all cases. Bone lengthening is also associated with a risk of joint contractures or stiffness, nerve palsy, and limb deformity [54]. Moreover, the entire process, and particularly the consolidation phase, requires an extensive period of time. In patients with war-related bone loss, fixation was maintained at approximately 1.5 months/cm of bone regeneration [46].

One area of need for bone tissue regeneration involves device-associated infections. These are typically treated with a two-stage reconstruction approach. This approach involves complete removal of the hardware and tissue debridement, and later reconstruction after eradication of the infection with antibiotics [55,56]. The use of poly (methyl methacrylate) or PMMA cement spacers impregnated with antibiotic agents in two-stage reconstruction has been common practice in Europe and has experienced widespread clinical use in US hospitals over the past few years [57,58]. These temporary spacers, which are typically installed after tissue debridement, are intended to provide sustained local elution of effective tissue concentrations of antibiotics to treat the infection while maintaining limb length, preserving tissue stock, minimizing soft tissue fibrosis and contraction, and in the case of articulating spacers, maintaining joint mobility until the lost tissue is reconstructed [59].

An innovative regenerative approach to treat this complicated scenario follows the two-stage guidelines of the Masquelet technique [60], which described the in situ formation of a periosteum-like pseudosynovial membrane around temporary antibiotic-eluting bone cement implants, which if preserved can provide nutrition and vascularization during the regenerative phase of the reconstruction. Fig. 81.2A shows an X-ray of a classic fractured tibia with atrophic nonunion and clinical evidence of osteomyelitis [6]. Stage 1 treatment of this case involved thorough debridement of the infected, necrotic bone and the placement of vancomycin-eluting PMMA cement beads in the resulting defect alongside the IM nail (Fig. 81.2B). This resulted in eradication of the infection and the endogenous formation of a pseudosynovial membrane over almost 1 year. The second stage then involved removal of antibiotic-eluting cement beads with careful preservation of the nutritive, induced biologic membrane, and subsequent installation of two titanium 15 mm diameter spinal cages to provide structural scaffolding for osteoinductive rhBMP-2 (INFUSE Bone Graft) that was placed "off-label" in the defect (Fig. 81.2C). To introduce BMP-2 responsive cells, autogenous cancellous bone and bone marrow were mixed with β-tricalcium sulfate granules (chronOS Bone Void Filler) and used to augment the defect, and the biological membrane was closed around the implanted biologics, morselized cells and tissue, and metallic scaffold. Four months following reconstruction, there was radiological evidence of new bone formation, and 1 year later there was resumption of independent ambulation with evidence of radiological and clinical healing [6] (Fig. 81.2D).

FIGURE 81.2 Tissue engineered reconstruction of a MRSA-infected tibial nonunion. (A) Radiograph of the MRSA-infected tibia 5 months after fracture, with no clinical evidence of healing. (B) Radiograph of the infected tibia after the first stage of the Masquelet technique, which involves resection of 17 cm of necrotic bone and insertion of vancomycin-eluting cement. (C) Radiograph following the second stage of the Masquelet technique, which involves exchanging the IM nail, with spinal cage support for INFUSE Bone Graft and autologous cancellous bone reamings. (D) Radiograph of the tibia 1 year following the two-stage Masquelet reconstruction, showing bone regeneration in the massive tibial defect. *IM*, Intermedullary; *MRSA*, methicillin-resistant *Staphylococcus aureus*. *Reproduced with permission from O'Malley NT, Kates SL. Advances on the Masquelet technique using a cage and nail construct. Arch Orthop Trauma Surg 2012;132(2):245–8.*

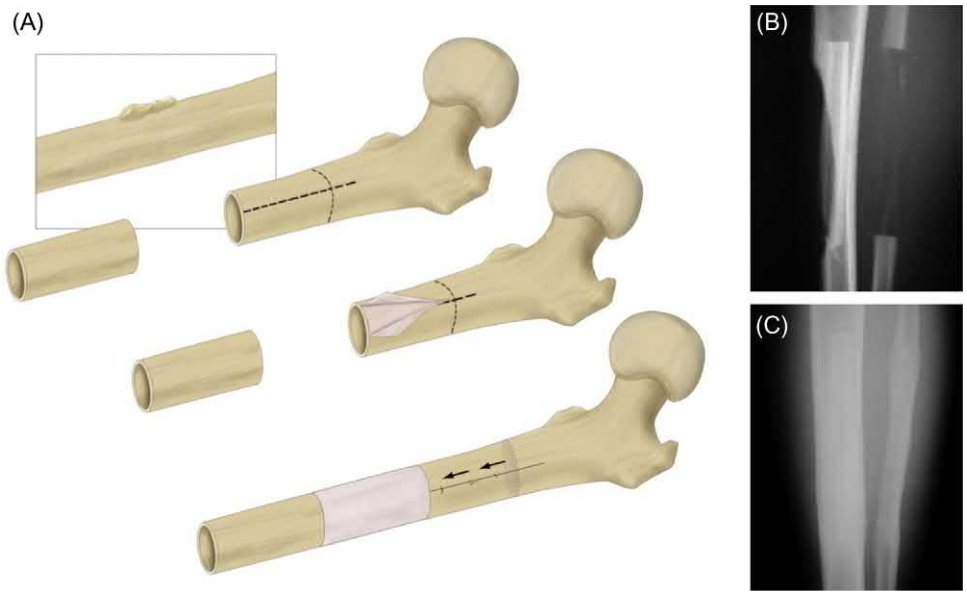

FIGURE 81.3 Exploiting the inherent regenerative capabilities of the periosteum to reconstruct the massive diaphyseal defects. (A) Schematic representation of the concept, which involves circumferential elevation a periosteal membrane off of healthy diaphyseal bone adjacent to the bone defect, and to then osteotomize the healthy bone (sans the periosteum) and transfer it to the defect out of the periosteal membrane. In theory the retained periosteum with its soft tissue attachment maintains vascularity and osteogenic progenitors. (B) Radiograph showing the reconstruction of a tibia with malignant cortical tumor with an autologous, pedicled fibula transfer, following elevation and in situ retention of the fibular periosteum. (C) Complete periosteum-enabled regeneration of the fibula is achieved by 3 months postreconstruction. *Reproduced from Knothe UR, Springfield DS. A novel surgical procedure for bridging of massive bone defects. World J Surg Oncol 2005;3(1):7, under the terms of the Creative Commons Attribution License (http://creativecommons.org/licenses/by/2.0).*

A similar approach to treat defects created by tumor resection exploits the endogenous osteoinductive properties of the periosteum and the osteoprogenitors it harbors. The concept is to circumferentially elevate a periosteal membrane off of healthy diaphyseal bone adjacent to the bone defect, and to then osteotomize the healthy bone (sans the periosteum) and transfer it to the defect out of the periosteal membrane. The retained periosteum with its soft tissue attachment maintains vascularity and osteogenesis can be augmented with cancellous bone grafts [61] (Fig. 81.3A). The feasibility of this approach was demonstrated in an osteosarcoma case by the reconstruction of

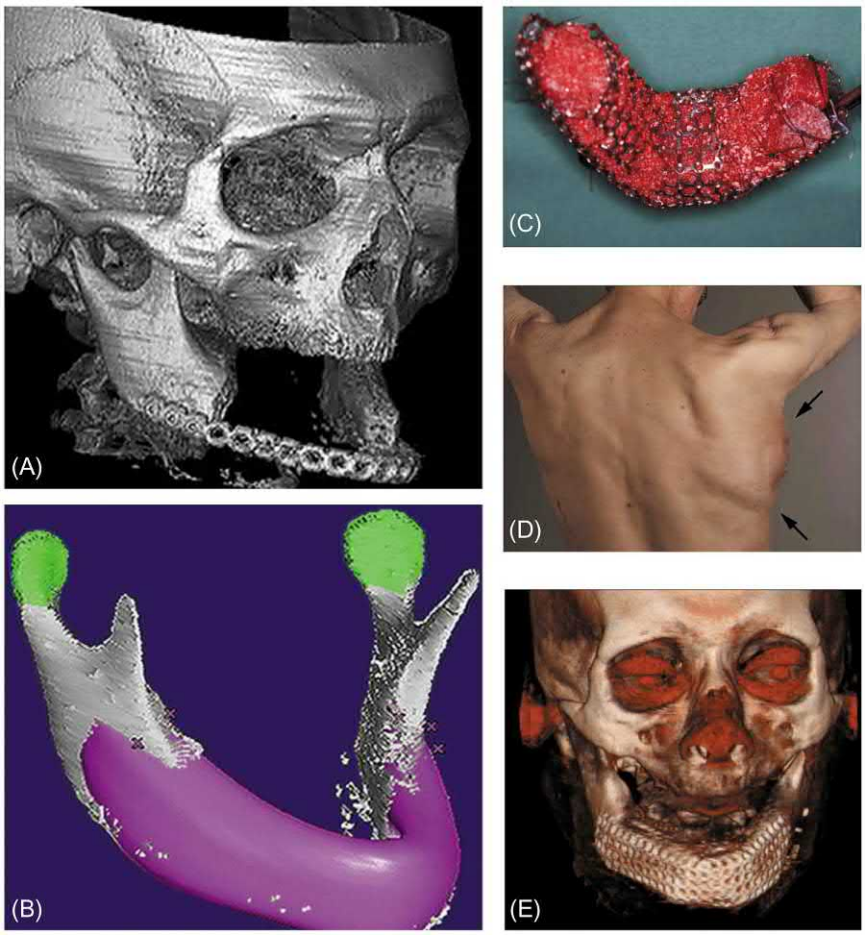

FIGURE 81.4 Image-guided tissue-engineered reconstruction of a massive mandibular defect. (A) The region of interest (jaw) is imaged using 3D CT. (B) The CT data is then fed to CAD software to generate an idealized virtual replacement of the missing parts of the mandible. (C) A titanium mesh is then formed in the shape of the missing bone model and augmented with BioOss hydroxyapatite blocks, OP-1 collagen implant, rhBMP-7, and autologous bone marrow aspirate. (D) The engineered mandibular graft is implanted in a heterotopic muscular pouch in the patient to establish vascularization and initial osteogenesis. (E) The graft was finally implanted orthotopically to reconstruct the mandibular defect. The patient had functional mastication and satisfactory esthetic outcome. *3D*, Three-dimensional; *CAD*, computer-aided design; *CT*, computed tomography. *Reproduced with permission from Warnke PH, Springer IN, Wiltfang J, Acil Y, Eufinger H, Wehmoller M, et al. Growth and transplantation of a custom vascularised bone graft in a man. Lancet 2004;364(9436):766–70.*

an iatrogenically created defect in the fibula following lifting and in situ retention of its periosteal membrane (Fig. 81.3B). The fibula graft was transferred to augment regeneration of a surface defect in the tibia that resulted from resection of a low-grade surface osteosarcoma. The periosteum membrane that was left behind was activated in situ to serve as an osteoinductive and osteoconductive sleeve and led to complete regeneration of the fibula defect within just 6 months (Fig. 81.3C).

The two approaches described previously utilize the principles of tissue stabilization, recruitment/delivery of stem cells, bone tissue differentiation, angiogenesis, and remodeling. The approaches also represent a personalized *point-of-care* method of tissue engineering of critical diaphyseal defects. They clearly borrow from the first principles of conventional tissue engineering, but circumvent the regulatory process via *off-label* use of several approved products (e.g., INFUSE, chronOS, and Bone Marrow). These cases represent individual success stories and demonstrate the safety and efficacy of biologics, scaffolds, and cells without in vitro manipulation; an alternative paradigm in tissue engineering that has been recognized for some time but one that has received less attention in the basic science literature. Advances in image-guided fabrication of biocompatible, osteoinductive scaffolds such as 3D bioprinting, which in theory enables simultaneous printing of biofactors and antibiotics within the patient-specific scaffold for sustained release can potentially lead to single-stage reconstruction procedures, accelerated recovery time, and improved the clinical outcome.

Clinical successes and opportunities in regenerative repair of craniofacial defects

The face distinguishes one human being from another. When the face is disfigured because of trauma, tumor removal, congenital anomalies, or chronic diseases, there is a critical need for functional and esthetic reconstruction [8]. These scenarios lend themselves to image-guided scaffold fabrication to restore the original shape of the face or jawbone. Success in this approach was first demonstrated by a report in the Lancet [9]. In this case the

patient, who lost a significant part of their mandible due to cancer, underwent 3D CT of the head and computer-aided design to generate an idealized virtual replacement of the missing parts of the mandible (Fig. 81.4A and B). A titanium mesh scaffold was then formed in the shape of the model and was filled with bone mineral blocks (BioOss Blocks) and augmented with bovine collagen type 1 (OP-1 implant) soaked with recombinant human BMP-7, and an autologous bone marrow aspirate to provide BMP-responsive osteo-regenerative cells (Fig. 81.4C). The titanium mesh cage was then implanted heterotopically into a pouch of the patient's right latissimus dorsi muscle (Fig. 81.4D) to establish vascularization and initial osteogenesis prior to orthotopic implantation to reconstruct the mandible (Fig. 81.4E). Skeletal scintigraphy bone scans showed evidence of uptake indicative of viable bone metabolism within the engineered mandible at both the heterotopic and orthotopic implantation sites, and postoperative CT imaging demonstrated radiographic evidence of healing and incorporation, with patient-reported functional improvements in chewing and a satisfactory esthetic outcome [9]. Other reports have since followed suit and demonstrated similar patient-specific, *point-of-care* reconstruction of the mandible with successful functional and esthetic outcomes [62,63].

Conclusion

Despite regulatory bottlenecks, surgeons and scientists will likely, and should, continue to push the frontiers of what is surgically possible, armed with innovations in cell-free tissue-engineering products, their skill and ingenuity, and most importantly their professional ethics and the vow they live by to do no harm. Cell-free refers to the recruitment of endogenous cells, including stem/progenitor cells, toward bone regeneration. Cell-free approaches arguably do not represent orthodox or conventional medical or tissue-engineering products from a regulatory or business standpoints, and the debates might not be settled by these $n = 1$ clinical reports, a far cry from randomized clinical trials required for level 1 data of safety and efficacy for regulatory approval. Nevertheless, these cases and similar ones not described herein successfully restored form, function, and quality of life to the afflicted patients. These *point-of-care* innovations might just be the bridge to wide clinical translatability and adoption of bone tissue-engineering approaches and products.

Chapter 82

Tissue-engineered cardiovascular products

Doris A. Taylor, Camila Hochman-Mendez, Joern Huelsmann, Abdelmotagaly Elgalad and Luiz C. Sampaio
Regenerative Medicine Research, Texas Heart Institute, Houston, TX, United States

Clinical situation/reality

Cardiovascular disease encompasses a number of clinical scenarios, including vascular disease, structural anomalies, (both congenital and acquired), and ischemic heart disease. In the United States, more than 800,000 people die from cardiovascular disease every year, that is, 1 in every 3 deaths according to the Centers for Disease Control and Prevention and US Department of Health and Human Services. The economic toll of cardiovascular disease is also massive, accounting for $350 billion in US health-care spending during 2014–15 [1].

The tissue engineering field employs biomaterials, cells, or their combination to develop biological substitutes that can restore, maintain, or improve tissue or organ function [2]. Since its inception, the intensive multidisciplinary nature of cardiovascular tissue engineering has revolutionized our understanding of cardiovascular biology and marshaled advances in both cell and scaffold technologies. The areas to which cardiovascular tissue engineering has mostly been applied are vascular and valve disease, congenital heart diseases, and more recently ischemic heart disease and heart failure. Only in two of these areas—valvular disease and congenital heart disease—have tissue engineering therapies (fixative-treated xenogeneic valves and patches made from pericardium) advanced to standard of care. However multiple tissue-engineered cardiovascular products are in clinical use or testing.

In this chapter, we will discuss these clinical conditions, the current state of the tissue engineering art and novel tissue engineering approaches.

Considerations for tissue-engineered cardiovascular constructs

The ultimate goal of tissue engineering is to produce a fully functional transplantable construct that cannot be distinguished from its original counterpart. Unfortunately, cardiovascular tissue engineering has not yet reached that pinnacle. Instead, cardiovascular tissue engineering is evolving from the use of simpler first-generation anatomically based products to more complex and function-based ones.

Most first-generation cardiovascular tissue engineering products were relatively simple nonliving scaffolds, which could be approved as medical devices. These included bioprostetic heart valves and fixative-treated xenogeneic pericardial membrane patches. Second-generation products, which have emerged more recently, are more complex and usually contain cells or other biologics impregnated on a synthetic or biologic scaffold. Due to their inherent complexity, these have to endure a much longer approval process involving phase 1–3 clinical trials to demonstrate safety and efficacy, unless they are able to obtain special classification (Fig. 82.1), which warrants a fast-track process. As the field matures and biomanufacturing becomes more real, the need for cardiovascular design standards has emerged. Given the complexity of cardiovascular diseases and the lack of anatomic redundancy, functional design considerations for each tissue-engineered cardiovascular product are complex. For a summary, see Tables 82.1 and 82.2.

Components for tissue-engineered cardiovascular constructs

Cell sources

Obtaining the quantities of cardiac cells of the right type needed for generation of living mature myocardium has been a significant bottleneck in the tissue engineering field. The human myocardium contains $\sim 10^{11}$ cells, of which one-third are cardiomyocytes. Terminally differentiated cardiomyocytes have a scant ability to proliferate

First in Humans to Evaluate Collagen Patches With Stem Cells in Patients With Ischemic Left Ventricular Dysfunction (CARDIOMESH)	NCT03746938	Treatment	Interventional Single Group Assignment	Nonrandomized	Recruiting
Randomized Clinical Trial to Evaluate the Regenerative Capacity of CardioCell in Patients With Chronic Ischaemic Heart Failure (CIHF)	NCT03418233	Treatment	Interventional Parallel Assignment	Randomized	Recruiting
Transcoronary Infusion of Cardiac Progenitor Cells in Patients With Single Ventricle Physiology (TICAP)	NCT01273857	Treatment	Interventional Parallel Assignment	Nonrandomized	Completed
Randomized Study of Coronary Revascularization Surgery With Injection of WJ-MSCs and Placement of an Epicardial Extracellular Matrix (scorem-cells)	NCT04011059	Treatment	Interventional Parallel Assignment	Randomized	Not yet recruiting (new)
A Phase I, Open Label, Safety Study of INXN-4001 Delivered Via Retrograde Coronary Sinus Infusion in Patients With an Outpatient Left Ventricular Assist Device (LVAD)	NCT03409627	Treatment	Interventional Single Group Assignment	Nonrandomized	Recruiting
Human Umbilical Cord-Derived Mesenchymal Stem Cells With Injectable Collagen Scaffold Transplantation for Chronic Ischemic Cardiomyopathy	NCT02635464	Treatment	Interventional Parallel Assignment	Randomized	Active, not recruiting
Pericardic Adipose Pedicle Transposition Over the Myocardial Infarct (adiFLAP Trial) (adiFLAP)	NCT01473433	Treatment	Interventional Parallel Assignment	Randomized	Completed
CD133 + Autologous Cells After Myocardial Infarction	NCT00400959	Treatment	Interventional Parallel Assignment	Randomized	Completed
Randomized Controlled Pivotal Trial of Autologous Bone Marrow Mononuclear Cells Using the CardiAMP Cell Therapy System in Patients With Post Myocardial Infarction Heart Failure (CardiAMP Heart Failure Trial)	NCT02438306	Treatment	Interventional Parallel Assignment	Randomized	Recruiting
A Phase I, Open-Label Study of the Effects of Percutaneous Administration of an Extracellular Matrix Hydrogel, VentriGel, Following Myocardial Infarction	NCT02305602	Treatment	Interventional Single Group Assignment	Nonrandomized	Active, not recruiting
A Pilot Study Investigating the Clinical Use of Tissue Engineered Vascular Grafts in Congenital Heart Surgery	NCT01034007	Treatment	Interventional Single Group Assignment	Nonrandomized	Completed
Multi-center Assessment of Grafts in Coronaries: Long-term Evaluation of the C-Port Device	NCT01478061	Treatment	Interventional Single Group Assignment	Nonrandomized	Completed
Safety and Efficacy of a Vascular Prosthesis for Hemodialysis Access in Patients With End-Stage Renal Disease	NCT01840956	Treatment	Interventional Single Group Assignment	Nonrandomized	Completed
A Pilot Study for Evaluation of the Safety and Efficacy of Humacyte's Human Acellular Vascular Graft for Use as a Vascular Prosthesis for Hemodialysis Access in Patients With End-Stage Renal Disease	NCT01744418	Treatment	Interventional Single Group Assignment	Nonrandomized	Active, not recruiting
Phase I Open-label, First-in-human Study to Evaluate Feasibility and Safety of Tissue Engineered Veins in Patients With Chronic Venous Insufficiency	NCT03784131	Treatment	Interventional Single Group Assignment	Nonrandomized	Not yet recruiting

and therefore cannot be expanded in culture for most tissue engineering applications. Thus many studies have examined the efficacy of seeding scaffolds with a variety of cardiac stem and progenitor cell populations [4,5] rather than with mature cardiomyocytes. Although this provides "enough" cells, obtaining mature function from these immature cells remains a hurdle.

Considering the highly limited proliferative nature of cardiomyocytes, the large-scale differentiation of cardiomyocytes from human-induced pluripotent stem cells (hiPSCs) has revolutionized cardiac tissue engineering. hiPSCs remain the most feasible source of cells for generation of an autologous tissue or organ because they can be generated from patients of any age and can be expanded to large numbers in vitro [6,7]. If the goal is to seed a scaffold prior to implantation, a large number of cells—in the millions and billions, depending on tissue volume—must be generated and maintained in vitro. For this, several efficient differentiation protocols have been reported, but reliable scale up to billions of mature cardiomyocytes remains a challenge using existing technologies. [8] Nonetheless, other cell sources are being utilized for both tissue engineering and regenerative medicine applications, including bone marrow− or tissue-derived endothelial cells and mesenchymal stem cells [9−11]. Cells are a critical tissue engineering biomaterial, but cells alone do not comprise a tissue or an organ.

Scaffolds

Cells are a critical tissue engineering biomaterial, but cells alone do not comprise a tissue or an organ. Cells are often seeded onto scaffolds of biologic or synthetic origin. However, scaffolds can be used with or without cells in tissue engineering products. Scaffold sources are reviewed in-depth elsewhere [12].

Synthetic scaffolds

Hydrogels are simplified hydrophilic polymer networks obtained from both natural and synthetic sources that have been used as scaffolds in both the cardiac and vascular fields [13,14]. Some of the widely used hydrogels include collagen [15,16], gelatin [17], Matrigel [18], alginate [19], fibrin [20], poly(2-hydroxyethyl methacrylate) [21], poly(*N*-isopropyl acrylamide) [22], and poly(ethylene glycol) (PEG) [23]. Hydrogels provide mechanical support for cells to deposit extracellular matrix (ECM) and form newly synthesized tissues as they degrade [23,24]. Furthermore, the physical and chemical properties of hydrogels can be tuned to enhance cell viability and function. These materials can be utilized either by themselves or in combination with cells. In particular, hydrogel-based materials have been successfully utilized in cardiac tissue engineering as structural/mechanical supports in failing heart, as cell delivery tools to increase cell retention in vivo, and as growth factor delivery agents to promote vascularization after cell transplantation. Yet, despite the fact that the effect of hydrogel on long-term cell survival has been positive [25−27], the injection pressure necessary for in vivo cell administration in the presence of hydrogel is high, which can cause extensive early cell death and ultimately decrease cell delivery.

Although hydrogels are often viewed as simplified ECM, they have several disadvantages that impact their use in tissue engineering. First, controlling the physicochemical properties of hydrogels composed of natural materials is difficult, which can lead to degradation of these substances after implantation, and can pose challenges during their purification and sterilization [28]. Consequently, synthetic hydrogels such as PEG, polylactic acid, polylactic-*co*-glycolic acid, polycaprolactone, polyacrylamide, and polyurethane have been developed to minimize these drawbacks [29]. However, the cytotoxic potential of synthetic hydrogels is still under study, and the Food and Drug Administration (FDA) has approved only the use of PEG, polylactic acid, and polylactic-*co*-glycolic acid for clinical application. In addition, PEG is sensitive to matrix metalloproteinases, which are found in heart and modulate its elasticity altering biophysical and biochemical parameters that in turn could influence (cardiomyogenic) differentiation of any implanted cells [30]. Because of these disadvantages, the use of natural scaffolds, such as decellularized ECM (dECM), has been highlighted as a more promising tool for repair strategies.

Extracellular matrix as scaffold

Since the early days of cardiac tissue engineering, ECM proteins have been used to functionalize synthetic scaffolds to provide a native-like extracellular microenvironment. Traditionally, bioartificial scaffolds were created using ECM components and different types of commercially available natural hydrogels such as Matrigel (laminin, collagen type IV, and heparan sulfate) [25,26], collagen [27], or fibrin [31].

The regenerative medicine field has increasingly recognized the central role of ECM in the success of tissue and organ engineering applications. During development, cells coalesce with ECM forming functional units unique to each organ. ECM is composed mainly of different types of collagen, glycosaminoglycans, fibronectin, laminin, elastin, and growth factors. The highly organized spatial anisotropy of ECM provides unique biochemical cues and architecture, which are difficult to mimic. Degradation of many of these native compounds results in the release of soluble peptide molecules involved in regulating many biological functions of a tissue organ, such as

cell proliferation, migration, and differentiation, and angiogenesis [32–34].

ECM can be used as a tissue engineering scaffold in multiple physical forms: as a reconstituted powder, hydrogel, or in its original form as a macrostructure. Our group has focused on ECM as a scaffold, especially dECM. Utilizing a variety of detergents the decellularization process removes cellular content, leaving behind an elegant 3D structure with unique tissue–organ-specific composition and architecture. Both the composition and the 3D spatial organization of dECM bioartificial scaffolds are fundamental for promoting cell growth and differentiation, although it is unclear which of the two factors is more critical [35–39].

Decellularized extracellular matrix as an ideal scaffold

To be used as a scaffold or in vivo, ECM must be decellularized because cells elicit a major antigenic response [40,41]. The ideal decellularization protocol results in the elimination of allogeneic and xenogeneic antigens as well as the cellular and nuclear content of the tissue but preserves the composition, physiological properties, mechanical integrity, and vascular structure of the ECM.

Investigators have developed a wide spectrum of techniques to exploit the advantages of ECM in cardiovascular tissue engineering. Today, dECM is used alone or mixed with other biomaterials both in vitro and in vivo along the continuum from bench to bedside as an injectable therapy for heart failure [42]. dECM scaffolds colonized with cells of both cardiomyogenic and endothelial lineages prior to implantation were reported to be successfully remodeled in different animal models [43–46]. Implantation of dECM of myocardial origin into the right ventricle has been reported to restore regional mechanical function in preclinical models of ischemic heart failure [47,48], and in humans [49]. Numerous studies have reported that implantation of dECM facilitates the remodeling of different types of tissues, both in animal models and in the human clinical setting [50–57]. There is growing evidence of the capability of dECM to polarize the immune response toward a more regenerative path by direct injection of dECM in various forms [58].

Perfusion decellularization

The organ engineering field was transformed in 2008 with our group's publication of a method of whole organ perfusion decellularization and partial recellularization with neonatal rat cardiac cells [59]. By perfusing the organ vasculature with decellularization agents, cadaveric organs were stripped of their resident cell components. [40,60,61] The resulting scaffold contained a holistic ECM, including all compartments of the organ. It preserved the 3D composition and biologic activity of ECM, making it an attractive material for cell adhesion, differentiation, and proliferation [50,54,56]. This advance has enabled labs worldwide to generate organ and scaffolds with the complex functionality of native organ, including myocardium for tissue and whole organ engineering applications.

Tissue-engineered cardiovascular constructs

Vascular grafts

Coronary heart disease and peripheral vascular disease have a combined annual mortality incidence predicted to rise to 23.3 million worldwide by 2030. Current standard of care includes invasive approaches to reestablish flow through damaged vessels, ranging from percutaneous dilation of the vessel at the occlusion site by angioplasty or stent placement, to surgical bypass grafting. Autologous saphenous veins were first used as a vascular graft in a clinical application in the early 1950s. Today, autologous vessels (saphenous vein and internal thoracic artery) are the gold-standard grafts for small-diameter vessels; however, their use requires invasive harvesting and is limited to providing four grafts, which could be a problem for some patients.

An alternative to autologous vessels is the use of synthetic vascular grafts such as Dacron [62] and PTFE [63]. Synthetic grafts were first used in the 1970s for aortic and lower extremity bypass, respectively. Today, they are standard of care for large-diameter vessels. However, thrombosis is the leading cause of failure when synthetic grafts are used to bypass small-diameter vessels (coronary arteries and arteries below the knee).

Biologically based vascular constructs were developed to overcome the limitations of synthetic vascular grafts. Since the late 1970s acellular vascular grafts from bovine and human origin [64,65] (Artegraft, North Brunswick, NJ), Cryovein (CryoLife, Kennesaw, GA) have been commercially available for use primarily in small vessels. In the 1980s Weinberg and Bell first tried to fabricate biological grafts containing xenogeneic cells, including fibroblasts, vascular smooth muscle cells, and endothelial cells, embedded in collagen [66]. Although these rudimentary grafts recreated vessel layers (adventitia, media, and intima), they had poor mechanical properties and required a Dacron mesh to act as a structural support.

Today, two main approaches exist for generating autologous tissue-engineered vascular grafts (TEVGs): in vitro seeding of a mix of autologous cells (endothelial, smooth muscle cells, and fibroblasts) onto decellularized scaffolds, and in vivo recellularization of decellularized scaffolds by harnessing endogenous processes. Ideally,

TEVGs would be capable of growing and remodeling in vivo [67], have antithrombogenic properties and no immunogenic activity, and be similar mechanically to the corresponding native tissue. TEVGs are poised to be a potent therapeutic tool in vascular replacement.

Scaffold-free grafts

Tissue-engineered self-assembly is a technology for creating TEVGs based on cells alone—without a scaffold. Cell-sheet TEVGs are the most clinically advanced technique for generating scaffold-free TEVGs. The technique emerged in 1998 after the first clinical trial results were published [68]. Cell-sheet TEVG involves the use of a dense and cohesive sheet of cells rolled around a mandrel and matured under dynamic conditions to create a vessel-like construct. Since the first successful report [68], several the technique has been optimize using different cell types, including human adipose−derived stromal cells, dermal fibroblasts, vascular smooth muscle cells, mesenchymal stromal cells, and endothelial cells [69−75].

Novel tissue engineering self-assembly techniques in the preclinical phase include proof-of-concept vascular structures created by fusion of cell spheroids to form a tubular structure [76], or bioprinted vascular tree [77]. While these new cell-based approaches are promising, to date their use is limited due to a lack of mechanical and structural stability.

Scaffold-based tissue-engineered vascular grafts

Strictly speaking, both synthetic vascular grafts and acellular vessels are scaffold-based TEVGs. Scaffold support provides a physiological template on which cells can attach, proliferate, and integrate; and depending on the source, it may provide biological cues related to its composition and micro/macro-architecture. Currently, a more sophisticated TEVG with autologous cells is an unmet need being pursued by multiple groups [67,78], by using innovative tools to enhance cell seeding, proliferation, and maturation. To date, decellularized human vessel constructs are the most successful TEVGs when applied in vivo, although postimplantation thrombus events remain the major limitation to long-term patency [79].

There is currently a well-known, critical unmet need for novel vascular graft replacements for congenital heart disease. Existing synthetic vascular grafts are unable to grow and mimic the mechanical properties of the native tissue. Without potential for growth and remodeling in the native tissue, graft material−related failures are the leading cause of morbidity and mortality in the pediatric population. For patients born with single ventricle disease, the current standard of care includes surgical deviation of blood flow (e.g., Fontan procedure) using grafts, mostly of synthetic origin. Generating off-the-shelf TEVGs made from allogeneic [80] or autologous [81] cells for use in the Fontan circulation is an area of active research. In 2018 a phase 1 clinical study of four patients was completed evaluating the safety of TEVG as an extracardiac total cavopulmonary connection in single ventricle disease (NCT:01034007).

Another area where TEVGs are likely to have a major impact is in the treatment of peripheral artery disease. As previously stated, thrombogenic failure of synthetic grafts increases as vessel diameter decreases. New solutions are needed for medium- and small-sized vessels requiring bypass. As of August 2019, when using the terms “peripheral arterial disease” and “tissue graft,” only two clinical studies appear: one using synthetic scaffold coated with human allogeneic cells, and one using a novel acellular human vascular prosthesis. Both trials are active but not yet recruiting.

In summary, vascular grafts have been and will continue to be a major area of interest for tissue engineering, but in 2019 the field has not progressed to the point that functional vessels—at least in small-diameter vessels—are a clinical reality.

Valves

Every year, more than 5 million people in the United States are diagnosed with valvular heart disease [82]. No effective medical treatment exists to halt chronic valve dysfunction or disease progression. In 2010 approximately 106,000 valve replacements were performed in the United States [83] and the number is expected to increase to 850,000 by 2050.

Current valve prostheses

The standard of care for medically untreatable heart valve disease is surgical intervention. When repair is not feasible, replacement of the diseased valve with a device—a mechanical or biological prosthetic valve—each with benefits and drawbacks, is then mandatory.

Mechanical valves are considered more durable than biologic valves, usually lasting throughout a patient’s life span. However, mechanical valves carry a high risk of thromboembolism and require lifelong anticoagulation therapy. Bioprosthetic valves provide better hemodynamics and do not require long-term anticoagulation therapy; but, because of their biologic composition, they are prone to deterioration and complications resulting from immune reactions [84]. Thus current bioprosthetic valves have a limited life span, usually failing due to rupture or calcification. Neither mechanical nor biologic prosthetic valves have growth capability and therefore neither is ideal in pediatric patients. Next-generation tissue-engineered constructs are being developed to overcome these limitations.

Tissue-engineered valves

The ideal tissue-engineered heart valve would be a living conduit that could adapt and grow with the patient. Theoretically, a tissue-engineered valve would have laminar flow, eliminating the need for anticoagulation therapy; could actively remodel, preventing degeneration; and would grow as needed—all cumulatively preventing the need for reoperation. These valves would have the potential to overcome the limitations of existing prosthetics, which would improve the safety and outcomes of valve replacement procedures.

Although basic tissue engineering concepts have been applied to generate valves from cadaveric tissues for decades, these prostheses are most commonly built from porcine or bovine sources using acellular fixative-treated valvular constituents that the body recognizes as immunogenic. Furthermore, most first-generation valve constructs are mounted on nonbiological struts to hold the tissue at a desired anatomical conformation. Cell-containing cryopreserved human valve allografts are a xeno-free alternative made from human cadaveric tissue after valve fixation. Clinical experience has shown that these allografts fail within a decade [85], most likely when an immunological response leads to deterioration of the valve. Decellularization, or use of detergents and other chemicals to remove resident cell components, has been employed to reduce the immunogenicity of these allografts, but clinical trial results have been mixed [86,87]. Matrix-P and Matrix-P Plus were the first nonfixed decellularized xenogeneic valve substitutes tested for clinical use. These commercially available valve replacements are recellularized with autologous cells. Follow-up of patients implanted with Matrix-P valves showed very low graft failure in humans ($n = 3$ vs $n = 15 + n = 14$ uneventful), but other investigators reported poor effective viability in preclinical settings and poor recruitment of host cells, which was interpreted as a risk for graft dysfunction [88,89].

A newer approach is to repopulate decellularized valve scaffolds with autologous or xenogeneic cells prior to implantation. However, preclinical studies of implanted recellularized valves have shown moderate to limited success [90], which could be related to the inability of phenotypically appropriate cells to recellularize the valve leaflets. Currently, scientists are working on determining optimal recellularization methods, such as in vitro recellularization combined with chemical and/or mechanical conditioning [90]. In situ recellularization strategies have been described in studies of decellularized homografts, where the recruitment of endothelial and interstitial cells for valve and cavities occurs in vivo [91].

In summary, prosthetic valve replacement is an established, lifesaving therapy for patients with untreatable heart valve disease, although there are clear drawbacks to existing mechanical and biologic prostheses. Advances in tissue engineering and regenerative medicine have made it possible to envision and design a tissue-engineered valve that can function as a true replacement—a valve that grows with the patient, adapts to the microenvironment, and lasts the duration of the patient's life span. Optimizing recellularization techniques would allow for repopulation of decellularized valves with autologous cells, reducing risks of immunogenicity and thromboembolism.

Cardiac patches

Myocardial infarction, known colloquially as a heart attack, is the most common cause for the loss of large numbers of cardiomyocytes and therefore a decrease of the pumping power of the heart. During a heart attack, oxygen-rich blood flow in the culprit vessel decreases or ceases; if blood flow is not restored quickly, heart muscle cells in the downstream territory to die and are replaced by scar tissue. In the heart, scar tissue is an electromechanically inefficient area that fails to conduct or contract appropriately. In addition, inflammation occurs that drives a remodeling process that affects surrounding viable areas.

Cell therapy is a related field to tissue engineering that for the past two decades and has been trying to fulfill the promise to repair the damaged heart. Multiple cell types have been utilized, including mesenchymal stromal cells, adipose-derived stem cells and cardiopoietic progenitor, or pluripotent stem cells. Nonetheless, outcomes in the clinical use of cells have been disappointing. Beneficial clinical effects are frequently observed but are not often statistically significant [6,7,92,93]. In 2016 the European Society of Cardiology Working Group—Cell Biology of the Heart concluded, "The early promise of cell therapy has not yet been fulfilled"[7].

Cell therapy is premised on the concept of delivering a large number of cells to the site of injury that can subsequently influence the formation and maturation of scar or promote endogenous repair. However, studies have shown that within 96 hours of local cell injection, less than 25% of delivered cells are retained at the site of injection, or within the myocardium—severely limiting the local efficacy of cell-based cardiovascular treatments [94,95]. Improving retention of cells or cell secretome at the injury site could provide a major benefit to cell delivery. Researchers have been investigating the benefits of using cardiac patches or gels to deliver cells to increase cell retention.

Noncontractile cardiac patches

Cardiac tissue engineering approaches aim to prevent myocardial scarring, to slow or halt scar expansion, and/

or to restore the scar tissue to a state of working muscle that can electromechanically reintegrate into functional myocardium. Regenerative medicine approaches to prevent or repair myocardial scarring comprise simply delivering cells at the time of injury, or shortly thereafter, to mitigate scar formation/expansion and using scaffolds containing cells or other biologics to manipulate the damaged microenvironment.

A promising tissue engineering approach is using a scaffold to deliver cells directly on the epicardial surface of the injury site to cover and overlap the damaged region [6,7]. Studies have shown that ECM-based patches can serve as scaffolds that provide active support of cardiac muscle as well as biochemical signaling via the direct contact of the biomaterials that deliver paracrine signaling from incorporated cells.

Other applications of cardiac patches include repair of congenital or acquired damage to heart anatomical structures. Currently, patches produced from membranes, such as decellularized pericardium, are engineered from xenogeneic or autologous sources after being fixed and preserved [96]. Although these patches are generated based on basic tissue engineering principles, they are unable to grow with the organ and do not contain the histological and mechanical properties of the structure they are supposed to replace.

Bioprinted patches

The 3D printing or additive manufacturing of cardiac patches entails the computer-controlled layer-by-layer deposition of natural or synthetic polymers and living cells. The ability to control the internal shape and microarchitecture is a major advantage of this technique. Although bioprinting may eventually allow for the precise spatial control needed to fabricate integrative 3D structures [97], this approach currently faces many obstacles, especially related to the inability to scale up without low cellularity, the inability to generate vasculature, and the failure to obtain mature cells [98]. We believe that utilizing native ECM as a cross-linked bioink is currently the most effective option to address the required complexity and the most straightforward solution to many of the 3D bioprinting hurdles.

Contractile patches

Contracting integrated cardiac patches would be a tissue-engineered homerun. However, at present most contractile patches are epicardially applied constructs made of ECM or ECM components (e.g., collagen) impregnated with cells, using the engineered heart tissue (EHT) approach. Early EHT technology resulted in the vitro development of a contractile collagen ring–based patch that could be implanted epicardially. Using in vitro generation and bioreactor-assisted cultivation, the EHT approach moved from proof-of-concept in the late 1990s to the contemporary EHT constructs using iPSC technology [99,100].

Although these patches are contractile, EHT constructs lack vasculature and are limited in size and depth. Our approach to generating contractile patches is unique. We recellularize whole heart dECM with human endothelial cells and cardiomyocytes, mature it in a 3D bioreactor, and then excise a ventricular patch—generating a construct with micro- and macro-characteristics very similar the native tissue [101].

Hurdles for using cardiac patches

Achieving vascularization—a must for a beating patch A holy grail of cardiac tissue engineering is effective vascularization within a cardiac tissue scaffold to allow a continuous diffusion of nutrients and oxygen to the cells even in the interior of a thick construct. Several approaches have been developed to introduce vascular structures in scaffolds, mainly based on the delivery and stimulation of endothelial cells in complex hydrogel systems [102–105].

Yet, at the current state of research and development in tissue-engineered cardiac patches, we believe that the elegant simplicity of the methodology—casting cells and avoiding complicated seeding techniques—is likely to be undermined by the complexity required to provide sufficient vascularization for transit of nutrients and metabolites sufficient to permit cell survival. In the short term, utilizing decellularized ventricular wall patches that provide both native thickness and a complex vascular architecture is recommended [15]. Given the current ability to reendothelialize the vascular tree in both small and large hearts [15], we have developed a staged recellularization method that permits perfusable constructs.

Successful vascularization may promote the migration and incorporation of cells inside the damaged myocardium. Here, the role of ECM in achieving vascularization of a cardiac tissue-engineered construct. In decellularized organ scaffolds the ECM serves the dual purpose of providing structural support material and serving as a medium for the exchange of biochemical signals with the cells that adhere to it [106,107]. The ECM is also responsible for maintaining an adequate network of blood vessels and for binding growth factors, which preserve the appropriate structure of the organ during development and repair [108]. These characteristics are especially challenging to mimic when generating complex tissues or organs with heterogeneous cellular components.

Achieving electromechanical integration To achieve the goal of electromechanical integration and support, the mechanisms and techniques for driving cardiomyocyte

maturation are being widely investigated, and transferring these methods to generate clinically relevant cells is a focus of topical research [109–111]. Bioreactors are essential tools needed to translate these concepts into appropriate methods and to guide the necessary bioprocesses. In vitro studies designed to mimic the cardiac niche showed that biophysical stimulation by uniaxial stretching fundamentally affected the maturation of myocardial patches with various cell types and ECM compositions [112–115]. Another well-established key concept of biophysical stimulation is electrical stimulation by fields or contacting electrodes [116–118]. Also, the combined effects of both mechanical and electrical stimulation or the supremacy of one method are under debate and investigation [113,119–121]. Significant effort has been invested in optimizing bioreactor design according to good manufacturing practice requirements to enable a broad spectrum of tissue engineering applications [122]. These efforts must address the demand for a sufficient level of maturity to enable electromechanical integration; however, the technology is not currently available to replicate the highly complex, spatially vectored design of the native cardiac tissue in the architecture of artificially designed scaffolds.

A large-scale functional patch cannot achieve electromechanical integration into the native host myocardium based on the maturity of cardiomyocytes alone. The spatial organization of the cells must match with the high anisotropic structure that is regionally specific to the superordinate framework of the left ventricle. In other words, the patch needs to precisely fit the specific region of injury whose architecture varies based on individual complex heart topography.

Building the next level of complexity: whole heart

Although early repair is a goal of cardiovascular tissue engineering, the fact remains that heart transplantation is the only effective treatment for end-stage heart failure, and that the unmet need for donor organs across the globe is increasing unabated. While cardiac cellular reprograming and endogenous repair strategies have raised excitement and 3D printing has captivated the world, these approaches are in their infancy and have generated results unlikely to be translatable to humans for decades. Tissue-engineered cardiac patches may be promising for cardiac repair but are unlikely to address the worldwide organ shortage. Whole organ engineering has the potential to alleviate this by providing an alternative source of organ replacements from animal and human sources.

Generating functional hearts of any significant size is daunting. But the field of whole organ tissue engineering was transformed in 2008 when the publication of whole heart perfusion decellularization occurred. The ability to generate whole organ scaffolds with an intact but acellular vascular network provided the first opportunity to build cardiac tissue of more than a few cells thick. Engineering a bioartificial heart like any other tissue-engineered construct requires scaffolds, (human) cells, bioreactors, and controllable processes.

The number of published tissue-engineered whole heart studies worldwide is remarkably low [59,118,123–131]. The paucity of whole heart research could be attributed to the work involved in creating a single whole heart construct that overlaps several areas in tissue engineering and regenerative medicine. Furthermore, whole heart engineering entails extensive capital resources and intensive time and labor. Perhaps the more important issue is that whole heart engineering demands coordinated, high level of expertise, experience, and technology from multiple scientific disciplines, including cellular biology, mechanical and chemical engineering, cardiac electrophysiology, and cardiac surgery. This high level of multidisciplinary expertise is needed to overcome numerous technical and scientific hurdles: nondestructive decellularization techniques, scaling up and out of cell manufacturing, efficient cell delivery, and efficient whole organ repopulation strategies. Moreover, bioprocessing strategies and bioreactor technology are needed to provide controllable growth and maturation at the level of an organ.

Researchers in the whole heart engineering field have overcome many of these technical and component hurdles to generate decellularized whole heart constructs repopulated with hiPSCs. Lu et al. demonstrated that hiPSC-derived cardiomyocytes infused into the vasculature of a small rodent decellularized heart survived and contracted the wall [128]. Guyette et al. showed that injection of hiPSC-derived cardiomyocytes in human whole heart scaffolds resulted in contractile ventricular muscle [124]. Recently, porcine whole heart scaffolds were shown to recruit cells for remuscularization in a xenogeneic environment [130]. Despite progress toward a replacement bioartificial heart, effective recellularization is currently a major hurdle in the field.

Now, after a decade of whole organ engineering research and innovation, whole heart tissue engineering is an established field. Building a bioartificial heart remains an achievable end goal of cardiovascular bioengineering within our lifetime [132]. The current challenge is to improve and scale up/out the processes required for successful, full recellularization of a whole heart scaffold. This will entail generating sufficient numbers of high-quality cardiac cells, fully repopulating a scaffold with the cells, and maturing a physiologically functional recellularized human-sized heart. Maintaining sterility and

quantifying readiness of the nascent organ will also be critical for success [98].

Pathway to approval and commercialization

In the relatively young field of tissue—and especially whole organ engineering—there are no established standard methods to be followed. Methodology used to produce scaffolds, repopulate them with cells, engineer and produce cells, and to process engineered tissues lacks defined parameters. However, bioanalytical tools to develop critical process parameter and critical quality attributes for construct evaluation are the subject of ongoing research and scientific discussion. Furthermore, as tissue-engineered myocardial constructs move from simpler first-generation nonliving cardiac patches to more complex biologics, combination products or even organs, increasing discussion will need to occur about the best models for preclinical use and the design of first in human studies [101,121,133,134].

Biomanufacturing of tissues and organs will need to be automated if the technology is to be scaled to meet the global cardiovascular disease burden. Generally, the production of tissue-engineered constructs can be described as a sequential progression of scaffold preparation, repopulation, and bioreactor-assisted processing, of the resulting construct based on perfusion systems. However, for every single step, there is still a lack of nondestructive quality control and process automation that precludes the commercial development of these constructs on an industrial scale. Process analytics, development of standards, and controlled methodology will be the key to moving forward [125,135–138] (Fig. 82.2). To this end, over the past decade multiple organizations have emerged that are dedicated to the development of tissue engineering standards, and biomanufacturing processes. A brief compilation of these standard generating organizations along with governmental agencies that impact product approval in Europe and the United States are collected in Table 82.3.

To give patients access to these new regenerative medicine technologies, both the European Union and the US regulatory agencies have pioneered specific programs to expedite the pathway to approval. The European Medicines Agency (EMA) launched the PRIME (priority medicines) scheme on the basis of enhanced interaction and early dialog with developers of promising medicines that target an unmet medical need, to optimize development plans and speed up evaluation so these medicines can reach patients earlier. One of the main goals is to help the developers improve the design of clinical trials so that the data generated is suitable for evaluating a marketing authorization application (https://www.ema.europa.eu/en/human-regulatory/research-development/prime-priority-medicines). Similarly, the US FDA was authorized in Section 3033 of *the 21st Century Cures Act* to provide "regenerative medicine advanced therapy (RMAT) designation" to biologic therapies including tissue-engineered products that "are intended to treat, modify, reverse or

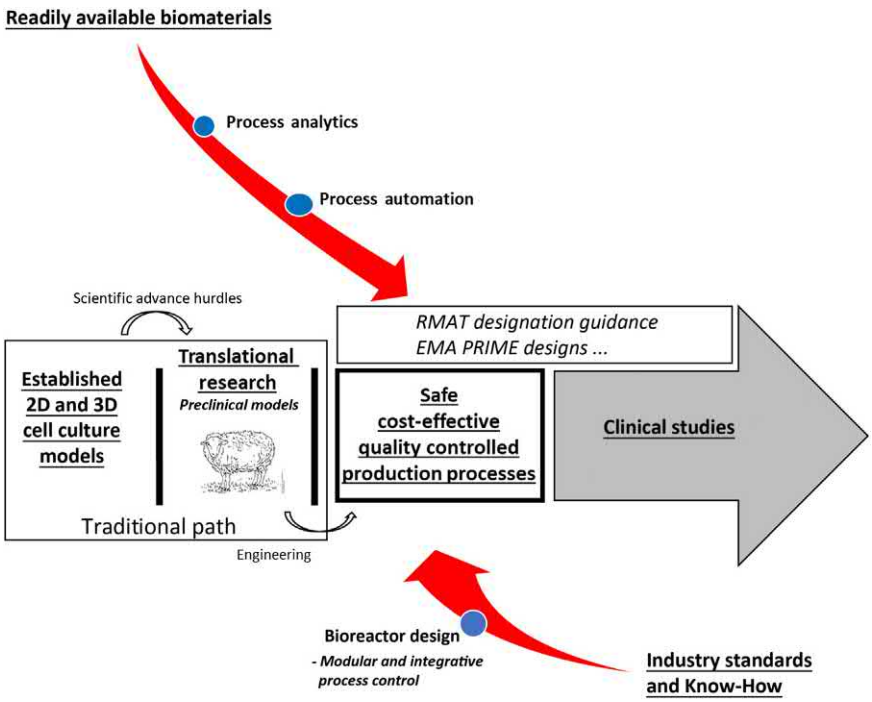

FIGURE 82.2 Steps for moving biomanufacturing of organs and tissues from bench to clinical use. Traditionally, candidate products established on in vitro models need to be tested in preclinical studies prior to the initiation of clinical trials. Scaling up biomanufacturing of tissue-engineered medical products will require developing process parameters that enable the use of readily available biomaterials, based on industry standards and know-how that yield safe processes for their use in the approval pathway. *EMA*, European Medicines Agency; *RMAT*, regenerative medicine advanced therapy.

TABLE 82.3 Standard development bodies in tissue engineering.

Agency	Goal	Website
ASTM International, *formerly known as American Society for Testing and Materials (ASTME)*	ASTM integrates consensus standards—developed with its international membership of volunteer technical experts—and innovative services to improve lives	www.astm.org
The National Institute of Standards and Technology (NIST)	NIST laboratory programs serve the cellular and gene therapy and regenerative medicine community through the development of a measurement infrastructure, including enabling tools, methods and protocols, bioinformatics and modeling tools as well as documentary standards and reference materials	https://www.nist.gov/ https://www.standardscoordinatingbody.org/
The Standards Coordinating Body for Gene, Cell and Regenerative Medicines and Cell-based Drug Discovery (SCB)	Launched by the ARM in 2017, the SCB's mission is to coordinate the accelerated advancement and improved awareness of the standards and best practices that address the rapidly evolving needs of the global regenerative medicine advanced therapyThe SCB and the NIST are jointly coordinating and contributing to the development of standards for accelerating R&D and clinical translation of regenerative medicine and advanced therapies	
The National Institute for Innovation in Manufacturing Biopharmaceuticals (NIIMBL)	NIIMBL is a public−private partnership dedicated to advancing biopharmaceutical manufacturing innovation and workforce development. Together with partners from industry, academia, nonprofits, and government agencies, NIIMBL collaborates on innovative manufacturing technologies that bring these lifesaving and life-enhancing products to market faster and at reduced cost, while maintaining safety and efficacy. In conjunction with technology advancement, it works to establish reference standards and measurement technologies to enhance efficiencies in the manufacturing process. Finally, NIIMBL also strives to cultivate a world-leading biopharmaceutical workforce through novel training and education programs	https://niimbl.force.com/s/
Institute of Electrical and Electronics Engineers (IEEE) Engineering in Medicine and Biology Society (EMBS)	To establish technical standards for diagnostic, therapeutic, health-care, and bioinformation systems	https://www.embs.org/
U.S. Food and Drug Administration (FDA)—Center for Biologics Evaluation and Research (CBER)	To protect and enhance the public health through the regulation of biological and related products, including blood, vaccines, allergenics, tissues, and cellar and gene therapiesGuidance documents describe FDA's interpretation of our policy on a regulatory issue [21 CFR 10.115(b)]. These documents usually discuss more specific products or issues that relate to the design, production, labeling, promotion, manufacturing, and testing of regulated products. Guidance documents may also relate to the processing, content, and evaluation or approval of submissions as well as to inspection and enforcement policies. Guidance documents are not regulations and	https://www.fda.gov/about-fda/office-medical-products-and-tobacco/about-center-biologics-evaluation-and-research-cber https://www.fda.gov/vaccines-blood-biologics/guidance-compliance-regulatory-information-biologics

(*Continued*)

TABLE 82.3 (Continued)

Agency	Goal	Website
	alternative approaches may be chosen to comply with laws and regulations	
Medicines and Healthcare Products Regulatory Agency (MHRA)—The National Institute for Biological Standards and Control (NIBSC)	To play a major national and international role in assuring the quality of biological medicines through product testing, developing standards and reference materials and carrying out applied research. NIBSC supports health policy development and implementation through provision of expert evidence-based advice and technical support and are an important component of the Department of Health's risk management strategy for public health. NIBSC is designated as the UK's OMCL for Biological Medicines, working closely with MHRA and operating within the European regulatory network to carry out independent official batch release testing of certain types of product as required by EU law	https://www.nibsc.org/
European Medicines Agency (EMA)—Committee for Advanced Therapies (CAT)	CAT is the EMA's committee responsible for assessing quality, safety, and efficacy of ATMPs and following scientific developments in the field	https://www.ema.europa.eu/en/committees/committee-advanced-therapies-cat

As the tissue engineering field continues to rapidly expand in the US and across the globe, industry-wide standards development and coordinating bodies have formed to regulate tissue-engineered medical products and regenerative medicine therapies. *ARM*, Alliance for Regenerative Medicine; *ATMPs*, advanced therapy medicinal products; *NIST*, National Institute of Standards and Technology; *OMCL*, Official Medicines Control Laboratory.

cure a serious or life threatening disease. . .where preliminary evidence indicates the drug as the potential to address . . .such disease or condition." This need for a path to expedite therapeutic strategies that fulfill an unmet need (Fig. 82.1) is an important step forward for tissue engineering.

Future perspectives

The first generation of cardiovascular tissue engineering products has matured, and second-generation products are beginning to reach first-in-human use. Of 85 trials listed at the NIH clinical trial site (https://clinicaltrials.gov/) in August 2019, which were found using the search term "tissue engineering," only six utilize cardiovascular products as the intervention. However, these six include TEVGs and cardiac patches.

We expect future innovations in tissue-engineered cardiovascular products to be closely coupled to surgical improvements in cardiac care. Today, mechanical left-ventricular assist devices (LVADs) work efficiently to unload the heart and can serve as destination therapy either as a bridge to recovery or to transplantation [139]. Advances in LVAD technology combined with a better understanding of patient selection have led to unparalleled survival and a reduction in adverse events associated with these pumps. This in turn has led to the idea that efficient, safe LVAD systems can provide both the time and the clinical scenario needed for evaluating regenerative interventions. This "bridge to regeneration" would provide significant opportunities, for example, to improve the neovascularization of transplanted tissue-engineered constructs such as epicardial or septal patches. It could also provide a unique environment to evaluate electromechanical and vascular integration of larger full-thickness constructs or even to introduce whole hearts into the circulation. As biomanufacturing of quality-controlled decellularized whole heart scaffolds advances and industry improves procedures for generating and processing autologous pluripotent stem cells, we anticipate significant strides in these regards over the next decade.

Introduction

One of the first documented cell culture experiments occurred in the early 20th century when Ross G. Harrison successfully cultured frog nerve tissue explants followed a few years later by Alexis Carrel and Montrose Burrows who proliferated cells from connective and epithelial tissue [1]. Since its introduction, cell culture has had a significant impact on research development regarding applications such as disease modeling, vaccinations, medicine, and human development and physiology. Recently, three-dimensional (3D) cell culture techniques have gained traction in various avenues of research due to its enhanced similarities to the microenvironment that cells experience in vivo. A subtype of 3D cell culture has been described as "organoids," although the actual definition of this term has been controversial since its introduction in the late 1900s [2]. For the purpose of this chapter, organoids will be defined as 3D culture models derived from primary or stem cells that are capable of self-organization and functionality similar to the tissue of origin.

Recently, there has been a resurgence of organoid models in literature according to PubMed citations including the term "organoid." As a matter of fact, since around 2010, there has been an exponential increase in publications involving organoids (Fig. 83.1). The recent increased interest in organoid models can be correlated with the enhanced culture methods and organoid models that can, to a degree, mimic functionality of human organs more precisely in vitro compared to standard two-dimensional (2D) culture and animal models. Similar to any 3D culture method, organoids provide an interactive 3D architecture for the cells, similar to an in vivo environment. Depending on the model, the extracellular matrix (ECM) that establishes the 3D architecture within the organoid can be self-secreted, exogenous, or a combination. Cellular behavior depends on these interactions that are generally lacking in 2D culture. 2D culture often shows altered cell behavior of monolayer culture on plastic [3,4]. Moreover, it is widely known that animal models, while generally beneficial in the clinical process, have proven to lack translational power for efficacy, safety, and toxicity in humans [5]. Organoids, on the other hand, have already shown to have excellent translational capabilities with drug analysis [6,7]. In the following sections, some of the current major organ models will be highlighted along with their cell sources and the current and prospective applications of these models.

Cell sources

Typically, organoids are derived from either primary adult cells or pluripotent and adult stem cells (aSCs). Improved isolation and culture techniques in the past decade have aided in propelling organoid research forward and developing models for various organs including heart [8], liver [9], lung [10], gut [11], retina [12], and pancreas [13]. Still, regardless of the improvements, these two major cell sources both have advantages and disadvantages regarding organoid culture.

First, primary adult cells are directly obtained from human tissue and are not immortalized. These cells are believed to have the greatest translational capability simply because they are unadulterated and are obtained directly from the source. Comparison studies to cell lines have shown primary cells to be superior in reflecting cell behavior regarding cell biomarkers, cytokine production and response, metabolism, and phenotypic characteristics [6,14–17]. For instance, a comparison between primary bronchial epithelial cells and common bronchial epithelial cell lines indicated major differences between differentiation potential, tight junction formation, and mucus production [18]. The utilization of primary cells in organoids

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00085-X

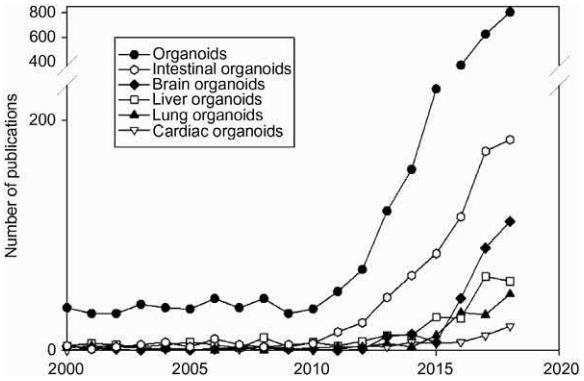

FIGURE 83.1 Number of articles published to PubMed including the organoid search term.

significantly enhances their translational capabilities regarding responses to drugs, infection, toxicity, and disease.

The major limitation of this cell source is its limited supply and expansion capabilities. Primary cells typically have slow growth and lose significant characteristics, viability, and proliferation after only a few passages. Various immortalization techniques have been investigated using transduction and oncogenes, but this genotypical alteration can lead to unwanted phenotypical change with differentiation and cellular function [6,19]. One methodology that has been investigated to solve this issue is the use of a Rho Kinase (ROCK) inhibitor, such as Y-27632, to prolong their expansion capacity [20,21]. For example, Gentzsch et al. demonstrated that bronchial epithelial cells cultured on a fibroblast feeder layer with Y-27632 were able to exponentially grow through 25 population doublings without significantly affecting functional characteristics [21]. While ROCK inhibitors have not shown to significantly alter phenotypical expression of cells, its impact has not fully been investigated for all cell types and may be causing undesirable changes. Another possible solution to the viability and prolonged functionality of primary cells has been organoids themselves. Deegan et al. demonstrated increased viability of hepatic cells in vitro in organoids when they typically cannot be maintained past 7 days on plastic [22]. Despite these improvements, the availability of primary cells significantly hinders their desired phenotypical properties.

The other major cell source for forming organoids has been the variety of stem cells available: aSCs, embryonic stem cells (ESCs), and induced pluripotent stem cells (iPSCs). Utilizing environmental and growth factors, the stem cells can be differentiated into the cells of interest for the specific organoid model. aSCs, or progenitor cells, are commonly used in a wide range of organoid models but are organ-restrictive. The advantage of aSCs is the rather simple protocol required for terminal differentiation into somatic cells. Unlike aSCs, ESCs are pluripotent stem cells (PSCs) that are isolated from the inner cell mass of blastocyst [23]. Their pluripotency allows them to differentiate into cells derived from all three major germ layers allowing for application in any organoid model. This property allows PSC-derived organoids to be excellent in vitro models for developmental biology and morphogenesis [24,25]. One of the major disadvantages that has been associated with ESCs is the ethical concern of their derivation from human embryos. As a result, iPSCs were developed through the reprogramming of adult somatic cells through transfection with ESC-associated genes: Oct3/4, Sox2, c-Myc, and Klf4 [26]. This induced pluripotency results in embryonic-like pluripotency providing comparable properties and applications to ESCs [27,28].

All of these stem cells have shown some capability to self-organize into organoid structures in vitro during their differentiation process and have been a defining feature of stem cell–derived organoids [24,29–31]. Unlike primary cells, the major advantage of stem cells is the potentially infinite expansion capabilities of the cells in vitro [32,33]. With the advancements in media and growth factors even aSCs have shown to have improved expansion. Furthermore, even though there is a limited supply of aSCs and ESCs, the advancements with iPSC development provide the opportunity for a limitless supply of cells for organoid fabrication [34]. Nevertheless, even though stem cell populations can differentiate into a myriad of cell types, the time and cost associated with differentiation is a setback. Another issue is ensuring complete differentiation and phenotypical expression matching the desired organ's cells, as this has not been fully quantified and confirmed for several differentiation protocols [35]. If the differentiation is not complete, the responses of these models could be affected. Overall, the availability of cells along with the desired application has typically dictated the cell type for each organoid model.

Types of organoid models

There have been a range of methodologies to produce varying structural organoids in vitro. For the purpose of this chapter, two main organoid models, or a combination of these models, will be reviewed: spheroidal models and ECM layered models. Spheroidal models, commonly known as "spheroids," are multicellular aggregates of cells that form a spheroidal shape due to some external stimuli [36]. While no exogenous ECM or 3D architecture is provided, this model allows for excellent cell–cell interactions and interactions with cell-secreted ECM. Moreover, spheroids have shown to exhibit chemical and cellular gradients similarly seen in vivo regarding waste, pH, carbon dioxide, oxygen, and drugs [37–39]. The first methodology developed to fabricate spheroids was the hanging drop method that utilizes the gravity within a

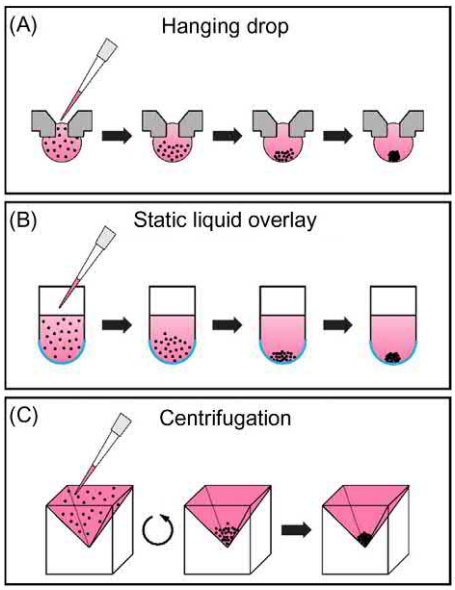

FIGURE 83.2 Spheroidal organoid fabrication methodologies. The three main methods to fabricate spheroids are by (A) the hanging drop method, (B) static liquid overlay with nonadherent surfaces, and (C) centrifugation in microwells.

hanging droplet of media (Fig. 83.2A) [40]. Beyond this method, other protocols have been developed to fabricate spheroids using centrifugation and the static liquid overlay technique (Fig. 83.2B and C) [36,41]. The multiple techniques allow for either mass or individualized production of spheroids. Extensions of this spheroidal model are the budding and branching models that can occur with stem cell and duct-like organoids. These appendages can be attributed to the self-organization of the cells representing the morphogenesis of the organ, forming structures, and ducts related to the organ of interest [42–44]. The second major organoid model is culturing cells or tissue fragments within or on a 3D architecture, typically a hydrogel, that is architecturally and compositionally similar to the in vivo environment [45,46]. The advantage of this added ECM component is the enhanced cell–environmental interaction as well as the cell–cell interactions in the previous models. In addition, it is typical to encapsulate spheroids within the hydrogel matrix to support organoid functionality and morphogenesis [8,47–49]. Thus it is common to see combinational organoid models that utilize any amalgamation of spheroids, ECM scaffolds, and tissue fragments. Finally, groups have utilized hydrogels and scaffolds to develop layered organoid systems to represent organs whose primary function involves interaction with the external environment such as the lung, gastrointestinal (GI) tract, and skin. To fabricate a representative model in these cases, Transwell culture systems have been widely utilized to allow for a multilayer system involving an apical epithelium and a basal stroma [10,50,51]. The major advantage of this layered system is the ability to remove the apical media for an air–liquid interface (ALI) that has shown to be crucial in epithelial cell differentiation and maturation [52–54]. Since most epithelial cells are continuously engaging with air in vivo, ALI culturing is the primary method to aid in recapitulating this physiological environment. In addition, this design allows for supplementary analyses that are otherwise unfeasible or insignificant in other designs. A common measurement of layered systems is the transepithelial electrical resistance to quantify the integrity and permeability of the epithelial or endothelial barrier. This measurement requires an apical and basal compartment to measure the resistance and voltage difference. Other experimental analyses for aerosolized and particulate scenarios are similarly not physiologically relevant in submerged systems and are severely altered in the medium regarding characteristics such as size, solubility, charge, and chemical properties [55].

Cardiac organoid

The heart is the first functional organ to develop in the human body and develops from the mesoderm [56]. When fabricating cardiac organoids, the main cell of interest has been the cardiomyocytes although some models have also utilized cardiac fibroblasts and endothelial cells. Cardiomyocytes are the muscle cells of the heart responsible for the contractile function that pumps the heart. Since primary cardiomyocytes are not readily available, the leading method of derivation is differentiation of PSCs. To obtain cardiomyocytes from PSCs, the main methodology has been to first reduce heterogeneity with bone morphogenetic protein (BMP) 4 and activin A followed by inhibition of Wnt signaling to induce cardiogenesis [57]. Precardiac organoids derived from PSCs demonstrated the importance of Bmp/Wnt signaling in the development of the two heart fields [58]. The main issue with differentiation is complete maturation that is required for drug cytotoxicity, toxicity, regeneration, and apoptosis sensitivity [59]. In addition, there are several subcategories of cardiomyocytes including ventricular cells, purkinje cells, and atrioventricular cells that could affect analysis [60].

Most of the cardiac organoids have been fabricated as spheroidal organoids [8,61–64]. The primary characterization of these cardiac organoids has been their capacity to "beat" similar to the organ. Devarasetty et al. fabricated spheroids from iPSC-derived cardiomyocytes using the static liquid overlay technique in nonadherent 96-well plates and were able to image and quantify this beating behavior [8]. In order to track specific organoids, they were encased within fibrin–gelatin hydrogel. The system was verified by quantifying the attenuation and stimulation

of cardiac beating through toxin and drug exposure. Another spheroidal model combined cardiomyocytes, cardiac fibroblasts, and endothelial cells for cardiac fibrosis modeling [64]. Besides the spheroidal model, variations of a microtissue organoid model have been developed by combining the cells with ECM [65–69]. A cardiac injury model demonstrated the innate regenerative capabilities of the cardiomyocytes after acute injury [68]. Another ECM-based model was able to deconstruct the pacemaker functions of the cardiomyocytes through imaging modalities [65]. Similar to the spheroidal model, the beating capacity of the cardiomyocytes can be observed but with the additional component of external stimulus in the ECM model. Each of these models has implications in the effects of external stimuli, such as drugs or toxins, on the viability and functionality of cardiomyocytes.

Liver organoid

The liver forms from the endoderm germ layer, and its primary functions of interest for organoid modeling are its synthesis and breakdown of molecules along with its metabolism of drugs [70]. Similar to cardiac organoids, the liver organoids have one primary cell of interest, the hepatocyte, with other secondary cells including Kupffer cells, hepatic stellate cells, and hepatic endothelial cells. Due to the improved viability of the usually fickle primary cells in organoids, it is common for both primary and PSCs to be utilized [71]. To differentiate PSCs into hepatocyte-like cells, one of the most efficient methodologies follows a strict timetable of activin A treatment, followed by BMP 4 and basic fibroblast growth factor (FGF) 2, then hepatocyte growth factor, and finally oncostatin M for mature hepatocytes [72].

Takebe et al. created liver bud organoids from iPSC-derived hepatic cells combined with human umbilical vein endothelial cells and human mesenchymal stem cells within a Matrigel hydrogel to model early organogenesis [73]. The self-organized buds showed gene expression similar to in vivo liver buds and were able to perform liver-specific functions and form functional vasculature upon transplantation into a mouse model. The analysis even showed metabolites specific to humans in the blood. Another spherical liver organoid system was capable of recapitulating glucose metabolism in normal and stressed conditions using hepatocytes [74]. The data collected illustrated more realistic sensitivity to the hormonal influences of insulin and glucagon that would be seen in vivo. For instance, high glucose stimulation resulted in lipid accumulation and formation of reactive oxygen species that has yet to be observed in 2D culture. Finally, one of the major interests of liver organoids has been their improved hepatotoxicity response to stimuli. A spheroidal model of primary hepatocytes, hepatic stellate cells, and Kupffer cells generated appropriate responses to common environmental toxins such as lead and mercury [62]. The utility of liver organoids in research is substantial as the organ processes most of the substances that enter the body.

Brain organoid

The brain is the major organ that develops from the ectoderm and has been modeled in a variety of organoids ranging from blood–brain barrier (BBB) models to cerebral cortex models. The BBB models have gained the most attraction in order to understand the regulation of this barrier and possible methods to bypass it for treating neurological diseases. Depending on the organoid model desired, there are six cells of interest in the brain: neurons, oligodendrocytes, microglia, astrocytes, pericytes, and brain endothelial cells [75]. It is typical of these organoids to either be primarily composed of PSCs or partly composed of PSCs. For instance, it is typical to differentiate neurons from PSCs using a variety of protocols for specific types of neurons such as cortical [76,77] or midbrain [78]. Similarly, differentiation protocols have been established for oligodendrocytes [79], microglia [80], astrocytes [81], and BBB endothelial cells [82]. Even certain brain regions can be generated through endogenous delivery of factors such as a functional adenohypophysis in 3D culture [83].

One of the first organoid models developed was capable of forming multiple regions of the brain from embryoid bodies (EBs) derived from neuroectoderm [84]. The model was especially significant as it did not use any growth factors to drive differentiation, but instead embedded the EBs into a Matrigel hydrogel that allowed for outgrowth. The final organoid contained markers for the following brain regions: forebrain, hindbrain, dorsal cortex, prefrontal cortex, hippocampus, and choroid plexus. This cerebral organoid provides an excellent model to study the neurodevelopmental processes involved between the neuroectoderm and cerebrum and possible mechanisms of neurological disease. On the other hand, one of the most complete organoid models developed has been a spheroidal model that contains all six main cell types of the brain (Fig. 83.3) [85]. This model utilizes the hanging drop method to form a spheroidal cerebral cortex encased in brain microvascular endothelial cells and pericytes to create a functional BBB. The advantage of this model is the interaction of all major cell types of the brain along with a highly functional BBB that is not reproducible in monoculture of brain endothelial cells. Recently, a similar BBB organoid model was established utilizing endothelial cells, pericytes, and astrocytes [86]. This model focuses specifically on using confocal fluorescence microscopy and mass spectrometry imaging to generate accurate,

Highly efficient neural conversion of human ES and iPS cells by dual inhibition of SMAD signaling. Nat Biotechnol 2009;27(3):275, under CC BY licensing.*

scalable quantification of drug transport. Altogether these models provide a range of brain organoids that can be effective tools to elucidate developmental pathways and biological processes in the brain crucial for treatments.

Lung organoid

The lung and its associated airways originate from the endoderm and similar to the brain can be separated into subcategories: airway and alveolus models [87]. For the airway models the primary cell of interest is the bronchial epithelial cell that is capable of differentiated into Clara, goblet, and ciliated cells. Specialized media that is widely commercially available promotes this differentiation at ALI. The airway models are principally utilized for modeling related pathophysiologies with the cilia, mucus production, and hydration of the airways. For the alveolus models the primary cell of interest is the type I pneumocytes that cover more than 90% of the surface and facilitate the main function of gas exchange. Even though primary cells are typically used in most organoid models, PSC-derived airway epithelium can be obtained by inhibition of notch signaling [88]. Similarly, ESC-derived endoderm has been differentiated into a distal lung phenotype organoid using inhibition of the Hedgehog pathway [89]. There also exists the resident basal progenitor cells that are the stem cells of the airways and therefore have an application in airway organoids [90,91].

Rock et al. developed one of the first tracheospheroid models from isolated basal cells from the trachea [91]. This model was rather incomplete in differentiation as it lacked markers for mature Clara and goblet cells. Since then both tracheospheroid and bronchospheroid models have been optimized to discern the signaling cues for differentiation into the functional cells of the airway epithelium [92–94]. In addition, this has led to the establishment of the alveolospheres that are composed of type II pneumocytes [95]. This model demonstrated the stem cell capability of type II pneumocytes to self-regenerate and differentiate into type I pneumocytes. A more robust lung spheroidal model was developed through the differentiation of ESCs and iPSCs to create organoids with distinct epithelial and mesenchymal compartments [27]. The model had similar transcriptional profiles to human fetal lung suggesting translational capabilities to study lung development and disease. Another model generated lung bud organoids within a Matrigel hydrogel that developed characteristic branching airways and alveolar structures [96]. As mentioned previously, there has been considerable progress in developing layered organoid systems to provide an ALI structure similar to in vivo. Recently, a coculture organoid model of bronchial epithelial cells and lung fibroblasts was established to recapitulate airway remodeling [10]. The epithelial and mesenchymal cells were able to directly cooperate, and their combined interaction with exogenous transforming growth factor (TGF) β1 was analyzed histologically and transcriptionally. A tri-culture layered organoid model of bronchial epithelial cells, lung fibroblasts, and lung vascular endothelial cells was developed allowing for polarization of the epithelial layer and the three distinct layers of the airway: epithelial, mesenchymal, and endothelial [7]. These additional layered models provide the opportunity to examine the entry of aerosolized contaminants and toxins across the airway barrier compared to standard media spiking.

Gastrointestinal tract organoid

The GI tract develops in an anterior–posterior pattern from the endoderm into three sections: foregut, midgut, and hindgut [97]. From these three sections the entire GI tract is formed from the esophagus to the colon to the rectum. The three main specialized cells of the gut are the enteroendocrine cells that are responsible for secretion of GI hormones, the enterocytes that are primarily responsible for nutrient absorption, and the Paneth cells that secrete antimicrobial peptides. The cecum and the small intestine section of the GI tract have been of primary interest since they are the sites of the microbiome and nutrient absorption. The primary stem cells of the intestinal epithelium are the Lgr5 stem cells located at the bottom of the intestinal crypts [98]. Since the identification of these cells and their differentiation, they have been the primary stem cell source for intestinal organoids. For PSCs a combination of Wnt and FGF signaling has been known to differentiate the stem cells into midgut and hindgut fates [99].

Sato et al. fabricated one of the most complete intestinal organoids using Lgr5 stem cells in a Matrigel culture system [100]. The resulting self-organized organoid

contained all of the major cells of the gut, including enterocytes, enteroendocrine cells, Paneth cells, and goblet cells. When cultured for longer time periods, the organoid was capable of forming a mesenchymal layer with smooth muscle cells and fibroblasts. A significant issue that was noticed in this model though was the lack of a gradient for BMP signaling that should be apparent. Since then, Gjorevski et al. have optimized ECM matrices for the differentiation of stem cells into intestinal organoids in vitro without excessive exogenous factors [101]. Another gastric model was developed through temporal signaling of Wnt, BMP, FGF, retinoic acid, and epidermal growth factor [25]. The novel organoid model developed gastric glands and was capable of modeling *Helicobacter pylori* infection. A nutrient absorption small intestine organoid has also been fabricated using intestinal biopsies to create a layered organoid for apical and basal separation [102]. The microfluidic design showed epithelium with villi-like projections and enterocytes for nutrient absorption. Enzymes necessary for nutrient digestion were collected in the apical layer, further cementing the design as an excellent model for physiological digestion and absorption of nutrients. Another small intestinal organoid derived from mice expressed the presence of several important nutrient transporters and receptors for nutrient sensing, secretion, and absorption (Fig. 83.4) [103]. Other sections of the GI tract have similarly been modeled through organoid fabrication [104–106]. Each of these models is promising for mimicking not only normal physiological responses of the gut but also pathophysiological responses with the introduction of foreign bacteria.

Other organoid models

With the resurgence of organoids, there has been an expansion in the types of organs modeled with organoids beyond the major organoids listed previously. For example, pancreatic organoid cultures have been isolated from adult human tissue explants with endocrine differentiation potential [107]. The long-term expansion and endocrine functionality of the organoids have serious implications in beta cell replacement therapy. Takasato et al. derived kidney organoids from human iPSCs that were capable of nephrogenesis, forming distinct nephrons and ductal networks [31]. Recently, a 3D testicular organoid model was developed composed of spermatogonial stem cells, Sertoli cells, Leydig cells, and peritubular cells that was capable of hormone production with corresponding cell-specific gene expression [108]. The model was utilized to quantify the gonadotoxicity of common chemotherapy drugs and has since been used as a tool to characterize the effects of the Zika virus pathogenesis [109]. The testes organoid provides a more translational model for the human reproductive system that is not reflective in any animal model. Even less prominent organs, such as the retina, have an organoid model in development. A retinal organoid derived from ESCs demonstrated a species-specific difference in the optic cup between mouse and human [12]. Other organoid models include fallopian tubes [110], prostate [111], hair follicles [112], thyroid [113], tongue [114], skin [115], and thymus [116]. In the next decade, it is plausible that most organs will have developed some in vitro organoid model.

Applications

Tumor and disease models

A major limitation of cancer research has been the ability to accurately model tumor progression and phenotypes in vitro. Similar to previous statements, 2D culture fails to provide not only the 3D environment experienced in vivo but also the stiffness and surface topography that are crucial in cancer phenotypes [117]. While considered by many to be its own subcategory of organoids, tumor organoids can be fabricated from the isolated cells of cancerous tumors for various cancer types including prostate, colon, stomach, pancreas, and lung [105,118–121]. Pancreatic cancer organoids derived from human and murine models were shown to more adequately reflect the in vivo phenotype and cancer progression through proteomic and transcriptomic analyses [119]. Histological analysis of another pancreatic cancer organoid model displayed similar morphological features and differentiation markers to the tumor of origin [122]. Another major issue with current cancer research is the lack of the hypoxia experienced by tumors in vivo [123]. A glioblastoma organoid model was able to demonstrate this hypoxia condition

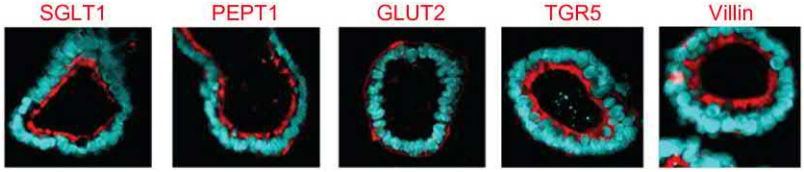

FIGURE 83.4 Small intestine organoid expressing key nutrient transporters (red), villin (red) expressed in microvilli, and the bile acid receptor TGR5 (red). Nuclei (blue) of cells were stained with DAPI. *Reproduced from Roberts DJ. Molecular mechanisms of development of the gastrointestinal tract. Dev Dyn 2000;219(2):109–20, under CC BY licensing.*

[124]. A hypoxic gradient was observed across the organoid with a characteristic hypoxic core. This same model demonstrated the cell heterogeneity that is observed with most cancers that are not recapitulated in vitro with other current methods. These improved tumor models could play a key role in the understanding of specific tumor progression and its changing behavior through chemotherapy and radiation therapy.

Beyond the development of tumor organoid models, other disease-specific organoid models have been investigated to aid in elucidating mechanisms specific to human disease. There are currently significant gaps in disease modeling regarding 2D culture and animal models due to the vast differences in animal biology and cell culture. Moreover, the simplicity of 2D culture and complexity of animal models create a difficult environment to collect quantifiable data about the diseases. Already, a variety of organoid models have been fabricated in order to recapitulate hereditary [84,125–133], acquired [93,96,134–136], and infectious disease [25,96,137–140]. Intestinal and lung organoids alone have been manufactured to model all three main types of disease. For instance, an intestinal model developed by Schwank et al. derived from cystic fibrosis cells was able to model the diseased phenotype using a forskolin-induced swelling protocol [141]. The organoid model was utilized to verify proof-of-concept gene correction with the novel CRISPR/Cas9 genome editing system. Likewise, nasospheroids have been fabricated with cells from a nasal biopsy of cystic fibrosis patients for a quantifiable robust model for cystic fibrosis regulator membrane protein activity [142]. Another lung organoid model derived from primary cells exhibited a fibrotic phenotype comparable to pulmonary fibrotic diseases after treatment with the stimulus TGF β1 [134]. A major breakthrough occurred with the most recent epidemical Zika virus using brain organoids. Cortical neurorganoids provided the first quantifiable evidence of the link between the virus and microcephaly with increased cell death, reduced proliferation, and reduced volume in virus-infected organoids [139,143]. Fabricating diseased organoids, whether hereditary, acquired, or infectious, could allow for improved molecular understanding resulting in improved treatment protocols.

Drug analysis

One of the most promising translational applications of organoids has been their capabilities for drug analysis. As mentioned earlier, 2D culture and animal models have proven to be inadequate in multiple occasions to recapitulate human physiology for drug testing. With drug development, 2D culture drug diffusion kinetics are not translational for human models, while animals' metabolisms vary significantly from humans [5,144]. Other unnatural characteristics of 2D culture include biochemical composition, culture-induced mutations, cell characterization, and surface tension [144,145]. These poor characteristics have played a role in the decrease in the development of drugs that has also been associated with a significant increase in developmental costs [146]. In multiple occasions, 3D culture alone has shown to be superior to standard 2D culture [147–149]. Organoid models, including tumor models, can provide a secondary or replacement model to determine if drugs have the efficacy and safety to reach clinical trials where most of the cost is incurred.

The primary organoid model for general drug analysis has been liver organoids due to the drug metabolic properties of the liver [136,150–152]. One study developed 3D liver microtissue organoids using primary hepatocytes and nonparenchymal liver cells for inflammation and drug toxicity testing in a 96-well plate format [150]. The liver model was able to recapitulate the hepatotoxicity that only occurs due to the interaction of inflammatory stimuli and the drug trovafloxacin. In comparison, 2D culture of hepatocytes did not illicit the same response. In addition, there have been disease- and cancer-specific studies, to quantify the direct interaction of drugs with the target organ [153–157]. In a cystic fibrosis rectal organoid model, physiological responses and restoration were observed with appropriate drug treatment [158]. Comparable studies have been completed with cystic fibrosis lung and intestinal organoids [159,160]. Some researchers have even investigated establishing organoids with patient-derived cells in order to develop personalized medicine (Fig. 83.5) [122,141,161–164]. In vitro expansion and analysis of patient-derived organoids can reveal patient-specific mutations and phenotypes allowing for more tailored treatments. As such, Mazzocchi et al.

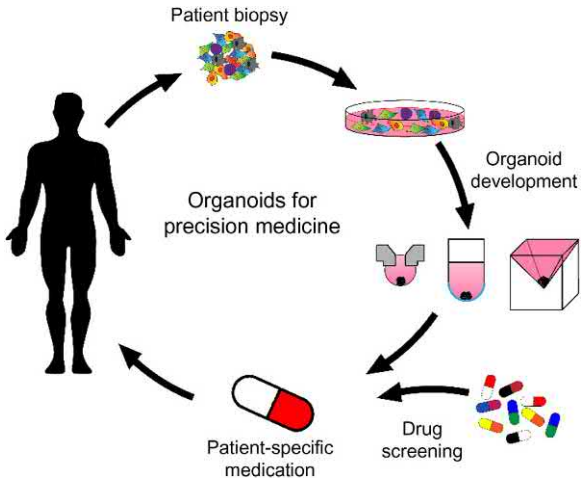

FIGURE 83.5 Personalized medicine concept utilizing patient biopsies to fabricate organoids to optimize patient-specific medication.

successfully microengineered mesothelioma tumor organoids from human patient tumor biospecimens [161]. This biofabricated model was able to demonstrate both specific tumor organoid drug responses along with biomarker testing for experimental drugs. Similarly, the same group demonstrated that patient-derived lung adenocarcinoma cells from pleural effusion aspirate behaved differently in tumor spheroidal organoids compared against 2D culture [120]. Chemotherapy drug resistance seen in the tumor organoid model was comparable to the donor's phenotype, while 2D culture of the same cells was susceptible to the same therapy. The 2D culture of the tumor-derived cells also lost their ability for tissue-like reorganization when grown on plastic indicating obvious phenotypical changes.

Organ-on-a-chip

One of the most common applications of organoid culture models in research has been its integration into a microfluidic device, known as an organ-on-a-chip (OOC), to simulate physiological fluid flow for exchange of nutrients and molecules. This supplementary component to the design strengthens the previous aforementioned applications of tumor and disease modeling and drug analysis. For example, tumor organoids integrated into microfluidic devices can simulate the metastasis and angiogenesis potential of tumors [165]. Other more specific organoid models, such as lung and GI tract, specifically benefit from the flow and mechanical capabilities of OOC platforms. The lungs are constantly interacting with the external environment with air flow that can contain pathogens, drugs, toxins, and other particulates. Varying levels of lung OOC designs have been fabricated for specific purposes that require the air interface and flow in the microfluidic design [166–168]. Huh et al. were able to establish a lung-on-a-chip that could simulate mucus plug ruptures and the associated cellular damage that can occur due to poor mucosal clearance like with cystic fibrosis [169]. Similarly, for the GI tract, Ramadan et al. developed a human GI tract OOC that allowed for flow of nutrients across its apical layer [170].

As OOC designs have cemented themselves in research, groups have integrated OOC designs together to create multiorganoid devices [7,171–174]. Multiorganoid integration further increases the significance of OOC designs, as tissues and organs are not isolated within the body; they interact with each other. Xiao et al. designed a five-organoid chip to recapitulate the female reproductive tract and its interaction with the liver [173]. The system successfully underwent a complete menstrual cycle with corresponding hormonal fluctuations and follicular maturation and differentiation seen in vivo. Moreover, there were significant phenotypical changes in the organoids in this multiorganoid system compared to static culture. These interactions between organoids are crucial in normal organ function, disease modeling, and toxicity analyses. For instance, multiple organoid designs provide a more complete system for tumor metastasis. A lung cancer metastasis multiorganoid chip was designed to investigate lung cancer metastasis to brain, bone, and liver [175]. The chip design successfully showed the transitional properties of the cancer cells and their invasive capacities to the organs. Finally, multiple drugs have been recalled or terminated due to secondary toxic effects on nontarget organs. Skardal et al. were able to demonstrate this characteristic in their three-tissue OOC platform of liver, heart, and lung (Fig. 83.6) [7]. Utilizing this model, they were able to quantify the secondary cardiotoxicity that is associated with bleomycin treatment through lung inflammation. This cardiotoxicity was not present in the isolated cardiac OOC design, thus requiring the interaction between the systems. The final aspiration of these microfluidic designs is to integrate enough OOC designs into one system, called body-on-a-chip, that can essentially mimic the entire physiological and metabolic functions and responses of the human body.

Developmental biology

An additional application of organoid models is specific to the stem cell–derived organoids and their potential in modeling human developmental biology and morphogenesis. Prior to these models, there was no human-derived model to adequately study human development except for

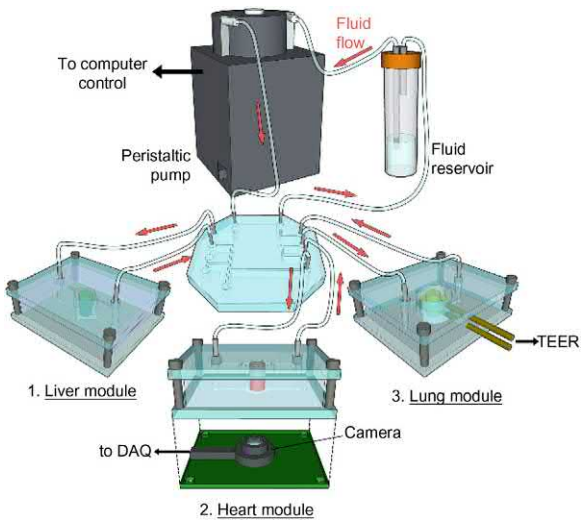

FIGURE 83.6 Multiorganoid microfluidic setup containing a liver organoid, heart organoid, and lung organoid connected in series with a peristaltic pump. *Reproduced from Hogan BL, et al. Repair and regeneration of the respiratory system: complexity, plasticity, and mechanisms of lung stem cell function. Cell Stem Cell 2014;15(2):123–38, under CC BY licensing.*

the limited access and limited progression of human embryos. There have been some developmental questions that have been impossible to answer until now due to ethical limitations [176]. With the development of organoid models, they have shown to recapitulate in vivo developmental stages in real time allowing analysis and quantification. This real-time progression of development has already been seen with varying levels of organoid models and has elucidated key signaling pathways.

McCracken et al. demonstrated the importance of Wnt/β-catenin signaling through the fabrication of gastric organoids derived from ESCs and iPSCs [177]. During the differentiation, continued activation of Wnt signaling was crucial in the formation of fundic organoids with stomach acid-producing cells capable of secreting digestive acids and enzymes. Likewise, sustained FGF signaling was critical for the nephrogenesis process in iPSC-derived kidney organoids [31]. Specific patterning of signaling played a role in the formation of segmented nephrons with distinct endothelial layers and renal interstitium. Even more intricate and specific organoids have been developed such as hair follicle organoids from progenitor cells [112]. While this model has been less investigated, it has shown the importance of plasticity of keratinocytes and inducibility of dermal cells in the formation of hair follicles. These are just a few examples of studies that have elucidated key developmental stages and signaling pathways. Other organoid models of lung [27,96], liver [178], brain [84], and pancreas [179] have shown similar potential. Through the differentiation of stem cells within the organoids, the actual signaling network that dictates development becomes apparent. Similar to drug analysis, organoid cultures can be developed with animal-derived cells to compare and contrast the developmental stages between humans and other animals. These studies are transforming the methodologies we employ to study human developmental biology and can have remarkable potential in this field and congenital diseases.

Conclusion

As detailed earlier, a variety of organoid culture methods are being investigated, and each shows promise in several translational areas. The types of organs modeled along with their complexity continue to grow. While primary cell sources provide the most characteristic cellular function, the continuing derivation and understanding of stem cells provide a more limitless supply of cells for scalable fabrication. Despite this rapid progress, there are limitations that have yet to be fully addressed with most models such as integration of immune cells and blood vessels and reproducibility of models. As immune cells circulate throughout the entire body, their incorporation is crucial in mimicking organ functionality to thoroughly model the organ's reaction to any type of stimuli, especially infection and inflammation. One of the most significant hurdles is mimicking the complexity and interaction within and between the organs as multiorgan models have illustrated the importance of their interaction. Still, the applications of these organoids are vast and highly impactful ranging from cancer modeling to infection and disease modeling to drug analysis. With the use of stem cells, further understanding of development biology, stem cell biology, and tissue regeneration can also be investigated. Patient-derived cells provide a more unique application, specifically for cancer and disease, with personalized medicine to determine the optimal treatment for each specific patient. The second major goal of organoid models appears to be a multiorganoid system known as the body-on-a-chip. While the complexity of this system is a major challenge, this platform could not only beneficially disrupt the drug development process, it can provide a more quantifiable method to study the interactions between major organs. As these models continue to advance, they are establishing themselves as easy-to-use products that have exceptional research and translational potential. Similar to general 3D cell culture, organoids are changing the current perception of cell culture and can dramatically change the development of science and medicine.

Introduction

The US Food and Drug Administration (FDA) is responsible for regulatory oversight for a wide range of products, including food, medical products, products for veterinary use, and tobacco products. Within the FDA, the Center for Drug Evaluation and Research (CDER), the Center for Devices and Radiological Health (CDRH), and the Center for Biologics Evaluation and Research (CBER) are responsible for overseeing the regulation of human medical products which are drugs, devices, and biologics. The Office of Tissues and Advanced Therapies (OTAT) in CBER regulates a wide range of products, including gene therapies, cell-based products, tumor vaccines, human tissues for transplantation, xenotransplantation products, blood- and plasma-derived products, certain combination products, and certain medical devices. This chapter discusses issues relevant to cell-based products regulated by OTAT.

The 21st Century Cures Act, signed into law on December 13, 2016, outlines provisions to help accelerate medical product development [1]. Title III Section 3033 specifically applies to regenerative medicine therapies (RMTs) that can be designated as regenerative medicine advanced therapy (RMAT) if they meet certain criteria. RMAT designation offers a new expedited program to facilitate the development and review of certain RMTs intended to address an unmet need in patients with serious conditions [2]. Products that may be eligible for RMAT designation include cell therapies, tissue-engineered products, human cell and tissue-based products, and combination products using such therapies except those regulated under Section 361 of the Public Health Service (PHS) Act (42 U.S.C. 264) and Title 21 of the Code of Federal Regulations (CFR) Part 1271 (21 CFR Part 1271). Also included are certain gene therapy products, including genetically modified cells, which lead to a sustained effect on cells or tissues, and xenotransplantation products [2].

Section 3051 establishes an expedited review pathway for devices [3]. Section 3036 outlines provisions for FDA to collaborate with other government agencies and stakeholder to develop standards to support innovation for RMT products. These programs will be described in more detail next.

Cellular and gene therapy products are regulated as biologics. Therefore this chapter primarily discusses the investigational new drug application/biologics licensing application (IND/BLA) pathway. However, since biologics can be combined with or delivered by medical devices, some device-related issues will also be covered within these specific contexts.

Regulatory background

To understand the regulatory process, it is helpful to have some background knowledge of the relationship between laws, regulations, and guidance documents. Laws, which are enacted by Congress and signed by the President, provide the legal mandate for FDA's regulatory oversight. In many cases, FDA publishes regulations (rules) to

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00086-1

implement a law's legislative mandates.[1] Rules can be modified by FDA over time to allow for changes in science or technology as long as the revised rule remains responsive to the legislative mandates. As an example, FDA published a revised rule regarding sterility testing for biological products [4]. This new rule provides manufacturers of biological products with greater flexibility and encourages the use of the most appropriate and state of the art test methods.

Unlike laws and regulations, which are both legally enforceable by FDA, guidance documents represent the Agency's current thinking on specific topics and are not legally enforceable. Guidance documents are intended to provide general advice to interested stakeholders and product developers (sponsors) on how to comply with certain laws and regulations. FDA issues guidance documents that provide advice on topics ranging from the regulatory process to the agency's scientific expectations for meeting regulatory requirements for specific product classes. For example, if FDA recognizes a need to provide guidance documents for developers of a specific product type, or for a specific clinical need, FDA may publish guidance documents that explain FDA's thinking on the applications of the regulations to those specific areas.

Over the last decade, FDA has published numerous guidance documents that are relevant to the development of cell-based products. These include guidance documents on cell manufacturing and characterization for cell-therapy products [5], on potency [6], as well as guidance documents that address FDA crosscutting issues, such as evidence of effectiveness [7]. On the public website, FDA updates information regarding newly published guidance documents and the guidance agenda for upcoming years [8]. Investigators may also wish to refer to other resources, such as OTAT Learn, a web-based educational series that provides outreach to OTAT stakeholders on a broad range of topics [9], or the CDRH Device Advice [10] webpage, which provides links to extensive regulatory information including CDRH Learn [11]. References to these and other resources, including draft[2] and final guidance documents, can be found at the end of this chapter.

Overview of development and approval process

The development of a cell-therapy product is an iterative process to establish the manufacturing process, characterize the product, and generate safety and efficacy data from clinical trials (Fig. 84.1) before the product can be approved and made available in the consumer market [12]. Before testing a cell-therapy product in humans the potential toxicity of a product must first be rigorously tested by well-designed in vitro and/or in vivo studies (i.e., preclinical testing). Once early-stage product development is successful, the sponsor submits detailed information regarding the manufacturing process and facility as well as data from preclinical testing and product characterization to seek an agreement from FDA to initiate a clinical investigation in humans (human testing). As illustrated in Fig. 84.1, human testing of investigational drugs is typically conducted in phases [from early, small-scale (Phase 1/2) to late-stage, large-scale studies (Phase 3)]. Each phase is considered a separate clinical trial and, after completion of a phase, the sponsor is required to submit their data to FDA for review, and the data are used to support a sponsor's proposal to continue to the next phase of studies. After the successful completion of clinical trials, a BLA can be submitted for permission to introduce or deliver for introduction, a biologic product into interstate commerce (21 CFR 601.2). After FDA has approved a product for marketing, FDA may require postmarketing studies as postmarketing requirements to gather additional information about the safety, efficacy (if the BLA was approved based on a surrogate or intermediate endpoint via the accelerated approval pathway), or use in a pediatric population. Up-to-date product approval information is provided on the FDA public webpage [13]. In the following subsections, detailed information regarding early-stage development, clinical trials, license application, and postmarketing surveillance are described.

Early-stage development

In order to successfully develop a cell-based product for marketing approval, the development program must address certain key issues: a well-defined product having consistent safety and quality attributes from lot to lot, which may be achieved through a reproducible, well-controlled, adequately scaled manufacturing process and establishment of product's critical quality attributes; preclinical testing incorporating proof-of-concept (POC) and toxicology studies that provide scientific rationale and support the proposed use of the product; clinical evidence of effectiveness; and clinical evidence of an acceptable safety profile weighed against the benefit of the therapy.

1. The Government Printing Office annually publishes all current regulations (rules) in the CFR (in print and electronically). The CFR is divided into 50 titles or subject areas, and Title 21 pertains to food and drugs. Specific parts of CFR are referred to throughout this chapter and the Appendix to this chapter provides a summary of the parts of Title 21 that are most closely related to material in this chapter.

2. Draft guidances are published for comment and are not for implementation until finalized. Stakeholders should contact the relevant product office or division for the most up-to-date agency perspective on an issue discussed in draft guidance.

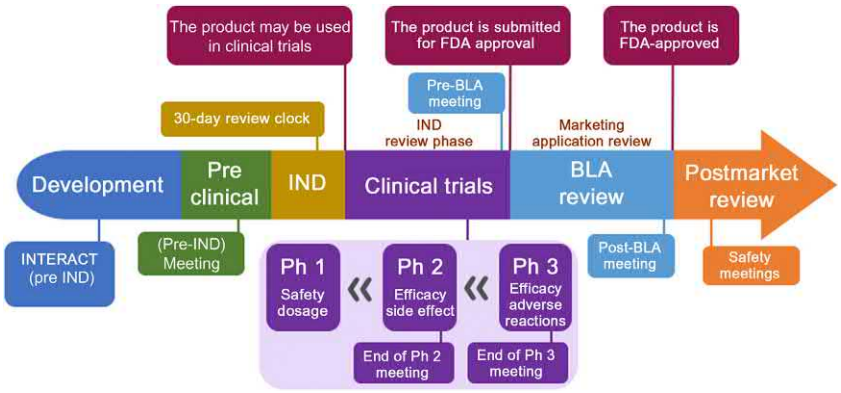

FIGURE 84.1 Interactions with FDA throughout the product lifecycle. Product development is an iterative process, with frequent FDA and sponsor interactions. Ph, Phase; "«" denotes the increase of clinical trial sizes from Phase 1 to Phase 2 to Phase 3.

Consideration of each of these key areas at an early stage may improve the overall efficiency of product development.

Chemistry, manufacturing, and controls

There are several key CMC (chemistry, manufacturing, and controls) issues to consider early in the development of a cell-based product, including sourcing of the biological material used for product manufacture, cell banking strategy, identification of critical cellular product quality attributes, development of a sufficiently robust manufacturing process to support clinical testing under an IND, and whether or not the cellular material is a component of a combination product.

When the cell-based product to be delivered consists of cells not derived from the recipient, it is necessary to perform a donor eligibility determination that involves both screening and testing of the selected donor to adequately and appropriately reduce the risk of transmitting relevant communicable disease agents and diseases (21 CFR Part 1271 Subpart C) [14–21]. In accordance with 21 CFR 1271.155, sponsors may submit to FDA a request for an exemption from or alternative to any of the donor eligibility determination requirements found in 21 CFR 1271 Subpart C [22]. Generally, a separate exemption request must be made at both the IND phase and when filing a BLA. It is important to consider the issue of donor-sourced biological material and donor eligibility requirements early in the development program including the use of human cell banks and cell lines since incomplete or insufficient information could necessitate additional product safety testing.

The strategy for manufacturing a cellular product that is initiated using starting material from a characterized source of cells may, in some cases, involves the establishment of a two-tiered cell bank, the master cell bank (MCB), and the working cell bank, which is derived from the MCB [23]. Early consideration of a cell banking program capable of supporting aspects of both preclinical and clinical development is important. In the event that it is necessary to establish new cell banks during product development, plans should be in place to demonstrate their comparability to the cell banks used previously for product manufacture.

Comprehensive cell characterization is a cornerstone in the development of cell-based products. A multiparametric analytical testing approach designed to assess distinguishing critical quality attributes of a cell-based product will help meet regulatory expectations for demonstration of product identity, purity, and potency. Characterization of the cellular product serves to inform the development of an overall product testing strategy and establishment of appropriate acceptance criteria to ensure product quality. Careful efforts devoted to cellular product characterization during the initial stages of premarket development may aid in the detection of subpopulations of cells in the final product that could present safety concerns requiring the implementation of mitigation strategies such as target cell selection/enrichment or off-target cell depletion to manage any risks posed to recipients.

Early attention to details associated with the design of a robust manufacturing process is recommended. Consideration should be given to the feasibility of reproducibly generating cells that possess the desired critical quality attributes at a scale capable of producing sufficient cell numbers to support overall product development. This includes assessing the quality and accessibility of reagents crucial for the execution of the manufacturing process. It should be noted that unanticipated changes in critical reagents could have a negative impact on product quality.

Pharmacology and toxicology

Prior to initiation of a clinical trial, a sponsor will need to provide adequate data generated from pharmacological and toxicological studies to establish that it is reasonably safe to conduct the proposed clinical investigation. The results

of these studies provide data critical to (1) establish the scientific rationale and biological plausibility of the proposed approach (i.e., demonstration of POC); (2) identify and characterize potential local and systemic toxicities, including the time frame for onset (i.e., acute vs long term), incidence, severity, and transient or chronic nature of the findings; (3) determine a possible dose−response relationship for guiding dosing for the planned clinical trial; (4) support subject eligibility criteria; and (5) identify physiologic parameters to help guide appropriate clinical monitoring [24].

Multiple in vitro and in vivo studies, spanning several iterative prototypes of the product and delivery device, may be necessary to translate a cell-based product from the bench to the initial clinical trial. During this process the incorporation of key features into the design of early discovery-phase animal studies may maximize the relevance and interpretability of collected data and facilitate translation to the clinic. For example, if safety endpoints are incorporated into discovery-phase studies, it may be possible to identify potential safety concerns early in product development, which can then be managed (such as through changes to product design or manufacturing) and investigated further in subsequent preclinical studies. Similarly, archiving relevant biospecimens during preclinical development allows for the opportunity for subsequent analysis if unanticipated adverse events (AEs) arise in later studies, which may help identify the cause of an observed toxicity. This, in turn, may inform the design of appropriate follow-on investigations.

For cell-based products, early investigation into cellular distribution, cell fate, host response, and the rate of resorption/degradation for products that contain a scaffold or matrix may be beneficial. As the target tissue undergoes remodeling, the structural properties, donor and host cell activity (such as migratory activity, proliferation, and phenotypic changes), and the rate of tissue in-growth will likely change. An understanding of these in vivo parameters and their impact early on in product development will help identify appropriate endpoints, outcomes measurements, and study durations for definitive preclinical studies. For example, if the product is designed to provide mechanical support or structure, an assessment of biomechanical properties and function at multiple time points during degradation or remodeling may be particularly important. In some instances, it may not be possible to conduct complete functionality testing of a product prior to implantation, as it may undergo remodeling in vivo with accompanying changes in biomechanical performance. Appropriate characterization of this parameter following implantation would then be an important consideration when designing the POC and safety studies.

Some additional early considerations for preclinical development may include selecting a biologically relevant animal model, maintaining cell survival in vivo, the use of appropriate control groups, and assessment of in vivo safety and activity.

Clinical

Development of novel cell-based products is an iterative process. Therefore it may be prudent for the sponsor to develop a target product profile. This is a "living" document that should be updated periodically as even well-considered investigational plans are likely to need revision as additional data are acquired. Nonetheless, early thought to the tentative design of the clinical studies can provide a framework for the overall development program, including preclinical studies. Preclinical studies usually mimic the clinical situation as closely as possible; therefore coordinating the preclinical and clinical programs may help improve efficiency. For example, if a preclinical animal study uses a specific delivery procedure, and then it is decided that the first-in-human will use a different delivery procedure, additional preclinical studies may be necessary to support the safety of the new clinical procedure. Early phase studies generally have a primary objective of assessing safety. However, primary or secondary objectives usually include bioactivity assessments. Such preliminary activity data can help guide the subsequent development program.

When selecting the study population for the first-in-human study trial, sponsors should consider the target indication, interpretability issues, and the risk of the study procedure. A product that can potentially cause long-term adverse effects is usually felt to have an unacceptable risk when administered to normal healthy volunteers. Therefore first-in-human studies for cell-based products usually enroll a study population of subjects who have a specific disorder. When possible, such studies should be conducted in individuals who can understand and consent to the study procedures and risks (see Section 12B Clinical Research Involving Children).

Selection of the number of subjects that will be enrolled in an early phase study should take into account the characteristics of the study population to include age and comorbid conditions, the cell-based product, and potential long-term effects. Enrolling a relatively small number of subjects avoids exposing a large number of subjects to risk, while allowing for the collection of preliminary evidence of safety.

In the absence of preliminary evidence of safety for a single dose and data regarding the time course for bioactivity of the biologic, repeat dosing may represent an unreasonable risk. Therefore a single-dose regimen is appropriate for most first-in-human trials. In addition, prior to the collection of preliminary safety data for the product, a first-in-human study should avoid concurrent administration of the

product to multiple subjects. Staggered administration to sequential subjects provides an intersubject interval to monitor for acute and subacute AEs. This approach may prevent multiple subjects from experiencing an AE related to the product.

The safety monitoring plan should include assessments that can capture early, intermediate, and delayed AEs that may be expected, based on preclinical and clinical data, as well as on theoretical concerns.

Stopping rules are criteria, usually based on a number or frequency of specific AEs, that if triggered would temporarily halt the study, pending a safety review. Stopping rules should be considered for all studies and may be required for higher risk studies.

US Food and Drug Administration/ sponsor meetings

OTAT holds informal and formal meetings with sponsors prior to and during product development as illustrated in Fig. 84.1. There are various formats for meetings with FDA, including written responses, teleconference, or face-to-face. There are several different types of formal meetings that can occur between OTAT and sponsors. These meetings often represent critical milestones in the product development program, and each is subject to different procedures.

For sponsors developing novel investigational products, using innovative or complex manufacturing technologies, or using cutting-edge testing methods who are at an early stage of product development, CBER offers an informal meeting, Initial Targeted Engagement for Regulatory Advice on CBER products, also known as the INTERACT program [25]. In addition to these early interactions, additional presubmission and submission-related meetings provide sponsors the opportunity to obtain nonbinding feedback from FDA on specific questions prior to submission of an IND or BLA. Such meetings may help sponsors to avoid missteps or delays that may be costly in terms of time and financial resources.

A meeting package that includes targeted, thoughtful, and clearly articulated questions, as well as a detailed summary of information, facilitates a productive meeting. Information about what should be included in meeting packages, meeting timelines, and meeting procedures can be found in FDA guidance documents [26–28], the OTAT Learn webinar series, or by contacting the Division of Regulatory Project Management in OTAT. The Office of Communication, Outreach and Development (OCOD)[3] at CBER also serves as a liaison with CBER components to provide advice and assistance to manufacturers and scientific associations to promote their understanding and compliance with FDA regulations.

Submitting an investigational new drug application

An IND is required (21 CFR 312) prior to clinical testing of a cell-based product that has not been approved by the FDA. A complete IND package consists of all required forms and sections, as specified in 21 CFR 312.23(a) and itemized in the checklist on page 2 of Form FDA 1571. A more detailed description of the key information that should be submitted with the original IND application is provided in the following subsections.

Required US Food and Drug Administration forms

Forms 1571, 1572, and 3674 should be included in an IND submission. These forms can be found on the FDA website, along with more detailed instructions for completing the forms [29,30].

Form FDA 1571 is a formal contract indicating that a sponsor will adhere to IND regulations to include requirements for informed consent, obtain institutional review boards (IRB) review of the IND, and comply with the IND regulations. FDA 1571 also contains basic administrative information regarding the sponsor, investigational drug, and proposed clinical trial [e.g., indications(s), phase of investigation, data monitoring] and includes a checklist of submission components. A signed Form FDA 1571 is required for all original IND submissions. For a sponsor–investigator IND, the sponsor–investigator should be named and must sign the form. For an IND sponsored by a pharmaceutical firm or research organization, the name of the sponsor's authorizing representative should be entered, and that individual must sign the form.

Form FDA 1572, the Statement of Investigator, is an agreement that an investigator will provide certain information to the sponsor and will comply with FDA regulations. This form serves the dual purpose of enabling the sponsor to establish and document the qualification of the investigator and clinical site, and informing the investigator of his/her obligations. Although it is the IND sponsor's responsibility to obtain a signed Form FDA 1572 from each investigator [21CFR 312.53(c)], the FDA does not require that Form FDA 1572 be submitted to the Agency. However, since Form FDA 1572 collects all the information that must be submitted to the FDA as per 312.23(a)(6)(iii)(b), many sponsors choose to submit

3. Consumer Affairs Branch (CBER): ocod@fda.hhs.gov.

Form 1572 along with the curriculum vitae of the investigator(s) [31].

Form FDA 3674, "Certification of Compliance with Requirements of ClinicalTrials.gov Data Bank," ensures compliance with the requirement for registering and reporting results from human clinical trials of human drugs (including biological products) and devices to the clinical trials databank [32].

Investigational new drug application contents

In addition to the forms described above, all IND submissions must include a table of contents, an introductory statement, and a general investigational plan. An Investigator's Brochure (IB) is required when clinical investigators at multiple clinical sites are participating in a protocol conducted under the IND. An IB is not required for single-site, sponsor−investigator-initiated INDs [21 CFR 312.55(a)]. Information to be contained in an IB is described in 21 CFR 312.23(a)(5). A well-organized IND submission includes distinct, stand-alone sections for the clinical protocol, product/CMC information, preclinical pharmacology/toxicology information, and other sections as described below. The electronic common technical document (eCTD) represents the standard format for submitting applications to FDA/CBER [33,34].

Previous human experience/electronic common technical document Module 2.5: clinical overview

The IND should include detailed summaries of any available safety and efficacy data from previous clinical experience with the study agent or related products. The FDA will consider this safety and efficacy data, along with the comparability of the study products, the study populations, and the delivery procedures, when reviewing the IND.

Chemistry, manufacturing, and controls information/electronic common technical document Module 3: quality

The Quality section of the IND contains information about the manufacture of the investigational product, including details about the starting material and reagents used in the manufacturing process to produce the drug substance (DS) and the drug product (DP) [5,35]. The DS is composed of the active pharmaceutical ingredient (e.g., a target cell population identified by specific cell surface markers or a specific cell phenotype) and is intended for further manufacturing to produce DP. The DP represents the final formulated material intended for administration. Final formulated DP is derived from a single or multiple DS and any added excipients used to constitute the final formulated investigational cell-based product. For manufacturing process steps that use materials and reagents of human or animal origin, it is necessary to provide documentation of compliance with 9 CFR 113.53: Requirements for ingredients of animal origin used for the production of biologics. The CMC information should include a description of the safety and quality attribute testing performed on the final product prior to release for the administration to study subjects. The CMC information typically provided in IND includes, but is not limited to

- description of starting material(s), reagents, and excipients, including safety and quality of these materials; if starting material is from an allogeneic donor, information about the eligibility of the donor (i.e., donor screening and testing);
- details of the manufacturing process and manufacturing controls;
- details of in-process testing performed at key stages of the manufacturing process;
- characterization of DS and DP for assessing their safety and quality including specifications which include specific test methods and acceptance criteria;
- data pertaining to the stability of formulated DP in the final container;
- information regarding the intermediate and final product storage containers and optimal storage conditions;
- container labels; and
- procedures for tracking the investigational product at each step throughout the manufacturing process.

Pharmacology and toxicology data/electronic common technical document Module 4: nonclinical

FDA determines whether the pharmacology/toxicology data submitted with the IND provide sufficient evidence that the investigational product is reasonably safe for initial testing in humans [21 CFR 312.23 (a)(8)]. For each preclinical study intended to support the safety and rationale of a proposed clinical trial, a complete study report should be provided that includes (1) a prospectively designed protocol, (2) a detailed description of the study performed (i.e., description of animal model, control and test articles used, dose levels, detailed procedures for test article administration and collection of all study parameters), (3) results for all parameters evaluated (i.e., individual animal data as well as summarized and tabulated results), (4) an analysis and interpretation of the resulting data, and (5) a statement of compliance with good laboratory practice regulations (21 CFR Part 58).

Clinical protocol/electronic common technical document Module 5: clinical

An IND submission should contain a clinical protocol for each planned study. The complexity of the protocols will vary with the phase and size of the planned clinical investigation; generally, some key elements of the study design include the study objectives, proposed study population, dose and regimen, treatment plan, monitoring plan and follow-up, and planned assessments/endpoints and analyses.

Additional information

All other pertinent information may be incorporated under various regional information and literature reference headings within the relevant eCTD module (i.e., Administrative Information, Quality, Nonclinical Study Reports or Clinical Study Reports, delivery device information and data). Additional supporting information could consist of copies of relevant publications, plans for assessing safety and effectiveness in a pediatric population, certificates of analysis obtained from manufacturers/suppliers of nonclinical grade reagents, and copies of meeting minutes from pre-IND interactions. In circumstances when information pertaining to the investigational product has been wholly or partially submitted to the FDA in previous premarket submission(s) and/or master file (MF)(s), a letter of cross-reference authorization may be provided in Module 1 Administrative Information of the IND submission. A letter of cross-reference authorization grants FDA permission to review specific proprietary details contained in the cross-referenced files to support other premarket or marketing applications. The letter of cross-reference authorization is provided by the sponsor/holder of the cross-referenced IND (s) and/or MF(s) and should refer to specific information and sections of the IND and/or MF that are authorized to access for review.

US Food and Drug Administration review of an original investigational new drug application submission

When a sponsor submits an original IND, the FDA reviews the submission within the next 30 calendar days. Unless the FDA imposes a clinical hold, the clinical studies described in the original IND submission may be initiated at the conclusion of the 30-day review period. A clinical hold is an order by the FDA to delay a proposed clinical investigation or to suspend an ongoing study. When FDA review of an IND results in a clinical hold, the sponsor receives a clinical hold letter within 30 days of being notified that the IND is on hold. The clinical hold letter summarizes the deficiencies that caused the clinical hold to be enacted.

The IND regulations outline the general reasons for which an IND can be placed on clinical hold (21 CFR 312.42). A retrospective analysis performed by FDA staff evaluated clinical hold letters issued over a 3-year period. This analysis identified some common reasons for clinical hold of INDs regulated by OTAT including CMC deficiencies (donor eligibility determination, MCB qualification), insufficient information to assess the risks to study subjects, and issues with the proposed study population or procedures (e.g., unacceptable risk associated with performing the investigational procedures in the proposed study population) [36].

Later-stage development topics

Compliance with current good manufacturing practice

Similar to other aspects of product development, the current good manufacturing practice (cGMP) requirements increase over the course of product development. For Phase 1 studies, investigational cell−based products are exempt from the cGMP regulations in 21 CFR Parts 210 and 211, with certain exceptions [37]. However, to ensure product safety, FDA has issued a guidance document regarding cGMP requirements that addresses sterility assurance, quality oversight, and facilities control during Phase 1 studies [37]. cGMP regulations in 21 CFR 211 apply to cell-based products in Phases 2 and 3 clinical studies. Adequate documentation and records management should also be in place for all phases of clinical study.

Because cGMP applies to both the manufacturing process and the facilities, it is important to note that many elements of product manufacturing and characterization and cGMP compliance cannot be separated and should develop concurrently. Examples of cGMP activities that may develop over time as clinical development progresses include process improvements and process validation, as well as analytical methods development and validation. Process controls and acceptance criteria should be further refined prior to Phase 3 based on knowledge of the manufacturing process and critical product attributes related to safety and efficacy. Sponsors can request a meeting with CBER's Office of Compliance and Biologics Quality (OCBQ), specifically with the Division of Manufacturing and Product Quality (DMPQ), to obtain specific advice on facility design, process controls, equipment qualification, and process validation.

Product readiness for Phase 3

To initiate Phase 3 clinical studies that are intended to provide substantial evidence of effectiveness and safety, it

is necessary to have in place a consistent, reproducible, and adequately controlled manufacturing process. Standard operating procedures that direct each stage of the manufacturing process should be finalized prior to Phase 3. Before initiating a Phase 3, pivotal clinical trial, analytical assays for process intermediate(s), and final product evaluation should have been identified, developed, qualified, and implemented. Acceptance criteria for these assays should be established and the range of accepted variation appropriately set to reflect testing results accumulated through prior manufacturing experience. Any changes introduced at this point in product development should be conservative with respect to any overall impact on the manufacturing process and product quality. Representative examples would be the modification of procedures to increase production capacity or instituting a change in the supplier of a key reagent. Final product formulation, storage conditions, as well as shipping and handling procedures should be established prior to initiating Phase 3 clinical testing.

Potency assay

By the time Phase 3 clinical testing is initiated, an assay or matrix of assays developed to measure product potency should be identified, qualified and incorporated into the panel of final product release tests [21 CFR 600.3(s)]. The results from potency testing provide important information that relates directly to manufacturing process consistency and reproducibility, attest to the comparability of products manufactured using starting materials obtained from different donors, is valuable for assessing the impact of changes made to the manufacturing process on final product critical quality attributes, and provides evidence of product stability under established storage and shipping conditions.

The most appropriate assessment of cell-based product potency related to its propensity to elicit a relevant clinical effect will be determined by identifying quality attributes specific to the product and the clinical indication for which it is intended. Quality attributes related to potency may include intrinsic molecular, biochemical, immunologic, phenotypic, physical, and biological properties of the cell-based product. Accordingly, the FDA assesses the suitability of a specific potency assay on a case-by-case basis in consideration of the factors mentioned.

Cell-based products are characterized by dynamic biological properties that present significant challenges to the development of a reliable, quantitative potency assay. As such, development of a potency test for these products is done frequently in a step-wise, incremental approach that allows for its modification as new information about the product characteristics, including mechanism of action, is discovered during the process of clinical development. In conjunction with other lot release tests the potency assay is intended to demonstrate that only those manufactured product lots which meet predefined acceptance criteria are administered to enrolled study subjects throughout the entire life-cycle of product development [6].

It may be the case that a single biological or analytical assay does not provide an adequate measure of product potency, and it could be necessary to develop a matrix of complementary assays that assess different product attributes, each affiliated with product quality, consistency, and stability to demonstrate product potency. The potency assay matrix could include testing for relevant nonbiological attributes such as mechanical and biophysical properties that are important for product function, and the matrix approach does not require all assays to be quantitative.

Pharmacology and toxicology

Preclinical studies to support the safety of the first-in-human clinical study are typically completed prior to submission of the IND. However, additional animal studies may be necessary in certain circumstances later in development. For example, depending on the product type, target population, and any concerns that arose during earlier phases of testing, reproductive and developmental toxicity studies may be needed to support licensure. These studies can usually be conducted concurrently with Phase 3 trials [38]. In other instances, additional nonclinical studies may be necessary prior to initiation of later-phase trials, such as following any significant changes to the dose level(s), dosing regimen, or target population. Similarly, if there is a modification to the manufacturing of the product, the comparability of the later-phase product to the product evaluated in earlier-phase clinical trials may be unclear. In this case, bridging nonclinical studies may be necessary to establish comparability. After clinical development has begun, additional nonclinical studies are sometimes warranted to provide insight into the in vivo pharmacology and mechanism of action of the product. For example, preclinical data may aid in the identification of an appropriate potency assay for Phase 3.

Phase 3 clinical development

By the time the Phase 3 clinical studies are planned, it is important for sponsors to understand some of the key issues that inform the design of Phase 3 trials. Early-phase trials offer an opportunity to optimize study procedures in terms of product delivery, dose regimen, and concomitant treatments and to identify potential safety concerns as well as gather early evidence of activity. Early-phase clinical studies can also provide an

understanding of the appropriate study population, the treatment effect size for the Phase 3 primary endpoint, the time frame for product bioactivity, and the durability of response.

When submitting a Phase 3 protocol, the FDA recommends that sponsors consider submitting a request for a Special Protocol Assessment (SPA) [39]. Concurrence on a protocol under the SPA program is an agreement between the FDA and a sponsor on the design and size of a Phase 3 trial that is intended to provide evidence of effectiveness.

Combination products

A combination product is composed of two or more different types of medical products (e.g., drug−device, device−biologic, drug−biologic, and drug−device−biologic). Under Title 21 of the CFR Part 3.2(e) [21 CFR 3.2(e)], combination product includes

1. a product comprised of two or more regulated components, that is, drug/device, biologic/device, drug/biologic, or drug/device/biologic, which are physically, chemically, or otherwise combined or mixed and produced as a single entity;
2. two or more separate products packaged together in a single package or as a unit and comprised of drug and device products, device and biological products, or biological and DPs;
3. a drug, device, or biological product packaged separately that according to its investigational plan or proposed labeling is intended for use only with an approved individually specified drug, device, or biological product where both are required to achieve the intended use, indication, or effect and whereupon approval of the proposed product the labeling of the approved product would need to be changed, for example, to reflect a change in intended use, dosage form, strength, route of administration, or significant change in dose; or
4. any investigational drug, device, or biological product packaged separately that according to its proposed labeling is for use only with another individually specified investigational drug, device, or biological product where both are required to achieve the intended use, indication, or effect.

In certain instances, a cell-based product may be regulated as a combination product. This includes cellular (biological) components that are physically or chemically combined with a drug and/or device. Cellular components physically or chemically combined with devices are often in the configuration of a "cell-scaffold" construct. In such cases, sponsors will need to develop a testing strategy that assesses the final combination product construct as well as key safety and quality attributes of the individual components brought together to create the combination product [40]. Cell-based products may require administration to a patient by a specific type of delivery device, which may constitute a cross-labeled combination product. In these cases, it is important to demonstrate the compatibility of the cell-based product with the delivery device, that is, delivery of the product using the device does not adversely affect cell-based product quality (e.g., viability, function, delivered dose, etc.). For any combination product, each constituent part retains its regulatory status (as a biologic or device, for example). As a result, the differences in regulatory pathway and requirements for each component can impact aspects of the lifecycle of the combination product, including its preclinical testing, clinical investigation, marketing application, manufacturing and quality control, AE reporting, labeling and advertising, and postapproval modifications.

In general, combination products are assigned to the FDA center that will have primary jurisdiction for its premarket review and regulation. Consistent with Section 503(g) [1] of the FD&C, assignment to a center with primary jurisdiction for premarket review and postmarket regulation is generally based on a determination of the "primary mode of action" (PMOA) of the combination product. For example, if the PMOA of device−biologic combination product is attributable to the biologic component, such as cellular and gene products, CBER would have primary jurisdiction over the combination product because CBER is responsible for premarket review of that biological product. In the case of a catheter device that is designed to deliver cellular therapies as another example, although the biologic and the device need to be studied together to mediate the intended therapeutic effect, it would likely be determined that the cells provide the PMOA; therefore CBER would lead the review of the combination product and CDRH would provide consultative review for the delivery catheter.

For combination products that include biological products and human cells, tissues, and cellular and tissue-based products (HCT/Ps), a manufacturer of a combination product must comply with the cGMP requirements that would apply to the biological products or HCT/P if it were not part of a combination product. For HCT/Ps, current good tissue practice requirements outlined in 21 CFR 1271 would apply in a complementary manner. The manufacturer should also comply with drug cGMP and device quality system regulation requirements as applicable in accordance with 21 CFR part 4 [41]. CBER and CDRH often collaborate in the premarket review of combination products that contain both device and biological components. Regarding the device component (e.g., a scaffold or delivery device), insight into considerations for product manufacture, biocompatibility, electrical safety, electromagnetic

compatibility, software validation, and physicochemical and mechanical testing may be obtained by review of FDA Guidance documents and the published summaries of cleared 510(k) and approved premarket applications (PMAs). FDA has published guidance documents that provide current thinking on approaches for evaluating the biological responses to biomaterials and material sourcing issues [42], as well as physiochemical analyses and preclinical tests that may be appropriate for scaffolding materials [43]. A review of relevant CDRH-recognized consensus standards may also be helpful [44].

Tissue-engineered and regenerative medicine products

Many of the tissue-engineered and regenerative medicine (TE/RM) products in the market or currently under development are products in which cells are combined with a biomaterial scaffold [45]. The scaffolds usually serve as the matrix that provides mechanical and chemical support for tissue regeneration. One of the regulatory challenges for a cell-scaffold product lies in the fact that the final product combines distinct components that are prepared through disparate manufacturing processes. This complexity necessitates a thorough characterization of individual components as well as the characterization of the assembled final product to ensure the safety and effectiveness of the final TE/RM product. If degradable biomaterials are used as structural scaffolds or for encapsulation of a cellular component, detailed information regarding the profile/kinetics (e.g., molecular weight, diffusion/mechanical properties, and degradation by-products) should be provided. In addition, most cell-scaffold TE/RM products cannot be terminally sterilized but use aseptic techniques and processes during manufacturing of the product; therefore information regarding scaffold sterilization methods used and stability/shelf-life are also critical. The flowchart shown in Fig. 84.2 provides the summary of some of the main characterization and safety considerations for each of the two main components, cell and scaffold, individually and in combination. It is also important to keep in mind that, oftentimes, the assembled product may be an intermediate form since final remodeling may occur in vivo, and/or maturation or preconditioning in a particular bioreactor is needed to achieve intended functions of the tissue construct prior to administration to patients. When in vivo remodeling, including scaffold degradation, is expected, the product may require extensive preclinical testing using adequate in vivo and in vitro models to assess the safety and performance of the final construct for potential construct failure prior to initiating a clinical trial. When maturation of an engineered tissue construct takes place in a bioreactor, it becomes important to evaluate information regarding material compatibility (including potential extractables and leachables), sterilization method (including sterilant residual), stability of construct in the bioreactor, characterization of the construct before and after bioreactor preconditioning/maturation, and sterility of the preconditioned/matured final construct. In some circumstances, the final product is not available for any destructive testing. In such cases, surrogate samples may be used in place of the final product if manufacturers provide sufficient information regarding how the surrogate samples are manufactured and provide supporting information and/or data to demonstrate the surrogates are representative of the final product.

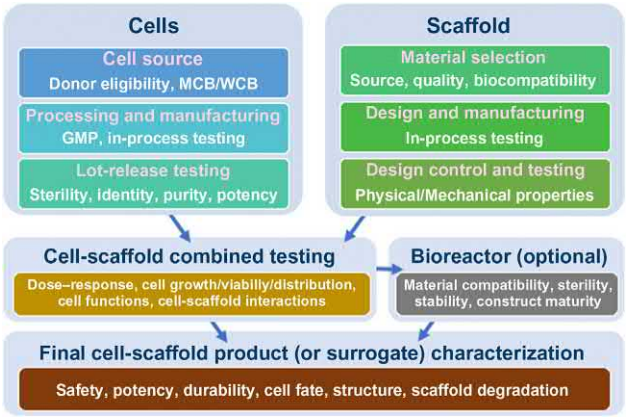

FIGURE 84.2 Safety and effectiveness consideration for a cell-scaffold TE/RM product. *GMP*, Good manufacturing practice; *MCB*, master cell bank; *TE/RM*, tissue-engineered/regenerative medicine; *WCB*, working cell bank.

A common misconception when developing tissue-engineered products is the importance of using "FDA-approved biomaterials." This misunderstanding may arise because certain types of biomaterials have been commonly used in TE/RM applications. In addition, FDA may take into consideration published scientific literature (when sufficient physicochemical data exist to demonstrate the similarity of previous and proposed biomaterials) as well as sponsor-derived test data to determine the safety of a biomaterial in a proposed product. However, it should be emphasized that FDA does not "approve biomaterials." This is because the clinical behavior and safety profile of a material can be profoundly affected by other factors, including the biomaterial source, manufacturing process, other components in the final product, anatomic location of the implantation site, and intended biological/physiological function of the final construct. When weighing the value of previously published data (and/or the need for additional studies), one should consider the intended use, source, manufacturing process, route of administration, and composition of the previous product.

3D bio-printed tissue-engineered/regenerative-medicine products

3D printing, including bioprinting, is rapidly emerging due to its potential to produce new medical products with unprecedented structural and functional designs. Bioprinting is increasingly used to generate TE/RM products by printing biological materials that include cells, biomaterials, and biomolecules. As described in an article by Ricles et al., differences in manufacturing methods between 3D printing and traditional manufacturing approaches have added specific technical considerations for 3D-printed products into the FDA scientific evaluation [46]. Because of the increased complexity of biological products, some additional technical considerations such as the printing parameters and consistency, material selection, finishing steps, vascularization of the construct, biocompatibility, mechanical and physicochemical properties, and biological function of the finished product may need to be considered.

Medical devices

A medical device is defined in Section 201(h) of the Federal Food, Drug, and Cosmetic Act (FDCA) in part as an instrument, apparatus, implant, etc., that is intended (1) for use in the diagnosis or other conditions; (2) for use in the cure, mitigation, treatment, or prevention of disease; or (3) to affect the structure or any function of man or other animals and which does not achieve its primary intended purposes through chemical action and is not dependent upon being metabolized for the achievement of its primary intended purposes. An investigational device exemption (IDE) application is typically required for a clinical investigation of an investigational product that meets the legal definition of a significant risk medical device or of a combination product in which the device component is thought to be providing the PMOA [40,47]. Information about the required contents of an IDE can be found in 21 CFR 812.20.

A risk-based approach determines the level of information for premarket review of medical devices. A premarket notification [510(k)] application seeks to demonstrate that a moderate risk medical device is substantially equivalent to another device already being marketed within the United States by presenting data on device design, bench testing and possibly clinical studies (21 CFR Part 807) [48]. For high-risk devices, including life-sustaining or life-supporting device, sponsors submit a PMA application that describes device composition and manufacture as well as the results of preclinical and clinical studies (21 CFR Part 814) [49,50]. Some of these devices are approved under Humanitarian Device Exemption applications, because these medical devices were designated as Humanitarian Use Devices which are intended to benefit patients in the treatment or diagnosis of a disease or condition that affects or is manifested in not more than 8000 individuals in the United States per year [defined by 21 CFR 814.3(n) and updated by the 21st Century Cures Act].

Least burdensome principles

Since the Food and Drug Administration Modernization Act of 1997 (FDAMA), Congress has directed FDA to take a least burdensome approach to medical device premarket evaluation in a manner that eliminates unnecessary burdens that may delay the marketing of beneficial new products, while maintaining the statutory requirements for clearance and approval. Accordingly, FDA issued the least burdensome guidance document, "The least burdensome provisions: concept and principles 2019," after the enactment of FDAMA [51]. Based on the least burdensome principle, the term "least burdensome" is the minimum amount of information necessary to adequately address a relevant regulatory question or issue through the most efficient manner at the right time. The guidance document stated that while the least burdensome provisions from FDAMA applied to PMA and 510(k) submissions, FDA believes that the least burdensome principles should be implemented for all medical device premarket regulatory activities.

Breakthrough device program

The 21st Century Cures Act provides new authority, the Breakthrough Devices Program, to help speed the review of certain innovative medical devices [52,53]. The Breakthrough Devices Program is a voluntary program for certain medical devices and device-led combination products that provide for more effective treatment or diagnosis of life-threatening or irreversibly debilitating diseases or conditions. The goal of the Breakthrough Devices Program is to provide patients and health care providers with timely access to these medical devices by speeding up their development, assessment, and review, while preserving the statutory standards for premarket approval, 510(k) clearance, and De Novo marketing authorization. The Breakthrough Devices Program offers manufacturers an opportunity to interact with the FDA's experts through several different program options to efficiently address topics as they arise during the premarket review phase, which can help manufacturers receive feedback from the FDA and identify areas of agreement in a timely way. Manufacturers can also expect prioritized review of their submission.

Evaluation of devices used with regenerative medicine advanced therapy

Section 3034 of the 21st Century Cures Act mandates that FDA issue guidance document clarifying how FDA will evaluate devices used in the recovery, isolation, or delivery of RMAT [3]. Although Section 3034 of the Cures Act refers to "recovery, isolation, or delivery," these terms are not defined in the Cures Act. Accordingly, FDA issued the guidance document "Evaluation of devices used with RMAT" to define the terms and to address how FDA intends to simplify and streamline its application of regulatory requirements for devices used to make combination device and cell or tissue products.

In the guidance document, the terms "recovery," "isolation," and "delivery" have the following definitions:

- *Recovery* means obtaining cells or tissues from a human donor.
- *Isolation* is processing that results in selection, separation, enrichment, or depletion of recovered cells or tissues that will become components of the final product.
- *Delivery* refers to any method by which an RMAT is introduced onto or into the body of a human recipient, for example, infusion, injection, topical application, or inhalation.

FDA recognizes that a wide range of devices may be used in conjunction with an RMAT. For example, the devices can be simple, low-risk devices, such as a manual surgical instrument (e.g., scalpel) for recovering cells and tissue. Devices used with RMATs may also be complex, higher risk devices, such as an automated cell collection system that selects and processes specific cells intended for an immediate return to the patient. In addition, devices can be constituent parts of an RMAT that is a combination product. It is noted that FDA does not consider scaffold devices combined with a cellular product to be within the scope of this guidance document. While such constructs may be eligible for RMAT designation, the scaffold constituent part would generally be considered a part of the RMAT and would generally not be considered solely a "device used in the delivery of an RMAT" because such scaffolds provide more than a delivery function.

Expedited review programs

There are several programs to facilitate and expedite the development and review of therapies that address unmet medical needs for the treatment of serious or life-threatening conditions [2]. These include four designation programs and one approval pathway: fast track designation, breakthrough therapy designation, RMAT designation, accelerated approval, and Priority Review (Table 84.1 and 84.2). CMC requirements for BLA submission remain the same even if the clinical testing is performed in the context of an expedited review program. The designation programs, particularly Breakthrough Therapy and RMAT designations, call for earlier attention from the FDA to these potentially promising therapies, offering sponsors earlier and more frequent interactions to receive FDA input on efficient trial design and overall drug development.

Fast track designation was established under the FDAMA to expedite the development and review of a new therapy to treat serious or life-threatening conditions and address an unmet medical need. The information necessary to demonstrate unmet medical need varies with the stage of drug development. Nonclinical or pharmacologic data will suffice in early-stage development while clinical data should be utilized in more advanced stages. If there

are existing therapies, a fast track eligible therapeutic must show some advantage over available treatment. A therapy that receives fast track designation is eligible for more frequent interactions with the FDA, rolling review, and accelerated approval or priority review if the requisite criteria are met.

Breakthrough therapy designation is a program that is intended to expedite the development and review of drugs for serious conditions when preliminary clinical evidence demonstrates that the product has the potential to provide a significant improvement in safety or effectiveness over existing therapies. This designation conveys the major advantages of the fast track program (rolling and priority review) as well as early intensive FDA guidance on efficient product development and commitment from senior managers.

The RMAT designation program is the newest program that was enacted in December 2016 pursuant to the 21st Century Cures Act to facilitate the development of RMTs. RMTs to treat, modify, reverse, or cure serious conditions are eligible for this program. The advantages of the RMAT designation include all the benefits of the fast track and breakthrough designation programs, including early interactions with the FDA to discuss potential surrogate or intermediate endpoints to support accelerated approval. In addition, the statute addresses potential ways to satisfy postapproval requirements.

Accelerated approval allows for the approval of a product for the treatment of a serious condition that has meaningful advantage over available therapies based on an effect on either a surrogate endpoint or intermediate clinical endpoint, with the requirement of confirmatory clinical data. Priority review allows for a shortened review clock of 6 months for products intended to treat serious conditions and, if approved, would provide a significant improvement in safety or effectiveness over available therapies.

Other regulatory topics

Minimal manipulation and homologous use of human cells, tissues, and cellular and tissue-based products

Due to the unique nature of HCT/Ps, the FDA implemented a tiered, risk-based approach to the regulation of HCT/Ps. Under these regulations, referred to as the "tissue rules" in 21 CFR part 1271, those HCT/Ps that meet all of the criteria in 21 CFR 1271.10(a) or fall within detailed exceptions (21 CFR 1271.15) do not require premarket review and approval. HCT/Ps that do not meet all of the criteria in 21 CFR 1271.10(a) and do not fall within detailed exceptions will be regulated as drugs, devices, and/or biological products and require premarket review and approval under the FDCA and/or Section 351 of the PHS Act.

Minimal manipulation

One of the four criteria for determining how an HCT/P is appropriately regulated is whether the HCT/P is minimally manipulated [54]. As defined in 21 CFR 1271.3(f)(1), minimal manipulation for structural tissue means processing that does not alter the original relevant characteristics of the

tissue relating to the tissue's utility for reconstruction, repair, or replacement. As defined in 21 CFR 1271.3(f)(2) minimal manipulation for cells or nonstructural tissues means processing that does not alter the relevant biological characteristics of cells or tissues. For applying the HCT/P regulatory framework, HCT/Ps that provide physical support or serve as a barrier or conduit, or connect, cover, or cushion are generally considered structural tissues, whereas HCT/Ps that function in metabolic or other biochemical capacities in the body are generally considered cells or nonstructural tissues. The determination of whether an HCT/P is minimally manipulated is dependent on the effect of manufacturing on the original relevant characteristics of the HCT/P as the HCT/P exists in the donor, not based on the intended use of the product in the recipient. As defined in 21 CFR Part 1271.3(ff), processing refers to "any activity performed on an HCT/P, other than recovery, donor screening, donor testing, storage, labeling, packaging, or distribution, such as testing for microorganisms, preparation, sterilization, steps to inactivate or remove adventitious agents, preservation for storage, and removal from storage." Other forms of processing also include cutting, grinding, shaping, culturing, enzymatic digestion, and decellularization.

Homologous use

A second criterion for determining how an HCT/P is appropriately regulated is the criterion of homologous use. As defined in 21 CFR 1271.3(c), homologous use means "the repair, reconstruction, replacement, or supplementation of a recipient's cells or tissues with an HCT/P that performs the same basic function or functions in the recipient as in the donor." FDA generally considers an HCT/P to be for homologous use when it is used to repair, reconstruct, replace, or supplement recipient's cells or tissues that are identical to the donor cells or tissues and perform one or more of the same basic functions in the recipient as the cells or tissues performed in the donor, or when used to repair, reconstruct, replace, or supplement recipient's cells or tissues that are not identical to the donor cells or tissues but that perform one or more of the same basic functions in the recipient as the cells or tissues performed in the donor. It is important to note that an HCT/P may still perform the same basic function or functions even when it is not used in the same anatomic location in the recipient as it existed in the donor.

Clinical research involving children

FDA regulations in 21 CFR Part 50 Subpart D outline special protections for children, which are in addition to the safeguards for all clinical trial subjects that are contained in 21 CFR 312. For clinical studies involving more than a minor increase over minimal risk, the additional safeguard under 21 CFR 50, Subpart D, and in particular 21 CFR 50.52 (i.e., such clinical investigations must offer the prospect of direct benefit to the pediatric subjects), is applied. In general, initial studies of cell-based products should be conducted in an adult population prior to investigations in a pediatric population to procure some preliminary safety- and activity-related information. However, in some situations, first-in-human studies may be ethical in a pediatric population, for instance, when the disease primarily affects children and the benefit/risk profile in adults may not be favorable.

For pediatric studies that involve more than minimal risk, the considerations for IRB approval are outlined in 21 CFR 50.52 [55].

Expanded access to investigational drugs for treatment use

FDA's expanded access regulations (21 CFR 312 Subpart I) allow access to investigational drugs for the primary purpose of diagnosing, monitoring, or treating a patient's disease or condition, rather than for generating scientific data intended to characterize the drug [56]. The intent of these regulations is to facilitate the availability of these products to patients with serious diseases or conditions when no comparable or satisfactory alternative therapy exists. The regulations describe the criteria that must be met to authorize expanded access.

Charging for investigational drugs under an investigational new drug application

The IND regulations allow sponsors to charge for administration of investigational products in clinical trials and to charge for investigational products made available under FDA's expanded access regulations (21 CFR 312.8) [57]. These regulations specify general criteria for authorizing charging, specific criteria for charging for an investigational drug in a clinical trial, and specific criteria for charging under the expanded access provisions and clarify what costs can be recovered.

Responsibilities of sponsors and investigators

Sponsors and investigators are responsible for specific activities to ensure that the rights, safety, and welfare of subjects are protected, to ensure the quality of the clinical trial, and to meet regulatory requirements (21 CFR 312 Subpart D). The FDA regulations (21 CFR 312.3) divide clinical trial responsibilities among these two parties: sponsors are responsible for communicating with FDA through the IND and managing the clinical trials; clinical

investigators conduct the studies and administer the investigational product to subjects.

Sponsor responsibilities (21 CFR 312.50–59)

Sponsors have several responsibilities for managing the clinical trials under an IND. Sponsors must select investigators who are qualified by training and experience to administer the investigational product to study subjects and conduct safety and efficacy monitoring. Each study site should have an investigator who signs Form FDA 1572, listing the name, address, and the locations where the study will be conducted, all subinvestigators, and the IRB responsible for review of the study (21 CFR Part 56). The investigator is not required to be a physician, but it is reasonable to assume that a physician will be part of the study team. The FDA expects that the sponsor will evaluate potential clinical sites to determine that the facilities and resources are adequate to conduct the study [58].

Sponsors must provide investigators with the protocol, the IB, and any other instructions necessary to conduct the study. As the study progresses, the sponsor must communicate any protocol revisions and new information about the safety of the investigational product to the investigators. Sponsors must also monitor the progress of all investigations conducted under the IND to ensure they are conducted in accordance with the general investigational plan and protocol [59]. If an investigator is not complying with the protocol, the sponsor must either obtain an assurance of compliance from the investigator or discontinue shipments of the product to the investigator. Particularly for cell and gene therapy products, including xenogeneic cellular products, the protocol may need to include procedures for long-term monitoring of subjects, in accordance with FDA and PHS regulations and PHS guidelines.

IND safety reporting is another sponsor responsibility (21 CFR Part 312.32). Sponsors must promptly (≤15 calendar days) notify FDA and all investigators receiving investigational product in an IND safety report of potential serious risks. Sponsors must also promptly (≤7 calendar days) notify FDA of any unexpected fatal or life-threatening suspected adverse reaction.

Sponsors must maintain adequate records of financial interest and records of the receipt, shipment, use, or other disposition of investigational product. All records related to the IND must be retained for 2 years after a marketing application is approved, or for 2 years after shipment and delivery of the investigational product was discontinued and FDA was notified. Sponsors must permit access for FDA to inspect the study records. A sponsor may transfer any or all of the sponsor's IND obligations to contractors, who then assume the obligations of the sponsor for the designated activities.

Clinical investigator responsibilities (21 CFR 312.60–69)

Clinical investigators are responsible for protecting the rights, safety, and welfare of the subjects under the investigator's care. Investigators are required to conduct the study in accordance with the protocol, for example ensuring that subjects meet the eligibility criteria and that all follow-up assessments are performed as scheduled. They must personally supervise the administration of the investigational product and the conduct of the study. The investigator may delegate certain duties to the subinvestigators that are under his/her supervision, but he/she cannot transfer his/her regulatory obligations to others. Investigators must obtain the review of the study by the IRB that oversees their clinical site and must obtain the informed consent of study subjects prior to enrolling them into a study. The investigator shall also notify the IRB (21 CFR 312.66) of all unanticipated problems involving risk to human subjects or others.

Investigators must limit the use of the investigational product to only the subjects enrolled in the study and must maintain records of the storage and use of the product. Investigators must report AEs and progress reports to the IRB and to the sponsor so both are aware of new information about the safety of the investigational product. Investigators must also submit financial disclosure forms to the sponsor and update them when required. Investigators must prepare and maintain adequate and accurate case histories for each subject and must retain all study records for 2 years after a marketing application is approved, or for 2 years after the investigation is discontinued and FDA is notified. Investigators should plan for how they will maintain these records for several years, especially if they are participating in early-phase studies. When the study at a clinical site has been completed, the investigator must submit a final report to the sponsor and must allow access for FDA to inspect the study records.

Sponsor–investigator responsibilities

A sponsor–investigator is an individual who is the IND sponsor and is the only clinical investigator for a clinical study of the product he/she is developing. Sponsor–investigators are required to fulfill all the responsibilities of sponsors and of investigators, except for the requirement for an IB. Sponsor–investigators must consider how to monitor the clinical trial he/she is personally conducting. Some options include the review of the study by someone unaffiliated with the research, such as a colleague in another department, from an institution's research office, or by a contract research organization.

Clinical research conducted outside of the United States

A sponsor who is conducting a foreign clinical study may choose, but is not required, to conduct the foreign clinical study under an IND. When a foreign clinical study is conducted under an IND, all FDA IND requirements must be met unless a waiver is obtained. FDA may accept a well-designed, well-conducted, non-IND foreign study as support for an IND or application for marketing approval if the study was conducted in accordance with good clinical practice and if FDA is able to validate the data from the study through an onsite inspection, if necessary (21 CFR 312.120). Regarding the ability of data from a non-IND foreign study to support a marketing application (21 CFR 314.106), an important consideration is the applicability of the data to the US population [60].

Use of standards

The 21st Century Cures Act, Title 3 Section 3036 directs FDA, in consultation with the National Institutes of Standards and Technology (NIST) and stakeholders to "facilitate an effort to coordinate and prioritize the development of standards and consensus definition of terms, through a public process, to support, through regulatory predictability, the development, evaluation, and review of regenerative medicine therapies and regenerative advanced therapies, including with respect to the manufacturing processes and controls of such products." [1]

The scientific and manufacturing novelty of many RMTs including TE/RM products, present unique challenges for meeting regulatory requirements with respect to product testing, performance characteristics, testing methodologies, scientific protocols, product quality, ingredient specifications, and compliance criteria. Increased development and use of standards have the potential to transform product development, contribute to regulatory predictability, and facilitate the overall development of RMTs [42,44,61,62].

US Food and Drug Administration international regulatory activities

With the globalization of medical products, especially RMTs, OTAT is leading several initiatives that help facilitate FDA's goals to safeguard global public health and enable the availability of safe and effective products [63]. The International Pharmaceutical Regulators Program (IPRP) Cell Therapy Working Group (CTWG) is a forum for regulatory bodies that allows for open discussion and sharing of best practices for the regulation of cell and tissue-based products. The scope of products covered in the CTWG includes cell-therapy products without gene modifications, tissue-engineered products, and xenotransplantation products. Discussions are focused on topics that may be suitable for regulatory convergence, and producing publicly available position papers and to support harmonization initiatives such as the Asia Pacific Economic Cooperation (APEC) and Pan American Health Network for Drug Regulatory Harmonization (PANDRH), International Council of Harmonization of Technical Requirements for Pharmaceuticals for Human Use (ICH), Pharmaceutical Inspection Convention and Pharmaceutical Inspection Cooperation Scheme (PIC/S), and World Health Organization (WHO).

OTAT is also focused on activities that foster the independent development of national guidelines and regulations that reflect a shared regulatory perspective internationally. International activities for RMTs range from formal arrangements with international regulatory authorities to ad hoc product-specific discussion with international regulatory partners. Examples of formal activities include "Cluster" meetings on various topics such as the advanced therapy medicinal product cluster with the European Medicines Agency (EMA), Health Canada, and Japan Pharmaceuticals and Device Agency to assist sponsors and product developers in making submissions to the FDA and EMA for a specific product, sponsors and developers can request Parallel Scientific Advice or Consultative Advice. These processes are outlined in "General Principles EMA-FDA Parallel Scientific Advice (Human Medicinal Products)" [64].

The role of cell-based products in medical product testing

A major priority of the FDA's strategic plan for advancing regulatory science includes efforts to modernize toxicology to enhance product safety. This emphasis recognizes the need to improve the predictive value of preclinical studies for all medical products, and the potential role for cell and tissue-based assays (a subset of bioengineered tissue products) in achieving this goal [65]. Implicit in this goal is the need to improve manufacturing processes, to increase the understanding of the biology, and clinical applicability of cell and tissue-based assays.

Conclusion

Federal regulations address many aspects of drug development, including CMC, preclinical development, and clinical trials. Efficient drug development depends on an understanding of these regulations and the regulatory process. OTAT collaborates with sponsors to address the challenges that arise during the development of cell-based products [66].

Acknowledgments

We thank Drs. Steven Bauer, Brenton McCright, Steven Oh, Tejashri Purohit-Sheth, Carolyn Yong, Rachael Anatol, and Kimberly Benton for their review of this chapter.

Chapter 85

Business issues

Matthew Vincent
Avacta Life Sciences, Cambridge, United Kingdom

Introduction

Imagine a world of medicine where replacement or repair of body parts could be accomplished using tissues grown in a laboratory. Or better yet, the body could be induced to repair and regenerate itself—to harness the body's natural healing processes and activate these processes when and where they are critically needed. Aubry de Grey, a biomedical gerontologist whose research focuses on how regenerative medicine can prevent the aging process, has famously stated that "The First Person to Live to 150 has Already Been Born"; a headline which could all too easily be dismissed as being overly boastful. The question to ask ourselves, however, is should we be so quick to write off such a possibility? Whether or not the first sesquicentenarian is already among us aside, the progress in preclinical and clinical regenerative medicine programs, particularly stem cells, has picked up considerable pace and is being continually primed by a growing pipeline of promising research and therapeutic programs aimed at repair and regeneration. In the last 120 years, as a consequence of lifestyle and nonregenerative advances in medicine, we have seen an increase in average life expectancy from 43 to 85 years. As we achieve the ability to extend or replace tissues and organs—to begin to realize the aspirational goals of tissue engineering, and regenerative medicine in general—would doubling life expectancy over the next 150 years period in fact be a possibility? And if so, what are the societal and commercial implications?

The past 30 or so years have seen the emergence of an area of medicine called tissue engineering and regenerative medicine. This discipline is a truly multidisciplinary field, involving scientists, engineers, and physicians working to construct biological substitutes which can replace (or help regenerate) diseased and injured tissues. It promises to revolutionize the ways we approach health and quality of life for tens of millions of people worldwide. The field has already produced notable examples of actual therapies, including skin replacement and cartilage repair. The pump is primed, but companies, payers, and policy makers will need to assess long-range cost benefit trade-offs for engineered tissues and cell therapies when compared to traditional therapies. Understanding the interplay giving rise to opposing pressures—one from an expanding elderly population to improve health in old age, and the other a growing concern for containing health-care costs—will be critical to tissue and cell therapy companies as they plan for and address concerns about how patients can afford innovation in this important area of treatment.

The aging population

To consider the implications that further enhancing longevity through tissue engineering may have on society and medicine, one needs to start by understanding current trends and projected impacts. The age structure of the overall population is projected to change greatly over the next 40 years. The world's population is aging, primarily as a function of declining fertility coupled with increasing life expectancy. Aging is occurring not only in high-income countries but also in middle- and low-income countries. In fact, between now and 2050, the world is projected to experience rapid growth in its older population. Fig. 85.1 shows the projected growth of two groups of older people—those aged 65−79 and those 80 years and older. The rapid growth of the over-80 group is related to increases in life expectancy related to improving medical care and nutrition, which have occurred during the century.

People live longer now than at any time in the past; with advances in medicine promising to extend life expectancy even further. The US life expectancy at birth rose from 47.3 years in 1900 to 76.9 years in 2000. Greater longevity, combined with relatively low fertility rates, has rapidly increased the proportion of the oldest old among

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00087-3

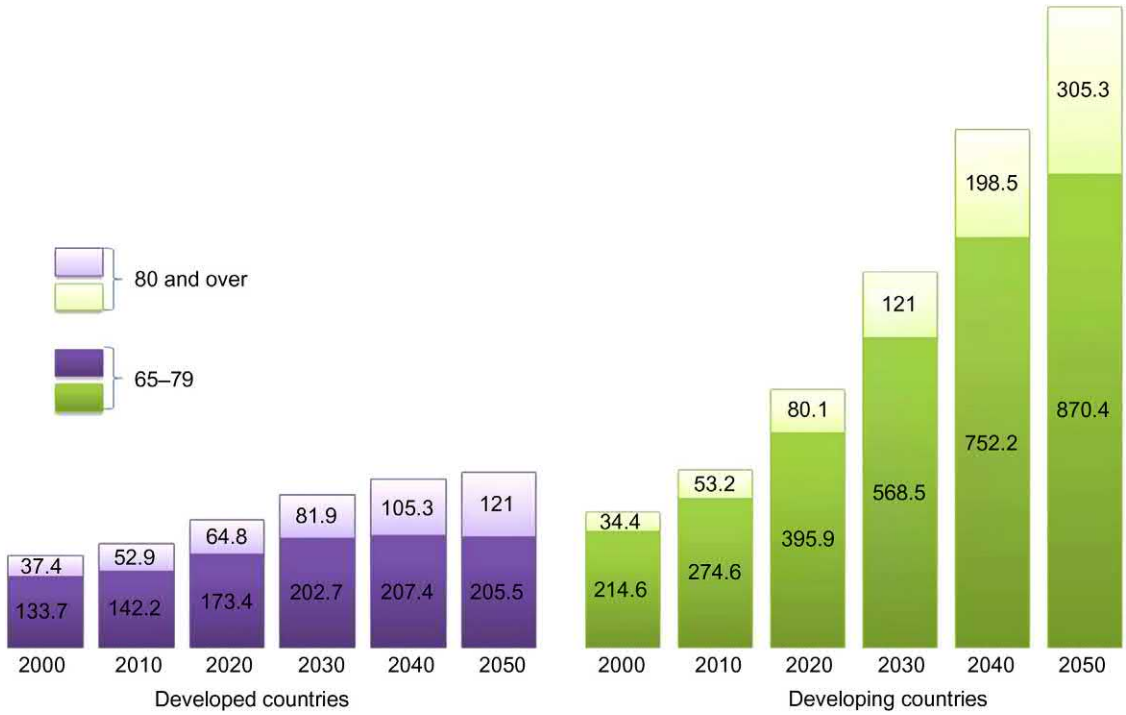

FIGURE 85.1 Population aged 65 and over for developed and developing countries (in millions). *U.S. Cenus Bureau Publication. 65 + in the United States. p. 23–209.*

the total older population. In 1900 only 4.0% of all older people were aged 85 and older; by 2000 that proportion had grown to 12.1% [1].

In 2050 the number of people over the age of 65 living in (now) developed countries is projected to exceed 325 million, with more than 1.5 billion persons in this over-65 category when including the developing countries in the equation—a nearly tripling of the number of over-65 people living in all these countries today. In the United States, as an example, the number of Americans aged 65 and older is projected to be 88.5 million, more than double the population of 40.2 million in 2010. The baby boomers are largely responsible for this increase in the older population, as they recently began crossing into this category in 2011. By 2050 the US population is projected to grow by 439 million, an increase of 42% relative to the 2010 census numbers of 310 million. The nation will also become more racially and ethnically diverse. The population is also expected to become much older, increasing from 15% today to nearly 20% of the US population being aged 65 and older by 2030, and continuing to increase to about 22% by 2050. Those over the age of 85 accounted for 5.8 million Americans in the 2010 census and are expected to reach 8.7 million by 2030 and then 19 million by 2050. In terms of overall population, this "oldest" old population will increase to 4.3% of the population by 2050—representing only 1.8% of the population in the 2010 census.

Much of the advances in longevity early in the 20th century arose from improvements in socioeconomic and living conditions and a decrease in infectious disease deaths. Gains during the latter part of that century came from periodic breakthroughs in public health and biomedical research that have led to new treatments for, and a later onset of, chronic diseases [2]. If improvements in treating and even preventing the onset of chronic diseases can be sustained and further enhanced, then the age structure of the older population will be even more positively affected than the previous projections suggest. This aging of the population will have wide-ranging implications. The projected growth of an older population will present challenges to policy makers and programs, such as Social Security and Medicare in the United States. The health status of the aging population is essential not only to those who comprise this age group but also to the broader population because of the impacts on social and economic systems. As the older population grows not only in size but more importantly in their proportion of the total population, the potential implications for families, businesses, and health-care providers will become increasingly significant.

Chronic diseases and impairments, which are among the leading causes of disability in older people, can negatively impact quality of life, lead to a decline in independent living, and impose an economic burden. About 80% of seniors have at least one chronic health condition and

50% have at least two [3]. Indeed, of the roughly 150,000 people who die each day, about two-thirds die of age-related causes. In industrialized nations the proportion is much higher, reaching 90% [4].

Concern is growing that medical advances leading to longevity will, in turn, lead to an older population who have a higher incidence of functional and cognitive impairment. With increases in life expectancy and a simultaneous rise in the number of people with chronic diseases and disability, researchers are focusing on facilitating both longer life and disability-free healthy life. Focusing on the quality as well as length of life, the World Health Organization has introduced estimates of "healthy life expectancy" (HALE), which is defined as the average number of years of life free from disability, physical performance limitations or impairments, other disabilities, or social handicaps [5]. Using various measurements and methods of analysis, including HALE, recent studies conclude that in addition to living longer, the current generation of older people is healthier and less disabled than the preceding ones [6–8]. But Fig. 85.2 illustrates, as life expectancy increases so does the incidence rate of chronic and degenerative health conditions, threatening to create a wider gap between HALE and total life expectancy.

Currently, the vast majority of treatments for chronic and/or life-threatening diseases are palliative. Others delay disease progression and the onset of complications associated with the underlying illness. Only a very limited number of therapies available today are capable of curing or significantly changing the course of disease. The result is a health-care system burdened by costly treatments for an aging, increasingly ailing population, with few solutions for containing rising costs. Fig. 85.3 demonstrates the predicted impact that our aging population is expected to have on the cost of healthcare in less than 20 years time. The demographics shift in aged populations toward older adults in the United States alone will likely add more than one trillion dollars to the direct cost of healthcare, and multiples of that amount for the indirect costs associated with accommodating the needs of older Americans. According to a 2017 report from the National Health Expenditure Accounts, health-care expenditures in the United States are currently about 18% of GDP, and this share is projected to rise sharply. If health-care costs continue to grow at historical rates, the share of GDP devoted to healthcare in the United States is projected to reach 34% by 2040. Viewing the distribution of the cost across all working Americans, Fig. 85.4 shows the potential impact on total compensation when the projected rising cost of healthcare is factored into predicted salaries.

Rise of regenerative medicine

The best way to address the escalating economics of healthcare includes developing more effective treatments, and even cures, for the most burdensome diseases—diabetes, neurodegenerative disorders, stroke, macular degeneration, and cardiovascular disease, for example—to facilitate longer, healthier, and more productive lives. Regenerative technologies, such as cell- and tissue-based therapies, have the power to be a critical component in reducing the otherwise predicted increase in health-care costs resulting from aging. A more effective, sustainable health-care system is a potential as a consequence of the innovations occurring in regenerative medicine. However, it will require the concerted efforts of patients, government and private insurance companies, doctors, life science companies, private investors, and governments. Regenerative medicine promises to completely change the way we think about disease, aging,

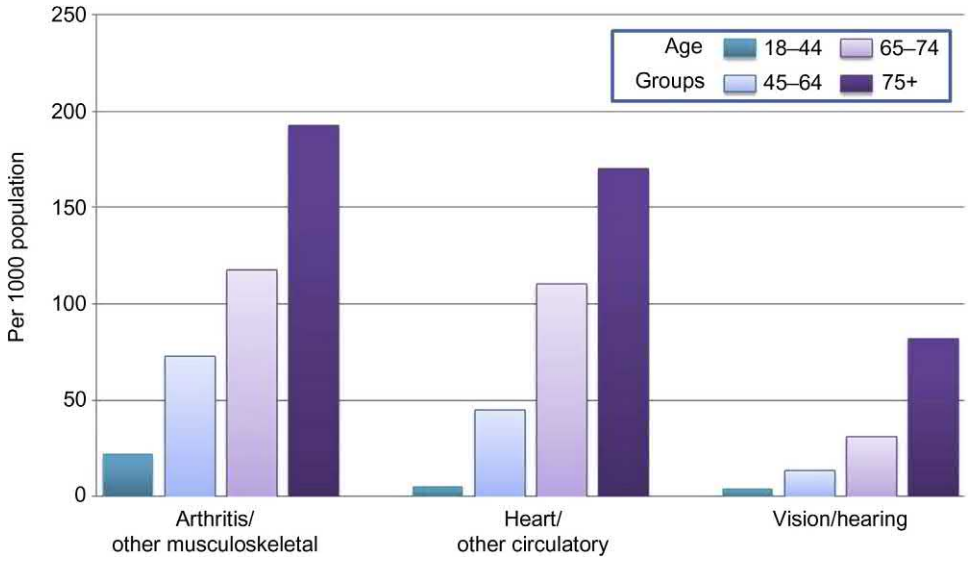

FIGURE 85.2 Exemplary chronic health conditions. *U.S. Cenus Bureau Publication. 65+ in the United States. p. 23–209.*

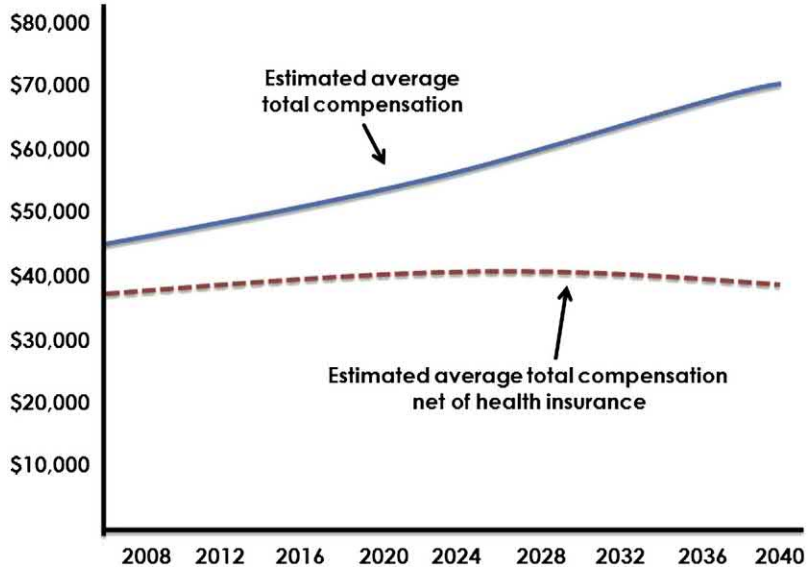

FIGURE 85.4 Projected annual compensation and compensation less health insurance premiums. *Office of the President, Council of Economic Advisors. The economic case for healthcare reform; June 2009.*

and even the practice of medicine itself—and, as the promise goes, to help bend down the ascending curve of projected health-care costs.

Regenerative medicine, and particularly cell and tissue therapies, has already had some clinical impacts. More than one million patients worldwide have already had bone marrow or hematopoietic stem cell transplants, with more than 50,000 new transplants being carried out each year [9,10]. A more recent category of approved products includes tissue-engineered skin, with more than 250,000 patients having now received artificial skin grafts [11]. In parallel, treatments for oncological and inflammatory diseases now include adoptive cell transfer and engineered immune cells, such as CAR-T, CAR-NK, and CAR-Treg cells. While the number of patients treated with cell therapies is still low by the standards of conventional drug- or biologics-based treatments, there is a robust pipeline of new therapies in clinical or preclinical testing.

However, the realization of the power of cell therapies, and with it the emergence of this growing area of medicine, is not only dependent on resolving the science but also on a number of business factors unique to cells as therapeutic agents. Regulatory oversight, clinical endpoints, drug labeling, pricing and reimbursement, manufacturing, cold chain, and essential infrastructure are some of the many components from the business perspective which typically have unique and far-reaching consequences in the path from the laboratory bench to patient treatment. Laminated onto these business issues can be layers of political, legal, and ethical sensitivities which need to be considered. Regenerative medicine is uniquely capable of altering the fundamental mechanisms of disease; however, to realize its potential,

we must think differently about therapeutic development and commit to investing in these transformative technologies. A more effective, sustainable health-care system is possible through regenerative medicine, but it will require the combined efforts of patients, payers, health-care providers, biotech and pharmaceutical companies, private investors, and governments working together.

The reality is that not every new company or technology in this space can or will succeed. Not every new invention relating to regenerative medicine is necessarily commercially tractable. The technology may be too complex or high touch to be used in an FDA-regulated commercial setting, or too costly, particularly where reimbursement by insurance entities or the government needs to be considered. Unfortunately, great science does not always translate into great business. The history of the life science industry is littered with many examples of brilliant research and breakthroughs unable to be translated into a viable commercial product. Understanding what are often the gating issues and how to manage through those issues, including recognizing the "go/no go" decision points, can greatly increase the likelihood of success. Realizing the promise of regenerative medicine from the perspective of the life science company will require understanding the regulatory policies in the major markets, appreciating the impact of final manufacturing, final formulation and the cold chain of the distribution, as well as developing strategic business and reimbursement plans. Added to this equation for success is the inevitable complexity of intellectual property issues.

Product development

Tissue engineering encompasses an array of technologies in biology, chemistry, and physics into materials, devices, systems, and a variety of therapeutic approaches—including cell-based therapies—to augment, repair, replace, or regenerate organs and tissues (see Fig. 85.5), with the end goal often being curative by targeting the root cause of disease. This rapidly evolving, interdisciplinary field in healthcare is transforming the practice of medicine, medical innovation, and the production of medical devices and therapies.

Living cells are incorporated into regenerative medicines to achieve a variety of positive effects, such as replacing damaged or diseased cells and/or tissue; stimulating healing and regeneration in diseased tissue; and delivering small molecule therapies to targeted areas. However, by their very nature, cell and tissue therapies face fundamentally different development and regulatory pathways to market when compared to traditional small molecule-based drugs or protein therapeutics. Alongside the complexity of the agent being administered to patients come added layers of safety and efficacy concerns. Cell therapies face the challenge of manufacturing a living product alongside associated difficulties in their storage and delivery. Depending on the solutions, companies may need to decide whether to focus on manufacturing a product or becoming a service-based entity, each of which requires a fundamentally different business strategy. As of 2018 the regenerative medicine industry to include more than 900 companies ranging from divisions of global pharmaceutical companies to smaller life science companies focused on regenerative medicine technologies, including gene and cell therapies, and engineered tissue therapeutics [12]. The product pipeline of these groups includes hundreds of cell-based therapies, small molecules, biologics, tissue-engineered cells and materials, and implantable devices with more than 1000 clinical trials using regenerative medicine technologies [12]. Other companies work toward providing research tools such as equipment, consumables, software, cells as drug discovery or toxicity testing tools as well as clinical tools, bioprocessing tools, and platforms that include equipment, consumables, reagents, and storage systems. The field also incorporates a variety of service companies specializing in clinical trial management, manufacturing, engineering, and financing among others.

An important concern for emerging life science in the regenerative medicine field relates to developing a compelling business model. It is important to understand the consequences arising from, for example, the choice of technology by a company with how it relates to the practical realities of commercialization, particularly manufacturing, distribution, and adoption by health-care providers, not to mention coding and reimbursement. There are fundamental differences

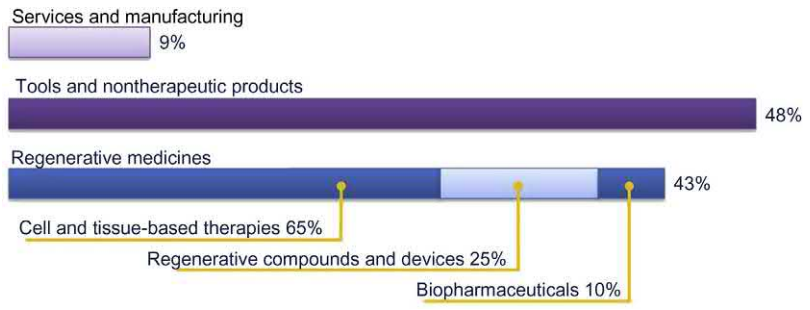

FIGURE 85.5 Regenerative medicine industry sectors. *Alliance for Regenerative Medicine. 2012 annual industry report.*

in the business models arising from the choice between an allogeneic cell or tissue product (a source which can be scaled-up and universally applied to patients) versus providing autologous cells or tissues requiring the manipulation of a patient's own tissues. The choice between the allogeneic and autologous therapy routes is proving to be a fundamental one for early-adopting companies with significantly different production, infrastructure, logistics, skills, and storage requirements for each approach. Autologous cell therapies already represent a significant industry, though principally as a service-based model rather than something more akin to a pharmaceutical or biologics business model. One advantage of autologous transplants is that the body recognizes the cells as self and therefore does not reject the transplanted materials. For example, bone marrow transplants have been successfully used for many years to restore immune function after chemotherapy, and therapeutic trials using patients' own stem cells to restore other tissues are already underway. The allogeneic cell transplants have greater potential for scale-up and widespread distribution, thus potentially benefiting from greater economies of scale. This model is closer to the traditional pharmaceutical model and shares many similarities to biomanufacturing processes that pharma have already invested in heavily over the last decade. However, allogeneic therapies face a greater risk of immunological rejection as the cells are typically not Human Leukocyte Antigens (HLA) matched to the intended recipient patient. For these reasons the allogeneic business model is anticipated to develop more slowly, beginning first with cells and tissues that are transplanted in immune-privileged sites in the body such as the Central Nervous System (CNS) or subretinal space, or for which the cell is itself immune-privileged, as is the case with mesenchymal stem cells.

In many respects, regenerative medicine companies are not harder to start up than other life science companies. Yet, establishing a successful cell therapy company poses some unique challenges, in part, because the field is only recently emerging and the regulatory oversight and reimbursement for patient therapy are still undefined in many ways. In the end, cell and tissue therapies are likely to be more expensive to develop than small molecule or protein therapeutics largely because the safety and proof-of-concept in relevant animals, if available at all, that the regulatory agencies want as part of the preclinical package. Yet, those risks can be dwarfed by the concern that potential therapies will get entangled in regulatory red tape before they can even work their way through clinical trials.

Embryonic stem cells

One of the fundamental issues arising from the use of adult-sourced human stem cells for allogeneic therapies or ex vivo engineered tissues derives from the limited replicative capacity that adult stem cells have in culture. Very often, the adult cells will undergo only a handful of cell doublings before large percentages of the cells in culture senesce or differentiate into unwanted cell types. In contrast, a human embryonic stem (ES) cell (hESC) line represents a nearly inexhaustible supply of pluripotent cells. Derived from a single clonal ES cell, the replicative capacity of an hESC line is enormous. However, for a long time, there was a concern in the industry around whether or not the regulatory agencies would permit a differentiated cell made from an hESC line to even be tested in patients. The concern, at least as it manifests itself in the industry and among potential investors, arose from the ability of ES cells to form any tissue in the body—including tumors. The fundamental question was under what circumstances would the FDA or EMA (for instance) permit a differentiated cell product to be tested in human patients? How would they control for the risk that a cell therapy product might be contaminated with an undifferentiated cell, particularly an ES cell?

That question was finally answered in 2010 when two companies, Advanced Cell Technology (now Astellas Institute for Regenerative Medicine) and Geron, obtained FDA to conduct Phase I/II studies in human patients using cells derived from hESC lines. While Geron ultimately abandoned its cell therapy programs to focus on oncology product lines, Advanced Cell Technology moved forward in clinical trials both in the United States and the United Kingdom for treating various forms of macular degeneration using retinal pigment epithelial (RPE) cells derived from an hESC line. In the company's IND and IMPD filings with the US and UK regulatory agencies, respectively, Advanced Cell Technology described a carefully controlled cell culture process that, when shifted from proliferation to differentiation, was incapable of supporting the growth of undifferentiated ES cells. Moreover, the company had developed a release assay for the final RPE cellular product that was several orders of magnitude more sensitive than Polymerase Chain Reaction (PCR) for detecting contamination with undifferentiated cells. Putting these two manufacturing steps together, along with safety data from hundreds of animals injected with the human RPE cells, the company was able to establish an acceptable reduced risk profile to be permitted to test the RPE cells in human patients.

In July 2011, Advanced Cell Technology treated its first two patients with hESC-derived RPE cells. One patient suffered from Stargardt's disease, a juvenile-onset form of macular degeneration, and the other patient suffered from dry age-related macular degeneration (AMD), the most prevalent form of AMD and the leading cause of blindness in people over the age of 65. In 2015 the company published its findings from its two prospective phase

I/II studies carried out in the United States intended to assess the primary endpoints safety and tolerability of subretinal transplantation of hESC-derived retinal pigment epithelium. The article reported among the 18 patients treated that there was no evidence of adverse proliferation, rejection, or serious ocular or systemic safety issues related to the transplanted tissue—and that the observed adverse events were associated with vitreoretinal surgery and immunosuppression. A total of 72% (13 of 18 patients) had patches of increasing subretinal pigmentation consistent with transplanted retinal pigment epithelium. Best-corrected visual acuity, monitored as part of the safety protocol, improved in the treated eye of 10 of the patients, improved or remained the same in 7 patients, and decreased in only 1 of the patients. In contrast the untreated fellow eyes (a pseudo same patient control) did not show similar improvements in visual acuity as observed in the treated. Vision-related quality-of-life measures increased for general and peripheral vision, and near and distance activities, improving by 16−25 points 3−12 months after transplantation in patients with atrophic AMD and 8−20 points in patients with Stargardt's macular dystrophy [13]. The interpretation of these results was that the studies provided the first evidence of the medium-term to long-term safety, graft survival, and possible biological activity of pluripotent stem cell progeny in individuals with disease, and in particular, it suggested that hESC-derived cells could provide a potentially safe new source of cells for the treatment of various unmet medical disorders requiring tissue repair or replacement.

Induced pluripotent stem cells

As described in greater detail in earlier chapters, terminally differentiated somatic cells can be reprogrammed to generate induced pluripotent stem cells (iPSCs) by the enforced expression of a few embryonic transcription factors. The resulting iPSCs are morphologically and phenotypically similar to ES cells and thus offer exciting possibilities in stem cell research and regenerative medicine. The first iPSCs were produced in 2006 from mouse cells and, subsequently, in 2007 from human cells [14,15]. The most widely used set of reprogramming factors, Oct4, Sox2, Klf4 and c-Myc, was identified initially by screening 24 preselected factors in mouse embryonic fibroblasts by Takahashi and Yamanaka. Forced expression of these factors initiates phenotypic and molecular changes in the targeted somatic cell, eventually leading to the reactivation of endogenous pluripotency genes and acquisition of pluripotency [16]. The ability to restore pluripotency to adult cells through the induction of a small number of reprogramming factors promises to create powerful new opportunities for modeling human diseases, and perhaps more excitingly, offers hope for patient-specific cell therapies.

However, the challenge now is to better define differences in the epigenetics and gene expression of the resulting cells and subsequently improve the reprogramming methods in order to make human iPSCs a truly tractable alternative to hESCs. While at first approximation ES cells and iPSCs appeared equivalent and suggested interchangeability, recent studies indicate that significant variations can exist that markedly affect the epigenetic and functional properties of the iPSCs. Through different mechanisms and kinetics, these two reprogramming methods reset genomic methylation, an epigenetic modification of DNA that influences gene expression, leading various groups to hypothesize that the resulting pluripotent stem cells might have different properties. Indeed, a number of reports have indicated that iPSCs often have some DNA methylation patterns which are characteristic of the somatic cell origin prior to induction of pluripotency. This "epigenetic memory" can favor differentiation of the resulting iPSC back along lineages related to the original parent cell and often also results in restriction of alternative cell fates. Indeed, techniques such as high-resolution methylation analyses demonstrated that differences in methylation patterns could consistently distinguish between iPSC and ES cells [17] and produced variety in the level of expression of gene programs. Even subtle changes in expressions levels for just a handful of genes have given rise to the rejection of iPSCs in mouse transplantation models, indicating that some iPSCs are immunogenic and raising concerns about their therapeutic use [18].

In the coming years the efficiency of generating iPSCs and the understanding of the mechanisms of cell programming and reprogramming are likely to improve. However, there are ongoing concerns over safety presenting a significant hurdle before we will see significant progress toward therapies. At this point, considering just the regulatory issues alone, the differences between iPSC and ES cell become the emphasis in calculating the remaining steps necessary to sufficiently characterize the properties and differentiation capabilities of iPSCs as sources of potential commercial therapeutic products. Such studies will be crucial for determining the suitable iPSC types for future stem cell−based therapies for human degenerative diseases.

So far, only a handful of patients have undergone iPSC-based treatments. In 2014 a woman with macular degeneration of the eye received a transplant of iPSC-based retinal cells derived from her own cells. The woman treated showed no apparent improvement in her vision, but the safety of the iPSC-derived cells seemed to be confirmed. In 2017 five additional patients were treated for the same eye condition with iPSC-derived retinal

cells, which were derived from allogeneic iPSC lines (i.e., derived from different donors). According to an article in the January 17, 2018 edition of the Japan Times, however, one of those patients developed a "serious" but non−life threatening reaction to the retinal cell transplant, forcing doctors to remove the transplanted sheet of cells.

Direct reprogramming of differentiated cells

In the last few years a number of studies have shown that a direct route can be taken to convert one differentiated cell to another, without going through an embryonic-like undifferentiated state. Direct reprogramming of differentiated cells has already been demonstrated, as explained earlier and the ability of certain genetic factors to dominantly specify cell fate has been known for some years. However, based on recent advances, this technology is likely to progress significantly over the next 5 years. Direct reprogramming has a number of major advantages, including the potential to produce therapies based on small molecules and/or biologics for in vivo reprogramming. This method would also produce cell therapies without the need to use a pluripotent cell stage; thus greatly reducing the risk of rogue cells leading to uncontrolled cell growth or inappropriate differentiation into an unwanted cell type.

Small molecule-induced differentiation

Small molecules can also induce differentiation and have advantages in terms of the ability of the clinician to control dosage. For example, small molecules have been used to generate iPSCs by acting as substitutes for genetic reprogramming factors. Such approaches offer the longer term potential to activate dormant stem cells in the adult body, and proof-of-concept for this has been most recently demonstrated through the use of a small naturally occurring molecule, thymosin-β4, to stimulate cell-mediated repair of a damaged mouse heart [19]. Other small groups also are making inroads with chemically induced pluripotency, for instance, showing that specific DNA-binding hairpin pyrrole-imidazole polyamides could be conjugated with chromatin-modifying histone deacetylase inhibitors such as Suberoylanilide Hydroxamic Acid (SAHA) to epigenetically activate certain pluripotent genes in mouse fibroblasts [20].

Reimbursement

At the end of the day, life science companies developing new drugs and treatments, including those in the regenerative medicine space, must justify their existence to the shareholders who invested and therefore funded the translation of a therapy from animal models to an authorized therapeutic product. That justification is largely based on the ability of the developing company to sell the product into the marketplace. Accordingly, before deciding to invest in developing a new regenerative medicine product, especially a cellular or tissue product, the company needs to carefully consider the sunk cost to get to an approved product and the resulting cost-of-goods once approved and weigh that against the likelihood of private insurance companies (private payers) and governmental payers (such as Medicare) being willing to reimburse the company for treatment of patients with the approved product, and if so, at what amount. Reimbursement is a multipronged process that requires evaluation of several components: coding, coverage, and payment.

It is the responsibility of companies to demonstrate clinical and economic value for new regenerative medicine therapies. The field of establishing cost−benefit trade-offs associated with new treatments is known as pharmacoeconomics. A pharmacoeconomic study evaluates the cost (expressed in monetary terms) and effects (expressed in terms of monetary value, efficacy, or enhanced quality of life) of a pharmaceutical product. There are several types of pharmacoeconomic evaluation: cost-minimization analysis, cost−benefit analysis, cost-effectiveness analysis, and cost−utility analysis. Pharmacoeconomic studies serve to guide optimal health-care resource allocation, in a standardized and scientifically grounded manner. In this regard, a pharmacoeconomic analysis will determine whether regenerative medicine approaches are clinically And economically effective, capturing such factors as the downstream costs associated with managing disease, assessing direct, and in some cases indirect, costs-associated morbidity and mortality in the patient population. This analysis includes assessing the downstream impact of a new treatment on patients' quality of life and comparing it with the incremental cost of treatment over time. For example, living with reduced vision due to ischemic retinopathy or an amputated limb due to a diabetic ulcer would each significantly reduce the quality of life value for a diabetic patient. When appropriate data are available, it is possible to develop a reliable set of outcomes and economic scenarios, consider trade-offs, and make better decisions regarding the value of a novel therapy.

Emphasis on economic justification for patient care is evident across all aspects of healthcare, from reimbursement decisions by government and private insurance entities to payers demanding data that support treatment pathways, to large payer systems that collect and analyze their own data. Companies are incorporating pharmacoeconomic assessment tools and decision-analysis processes earlier in product development. More frequently, pivotal clinical studies are designed to capture cost data as well as clinical outcomes. Every advanced cellular therapy

developed today will undergo some level of pharmacoeconomic analysis.

Obtaining a medical procedure code is important for reimbursement purposes, and this process begins prior to FDA approval. The Healthcare Common Procedure Coding System (HCPCS), developed and maintained by the Centers for Medicare and Medicaid Services (CMS), is the major medical procedure code system used for billing in the United States. Medicare is the largest single-payer of health-care services in the United States, with almost 50 million beneficiaries and a budget in excess of $425 billion in FY2012. While Congress has the authority to change Medicare benefit categories, CMS makes the decision whether to approve new treatments and these decisions also influence private health plans' coverage decisions, because of Medicare's size. CMS decisions are based on the statutory requirement to cover treatments that are "reasonable and necessary" from a clinical perspective; neither comparative effectiveness nor cost-effectiveness is currently an explicit criterion.

Medical providers submit claims to public and private insurance payers to receive payment for their services. This information is conveyed to payers through codes—numeric and alphanumeric characters which represent a specific service, procedure, or product provided to a patient. Two code sets are used. Current Procedural Terminology (CPT) codes are maintained by the American Medical Association (AMA) and are used to report office visits, surgeries, and other services reported by physicians. Changes to CPT codes (additions, revisions, or deletions) are made annually by the AMA. HCPCS Level II codes are alphanumeric codes maintained by CMS. These codes are typically used to identify supplies, products, and services not included in CPT, such as drugs and durable medical equipment. Changes to HCPCS codes are made quarterly by CMS.

To assess a new technology's clinical effectiveness and safety, CMS and private payers undertake technology assessments. For example, the assessment may determine if a technology achieves particular goals, which may include the following:

1. The technology must have received final approval from the appropriate governmental regulatory bodies, such as FDA.
2. The scientific evidence must allow conclusions to be drawn concerning the technology's effect on health outcomes.
3. The technology's beneficial effects must outweigh any harmful effects.
4. The technology must be as beneficial as any established alternatives.
5. The health improvement must be attainable outside investigational settings.

That being said, even if a product has a code, it is not always reimbursed. Some insurance payers, including Medicare, have separate coverage determinations that indicate when a service is or is not covered. Coverage determinations describe whether specific services, treatment procedures, and technologies can be reimbursed and under what conditions. Most frequently, Medicare coverage determinations are made by local insurance contractors through local coverage determinations and address coverage, coding, and billing guidance. Medicare also issues national coverage determinations for an item or service to be applied on a national basis.

For Medicare, services and products are reimbursed through payment systems determined by the site-of-service. The following payment systems are relevant to regenerative medicine: outpatient prospective payment system for outpatient hospital, ambulatory surgery center services; physician fee schedule for physician office services; and the inpatient payment prospective system for hospital inpatient services. Each payment system is unique and reimbursement strategies will need to be developed with site-of-service in mind.

Often insurers will require companies to demonstrate the cost-effectiveness of their products, especially relative to the costs of existing treatments for the underlying condition. In addition, payers are becoming more interested in the comparative clinical effectiveness of new products versus existing treatments. The burden is on the companies bringing forward new and innovative products to demonstrate why insurers should be paying for them. Accordingly, early in their clinical programs, companies should begin to plan their reimbursement strategy by conducting an initial reimbursement analysis of their product. The following questions will help companies determine where they should focus their efforts.

- *Where will the product be administered?* The reimbursement strategy will vary based on the site-of-service. If the product is performed in different settings (physician's office, hospital outpatient, etc.), it may require several different strategies based on the location where the service is performed.
- *Who is the customer?* Strategies will be different for physicians, hospitals, or specialty pharmacies as each one is reimbursed through different payment systems.
- *What patient population will receive the product?* For example, if the product is intended primarily for an over age 65 population, the payers of concern might be private commercial insurance but more likely would be Medicare and Medicaid.
- *Is the product unique or are other similar products on the market?* If similar products are on the market, it is possible that payment and codes already exist for the product.

- *Does a code exist which accurately reflects the product?* If no code exists, begin the process to secure a new code assignment. If it does exist, is the payment level appropriate for the product?
- *What clinical evidence exists?* Medicare and private payers examine clinical evidence when determining coverage. Companies should begin early with compiling clinical evidence as this will be needed for coverage and coding requests. In addition, the company should compile economic data related to the use of its product.

Emphasis on economic justification for patient care is evident across all aspects of healthcare, from reimbursement decisions by CMS to payers demanding data that support treatment pathways and to large payer systems that collect and analyze their own data. Companies are incorporating pharmacoeconomic assessment tools and decision-analysis processes earlier in product development. More frequently, pivotal clinical studies are designed to capture cost data as well as clinical outcomes. Every advanced cellular therapy developed today will undergo some level of pharmacoeconomic analysis. The following is a checklist for companies, along with timeframes, to help guide executives through the reimbursement process.

- *Conduct a reimbursement analysis and formulate a strategy.* The analysis ideally should be prepared as the company prepares for Phase II clinical trials, but if not, it should be done prior to commencing Phase III trials. The analysis should include an assessment of where and how the product will be administered, how the product will be coded, and how similar/comparative products and existing treatments are reimbursed. Based on this assessment, the company should begin formulating a reimbursement strategy.
- *Gather health economics and comparative clinical effectiveness data.* During Phase II and Phase III trials the company should collect pharmacoeconomic data to demonstrate the cost-effectiveness and clinical effectiveness of the product relative to existing treatments. More and more frequently, payers are expecting companies to demonstrate the "value" of their product prior to reimbursing it.
- *Secure a meeting with CMS (Medicare), private insurers, or both.* This will accomplish two goals. First, it will educate payers about the technology and its clinical and economic values. This is especially important for new technologies such as in regenerative medicine. Second, it will give the company an opportunity to ask questions and get a better understanding of the data needs that payers have when making coverage and payment decisions. This information can be used when designing your Phase II and III trials.

Conclusion

Regenerative medicine is not just a future hope, it is a reality today. Cell-based therapies and products are on the market now and many more are in advanced stages of being tested in patients. These products provide insight into what the future holds in terms of patient health and economic impact. Regenerative medicine is a multidisciplinary field, and to increase the likelihood of success, it is incumbent on those involved to draw on the expertise of a wide range of fields and stakeholders. Collaboration between academia, industry, and clinicians is a vital component for the future success of the regenerative medicine field. This rapidly emerging field of medicine, particularly cell-based therapies, has the potential to deliver dramatic clinical benefits and address important unmet medical needs. It is possible to translate clinical improvement into a robust assessment of the economic benefit derived from superior clinical outcomes.

Chapter 86

Ethical issues

Laurie Zoloth
University of Chicago, Chicago, IL, United States

Introduction

Case study: The small black box holds a perfectly shaped ear. The scientist at the front of the room explains how it was made. A scaffold of nanoparticles supports fibroblast cells that grew over the form, and the ear now looks and feels actual: it can be transplanted to tissue. For burn patients, this represents an enormous chance and change. It is the prototype of a new genre of medicine, one that uses powerful technologies and methods of bioengineering and cellular biology to transform the matter of the world.

The ear in the box is not a freak example of a new technique. It is, in fact, one of a number of new devices that utilize the convergent technologies of several different fields of science and engineering to create tissue that can mimic the structure and function of the natural world. Other examples include the creation of skin grafts, corneas, bone, cartilage, and, in some pilot studies, bladders. Based on the new technologies of genomics, informatics, nanoscale engineering, molecular biology, and stem cell research, tissue engineering can be said to alter the concept of medicine itself. Instead of treating ailing tissues or organs with drugs intended to repair their structure or function, tissue engineering aims at replacing the diseased or injured or aging tissues of the body with new ones entirely, made from component parts of the material of the world, both naturally occurring and synthetic.

Such an advance heralds a radical new potential ability to heal, a long-awaited solution to several intractable problems, and a serious alternative to cadaveric or living-donor whole organ transplants, which have long been an ethically challenged sector of medicine [1,2]. Yet such a remarkable reconstruction of the human body asks a great deal of any social world into which it is introduced, for it is the body that is the place of the self, the location of the acts of the sacred, and the sensory arbiter of the real. In fact, tissue engineering queries two of the very aspects of our humanity that we consider distinctive: our integral embodiment and our finitude. If we are indeed a collection of replaceable and adaptable parts, some people reason, what is it that separates us from any other engineered machine? If we can engineer, for example, a synthetic and improved lymphatic system, might we improve our chances to adapt to and overcome infectious disease? What other capacities for healing or alteration of our bodies might be prudent? How do we ensure that such changes are indeed ethical?

It is this query that has greeted the new biotechnologies of the body, one based, this chapter argues, in social reactions largely shaped by culture both ancient and contemporary. We then ask the following: What are the ethical challenges to the field of tissue engineering? Does tissue engineering raise new ethical issues, or is it a description of one of the modalities enabled by the convergence of other technologies that have been understood to be individually ethically freighted?

In this chapter, I suggest using an established ethical framework that was suggested in 1999 by a committee of the American Association for the Advancement of Science on inheritable genetic germline modification and used far more widely by the field of bioethics to assess new technologies. We then review the responses given to new technologies in the past from a variety of sources in bioethics, philosophy, and theology. Finally, we reflect on how the legal and regulatory structure for tissue engineering impacts on our reflections on ethical norms [3].

Research evaluation (adapted from the AAAS Working Group on Human Inheritable Genetic Modifications 1998–2000 [3])

- Are there reasons, in principle, why performing the basic research should be impermissible?
- What contextual factors should be taken into account, and do any of these prevent the development and use of the technology?

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00088-5

- What purposes, techniques, or applications would be permissible and under what circumstances?
- On what procedures and structures, involving what policies, should decisions on appropriate techniques and uses be based?

Are there reasons, in principle, why performing the basic research should be impermissible?

Principled reasons for objections to basic research are extremely difficult to conceive in research that is, by its very nature, intended to be translational and clinical. Yet ethical objections to the manipulation, replacement, and engineering of human tissue can be seen as part of a long continuum of dissent about medical technology that began to assume full voice in the 1970s, when successful genetic manipulation of bacterial genomes became possible [4].

All new technology raise new challenges—in particular, technology that refashions the embodied self, become a part of the "self" and the identity of the subject, and seem to raise the deepest anxieties. Even tissue engineering, an emerging field with clear targets, clinical successes, and patient needs, will raise familiar concerns.

First among these is the argument that humans possess an essential nature and live within an essential natural order that cannot be altered without harm. For Lewis [5], this is expressed as a concern that the very acts of rational science—dissection, analysis, and quantification—are a violation of the sacred integrity that lies behind all of nature:

> *Now I take it that when we understand a thing analytically, and then dominate and use it for our own convenience, we reduce it to the level of 'nature', we suspend our judgments of value about it, ignore its final cause (if any), and treat it in terms of quantity. This repression of elements in what would otherwise be our total reaction to it is sometimes very noticeable and even painful: Something has to be overcome before we can cut up a dead man or a live animal in a dissecting room.*

For Lewis the understanding of the body as replaceable is disturbing:

> *The real objection', he says, 'is that if man chooses to treat himself as raw material, raw material he will be, not raw material to be manipulated by himself as he fondly imagined, but by mere appetite' (*p. 274*).*

What Lewis imagines is that new transformative technology will be manipulated by "controllers" who will eventually transform man into mere matter, and, as a scholar more interested in metaphysical transformation than corporeal change, this is disturbing.

Bioethicist Callahan [6] echoes Lewis' concern, agreeing both with the argument that limits need to be placed on what is "decent" or "proper" to do to nature, and in the sense that such action is a part of a larger danger. Both are worried that power in the hands of scientists represents not only an altruistic desire to heal suffering but also a deeper desire for power. When such power is left to scientists, they argue, scientist may be driven by the interests of the elite, who increasingly fund their research projects, or even by a State, that may well (and historically has) use science to manipulate and control populations. Callahan argues

> *The word 'No' perfectly sums up what I mean by a limit – a boundary point beyond which one should not go … There are at least two reasons why a science of technological limits is needed. First, limits need to be set to the boundless hopes and expectations, constantly escalating, which technology has engendered. Advanced technology has promised transcendence of the human condition. That is a false promise, incapable of fulfillment. … Second … limits (are) necessary in order that the social pathologies resulting from technologies can be controlled. … [W]hile it can and does care, save, and free, it can also become the vehicle for the introduction of new repressions in society.*

These objections are not new, nor were they made in response to new advances such as tissue engineering. They were made well over 30 years ago, and yet are still made, despite, one may note with some irony, 30 years of medicine that have indeed seen rapid and successful advances, without their being used by the state for repression and without any fundamental change in the capacities for intellectual and spiritual self-possession.

Nevertheless, despite this empirical reality, powerful arguments of opposition to the manipulation and replacement of tissues and organs continue, with some people continually worried that "perfection" itself or dominance, or privilege is what is sought even when, consistently, healing remains the goal of medical research. Such critics, many from the disability community, raise principled objections to the use of tissue engineering if the goal is to alter the disability. Activists in the deaf community, for example, defend their disability as a culture and a language exchange, not as a loss of function. Others are concerned that our society's focus on "fixing things" will allow a devaluation of the persons that currently bear the broken bodies and parts. Bioethicist and disabled activist Adrienne Asch suggested that there is a "troubling side to every cure, that those of us who are uncured are seen as less valuable, perhaps even expendable."

For bioethicist McKenney [7] a community needs to "embrace brokenness" and to "deny that the worth of one's life is determined to how closely one conforms to societal standards of bodily perfection." McKinney is also concerned that if medicine is successful, it will create a social and economic system that "virtually demands that we be independent of the need to care for others."

Duty and healing: natural makers in a broken world

While the opposition to medical technology has indeed been persistent, it also has not been unchallenged. For many the response lies in the nature of brokenness and the human duty to respond to the need of the suffering other [8,9]. The principle at stake in the assessment of tissue engineering as an ethical act is not how its use might potentially violate an abstract community in the future, but the actual problem of what one must do as a moral being when one's neighbor is in need. In this important sense the duty to heal cannot be overridden by a "sense" of discomfort (as Lewis notes in the earlier quote).

It is the nature, goal, and meaning of science to address the human condition in all its yearning and capacity for defeat and failure. In this sense, there is no principle objection to the science of tissue engineering, and in fact there may well be a strong moral imperative to develop the technology.

Fletcher [10], in speaking of an earlier generation of medical technology and answering the critics of science, wrote

> *'The belief that God is at work directly or indirectly in all natural phenomena is a form of animism or simple pantheism. If we took it really seriously, all science, including medicine, would die away because we would be afraid to 'dissect God' or tamper with His activity'. 'Every widening and deepening of our knowledge of reality and of our control of its forces are the ingredients of both freedom and responsibility'.*

Gerald McKinney and Lawrence Childress use an argument that is rooted in Christian moral theology: that since human persons are fallen creatures in a fallen world, we cannot really be counted on to know the right and the good. God, who is transcendent, from this fallenness, has set us in this place, not essentially to alter it toward our own transonic, but to find its meaning and purpose. Yet the traditions of other faiths differ. For Jewish and Islamic theorists the world is morally neutral. Human persons may—and will—fail in their aspirations but can be trusted to have the capacity for moral behavior and moral yearnings. Finding meaning in suffering is not the core task. The task is to alleviate suffering, which is understood as chaotic, meaningless, and agonistic. Hence, many of the core objects in principle are rooted in religious constructions and understandings.

To make is to know: notes on an old problem about knowledge

The classic debates of the 1970s were largely in response to the concept of the first generation of gene editing and proposals for gene therapy. The issues they raise are not the only a set of problems engendered in the history of ethical responses to the technological gesture at the heart of tissue engineering. At stake as well is the special kind of knowledge that such making implies. For Aristotle and the Hellenists, useful knowledge, "practical wisdom," was phronesis. Phronesis implied actually doing an act; making, in order to know. The act of making, not the act of perception or contemplation alone, was how wisdom and, indeed, rationality and power were achieved. Hence, making new tissue is a somewhat different moral gesture than curing the body by altering it with drugs that essentially allow the body to heal itself.

Second, the use of technology within the body of the patient is a different matter than the use of technology essentially to enhance the body of the practitioner. For all earlier technology the thing that was changed or enhanced was the sense perceptions of the doctor. Stethoscopes and otoscopes allowed the sounds of the body to be more audible. X-rays, CT scans, and MRIs allow the inner vistas of the body to be revealed. EEGs and EKGs allow the electrical currents that animate the central and peripheral nervous systems to be charted in quantifiable units. Microscopes allow invasive bacteria to be seen at the microscopic and, increasingly, molecular levels. These earlier technologies extended the reach of what Bacon increasingly trusted and that the Greeks did not: the perception and observation of the phenomena of the world and the perception of the outcome of its deliberate perturbation.

Bacon's method presupposes a double empirical and rational starting point. True knowledge is acquired if we proceed from lower certainty to higher liberty and from lower liberty to higher certainty. The rule of certainty and liberty in Bacon converges …. For Bacon, making knows and knowing is making (cf. Bacon IV [1901], 109−110). Following the maxim "command nature … by obeying her" (Sessions [11]; cf. Gaukroger [12]), the exclusion of superstition, imposture, error, and confusion are obligatory. Bacon introduces variations into "the maker's knowledge tradition" when the discovery of the forms of a given nature provide him with the task of developing his method for acquiring factual and proven knowledge [11].

Thus the world is known by understanding the parts of the world and, from that, theorizing (knowing), by induction, to principles or axioms or laws of nature, physics, and chemistry. In contemporary science, knowing is done largely by "unmaking," by deconstruction of the component parts in ways scientists of Bacon's era were unable to imagine. Many of these "unmaking" techniques, such as the splicing of alternative DNA and the manipulation of cellular structures, allow a sense of inherent interchangeability, as if the real and the person were merely a set of Lego parts awaiting clever recombination.

What is a thing? The perils of deconstruction

Making actual tissue in mimesis of the real tissue of the actual body extends the Baconian act in radical ways. Here, the experimental perturbation is the unmaking of tissue and the remaking of tissue, only in more controllable form. This cannot help but excite concern about the nearly infinite possibilities for technological shaping of the self. Heidegger asks, "What is a thing?" and in so reflecting understands a thing as an object separate from the self. But what of a made thing, an object that becomes the self?

The technology of the alteration of the patient is distinctive. Devices for altering the functioning of the body that become a part of the body and are actually a tissue of the body are a step beyond the idea of a device held within the body. This is important in any ethical assessment of the technology, because the patient's consent and participation are needed for the final act of the technology to be completed. Such an event only happens in a specific context, for technologies, patients, and practitioners operate in a social, religious, and economic context. Here we turn to the second ethical consideration.

What contextual factors should be taken into account, and do any of these prevent the development and use of the technology?

Tissue engineering is a complex procedure still in experimental stages. Yet to be an ethical technology, it must be directed toward accessibility, just distribution, and efficacy. Hence, the troubling context of widespread healthcare disparity is a problem not only for this advanced technology but for all newly emerging technologies. Emergence into an unjust world asks certain moral questions of new technological advances. First among these is the query about burdensomeness versus benefit in a context in which the vast majority of the world's people suffer from easily treatable infectious diseases such as tuberculosis, malaria, AIDS, and infant diarrhea. How can tissue engineering be justly promoted in the face of other, pressing needs?

This objection can typically be met by noting that it would be deeply inappropriate to withhold medical knowledge until the world is entirely perfected, and that applications not only will be increasingly available to the poor (as in vaccines, once rare) but also that the very process of research has typically uncovered new and useful ways to understand disease.

The goal of tissue engineering is the widespread use of the technique. Unlike solid-organ transplants, which would always require significant resources far outside the capacities of developing-world clinics, tissue replacement, stem cell therapies, and other transportable therapies are designed for widespread use. The possibility to create a method for allografts that uses the patient's own cells and the possibility for autologous cells to provide an "off-the-shelf" source of tissue may provide the basis for access (but only if research priorities are discussed in advance of design), a process, as we describe later, that will need careful support and monitoring. The question of how to achieve this and how to enable a more just use of each technology has not yet been solved.

A second contextual factor for tissue engineering is that all human tissue is marked by its genomic identity. It is the very nature of cells that allows them to copy and reproduce and to carry identifying markers linked to some person somewhere. In the past, such use has raised serious objections. Such tissue can be traced and known, which may have implications for the person who is the source of the tissue, raising significant new issues in genetic privacy for the donor.

Further, whose is the tissue that is derived from the cells of a particular body? Who should have the rights to, and a fair share of, the profits derived from its use? In the seminal case in the field, Moore v. the Regents of the University of California [13], the issue of ownership was addressed. In this case, Mr. Moore had his T cell lymphocytes taken from his spleen during the course of treatment for hairy-cell leukemia, cells that proved effective in deriving resistant cell cultures. Patented after manipulation to make a new "product," the cells were indeed profitable. Mr. Moore's complaint was that he was not informed of, much less a part of, the scientific enterprise and the lucrative payout for his cells. The case was decided in favor of the research labs. But in the ensuing decades, alert patients with unique cell types or unusual cancers who sought for research have been selling their materials as personal possessions to the lab that wishes to procure them. Ownership is limited, however, by the common law of the United States and the European Union which constrains this ability to claim tissue as property. The goals of such restraints were put into place to prohibit the buying and selling of human tissue and organs, for fear, given the desperation of the poor, that selling the bodies of the poor would become permissible and led to their exploitation. Thus the entire process that allows for the derivation of tissue sources needs to be noted. The current context for tissue donation is a mixed system. Organs, tissues such as blood, corneas, and marrow are donated or exchanged without compensation. Gametes, however, are another matter entirely. Because the use of human sperm and eggs emerged in the context of fertility treatment and because this treatment was largely conducted in stand-alone, private clinics that functioned

without public oversight or regulation, the marketplace standards prevailed. What originally began as a compassionate exchange of gametes between family members when an infertile couple could not conceive quickly changed into a robust marketplace in human gametes. As of this writing, international standards prohibit the use of marketplace incentives for gametes or embryos.

A final context for the debate about the ethics of tissue engineering in general is the special case of human stem cells to make tissues. Because some applications of tissue engineering use stem cells as a part of the method of treatment [14], the debate about the ethics of the use of human stem cells is directly adjacent to this technology. For many the origins of tissue matter a great deal. For some Christians, many Roman Catholics, and some Hindu sects, the destruction of the human embryo, even at the blastocyst stage, is tantamount to killing. For these faith traditions the derivation of stem cells from embryos is always impermissible. For many other faith traditions, such as Judaism, Islam, Jainism, Buddhism, Confucian philosophy, and Daoism, the use of these cells is permissible within certain constraints, as we will see later. For all faith traditions, however, the manipulation of adult somatic cells in their precursor form is completely sanctioned. Precursor cells are not as flexible as pluripotent cells, and it is that very pluripotency and immortality that are important in tissue engineering. These factors raise concern. Yet the contextual factors alone do not prohibit entirely the use of this technology, for justice in distribution, the possibility of the loss of genetic privacy, and the controversy over stem cell research when pluripotent embryonic cells are used to affect many aspects of the new techniques in medicine. Hence, we turn to the third major issue.

What purposes, techniques, or applications would be permissible and under what circumstances?

Many of the salient, justifying arguments for the use of tissue engineering hinge on the telos, or goal, of the treatment: if the goal is to cure or treat human disease, the benefits will outweigh the burdens of the work—controversy, cost, and difficulty. Clearly, then, tissue engineering ought not to be used in a trivial or wasteful fashion. Human tissue is understood by many as deserving a special sort of "respect" [15].

This proviso may not be so simple, for a core problem in genetic engineering has been the use of the technique for "enhancement" of human characteristics or traits. The initial ethical discussions about therapeutic uses of medicine versus cosmetic ones imagined ethical bright lines that would define the boundary between the use of such technology to restore "species normal functions" [16] for each tissue and for the person as a whole. Yet medical practice has long gone beyond these lines, using surgery, for example, for cosmetic purposes. Will it be possible to restrict tissue replacement to burn victims, spinal cord injury, and diabetics? How can such a distinction be made?

Some tissue-replacement therapies, such as the use of skin grafts for full-face transplant, may also raise questions about the nature of identity. Indeed, the notion of a full-face transplant alerted us to the depth of resistance to identity—altering tissue replacements. (Could persons use any face? What if persons in need of facial transplants wished to change ethnicity? Should faces "match," and why?) Like many other aspects of this technology, this tension about identity was not new, only heightened. For example, the first years of organ transplant raised the same issues for recipients of hearts, a key aspect of identity in many cultures. If the face is our key determinant of the self in modernity and, even more so, if the brain is such, then how are we to understand the use of tissue engineering to transform identity?

Hence, linked inexorably to this technology are larger considerations of the use of tissue engineering for neuroscience, both for therapy and for enhancement. The applications of tissue transplant in Parkinson's disease are important. Yet will there be concern about this use of the neurons of a stranger in the brain of the self? Of all the possible uses of tissue engineering, the ones that may alter consciousness and memory are the most troubling. (What capacities or memories could neurons store?) Here, the need for restrictions on applications may be the clearest, yet it is not clear who ought to decide and who ought to ensure that the restrictions on unethical applications are maintained. By on what criteria will such limits be set?

New research possibilities also offer applications to engineer gametes for use and storage. Engineered follicles may now be saved, frozen, matured, and used in animal models to create the possibility of human fertility after cancer chemotherapy or other environmental risk.

With this, as with all such technology, there will have to be careful attention to how the market may drive technology toward specific research goals rather than others or to whether research goals will be framed only by the values of profit and efficacy and not by ones of more general interest: compassion, healing, and solidarity. The powerful applications and the potential for widespread use itself create the possibility for serious conflicts of interest, for serious market forces may be the core drivers of technology, especially in an aging population with increasing needs for all manner of new tissues and organs. This turns us to the consideration of our final set of issues.

On what procedures and structures, involving what policies, should decisions on appropriate techniques and uses be based?

Much of the first reviews of the ethical issues in tissue engineering have in fact focused on the issues of policy: safety, patents, and gating. Products and drugs are typically controlled via four levels of restraints. The first is elaborate premarket gating, first involving animal models and then typically done for pharmaceuticals in a decade-long series of tests, phased to test the drug on an increasing but controllable number of human subjects. Such trials must be gender balanced, and subjects must give full, informed consent and be able to leave the trial at any time (which could be difficult in the cases of implanted tissues).

The next gating is the system of intellectual property. Patents and licensing control the use of the products, and even the replication of the experiments. The next gating is that of financial backing. To perform the enormous clinical trials, to do premarket investigation, and, of course, actually to make and sell the product require a production apparatus, which must be assembled and supported. Finally, each drug or device must be approved for use by the insurers. As Smith (2004) notes, tissue engineering faces a gauntlet of issues and a "new order of magnitude in interactions and science patents." In addition, notes Smith, the "things" engineered are hybrids of two jurisdictions, that of drugs and that of devices.

Are genetically engineered insulin cells a drug, like insulin, a device, like a stent, or a biologic? Unlike stents, which are entirely synthetic, tissue engineering uses actual human cells, only manipulated in de novo ways.

Standards will need to be set for safety, efficacy, and fair use. Standards for clinical use, for clinical trial, and tissue stability and purity will be needed for the research and application to be safe.

Getting informed consent in this case will present significant challenges. Patients in need of organs, for example, are particularly desperate, and their consent may be deeply affected by their utter lack of options. Eight percent of the medical system is already devoted to organ transplantation, and the lack of organs is an overwhelming problem for nearly half of the patients hoping for transplants [17]. Yet the first year of the use of engineered tissue will be experimental and will need to be conducted under the strongest possible set of NIH guidelines. How the first trials of engineered tissue are conducted will set the tone and the future for all subsequent use.

The question of policy and the regulation of policy are manifested in many of the first documents that evaluate the ethical and legal implications of tissue engineering. While, as Smith notes, the United States faces a complex regulatory system, the European Union has regulated such research products as medical products, and these will fall under the regulatory gaze of the European Medical Evaluation Agency. In both the United States and the EU, the synthetic nature of tissue engineering, the very de novo quality of the work, and the uneasy greeting that met genetically modified food have created serious political opposition. Policies need to be crafted with transparency and full public participation, for such research needs not only public funding but public understanding of complex theory and practice of tissue engineering—what promises it can hold and what cautions need to be applied prior to use. Policymakers will need to attend to calls for justice in distribution, as was noted earlier, and will need to set in place structures for regulation.

How can new technologies best be regulated? I contend that a full array of regulatory structures can be employed. First among these are local committees, IRBS, and local review boards. The National Academies have played a large role in policy writing for both recombinant DNA and for stem cell research and, in both instances, called for special, national, ongoing oversight on such research. It would be prudent to reflect on the need for such a process for tissue engineering, for established structures largely address issues involving the use of donated tissue, not engineered tissue. Structures that protect human subjects also need strong enforcement, as noted earlier, both for donors and for recipients of tissues.

But regulation, government oversight, and market forces can only go so far in shaping just research goals and commitments. The goal of ethics is to develop moral agents who are aware of a constancy of duty toward subject and to humanity, who not only follow rules correctly but also, given the chance and grace to work at the frontiers of science, act with courage and decency in their research.

Conclusion

Tissue engineering suggests that an old dream—the replacement of human body parts—may be realized. While any sober and reflective scientist understands the long way to success of this idea, the science described in this volume clearly suggests that our society is on the road to the enactment of the possibility.
